One of the most important roles of NC assessment is the ability of tests or a battery of tests to detect the presence or absence of a brain disorder. Ideally, a cutpoint that defines “abnormality” on NC tests would correctly identify all patients with a brain disorder (100% sensitivity) and at the same time correctly identify as normal all those who do not (100% specificity). Unfortunately this degree of accuracy is almost never achievable except in conditions with very severe and generalized cognitive effects (e.g., advanced Alzheimer’s disease). In such cases, there is virtually no overlap between test scores of patients with these severe conditions and those of neurologically normal people with similar demographics. For clinical conditions such as HIV, however, in which deficits are more mild and variable, there tends to be an overlap of NC test score distributions for those eventually diagnosed with a brain disorder relative to those who are not diagnosed. In general neuropsychological practice, therefore, it is not possible to achieve 100% specificity and 100% sensitivity; there is also an inverse relationship between the two, such that a gain in specificity would inevitably result in a loss of sensitivity and vice versa. Therefore, when choosing cutpoints to define impairment, it is important to strike a balance between specificity and sensitivity with consideration of the relative implications of a false positive error (i.e., misclassifying a normal individual as impaired) versus a false negative error (i.e., misclassifying an impaired individual as normal).

While there is no universal consensus regarding optimal cutpoints for these classification decisions, it is recommended that specificity be maintained at a reasonably high level and balanced as much as possible with sensitivity. Prior research with other conditions with different NC tests and test batteries suggests that optimal balance between sensitivity and specificity is

typically achieved using a 1 SD cutpoint (Heaton et al. 2004; Taylor and Heaton 2001). This is consistent with the Frascati definition of mild NC impairment being >1 SD below the mean on demographically corrected scores; although it will result in a false positive error rate of approximately 16%, more conservative cutpoints generally provide more loss in sensitivity than gain in specificity. Importantly, the Frascati definition of moderate impairment (>2 SD below the mean), a criterion for HAD, will detect dementia but not mild impairment and results in close to 100% specificity (2% expected false positive errors).

Methods of Data Interpretation

Clinical Ratings

Clinical ratings by neuropsychologists were recommended by the National Institute of Mental Health (NIMH)-sponsored workgroup as the best method for detecting NC impairment in HIV/AIDS (Butters et al. 1990). Such ratings are considered the “gold standard” for assessing HAND (Antinori et al. 2007). Clinical ratings are derived using demographically corrected standard scores from individual NC tests that are categorized by domain of NC functioning (e.g., executive functions, learning). Trained neuropsychologists assign a rating for each NC domain according to a standardized clinical rating algorithm (see Heaton et al. 1994; Woods et al. 2004). A global clinical rating is then assigned by considering ratings across domains, with greater weight afforded to impaired test performances. The global rating does not simply average the domain ratings, but considers impaired domains more importantly, such that the global rating equals the rating of the two worst NC domain scores (if these scores have the same levels of impairment) or the worse NC domain score minus one (if these scores are different). Of note, in accordance with the Frascati guidelines for classifying HAND (Antinori et al. 2007), in order for an individual to be classified as having global NC impairment (i.e., global rating ≥ 5), he/she must show definite impairment (\geq mild) in at least two ability domains; this

ensures that no patient can be classified as globally impaired if they have an isolated deficit in one domain, even if it is severe.

A significant advantage of clinical ratings is that they allow trained neuropsychologists to consider individual patterns of strengths and even mild deficits across the NC test battery when making HAND classifications. Ratings also meet the published international guidelines for NC impairment in HAND classifications (Antinori et al. 2007), have excellent inter-rater reliability (Woods et al. 2004), and have been associated with a host of everyday functioning and health-related outcomes (e.g., ADLs, medication adherence, and health-related quality of life; Blackstone et al. 2017). Clinical ratings have also been associated with underlying HIV-associated CNS changes (e.g., synaptodendritic injury; Moore et al. 2006) and HIV disease-related outcomes (e.g., immunosuppression or failure to achieve virologic suppression on treatment; Heaton et al. 2011). A major limitation of this approach is that assigning clinical ratings is time consuming and requires that raters have training and experience in NC test interpretation. In addition, it could be argued that clinical ratings are at least somewhat subjective and less convincing relative to more objective, actuarial approaches, such as the global deficit score (see below).

Global Deficit Score (GDS)

The GDS is an alternative approach used to summarize and evaluate NC impairment on an entire test battery. The GDS is a summary score calculated by an actuarial approach, which weighs the NC test data in a similar manner to clinical ratings, by considering both the number and severity of deficits in an individual's performance across the test battery and assigning less weight to performances within and above the average range (Heaton et al. 1995; Carey et al. 2004a). The GDS is calculated by converting demographically corrected T-scores on individual NC tests to deficit scores ranging from 0 (no impairment; $T \geq 40$) to 5 (severe impairment; $T < 20$), which are then averaged to derive individual domain deficit scores and the GDS. A GDS cutpoint of ≥ 0.5 is a standard cutoff that yields the most optimal balance between sensitivity and

specificity (Heaton et al. 1995). This cutpoint on individual tests approximates the specificity of a 1 SD cutoff and is roughly equivalent to requiring an average of mild impairment on at least half of the administered measures for a diagnosis of neurocognitive impairment.

The GDS is entirely objective, well validated for use in HIV, and relative to clinical ratings is much less time- and resource-intensive. Similar to clinical ratings, the GDS is significantly associated with a number of functional and health-related outcomes, including ADLs (Scott et al. 2011), medication adherence (Andrade et al. 2013), and biological markers of HIV disease (e.g., CD4 count, cerebrospinal fluid viral load; Gonzalez et al. 2003).

Comparing Diagnostic Classification Systems: Clinical Ratings Versus GDS

Both the clinical ratings and the GDS approaches are sensitive to the mild and variable deficits observed in HIV. They also improve upon the group mean differences approach in identifying NC impairment in research (Heaton et al. 1995) and are valid indicators of functional and health-related outcomes. While the two approaches provide comparable classification rates, their overlap is imperfect. Evidence from a large multisite study conducted by the CHARTER group (Blackstone et al. 2012) compared the diagnostic classifications of both approaches in 1,574 HIV+ individuals and found an 83% ($n = 1,305/1,574$) concordance rate between clinical ratings and GDS impairment classifications. Of those discordant, the majority (16%) were classified as impaired by clinical ratings (i.e., meeting criteria for a HAND diagnosis) but not according to the GDS. Less than 1% were classified as impaired according to the GDS only. Therefore, while the GDS is slightly more conservative (slightly greater specificity), an impaired GDS virtually guarantees that an individual will be impaired by clinical ratings and meet Frascati NC criteria for HAND.

Measuring NC Change

Assessing NC change can be helpful in tracking the progression of disease, monitoring any cognitive effects of treatment (e.g., changes in ART

regimens), and detecting NC impairment associated with incident comorbidities (e.g., a new substance use diagnosis or a medical condition coinciding with aging). There are several challenges with regard to measuring NC change, including practice effects (improved performance due to prior exposure to the same tests), variable test-retest reliabilities across instruments, and perhaps most important, determining how to evaluate whether any individual change is real (versus chance variation) and clinically meaningful (e.g., what degree of change might indicate altered brain function or cause a significant increase in everyday functioning problems?). As with use of NC normative standards to classify HAND at a single point in time, reliable detection of cognitive change requires referencing test-retest results against appropriate normative standards. In this case, the comparison samples would be neuromedically stable individuals (e.g., HIV-uninfected controls), who ideally have been retested with all or most of the same tests in the NC battery being used. The latter would allow comparable norms for change on the entire NC battery, rather than on isolated tests.

A variety of statistical approaches have been used to evaluate NC change, including standard deviation change scores, the reliable change index (RCI), and regression-based change (RBC) formulas (Temkin et al. 1999). However, most studies provide normative change formulas for individual tests rather than summary change scores for more comprehensive batteries like those used to evaluate HAND. More recently, studies have proposed modifications of these approaches for use in deriving summary change scores based on multiple cognitive domains (Woods et al. 2006; Cysique et al. 2011). Woods et al. (2006) proposed a summary change score using the reliable change index (RCI) plus practice effect approach (i.e., RCI-PE), whereas Cysique et al. (2011) employed a multiple RBC score normative approach.

An advantage that the multiple RBC score approach has over the RCI + PE and others is that it predicts a follow-up score on each test while considering multiple other factors that could influence retest performance, including the

baseline score on the test in question and general NC “competence” at baseline (mean standard scores on all other tests in the battery). While demographic characteristics and test-retest interval may also be considered in the prediction models, they usually do not contribute much to predicted scores at follow-up. Importantly, this approach takes into consideration not only levels of baseline NC functioning but also normal test-retest variability (including practice effects) and regression to the mean and provides a basis for summarizing all changes across the NC test battery.

Using published, regression-based norms for NC change from Cysique et al. (2011), a recent study (Heaton et al. 2015) examined the incidence and time-dependent predictors of NC change within a longitudinal cohort of 436 HIV+ individuals who had at least four semiannual visits over a mean of 35 months. Of the entire sample, 22.7% declined, 60.8% remained stable, and 16.5% improved. At baseline, there were no differences in NC performance between those who declined, remained stable, or improved, but the three groups differed very substantially in NC outcomes at the last visit. Significant time-dependent predictors of NC change (i.e., decline or improvement) included markers of disease severity (e.g., albumin, total protein), ART status (on/off), some baseline demographics and estimated premorbid IQ, and comorbidities such as methamphetamine use, mood disorders, and current depression symptoms. While preliminary, this method of quantifying global NC change provides a significant step forward in our ability to detect and monitor HIV disease- and/or treatment-related NC changes and identifies potentially modifiable risk factors of decline that may be amenable to treatment as well as protective factors that may prevent decline.

The Use of Brief Screening Measures

Given the variable patterns of NC deficits in HAND, comprehensive NC testing is the optimal way of detecting these disorders, as well as determining the nature and severity of strengths as well as deficits (Butters et al. 1990). However, comprehensive test batteries can be burdensome and

costly, and as such, are not always practical or feasible, particularly in clinical settings and other settings in which time and/or other resources are limited. Below we will provide a brief overview of screening methods that have been used to detect HAND, with validity estimates based upon comparisons with more comprehensive testing. For a more detailed review of cognitive screeners (with associated references) and recommended guidelines, see Valcour et al. (2011) and Kamminga et al. (2013).

Traditional screening measures such as Folstein's Mini-Mental State Examination and the Mattis Dementia Rating Scale (DRS), which were developed to detect dementia in neurological populations (e.g., Alzheimer's disease), are generally ineffective at detecting HAND, except in its most severe forms. The HIV Dementia Scale (HDS), which was developed specifically for use in HIV, and its international counterpart, the International HDS (Sacktor et al. 2005), are more sensitive to HAND relative to traditional screeners, though less effective in detecting mild forms of HAND. As with other NC tests, performance of screeners may be improved with the application of demographically corrected normative standards.

Several fairly brief computerized screening measures have been used in HIV (for a detailed review with references, see Kamminga et al. 2013) including the California Computerized Assessment Battery (CalCAP), the CogState battery (www.cogstate.com), and the computer assessment of mild cognitive impairment (CAMCI). Similar to other screeners, these computerized methods demonstrate utility in detecting HAND, though their effectiveness in detecting milder forms of impairment is inconclusive. There is preliminary evidence to suggest that the CAMCI may hold some promise (Becker et al. 2011). The recently released National Institutes of Health (NIH) Toolbox Cognition Module is a computerized cognitive screener designed to assess five of the NC domains commonly affected by HIV (attention, executive functions, working memory, processing speed, and episodic memory) and has excellent demographically corrected norms based upon a large and diverse US sample (Casaletto et al. 2015; see also Weintraub et al.

2013). The five tests of the above cognitive abilities take only 20 min to administer and may have promise in screening for HAND, though validating studies have not yet been done within the HIV population.

Brief NC screening batteries comprised of small combinations of standardized NC tests (e.g., 2, 3, or 4) have also been developed to detect HIV-associated NC impairment (e.g., Carey et al. 2004b), even in the earlier stages of disease (Moore et al. 2012). Carey et al. (2004b) developed two brief screening batteries (each using two-test combinations), which demonstrated fairly good accuracy in detecting even mild NC impairment: (1) the Hopkins Verbal Learning Test-Revised (HVLT-R) and the Grooved Pegboard Test (nondominant hand) and (2) the HVLT-R and the Wechsler Adult Intelligence Scale (WAIS-III) Digit Symbol subtest. Moore et al. (2012) applied this approach to a cohort of patients with early-stage infection and found that tests of verbal learning (HVLT-R) and processing speed (Stroop color test) provided the most sensitive two-test screener for detecting impairment in this population; also the addition of a measure of attention/working memory (Paced Auditory Serial Addition Test [PASAT]) provided the best three-test combination. Importantly, these brief combinations of more traditional NC measures include well-standardized, reliable, and validated NC tests with available demographically corrected normative data, which is essential in achieving the best classification accuracy statistics. A drawback of these brief cognitive screens is that they assess a limited number of cognitive domains and therefore run the risk of missing some individuals whose "spotty" deficits primarily affect other domains.

Conclusions

HAND remains common in the cART era, affecting up to 50% of individuals with HIV/AIDS. By far the most prevalent forms of HAND (i.e., ANI and MND) are relatively mild and involve somewhat variable patterns of specific cognitive deficits across patients. As such, they are difficult to

reliably detect using existing NC screening methods. More comprehensive NC test batteries that tap multiple NC domains are needed to sensitively detect these mild forms of HAND. All tests included in NC batteries should have appropriate normative standards for classifying impairment, as well as for detecting meaningful change over time. When interpreting NC test results, it is important to use demographically corrected standard scores and carefully consider cutpoints for classifying impairment. Current Frascati criteria for classifying HAND provide the most clearly operationalized criteria for determining NC and functional impairment in addition to detailed guidelines for assessing the potential impact of comorbid conditions in the context of HAND. Data summary and interpretation methods (e.g., clinical rating algorithms, global deficit scores, summary regression-based change scores) should consider performance across all tests and domains in the battery in order to reliably detect HAND and disease- or treatment-related changes over time.

Neurotoxic Consequences of Antiretroviral Therapies

Rick B. Meeker¹, Kevin Robertson¹ and Christopher Power²

¹Department of Neurology, University of North Carolina School of Medicine, Chapel Hill, NC, USA

²Department of Medicine (Neurology), University of Alberta, Edmonton, AB, Canada

Antiretroviral Therapy (ART) and the Central Nervous System (CNS)

With the introduction of combination antiretroviral therapy (CART), also known as highly active antiretroviral therapy (HAART), for the control of human immunodeficiency virus (HIV) infection, it has been possible to suppress viral quantity in patients' blood, often to undetectable levels. This intervention has decreased the overall HIV/AIDS disease burden and increased the life span of HIV-infected individuals. However, HIV reservoirs persist in tissue compartments where there is limited access of antiretroviral drugs and/or the presence of long-lived latent HIV reservoirs. Given these circumstances, the complete control of HIV replication and the eradication of HIV have been difficult and infected individuals must continue on treatment regimens indefinitely. Antiretroviral therapies (ARTs) are essential for the

effective treatment of HIV infection, but these compounds also have intrinsic toxicity and with long-term treatment can damage organs over time. Thus, the therapeutic antiretroviral effects must be weighed against the toxic side effects in deciding on treatment options.

One of the more challenging HIV reservoirs is the central nervous system (CNS). HIV rapidly enters the CNS after primary infection where it establishes a persistent viral reservoir. CNS HIV infection frequently results in a spectrum neurological disorder manifested as cognitive, motor, and behavioral symptoms, known as HIV-associated neurocognitive disorders (HAND). The phenotypes in HAND range in severity from asymptomatic neurocognitive impairment (ANI) to mild neurocognitive disorder (MND) to HIV-associated dementia (HAD); it is difficult to predict what signs and symptoms will be apparent in any given individual. CART improves cognition and has greatly reduced the prevalence of HAD (<5%) among patients with HAND over the past decade. However, asymptomatic and mild neurocognitive impairments persist in ~25–40% of patients on CART with a trend toward increasing prevalence as patients live longer (Cysique and Brew 2009; Heaton et al. 2011). Although the magnitude of the reservoir and the extent of viral replication within brain tissue are not well understood, there is general consensus that control of HIV replication within the CNS would be advantageous in terms of preventing CNS disease and limiting the transfer of HIV from the CNS to systemic reservoirs capable of accelerated virus production. Consequently, strategies are under development to increase the penetration of ARTs across the blood-brain barrier through selection of antiretroviral drugs with high CNS penetration effectiveness (CPE, <https://hnrp.hivresearch.ucsd.edu>), together with other approaches that enhance drug delivery into the CNS parenchyma.

Increased delivery of ARTs to the CNS, however, comes with an increased risk of adverse effects due to drug interactions with neural tissues. Although these compounds have well-described toxic actions in many organs including the liver, kidney, fat, bone, muscle, and peripheral

nervous system (Thompson et al. 2012), little is known about the toxicity of ARTs in the CNS. Improvements in drugs and wider treatment options have reduced serious systemic side effects and have also improved tolerability and drug adherence. CNS side effects with current CART regimens have typically been minor relative to systemic toxic effects, but this may be due to the limited penetration of ARTs. As these efforts to suppress or eradicate HIV from the CNS advance, the potential risk(s) of adverse CNS events will likely increase.

Clinical Evidence for Neurotoxic Effects of Antiretroviral Therapies

A number of adverse effects have been reported in patients on ARTs as summarized in current treatment guidelines and reviews (Reust 2011; Thompson et al. 2012). The earliest and clearest clinical evidence of antiretroviral neurotoxicity was observed in the peripheral nervous system. The nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs), didanosine (ddI), dideoxycytidine (ddC), and stavudine (D4T) in particular, are known to cause peripheral neuropathy, while zidovudine (AZT) was recognized early on for its ability to cause a distinctive myopathy. HIV-infected patients taking the so-called d-drugs (ddC, ddI, D4T) developed distal symmetric sensory polyneuropathy, primarily in the feet. Pathologically, there is a “dying back” axonal neuropathy, which initially affects the distal branches of the longest nerves and then progresses proximally in a height-dependent manner. The clinical presentation is defined by numbness, aching, and/or burning in the toes progressing to the feet over weeks to months resulting in severe neuropathic pain. This drug-induced neuropathy can be difficult to distinguish from distal sensory polyneuropathy caused directly by the viruses, with only a history of d-drug exposure at the time of neuropathy onset as a discriminating feature. More recent studies of patients on CART regimens that avoid the neurotoxic ARTs and

maintain effective HIV RNA suppression (<400 copies/ml) and CD4+ cell counts >350 report ~30% of subjects with clinically detectable peripheral neuropathy (Evans et al. 2011), of which ~10% are symptomatic. In contrast very little information is available on the actions of ARTs in the CNS.

CART regimens with high penetration of the CNS are currently under investigation. While some studies have found beneficial cognitive effects with higher CNS penetration, results have been mixed (Cysique and Brew 2009). These equivocal findings may be due in part to combined beneficial and adverse effects of treatment. Additionally, the CPE score is largely predicated on ART concentrations in cerebrospinal fluid, which may not reflect tissue ART concentrations. Although the effects of ARTs in the CNS have not been adequately explored, a number of studies have indicated that ARTs can have adverse effects. Documented adverse effects that may reflect ART interactions with the CNS include sleep disturbances, abnormal dreams, depressed mood, nausea, fatigue, vomiting, fever, headache, and neuropsychiatric symptoms (Reust 2011). The strongest evidence of CNS toxicity is evident in the neuropsychiatric side effects of efavirenz, which include short-term effects of suicidal ideation, dizziness, clouded thinking, and lucid dreaming, as well as long-term impairments in neuropsychological performance (Ciccarelli et al. 2011).

One group showed that cognition improved for up to 96 weeks in a group of immunologically and virologically stable subjects who elected to interrupt ART (Robertson et al. 2010). Patients in these studies were not optimized for antiretroviral penetration suggesting that perhaps low ART concentrations can also penetrate the brain sufficiently to exert deleterious effects. Other studies have reported that abacavir may be associated with adverse psychiatric symptoms (Foster et al. 2003). Using proton magnetic resonance spectroscopy, a group directly assessed metabolic profiles in brains of HIV-infected patients treated with ARTs with known mitochondrial toxicity

(Schweinsburg et al. 2005). *N*-Acetylaspartate (NAA) levels were measured as an index of neuronal mitochondrial metabolism revealing that in white matter, NAA levels were significantly decreased in patients receiving didanosine and/or stavudine. Decreases in NAA levels were correlated with combinations of drugs and longer treatment duration. These studies provided the first in vivo indication that ARTs might be associated with neural cell damage.

Collectively, the above studies contribute to a growing body of indirect evidence in support of CNS ART neurotoxicity. However, the causal relationship between ART exposure and CNS effects is unknown, and it is often difficult to determine if the effects were due to direct toxic actions of the ARTs or secondary effects due to changes in systemic pathology, interactions with other drugs, or other confounding variables (Cysique and Brew 2009). For example, cardiovascular disease, lipodystrophy, and diabetes seen in HIV-infected patients are all correlated with changes in neurocognitive performance. Common symptoms such as nausea, vomiting, fatigue, and headache reported for NRTIs may be due to direct CNS interactions or systemic effects. Changes in sleep and cognitive and mood disorders associated with non-nucleoside reverse transcriptase inhibitors (NNRTIs) are more likely to be due to direct CNS effects. However, development of serious systemic effects such as hyperlipidemia or liver toxicity may confound the analyses. Protease inhibitors (PIs) carry increased risks of hypertriglyceridemia, hypercholesterolemia, and hyperglycemia, all of which could have wide-ranging effects on the CNS. Thus, there is considerable uncertainty regarding the direct impact of ARTs on the brain and its functions. As newer therapeutic strategies aim to deliver higher concentrations of ARTs to the CNS, the potential for toxic interactions will increase and may include novel effects not seen with current treatments. Support for this possibility comes from emerging in vitro studies, summarized below, in which the direct effects of antiretroviral compounds on neural tissue are beginning to be investigated.

Experimental Evidence for Antiretroviral Therapy-Mediated Neurotoxicity

Most information on the mechanisms that underlie potential toxic effects of ARTs has been generated for the NRTIs based on the early recognition of inhibitory effects on mitochondrial polymerase gamma (MtPol γ). These nucleosides, modified to terminate HIV reverse transcription, also inhibit MtPol γ activity leading to mitochondrial DNA depletion, increased oxidative stress, and a loss of mitochondrial function (Koczor and Lewis 2010). Organ systems with high dependence on mitochondrial protein synthesis are particularly vulnerable to these effects. Lactic acidosis, liver steatosis, and myopathy were prominent in patients treated with first-generation NRTIs. An increased risk for chronic kidney disease and development of peripheral neuropathies (particularly d4T and ddC) and dyslipidemia were also associated with chronic NRTI treatment. Newer NRTIs have been screened for these adverse effects and have a lower affinity for MtPol γ with fewer side effects. However, side-effect profiles of the NRTIs often cannot be explained solely by their ability to inhibit MtPol γ as the appearance of effects often does not correlate with the level of MtPol γ inhibition (Koczor and Lewis 2010). In addition, distal sensory polyneuropathy, often attributed to effects on MtPol γ in the past, continues to be recognized among well-controlled patients receiving PIs which are pharmacologically distinct from the NRTIs (Evans et al. 2011); this finding raises the possibility that PIs might also contribute to the development of polyneuropathy. Many factors may contribute to observed effects of ARTs including the confounding influences of HIV infection itself, pharmacokinetics, tissue distribution, cellular metabolism of each drug (e.g., NRTIs are prodrugs which require phosphorylation to triphosphate forms by cellular kinases), and unique drug actions. Little direct evidence is available to indicate how these compounds will interact with CNS cells at concentrations required to control HIV replication. Several studies have begun to

Neurotoxic Consequences of Antiretroviral Therapies, Table 1 In vitro neurotoxic activity of antiretroviral compounds

Class	Drug	TC ₅₀ (μM)	Log plasma conc/TC ₁₀
NRTI	Abacavir (ABC)	0.0077	2.80
NRTI	2',3'-Dideoxycytidine	5.0426	-0.63
NRTI	2',3'-Dideoxyinosine	0.0780	2.66
NRTI	Emtricitabine [(-) FTC]	21.3875	-0.31
NRTI	Tenofovir (TDF)	0.2651	1.07
NRTI	Lamivudine (3TC)	0.8434	1.79
NRTI	Zidovudine (AZT)	6.1348	0.59
NNRTI	Efavirenz (EFV)	0.6319	2.03
NNRTI	Etravirine (ETR)	0.0156	3.11
NNRTI	Nevirapine (NVB)	0.5678	2.61
PI	Amprenavir (APV)	0.0969	2.64
PI	Atazanavir sulfate (ATV)	0.0197	2.91
PI	Darunavir (DRV)	17.6049	0.58

EI	Maraviroc (MVC)	5.7972	-0.50

In vitro toxic activity was assayed on cultured primary rat neurons. NRTI, nucleoside/nucleotide reverse transcriptase inhibitor; NNRTI, non-nucleoside reverse transcriptase inhibitor; PI, protease inhibitor; EI, entry inhibitor; TC₅₀, median toxic concentration in primary neuronal cultures; TC₁₀, the drug concentration that is expected to cause minimal (10%) toxic activity based on the concentration-effect curve.

examine ART effects on neuronal function in vitro and ex vivo to assess potential interactions.

In vitro studies of ART neurotoxicity. The ability to examine effects of compounds on primary neuronal cultures allows sensitive direct assessments of potential toxic mechanisms under controlled conditions. Initial in vitro studies of the effect of various ARTs on cultured rat neurons demonstrated neurotoxic activity as assessed by alterations in calcium homeostasis and the development of dendritic pathology (Robertson et al. 2012). These pathological endpoints were chosen to provide assays of neuronal function likely to be sensitive to mild toxic effects expected in vivo. In this study, concentration-effect curves were generated for 15 antiretroviral drugs including 7 NRTIs, 3 NNRTIs, and 4 PIs and one entry inhibitor to determine the relative sensitivity of neurons to each compound. The median toxic concentration (TC₅₀) calculated for each drug varied widely as summarized in Table 1. Lower TC₅₀ values represent higher potencies. Potency does not take into consideration in vivo factors such as CNS penetration that contribute to the likelihood of neurotoxicity. Toxicity was not restricted to a

particular class of compounds. Of the NRTIs, abacavir, dideoxycytidine, tenofovir, and lamivudine showed the highest toxic potency. All NNRTIs tested had relatively high toxic potency. The toxicity of the PIs was generally lower than the NRTIs and NNRTIs but spanned a wide range with a toxicity rank order of atazanavir > amprenavir ≫ ritonavir > darunavir. To gain insight into the potential neurotoxicity at concentrations that would effectively suppress viral replication in the brain, a toxicity index was calculated as the log of the therapeutically effective plasma concentration divided by the TC₁₀ (representing a minimal 10% deflection of the concentration-effect curve). A toxicity index of 1 would then indicate that a therapeutic concentration was at the threshold of toxic activity with higher values indicating greater risk of toxicity. Overall, approximately half the compounds tested had an index ≥2, suggesting a clear risk of neurotoxicity. No correlation was seen with changes in the mitochondrial membrane potential and the rank order of CNS toxicity; abacavir > dideoxyinosine > tenofovir, lamivudine > dideoxycytidine, zidovudine > emtricitabine

(Robertson et al. 2012) did not parallel the reported inhibitor efficacy on MtPoly: zalcitabine \geq didanosine (dideoxyinosine) \geq stavudine \gg lamivudine $>$ tenofovir $>$ emtricitabine \geq zidovudine $>$ abacavir (Koczor and Lewis 2010). No significant cell death was seen for most compounds at relevant concentrations indicating that even though the compounds disrupt normal neural function, they are not highly toxic to nervous tissues. This increases the likelihood that neurotoxicity in vivo may be managed by careful drug selection and adjunctive neuroprotective therapies.

When clinically relevant combinations of the antiretroviral compounds were applied to cultured neurons at therapeutic doses, the results were unpredictable. In some cases, the expected additive effects were seen, whereas in other cases potential protective effects were observed (Robertson et al. 2012). Although more data are required to understand the nature of these interactions, the latter observation indicates that specific combinations of drugs might minimize neurotoxicity. Individual drug effects and drug-drug interactions in the CNS will undoubtedly be complex and mechanisms are only beginning to be explored. In some cases, toxic metabolites may also play a role. Enhanced neuronal calcium dysregulation and pathology has been reported in response to the efavirenz metabolite, 8-OH-efavirenz, which was an order of magnitude more toxic than the parent compound (Tovar-y-Romo et al. 2012). CNS cells other than neurons may also be targets. The NRTI, abacavir, and the PI, indinavir, at 10 μ M have been reported to inhibit the ability of microglia to phagocytose amyloid beta (Giunta et al. 2011), a process thought to be important for suppression of Alzheimer-like pathology that has been reported in HIV infection. NRTIs have also been linked to inhibition of telomerase activity in human peripheral blood mononuclear cells suggesting that they contribute to accelerated aging (Leeansyah et al. 2013). Each of the in vitro studies has limitations that must be taken into account when attempting to interpret in vitro results in the in vivo setting. In vitro assays cannot easily assess the effects of

long-term treatment, may depend on specific conditions of the assay, and cannot recapitulate the complex interactions that occur in vivo. Thus, the impact of particular ART interactions on CNS function must be validated in appropriate in vivo studies.

In vivo studies of antiretroviral therapy neurotoxicity. An important recent study has provided an in vivo assessment of antiretroviral toxicity in both macaques and rats treated with various antiretroviral drug combinations (Akay et al. 2014). Decreases in synaptic density in the hippocampus, assessed by synaptophysin immunoreactivity, were specifically linked to ART exposure in SIV-infected macaques and in rats treated for 7 days with the ARTs, zidovudine, ritonavir, and saquinavir. These same studies further demonstrated that the generation of reactive oxygen species contributed to cellular injury and that adjunctive antioxidant treatments may have therapeutic utility.

The above studies show that ARTs can be toxic to neurons and provide preliminary evidence highlighting how these drugs might cause cellular damage. More studies are needed to better understand the potential risks and the underlying pathogenic mechanisms. Future studies should include evaluation of interactions between antiretroviral drugs as well as interactions with other medications likely to be used to treat comorbid conditions in an aging HIV population.

Conclusions

Treatment of replicating HIV in the CNS carries a risk of off-target neurotoxic effects. Under current treatment regimens with limited penetration of ARTs into the CNS, there are few reports of serious CNS adverse events, perhaps because the virus also exerts direct and substantial adverse effects on the CNS. However, a growing body of data has demonstrated neurotoxic effects of several ARTs, which must be taken into consideration as new strategies are developed to suppress HIV replication in the CNS. Although too few studies are available at present to recommend particular

treatment strategies, preliminary evidence suggests that adverse effects of ARTs in the CNS may be avoided at least partially by the careful selection of specific ART combinations that minimize the risk of neurotoxicity. While effects on MtPoly are the most well-documented toxic mechanisms, other actions are likely to contribute to ART toxicity in the CNS. Indeed, the mechanisms of ARV toxicity in the CNS are poorly understood, necessitating more studies to understand the full range of neurotoxic effects and the mechanisms mediated by ARTs. CART selection strategies are currently guided by efficacy, resistance, toxicity, drug interactions, and penetration of the CNS. As improved strategies are developed to target the CNS viral reservoir, greater knowledge of the effects of ARTs on neural tissues will be needed to direct their use which both maximize their antiretroviral actions and minimize the neurotoxic effects and the associated clinical complications.

National Primate Research Center, Covington,
LA, USA

Definition

Invariant natural killer T-cells (iNKTs) are an innate T-cell subset unique in their possession of an invariant T-cell Receptor (TCR) and non-classical antigen presentation mechanism through the CD1d molecule. iNKTs recognize glycolipids presented on the nonpolymorphic major histocompatibility complex (MHC) class I-like CD1d molecule, unlike conventional T-cells which recognize peptides presented on MHC class I/II molecules. iNKTs can rapidly produce multiple cytokines in response to activation. This rapid cytokine production allows iNKTs to be powerful modulators of the immune response. iNKTs can produce T-helper type 1 (Th1), Th2, and Th17 cytokines depending on stimulus strength, type of stimulation, iNKT subset, and presenting cell type. As a result, iNKTs are able to affect and modulate immune responses to a variety of diseases, both chronic and infectious – including a potentially important role in controlling human immunodeficiency virus (HIV) infection. The ability of iNKTs to produce and direct a variety of immune responses shows the promising potential for development of immune therapies and adjuvants by harnessing and directing iNKT functionality. A better understanding of iNKT function would provide a powerful tool to direct both chronic and infectious diseases through modulation of the immune response.

Introduction

Invariant natural killer T-cells (iNKTs) are an innate, multifunctional T-cell subset. iNKTs are

able to produce T-helper type 1 (Th1), Th2, Th17 cytokines and influence the function of other immune cell subsets (Tupin et al. 2007; Godfrey et al. 2015; Van Kaer et al. 2015). This ability to produce cytokines covering a range of immune functions highlights the important role of iNKTs in immune modulation.

iNKTs were first discovered in nonobese diabetic (NOD) mice in the context of diabetes. In this murine model, mice spontaneously developed diabetes which was ultimately attributed to the absence of a subset of T-cells expressing NK1.1, a marker previously thought to be exclusively expressed on natural killer cells (NK cells). Natural killer T-cells were thus named for their mix of NK and T-lymphocyte markers. Further investigation led to the understanding that this newly identified population of cells was a heterogeneous T-cell subset. This in turn led to the classification of NKTs into at least two distinct groups: type I NKTs – which this chapter will focus on – and type II NKTs.

Common to both types of NKTs is their recognition of antigen presented in the context of CD1d molecules. CD1d molecules are major histocompatibility complex (MHC) class I-like molecules that are nonpolymorphic and comprised of a heavy chain with three alpha subunits associated with β 2-microglobulin. The CD1d molecule is highly conserved across species ranging from mice to humans and has a hydrophobic binding pocket that allows binding and presentation of lipid ligands. Type I NKTs, also known as classical or invariant NKT cells, are activated by a class of lipid ligands known as sphingolipids. iNKTs use an invariant TCR α chain – V α 24-J α 18 in primates and V α 14-J α 18 in mice – that preferentially binds to V β 11 and V β 8 in primates and mice, respectively. Both human and mouse iNKT cells are enriched in CD4⁺ and CD4/CD8 double-negative populations. Humans and non-human primates (NHPs) have a CD8⁺ population of iNKT cells that is absent in the mouse model.

Type II NKT cells, or nonclassical NKTs, are also CD1d restricted but possess more TCR variability than iNKTs. Like iNKTs, type II NKT cells are also activated by lipid ligands; however, the specific lipids able to activate type II NKTs differ from the lipid ligands of iNKTs. One subset of type

II NKT cells are activated by sulfatides instead of the sphingolipids employed in iNKT activation. Studies of NKT cells have been hampered by lack of tools for clear differentiation and identification of NKT subsets. The initial definition of NKT cells as T-cells expressing NK1.1 in mice and CD161 in primates is neither specific nor does it cover all NKT cells. Flow cytometry based methods using tetramers have greatly facilitated accurate identification of NKT cells, particularly iNKTs.

Currently iNKTs are most readily detected by the use of CD1d tetramers as well as a monoclonal antibody (clone 6B11) which recognizes the invariant region of the iNKT TCR. iNKT identification involves co-staining with T-cell receptor (TCR) V α -chain specific antibodies, such as V α 24 (in primates, V α 18 in mice), and 6B11 or CD1d tetramers (CD1dTM) loaded with the lipid antigen alpha-galactosylceramide (α -GalCer). Both the 6B11 antibody and α -GalCer loaded CD1dTM bind to the glycolipid binding site on the TCR of iNKTs. These Va24+ CD1dTM+ or Va24+ 6B11+ cells are defined as iNKTs. A subset of type II NKT cells can be identified with CD1dTM loaded with sulfatide lipid ligands.

The remainder of this entry will focus on iNKTs and their unique multifunctionality. Characteristics of iNKTs as well as their role in both chronic and infectious disease – with a particular interest to HIV – will be discussed.

Characteristics of iNKTs

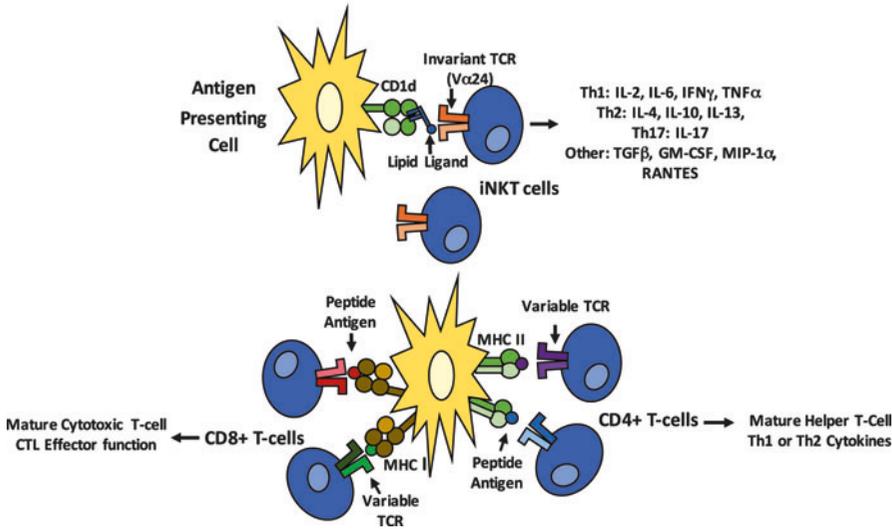

iNKTs are a nonclassical T-cell subset for multiple reasons (Table 1). While all T-cells have an alpha

(α) and beta (β) TCR chain, in the case of classical T-cells, the antigen recognition domain of the α and β chains are infinitely variable. This property allows classical T-cells to specifically recognize and respond to a broad range of peptides presented on MHC class I or II molecules (Table 1). While classical T-cells are a part of the adaptive immune system, iNKTs function as innate T-cells by virtue of having an invariant complementary determining region three (CDR3) region of the α chain and a restricted (but not invariant) β chain that recognizes glycolipid ligands presented on nonpolymorphic CD1d molecules (Godfrey et al. 2015). Due to their innate nature, iNKTs can rapidly recognize lipid antigens after encountering them for the first time.

The best studied lipid antigen capable of activating iNKTs is alpha-galactosylceramide, or α -GalCer, a derivative of the marine sponge, *Agelas mauritanus*. α -GalCer was first identified as a natural killer T-cell agonist in studies investigating novel antitumor agents. α -GalCer has a strong avidity for the iNKT TCR when presented by CD1d molecules on antigen presenting cells (APCs) and rapidly activates iNKTs leading to proliferation and cytokine production. While α -GalCer is not necessarily a biologically relevant lipid antigen for iNKTs in vivo, analogous glycolipids (both endogenous and exogenous or pathogen derived) have been identified. It has been suggested that endogenous lipids play a role in iNKT development and differentiation in the thymus. Endogenous lipids may also play a role in iNKT activation during infection with some pathogens where concurrent pathogen and “self” lipid recognition is necessary to elicit a response.

NKT Cells: Bridging Innate and Adaptive Immunity, Table 1 iNKTs versus classical T-cells

	Invariant natural killer T-cells	Classical T-cells
TCR	Invariant	Infinitely variable/diverse
Binding specificity	Limited to few lipid ligands	Multiple and diverse peptide-MHC combinations
Antigen presentation	CD1d (nonpolymorphic)	MHC class I/II (polymorphic)
Antigen	Lipids (glycosphingolipids)	Peptides
Effector function	Diverse Th0/Th1/Th2/Th17/ Cytotoxicity	CD4+ Th1 or Th2 helper T-cells or CD8+ Cytotoxic T-cells
Time to effector function in vivo	Rapid (hours to days)	Slower (days to weeks)
Type of immunity	Innate	Adaptive

NKT Cells: Bridging Innate and Adaptive Immunity, Fig. 1 Antigen presentation in iNKTs and Classical T-cells. Antigen presenting cells present antigens to

T-cell subsets – lipid antigens on CD1d in iNKTs and peptide antigens on MHC class I/II in classical T-cells – resulting in activation/maturation

α -GalCer is composed of a glucose head connected to a ceramide, which consists of a sphingosine backbone with a fatty acid tail. Sphingolipids with a similar sugar-ceramide structure make up the family of lipid ligands that can activate iNKT cells.

Modes of antigen presentation differ between iNKTs and classical T-cells (Fig. 1). In the case of iNKTs, APCs expressing the CD1d molecule – such as dendritic cells, macrophages and B-cells – present lipid ligands to iNKT cells that are recognized by the iNKT invariant T-cell receptor. Activated iNKTs produce a wide range of cytokines depending on multiple factors including the type of APC, ligand binding affinity, and duration of binding. In contrast, classical CD4 and CD8 positive T-cells recognize peptide antigens presented on APCs expressing either MHC class I or II molecules. Upon activation, classical CD4+ T-cells mature into helper T-cells with a Th1 or Th2 cytokine profile while CD8+ T-cells mature into cytotoxic T-cells with cytolytic activity. iNKTs are able to produce multiple effector functions from a single cell subset, whereas conventional T-cells generally have a single function specific to each T-cell subset. For example, a single subset of iNKTs can produce Th1 and

Th2 (Th0) cytokines as well as having cytolytic activity. In contrast, in conventional T-cell subsets there are CD4+ Th1 producing subsets and Th2 producing subsets that are distinct (Tupin et al. 2007).

iNKTs Across Species

As a component of the innate immune system iNKTs are evolutionarily conserved across multiple species. iNKTs can be found in a wide range of vertebrates including mammals such as mice, humans, NHPs, pigs, and horses. Functional CD1d is notably lacking from ruminants showing that while present in many mammals, iNKTs are not universal (Looringh van Beeck et al. 2009). CD1d/NKTs are not restricted to mammals and have been identified in birds, reptiles, and amphibians; although functionality of CD1d in these species has not been determined (Ohta and Flajnik 2015). The wide range of species possessing iNKTs suggests that these cells developed relatively early in evolutionary history. iNKTs have been most widely studied in mice and humans; more recently studies in NHPs have been performed.

NKT Cells: Bridging Innate and Adaptive Immunity, Table 2 iNKT frequency and phenotype varies between species

Species		Peripheral blood iNKT frequency (mean or range, % T lymphocytes)	CD4/CD8 phenotype				Tissue iNKTs	References
			CD4+	CD8+	CD4+ CD8+	CD4- CD8-		
Mouse	<i>Mus musculus</i>	0.5–2%	+	–	–	+	Highly enriched in liver; significant populations in bone marrow, thymus, spleen; lower in lymph nodes	Berzins et al. 2011
Primates								
Humans	<i>Homo sapiens</i>	0.1% (highly variable between individuals)	+	+	–	+	Enriched in omentum and liver; significant populations in spleen, bone marrow, and lymph nodes; lower in the thymus	Godfrey et al. 2015

^aPercent total lymphocyte population
 ND not described

iNKT frequency, distribution within the host, phenotype, and function vary based on tissue and host species (Table 2). In the murine model, iNKTs are enriched in liver and bone marrow. Significant iNKT populations are also seen in the thymus, spleen, and peripheral blood but to a lesser degree. iNKT frequencies between mice are relatively stable. Humans, however, have lower NKT frequencies than mice, and frequencies vary greatly between individuals. Not surprisingly, NHP iNKTs are more reflective of what is seen in humans than in mice. The NHP species that have been studied – sooty mangabeys and macaques (rhesus, cynomolgus, and pigtailed) –

consistently have lower iNKT frequencies than mice, and iNKT frequencies vary widely between animals (Fernandez et al. [2009](#); Rout et al. [2010](#), [2012](#)). Cynomolgus macaques have more similar iNKT frequencies to humans and therefore may represent the best NHP model to understand iNKT frequency and functionality in humans.

How Do iNKTs Act?

iNKTs act either directly or through downstream effects on other immune cell subsets. iNKTs activate and are able to cross-talk with other immune

NKT Cells: Bridging Innate and Adaptive Immunity, Fig. 2 iNKT pathogen response mechanisms. There are three proposed routes of iNKT activation: direct TCR

mediated activation (a), TCR and cytokine mediated activation (b), and TCR-independent cytokine directed activation (c)

regulatory and effector cells. Pathogen recognition causes iNKTs to produce a wide range of cytokines including IL-2, IL-4, IL-6, IL-10, IL-13, IL-17, transforming growth factor beta (TGF- β), interferon gamma (IFN- γ), and tumor necrosis factor alpha (TNF α). Through the rapidity of their response and their prolific cytokine production repertoire, iNKTs are able to directly affect a variety of downstream immune responses and recruit other effector cells. iNKTs can enhance immune responses through interaction with dendritic cells (DCs). iNKTs can induce activation and maturation of DCs through CD40 ligand on its surface interacting with CD40 on DCs and this in turn enhances DC-mediated antigen presentation to T lymphocytes and improves immune responses mediated by CD8+ cytotoxic T lymphocytes (CTLs) and CD4+ T-helper cells (Juno et al. 2012). NK cells, B-cells, and regulatory T-cells can also be directly influenced by iNKTs. iNKTs can also be directly cytolytic through granzyme B,

perforin, FasL, and TNF-related apoptosis-inducing ligand.

While iNKTs can directly recognize and react to pathogens possessing lipid antigens that are presented on CD1d molecules, they can also react to pathogens without these hallmark lipids. How are iNKTs activated by pathogens lacking lipid antigens? As shown schematically in Fig. 2, there are at least three proposed models for iNKT activation in response to foreign antigens (Tupin et al. 2007; Van Kaer et al. 2015).

The first proposed model of iNKT activation is through direct recognition. iNKTs can directly recognize and respond to pathogens with glycolipids analogous to α -GalCer. These are primarily bacterial or parasitic organisms which have glycolipids on their outer cell surface such as the glycosylceramides in the cell wall of *Novosphingobium* species (*Sphingomonas*, gram negative bacteria) as well as diacylglycerols expressed by *Borrelia* species, the spirochete etiologic agent of Lyme disease (Tupin et al. 2007).

The second proposed model is iNKT activation through simultaneous TCR and cytokine engagement. In this scenario, byproducts of invading micro-organisms are recognized by Toll-Like-Receptors (TLRs) on APCs initiating a stress response which results in upregulation of self-lipids presented on CD1d molecules and production of cytokines – namely IL-12 and IL-18 that can bind to their respective receptors expressed on the surface of iNKT cells.

Finally, iNKTs can be activated entirely in a TCR-independent cytokine directed manner through the receptors for IL-18 and IL-12 on their cell surface binding to cytokines produced in response to pathogen detection by a number of innate immune cells such as DCs and macrophages. While a given pathogen may primarily use one route of activation, it is likely that iNKT activation involves multiple activation routes.

The type of effector response of iNKTs is directly related to the type of stimulus as well as the route and strength of stimulation. Depending on the pathogen and type of immune response required, iNKTs can be protective or deleterious. Questions remain regarding the determinants of effector function in iNKTs: are there distinct NKT populations with specific effector function or is it the milieu or environment of NKTs that determine their ultimate effector function?

iNKTs and Disease

iNKTs have been shown to play an important role in several bacterial, parasitic, and viral infections (summarized in Table 3), and in cancer and diseases of chronic inflammation and immune activation such as autoimmune diseases, asthma, and metabolic syndromes (Mallevaey et al. 2006; Tupin et al. 2007; Berzins et al. 2011; Van Kaer et al. 2015). Murine studies have provided evidence for a protective role of iNKTs against tumor proliferation as well as against autoimmune conditions such as diabetes, multiple sclerosis, and systemic lupus erythematosus, whereas iNKTs can exacerbate certain diseases such as asthma and atherosclerosis. Protective and deleterious effects of iNKTs have also been described for several pathogens (Table 3).

Clinical studies in humans have also suggested that deficiencies in iNKTs, in frequency and/or function, contribute to a variety of chronic and infectious diseases. iNKT defects, either low frequency or incompetent cytokine production, have been suggested to play a causal role in the pathogenesis of autoimmune diseases (i.e., diabetes, lupus, arthritis, and multiple sclerosis), cancer, and infectious diseases including influenza and HIV. A pathologic role of iNKTs in human disease has been suggested for atherosclerosis, graft-versus-host disease, and asthma (Berzins et al. 2011). It should be noted that due to conflicting results in similarly designed studies as well as lack of a stringent, consistent definition for iNKTs in human studies, the link between iNKT dysfunction and disease is less clear than in the mouse model. A major question that remains across even the most convincing data linking iNKT defects to disease in humans is whether the observed defect is causal or reactive to disease progression. Further longitudinal investigation of the role of iNKTs in disease, especially in the NHP model, promises to fill gaps in understanding between human and mouse studies. Investigating the role of iNKTs in both chronic and infectious diseases involving inflammation will lead to a better comprehension of the role of iNKTs in HIV infection and progression to AIDS, a hallmark of which is chronic inflammation and immune activation.

iNKTs and HIV

In vitro studies, as well as in vivo studies in animal models and humans have begun to complete the picture of the role of iNKTs in HIV infection. While the mechanism and details of iNKT involvement in HIV/AIDS are unknown, multiple factors suggest that iNKTs play an important role in HIV progression to AIDS. First, the ability of HIV proteins to downregulate CD1d expression suggests the evolution of iNKT-related immune evasion mechanisms in HIV infection. Second, iNKTs are highly susceptible targets of HIV infection. Finally, massive dysregulation of iNKTs in AIDS susceptible hosts (i.e., humans and macaques) with maintenance of iNKT function

^aRole proposed

in natural hosts (sooty mangabeys) that do not progress to AIDS is another added factor implicating iNKTs in having a protective role in AIDS. Despite the strong evidence supporting iNKT involvement in AIDS, longitudinal and prospective studies are needed to show causality between iNKT dysfunction and AIDS progression. The sections below summarize our current knowledge on the interactions between iNKTs and HIV infection.

HIV Downregulates CD1d

HIV has evolved mechanisms to interfere with CD1d trafficking impeding antigen presentation through this route. HIV, for example, employs viral proteins Vpu and Nef to prevent CD1d expression on dendritic cells (DCs), which play an important role of antigen presentation to iNKTs (Juno et al. 2012). Vpu sequesters CD1d in early endosomes, impeding the ability of DCs to activate iNKTs. Furthermore, Nef promotes the

internalization of CD1d molecules from the cell surface to the trans-golgi network ultimately impairing the ability of the cell to present CD1d and activate iNKT cells. The evolution of mechanisms to overcome iNKT activity suggests an iNKT based role in HIV control. These mechanisms could effectively block the ability of iNKTs to respond to pathogens, thereby dysregulating normal immune response mechanisms.

iNKTs Are Susceptible to HIV Infection

Infection of iNKTs by HIV or simian immunodeficiency virus (SIV), the simian analogue to HIV and the primary model for HIV research, have been studied *in vitro* as well as *in vivo* in both humans and NHP models. *In vitro* studies have shown that iNKTs are highly susceptible targets of HIV/SIV infection (Fleuridor et al. 2003). Many iNKTs are CD4 positive and the majority express CCR5 and to a lesser degree CXCR4, the co-receptors of HIV, making them preferred targets for HIV/SIV infection (Sandberg et al. 2002). *In vivo*, in both NHP models and humans, CD4+ iNKTs are depleted early in SIV/HIV infection indicating they are primary target cells of these lentiviruses (Sandberg et al. 2002; Ibarrondo et al. 2013). This depletion is most likely due to direct infection of CD4-positive iNKTs as well as Fas-mediated apoptosis of the remaining CD4 negative iNKT subsets. Activation induced cell death is probably the main way that the CD4-negative iNKT subsets are depleted in HIV infection.

Studies in HIV-infected subjects on highly active antiretroviral treatment (HAART) have investigated the repopulation dynamics of iNKTs depleted during acute HIV infection. While several studies report iNKT recovery following treatment with HAART, there are conflicting results concerning the extent and rate of repopulation of CD4-positive and CD4-negative iNKT subsets. Due to the conflicting data on iNKT recovery, the effect of HAART on iNKT reconstitution remains inconclusive.

iNKT Dysfunction Is Associated with Chronic Immune Activation

Consistent with iNKTs being a primary target of HIV/SIV infection, the early depletion of gut

iNKTs in HIV infection is thought to contribute to iNKT dysregulation, a skewing toward pro-inflammatory cytokine production and ultimately chronic immune activation and progression to AIDS (Ibarrondo et al. 2013). NHP studies in natural and nonnatural hosts of SIV infection have highlighted the importance of preserved iNKT frequency and function in protection against AIDS (Rout et al. 2012). Natural SIV hosts such as the sooty mangabey monkey (*Cercocebus atys atys*) show marked differences in response to SIV infection when compared to nonnatural hosts, such as macaques (cynomolgus and rhesus) and humans. Natural hosts typically maintain high levels of viremia with no chronic immune activation and no progression to AIDS. In contrast, nonnatural hosts have high virus loads paired with chronic immune activation and inevitable progression to AIDS.

In the natural host, iNKT populations remain intact and functional, helping to maintain and find balance in the immune response. In chronically SIV infected macaques, the loss of CD4+ iNKTs correlates with an increase in SIV viral load as well as activation of CD4+ memory T-cells, contributors to increased inflammation. This maintenance of iNKT function and positive SIV outcome in sooty mangabeys contrasted with dysregulation of iNKTs and poor outcome in macaques highlights the importance of maintained iNKT function in protection from chronic immune activation and progression to AIDS (Rout et al. 2012).

Cytokine profiles of iNKTs in natural hosts compared to nonnatural hosts differ in distinct and possibly meaningful ways. For example, when comparing SIV-negative mangabeys and macaques, iNKTs from members of both species produce a variety of Th1 (IFN- γ , IL-2) and Th2 (IL-10, IL-6, TGF- β) cytokines. However, there are quantitative and qualitative differences between species with sooty mangabey iNKT activation resulting in higher levels of IFN-g, IL-13, and IL-17 production relative to the macaques (Rout et al. 2012). These differences in cytokine production in mangabeys versus macaques most likely represent functional differences between the species that may have a bearing on differential AIDS pathogenesis. Additionally, in the context

of SIV, macaque iNKTs lose much of their ability to produce cytokines following stimulation with α -GalCer and the residual effector activity is skewed towards a dominant proinflammatory IL-6 response, a factor that may contribute to increased immune activation (Rout et al. 2012).

Harnessing the immunomodulatory action of iNKTs could provide a promising tool to control immune responses and thus disease outcomes in the HIV setting as well as other diseases of chronic inflammation where iNKTs play a prominent role. It remains unclear whether the changes in iNKT frequency, phenotype, and functionality in the presence of HIV/SIV infection are causal with respect to negative disease outcomes. Longitudinal studies are needed to show direct causality.

Manipulation of iNKTs: Potential for a Therapeutic Role

In recent years much interest has been placed on the potential role of iNKTs in therapeutic measures. The ability to manipulate iNKTs would allow modulation of T-helper immune responses: the host immune response could be skewed towards an environment beneficial to pathogen control. Immune modulation through iNKT manipulation is a promising field that will lead to therapeutic interventions – both as direct therapies or as adjuvants to improve vaccine induced immunity – for a range of diseases in the future.

Orchestration of the immune response by iNKTs could be applied as an important therapy in disease settings where iNKTs play a role. Antitumor therapies involving iNKT activation are currently being studied. Researchers have looked into methods involving soluble α -GalCer (and other synthetic lipid) administration as well as lipid ligand loaded onto autologous antigen presenting cells in various formulations. These studies together show some positive clinical outcomes in patients including tumor reduction, reduction of tumor markers in the serum (Singh et al. 2014). While the current focus on iNKT therapies is to target various cancers, such therapies could be applicable to other iNKT-mediated diseases. Harnessing the immunomodulatory capacity of iNKTs as adjuvants to improve

immune responses, especially mucosal immunity, is also a promising field.

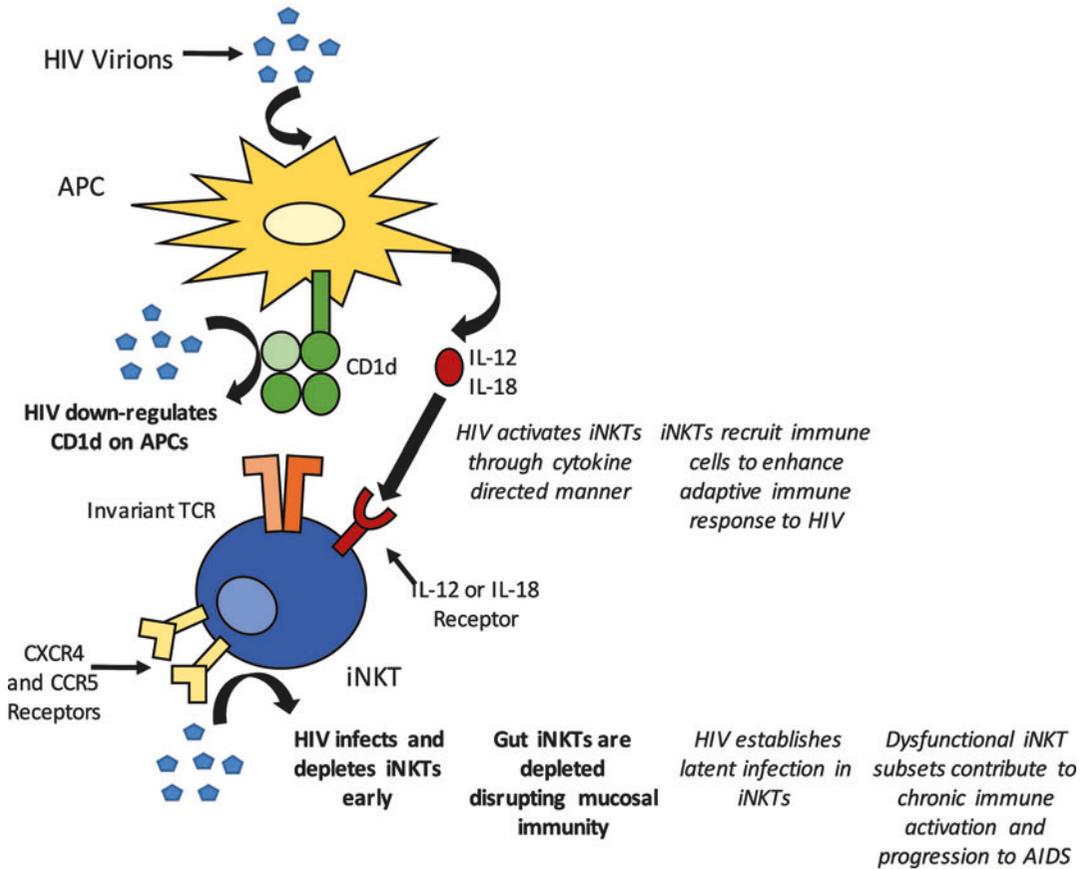

Conclusions and Remaining Questions

iNKTs are a heterogeneous nonclassical T-cell population. These innate T-cells are able to rapidly produce a range of cytokines and direct the immune response following activation by lipid ligands presented on the nonpolymorphic MHC class one like molecule CD1d. iNKTs recruit other immune cells such as DCs and macrophages and additionally shape the adaptive immune response through recruitment of B and T-cells. iNKTs can also have direct cytolytic activity. iNKTs play an important immunomodulatory role in multiple diseases related to chronic inflammation, most likely including HIV.

During HIV infection, iNKTs are rapidly depleted, showing they are a preferred target for HIV infection. Through this depletion, iNKT populations are disrupted in terms of frequency, phenotype, and function. In NHP models of HIV infection, dysregulation of iNKT function following SIV infection correlates with increased immune activation, inflammation, and progression to AIDS. HIV has evolved mechanisms to downregulate CD1d expression on antigen presenting cells, further impairing iNKT functionality. Although mounting evidence in human and NHP studies suggests that iNKTs are important in HIV infection and pathogenesis, further study is needed to conclusively show causality and illuminate mechanisms of iNKT activity during HIV infection.

Many questions remain in understanding iNKT biology, effector function, and potential therapeutic role in the context of HIV infection and mucosal immunity (Fig. 3 and Table 4).

The mechanism of iNKT activation in HIV infection and the consequence of HIV infection-mediated CD1d downregulation on *in vivo* iNKT activation are not known. It is proposed that iNKTs are activated by HIV through a TCR independent, endogenous lipid independent, cytokine mediated mechanism; however, the actual mechanism has yet to be definitively shown. It is known that iNKTs are able to improve adaptive immune responses by

	Known	Questions
Target cells	iNKTs are CD4+ and express HIV co-receptors CCR5 and CXCR4 iNKTs have enhanced susceptibility to HIV infection in vitro Both systemic and gut mucosal CD4+ iNKTs are infected and depleted early in HIV infection	Are iNKTs a latent reservoir for HIV? Is iNKT depletion irreversible? Does iNKT depletion lead to chronic immune activation?
iNKT dysfunction	CD4-negative iNKT are not depleted but become dysfunctional Increased expression of exhaustion markers PD-1 and LAG-3 on iNKTs in HIV-infected individuals	What is the consequence of iNKT dysfunction? 1. Impaired HIV/SIV-specific immunity? 2. Impaired immune response to opportunistic pathogens? 3. Enhanced proinflammatory environment? 4. Are iNKTs necessary to maintain gut mucosal immunity?
Immune evasion	HIV downregulates CD1d on APCs and as a result may evade NKT cells	How do iNKTs get activated in vivo in HIV infection? Does CD1d downregulation impair iNKT activation in vivo resulting in iNKT dysfunction?

recruiting immune cells and enhancing T-cell development in response to invading pathogens. While it seems likely that fully functioning iNKTs would play this role in HIV infection, it is unclear how iNKT loss and dysfunction impacts pathogen-specific immune responses against HIV and other pathogens. There are also open questions about the role of iNKTs in mucosal immunity and AIDS pathogenesis. Mucosal immunity is known to be important in HIV infection and pathogenesis. Gut iNKTs are depleted early on in infection, disrupting the protective gut mucosal barrier. Dysfunctional iNKT populations in the gut may contribute to further immune activation and progression to AIDS. Further study of gut mucosal iNKTs is needed to definitively determine the role of iNKTs in mucosal immunity during HIV infection. A major question concerning iNKTs in AIDS pathogenesis is whether the iNKT dysfunction and subsequent immune activation during chronic SIV infection is causal or reactive to viral infection and disease progression. Although iNKT depletion and dysregulation correlate with chronic immune activation and progression to AIDS, causality remains to be established. Many of these elusive questions can be best answered in NHP models where experimental conditions can be tightly controlled and there are opportunities for *in vivo* iNKT manipulation. Continuing to build the breadth of knowledge on this subject through longitudinal studies in humans and NHPs will lead to a full understanding of the capacity of iNKTs to regulate or contribute to disease in the context of HIV.

Nonhuman Primate Models of HIV Transmission

Elena Martinelli, Nina Derby and Melissa Robbiani

Center for Biomedical Research, Population Council, New York, NY, USA

Definition

A nonhuman primate (NHP) model of HIV transmission is an experimental infection of monkeys with simian immunodeficiency virus (SIV), a virus that is closely related to HIV, or a chimera of SIV engineered to express select HIV genes (SHIV). NHP models are used to study the biology of HIV transmission and pathogenesis or to test new strategies for treatment and prevention.

Introduction

Because the NHP and human immune systems closely resemble each other, the search for an animal model to study HIV-1 infection in the early years of the epidemic focused on experimental infection of chimpanzees (*Pan troglodytes*). Although these studies provided initial key information about transmission, infection of chimpanzees rarely resulted in disease and did so only after more than 10 years of infection. During the early 1980s, outbreaks of immunodeficiency-associated diseases occurred in Asian macaques at multiple primate centers. The animals succumbed to neoplasms and opportunistic infections (OIs), paralleling the newly described human disease now known as AIDS. Thus, macaques became the NHP model of choice for the vast majority of HIV studies.

Nowadays there are several NHP models of HIV infection, which are characterized by the infection of different monkey species with different SIVs. These SIVs and the disease profiles they manifest in the different species exhibit specific traits that enable the study of particular aspects of HIV transmission and pathogenesis. The most

common species used for these models are Asian macaques (*Macaca* species) – *M. mulatta* (rhesus; RM), *M. nemestrina* (pigtailed; MNE), and *M. fascicularis* (cynomolgus). Disease in these animals reproduces the disease course in humans, including acute and then progressive loss of CD4⁺ T cells followed by clinical immunodeficiency, OIs, and neoplasms. Sooty mangabeys (SMs) and African green monkeys (AGMs) are two other species that exhibit a nonpathogenic infection and have been studied to better understand disease progression.

During the more than 20 years of their use, NHP models have dramatically increased our knowledge of (i) the transmission of immunodeficiency viruses across mucosal barriers, (ii) the definition of relevant challenge viruses via different routes, (iii) the timing of viral dissemination, (iv) the establishment in the newly infected host of quiescent sources of infectious virus (reservoirs), (v) the quality and magnitude of innate (00151) and adaptive immune responses (00152-3), and (vi) the protective effect of candidate vaccines and topical microbicides. Herein we will describe (i) the similarities and differences between HIVs, SIVs, and SHIVs, (ii) the importance of these models in the study of the early events after transmission, (iii) the continuous striving to create and utilize a model that recapitulates the modalities of transmission and pathogenesis in humans, (iv) the models of coinfection with other sexually transmitted infections (STIs), (v) the pathogenic versus nonpathogenic models that provide insight into natural mechanisms of protection, and (vi) the use of these models in vaccine and microbicide testing.

SIV and SHIV Versus HIV

SIVs exhibit similar genomic organization and genetic sequence homology (53% nucleotide identity) to HIV (Courgnaud et al. 2002). The SIV is composed of the same three major genes *gag*, *pol*, and *env*, which are responsible for the structural (capsid, nucleocapsid, matrix), enzymatic (reverse transcriptase [RT], protease, integrase), and virus entry (envelope [Env])

proteins, respectively. Several accessory genes are also common to both viral lineages; HIV and SIV express the *tat*, *rev*, *vif*, *vpr*, and *nef* genes. However, only SIVcpz and HIV-1 express *vpu*, while SIVsm, SIVagm, and HIV-2 express *vpx*. Disparate *vpu/vpx* expression has been implicated in varied pathogenesis.

Like HIV, SIV replicates predominantly in CD4⁺ T lymphocytes but also infects dendritic cells (DCs) and macrophages. DCs can capture infectious HIV/SIV and transfer it to CD4⁺ T cells and also can become infected, synthesizing new virions, which are then transferred to CD4⁺ T cells. Thus, DCs play an important role in amplifying HIV and SIV infection and macaque DC biology largely mimics that of human DCs (Teleshova et al. 2013).

Both HIV and SIV are transmissible through mucosal (vaginal, rectal, oral) and intravenous routes. Mimicking the HIV early stages of infection, within 2–4 weeks after mucosal transmission (acute phase), SIV viremia peaks in the plasma (10^8 – 10^9 RNA copies/ml) and then typically resolves to a set point (10^4 – 10^6 RNA copies/ml). This coincides with the detection of virus-specific antibodies (Ab), CD4⁺ T cell, and CD8⁺ cytotoxic T lymphocyte (CTL) responses in peripheral blood and is maintained throughout most of chronic infection. Therefore, both the replication rate of SIV and the immune response to the virus are similar to HIV in particular in the pathogenic models of macaques.

Although the course of SIV infection (00191) closely resembles that of HIV infection in humans, the testing of prevention methods and therapies in the SIV model is hampered by the still large genetic diversity between HIV and SIV. Genetic diversity can translate into important differences in the structures of the proteins identified as potential targets of vaccines and antiviral compounds between SIV and HIV, and thus vaccine-elicited immune responses to HIV and other strategies to prevent HIV transmission are specific to the HIV molecules they target. To overcome these difficulties, chimeric viruses were generated that contain relevant pieces of the HIV genome in an SIV background. These SHIVs exhibit similar biology (host cell types,

transmission, viremia) to SIV and HIV, and they have become crucial models for research into novel HIV prevention strategies. The SHIV-RTs encode the RT of HIV in an SIV genetic background and are particularly useful to test the efficacy of prevention strategies based on anti-retrovirals (ARVs) that target the RT of HIV.

SIVs encoding the HIV Env protein gp160 (or its subunits gp120 and gp41) are used to test compounds that aim to block the interaction of the surface subunit gp120 with receptors on the target cell surface as this is a necessary step for infection. Such SHIVs are also important for the development and testing of vaccines because most vaccine strategies aim to generate a neutralizing Ab (nAb) response, which is directed solely against Env.

Notably, SHIVs bearing recombinant gp120s with specific characteristics are potentially powerful tools to study characteristics of the Envs of transmitted viruses. A striking feature of HIV sexual transmission, which is a particularly rare event, is that while a genetically diverse population of viruses (called a quasispecies) exists in an HIV-infected person, only one (the founder/transmitted virus, T/F) or a select few of those variants infect their partner during sexual transmission. F/T viruses appear to share common characteristics in their Envs such as shorter length of the gp120 variable loops and fewer sites of sugar moiety addition (potential N-linked glycosylation sites, PNGs) than chronically replicating isolates (Parrish et al. 2013). Importantly, as for HIV, mucosal SIV infection proceeds through a similar “genetic bottleneck” involving a T/F virus expansion. Generating SHIVs based on T/F Envs may allow scientists to study the contribution of these characteristics to viral fitness during transmission.

Early Events During Transmission

Sexual mucosal transmission (rectal or vaginal) is the most common route of HIV transmission. Although it has been the focus of many studies, there is still a lot to learn about how the virus penetrates mucosal barriers and establishes a systemic infection. This knowledge is key to the

design of new ways to block infection before the virus spreads and the immune system starts to fail. Although it would be unfeasible and unethical to study the early events following sexual exposure to HIV in humans (as this would require sampling the mucosal tissue a few minutes or hours after sexual intercourse), it is possible to expose NHPs rectally or vaginally to a determined amount of virus, mimicking as much as possible the events occurring in humans. In doing so, we can study how the virus interacts with the mucosal microenvironment and what are the characteristics of the host and/or the virus that facilitate infection. With this experimental model, it is possible to collect samples of tissues and blood at time points (hours or days) much closer to the time of exposure than is possible in humans. Blood, tissues, and lymph nodes (LNs) collected during this early phase have informed on the timing required for the virus to replicate in the mucosa, travel to the draining LNs where it finds an abundance of target CD4⁺ T cells to expand, and disseminate systemically. Moreover, it is possible to identify the cells that are preferentially targeted in the early phase and study their phenotype and the differential role of specific cell types in spreading infection. This information guides the design of targeted approaches to block viral replication immediately after exposure (Haase 2010).

Using NHPs, it was possible to determine that sub-activated “resting” CD4⁺ T cells are likely the first cells that the virus infects following sexual exposure. However, these cells do not allow the rapid viral replication achieved in activated memory CD4⁺ T cells. Therefore, the latter cell type, although less abundant, may be the major source of virus during the early stages (Haase 2005). Moreover, it was possible to determine the important role of DCs in the mucosa and draining LNs. In fact DCs capture the virus and transfer it to neighboring T cells and in this way facilitate infection. Moreover, DCs are permissive to viral replication and produced virions can also be transferred to T cells, a process that can fuel infection especially in the draining LNs. The NHP models also helped to identify the gut tissue and the gut-associated lymphoid tissue (GALT) as the first and primary reservoir of viral infection.

In fact the gut and the gut-draining LNs contain the highest concentration of HIV and SIV target cells and favor exponential virus growth. Another advantage of using NHP to study early events after transmission is the ability to culture tissue biopsies (rectal or vaginal) and examine viral replication in the tissues *ex vivo*. Such studies allow the investigation of virus replication in differentially conditioned mucosal microenvironments.

Studying the early events following SIV infection allows the study of viral and host-related characteristics that increase the chances of this event to occur. Identifying what renders some animals more susceptible than others can help to identify those characteristics of the human rectal and vaginal tissue that increase the risk of acquiring HIV (00386).

Low-Dose Challenge Models

In the initial transmission studies using NHPs (up until the early 2000s), the animals were exposed to large doses of pathogenic SIV to ensure that all macaques in a study became infected. However, it became evident that this type of challenge did not recapitulate the early events after mucosal transmission in humans, among them the fact that sexual HIV transmission is a relatively rare event and there are specific (mostly unknown) factors or combinations of factors that allow this event to occur. Challenging with a high dose of virus masks these factors and does not mimic repeated viral exposure, which is more physiologically relevant. Exposure in humans is, in most cases, a recurrent event and a NHP model that includes a single exposure is far from mimicking these more realistic situations, but this approach did provide some first critical insights into the earliest events of HIV infection across the mucosae. To cope with these differences, most laboratories that use NHP models of HIV infection are starting to infect the animals using “low-dose repeated challenge models.” These models have several advantages, which go beyond the fact that they mimic a real-life situation. They are commonly used to assess the efficacy of HIV vaccine candidates or preventive

treatments and consist of challenging monkeys repeatedly with low doses of SIV or SHIV. Such challenge data provide a unique opportunity to assess the importance of exposure history for the acquisition of infection.

Reaching statistical power is one of the major issues in NHP models. The animals are costly and their use has ethical considerations; thus, there is a need to limit the number of animals to a minimum, which can make it difficult to interpret the data. Repeated low-dose challenge models have the benefit of increasing the statistical power of a study several folds since every challenge that does not result in infection adds one animal to the study. This is possible since repeated challenges do not immunize the animals (Regoes et al. 2005).

Although repeated low-dose challenge models have many important advantages, they also have several caveats. Infecting all control animals requires a longer period of time than the single high-dose studies since fewer animals become infected at each challenge. In a typical setup of the repeated low-dose model, the animals are challenged once or twice per week with a low viral dose. However, the dose, or viral titer, used for the challenge can vary even of 10–20-folds, depending on the animal species, the site of inoculation (rectal or vaginal), and the virus used. Generally, depending on the question that is asked, the studies are stopped when all the control animals get infected. A different way of setting up the repeated low-dose model is to set the total number of challenges at the beginning of the study. This can vary from 10 to more than 20 and therefore the studies can last 5–6 months.

In performing statistical analyses on the efficacy of a preventive strategy to reduce susceptibility, whether using a high- or a low-dose model, it is important to take into account the animal-to-animal variation in susceptibility. This seems to be higher in some species such as RMs than in others such as pigtailed macaques and could be explained by the differential susceptibility of the two species (with the pigtail macaques being more susceptible). Finally these studies are also relevant for understanding the role of exposure history on HIV acquisition and forecasting the epidemiological spread of HIV (Regoes 2012).

Interaction with Other STIs

The risk of HIV sexual transmission is higher if one of the partners has another STI (also called a coinfection or co-pathogen). In particular, HSV-2-infected individuals are at least three times more at risk of acquiring HIV than HSV-2-uninfected individuals (Wald and Link 2002). Although part of this increased risk can be explained by the presence of active HSV-2 replication (which can result in ulcers and inflammation), the increase in risk is present even after the infection abates and in the absence of detectable inflammation. Therefore, there is a lot that remains to be explained on what renders HSV-2-infected individuals more at risk of acquiring HIV and what are the characteristics of the mucosal microenvironment of such individuals that facilitate HIV infection. Knowing these factors could help not only to find ways to block the HSV-2-driven increase in susceptibility to transmission but also to understand HIV transmission in the absence of other STIs.

The first model of vaginal HSV-2 infection and HSV-2/SIV coinfection in NHPs was established in Melissa Robbiani's laboratory in 2009 (Crostarosa et al. 2009). Since then, a model of HSV-2 rectal infection of RMs was also developed in Dr. Robbiani's laboratory (Martinelli et al. 2011) and several other laboratories are adopting models of HIV/STI coinfection. The Center for Disease Control is using pigtailed macaques to study *Chlamydia trachomatis* and *Trichomonas vaginalis* (Henning et al. 2011). These models are useful to test the effect of prevention strategies in circumstances of heightened susceptibility to HIV. They also allow exploration of the interaction of HIV and SIV with other pathogens in the mucosa, how the immune response to a pathogen affects the response to HIV and SIV, and how other pathogens modify the mucosal microenvironment in a way that increases its susceptibility to HIV and SIV. These models may consist of (i) co-challenging the animals with the two pathogens simultaneously (in a single or repeated exposure setting) or (ii) infecting the animals first with the co-pathogen and then with SIV/SHIV. Both of these experimental conditions are valuable as they mimic real-life circumstances of transmission in

discordant couples in the presence of other STIs, which is a very common scenario in people at high risk of HIV acquisition. These models also allow the testing of preventative strategies for their ability to (i) prevent SIV/SHIV in the face of another STI and/or (ii) prevent the STI itself.

Pathogenic versus Nonpathogenic Models

SIVs have coevolved with their natural host species for thousands of years. Unlike HIV infection of humans, when these African monkeys are infected with their species-specific SIV, either in the wild or in captivity, the virus does not cause disease. In contrast, SIV infection of Asian macaques causes a simian acquired immunodeficiency syndrome (SAIDS) that resembles AIDS in humans though it progresses faster (~ 2 years vs. ~ 10 years). SAIDS is characterized by $CD4^+$ T cell depletion, [► Chronic Immune Activation in HIV](#), the acquisition of OIs, and premature death.

SMs and AGMs are two species of African monkeys used as models of natural infection because when infected with SIV, they do not develop SAIDS and remain healthy. The first pathogenic model of infection in macaques was generated by the inoculation of RMs with a virus isolated from SMs (SIVsm). The SIV isolated from RMs infected with SIVsm (termed SIVmac) was found to be highly pathogenic in different species of macaques. SIVmac infections of RMs, MNEs, and cynomolgus macaques are the principal pathogenic models of HIV transmission and disease. Since the isolation of the first SIVmac, several other isolates (quasispecies) of SIVmac have been generated by inoculating macaques with different strains of SIVsm and isolating the virus at different times following infection.

The infection profile during acute SIV infection is strikingly similar between natural and experimental hosts (and HIV-infected humans): the major initial targets of infection are $CD4^+$ $CCR5^+$ T cells, and the virus replicates to high titer, resolving to a set point concomitant with the induction of T cell responses (00152-3). Mucosal $CD4^+$ T cells are extensively depleted during

acute infection, in particular in the gut tissue and LNs. Adaptive immune responses consisting of virus-specific nAbs and CTLs (00151-4) are elicited but do not effectively control infection in either case. On the other hand, a higher innate antiviral response and in particular a higher, more prolonged production of the antiviral cytokine and interferon- α (IFN- α) by a subset of DCs seem to be more a characteristic of the pathogenic models. This has been implicated in determining the different course of infection during the chronic phase.

More extensive studies of natural SIVsm and SIVagm (virus isolated from AGMs) infection have revealed other key differences between natural and experimental SIV (and HIV) infection that provide clues to the determinants of pathogenesis (Chahroudi et al. 2012). In natural hosts, the innate immune response resolves rapidly during the transition from the acute to the chronic phase (approximately 4–8 weeks postinfection), and [► Chronic Immune Activation in HIV](#) is absent. Mucosal $CD4^+$ T cells recover from their early depletion and their presence is responsible for the balancing act of mounting inflammatory responses against extracellular bacteria and fungi while protecting the tissue from inflammation in response to commensal bacteria and food antigens. The integrity of the gut mucosa is maintained and [► microbial translocation](#) (the migration of bacterial products from the gut into the blood across a compromised epithelium) is noticeably absent. LN architecture is preserved. The fraction of $CD4^+$ T cells responsible for long-lived memory responses (central memory), which is the preferential target of pathogenic SIVs, is not a major target of nonpathogenic SIV infection. Instead in natural hosts effector memory $CD4^+$ T cells (that are short lived even in the absence of infection) are preferentially infected (Chahroudi et al. 2012).

Mother to infant transmission (MTIT) is also different in natural and experimental infection. Whereas MTIT of HIV is quite efficient (35–40% for MTIT in absence of antiretroviral therapy vs. $<1\%$ per sex act), it is rare in natural hosts ($<7\%$ for SMs, even less for AGMs), and the availability of $CD4^+$ $CCR5^+$ target cells has been implicated.

Putting together these pieces of the puzzle, scientists are defining a model of pathogenicity linked to the events and the immune responses (00151-4) during the earliest stages after transmission (00383). The factors identified through these models that may play a role in determining the disease progression relate to the integrity of the gut mucosal tissue, the lymphocyte subsets that populate it along with restricted infection to short-lived effector cells, and the absence of vertical transmission.

Vaccines and Attenuated SIVs

The success of early vaccines for epidemic viral diseases such as smallpox, rabies, measles, and polio was aided by the fact that virus eradication was linked to the elicitation of vigorous specific immune responses, which helped to identify correlates of protection. The nature of naturally occurring protective immunity to HIV is still mostly unclear. Nonetheless, the development of an effective vaccine is a central goal of HIV research.

To this end, NHP models of HIV infection have been critical for dissecting the initial immune response after transmission and why it fails, and for developing strategies to boost this response. SIV and SHIV challenge models have been exceptionally useful to test an array of vaccine strategies – live attenuated (LAVs), inactivated, protein subunit, DNA, and viral vector vaccines, as well as combinations (e.g., DNA prime protein boost). Because LAVs are actually replicating (but weakened) strains of virus, they have the best chance of recapitulating all the classical desired immune elements – nAbs to block infection, CTLs to kill residual infected cells at transmission, CD4⁺ helper T cells to boost nAb and CTL production, and immune responses specifically localized to the sites of transmission and replication (genital and gastrointestinal mucosa).

One particularly important model for HIV vaccine design is the inoculation of RMs with *nef*-deleted SIVmac (SIVΔ*nef*). SIVΔ*nef* results in a highly attenuated infection that protects against future challenge with wild-type (WT) SIV although the protection is lower or

absent against different genetically distant strains (Freissmuth et al. 2010). The immune correlates of this protection have been difficult to elucidate. The degree of attenuation of the vaccine strain is inversely correlated with the level of protection from WT (e.g., a triple deletion mutant is more attenuated and less protective than SIVΔ*nef*). Neonatal macaques with lower immune capabilities are not protected from SIVΔ*nef*. However, the bulk of the data show no discrete link between immune responses and protection. Protection is achieved in the absence of a strong nAb response to the challenge virus. Antibody transfer from SIVΔ*nef* inoculated macaques into naïve macaques does not protect them from WT. Infected animals generally exhibit intact T cell function, making SIV-specific CTL responses that are superior to those in WT-infected macaques, but the data are inconclusive as to whether SIV-specific cellular responses are sufficient for protection from pathogenesis (Freissmuth et al. 2010).

To evaluate protection by vaccine candidates that elicit nAbs against the HIV Env, researchers challenge macaques with SHIVs expressing different HIV Env proteins. Which SHIV to use has been the subject of much debate over the years, but scientists generally agree that the most relevant virus should (i) contain Env from a primary rather than a lab-adapted isolate, (ii) use the CCR5 coreceptor, and (iii) be mucosally transmissible. There is enormous diversity in the genetic sequence of the HIV Env among different subtypes (clades) of virus. Early SHIVs were generated based on Env sequences from clade B Envs, those common to North America and Europe. New SHIVs are being developed that express Envs from clades A and C, which are the most prevalent clades in Africa. Ultimately, designing vaccines that target conserved regions of Env requires careful iterative engineering, and after 30 years of research, a strong candidate remains elusive.

Microbicide Testing

Microbicides (00378) are topical agents, which are applied intravaginally or intrarectally and are designed to prevent the ► [HIV-1 sexual](#)

transmission of HIV. They contain diverse active pharmaceutical ingredients (APIs) – anti-retrovirals (ARVs) and nonspecific inhibitors/immune modulators – formulated in easy-to-use products such as gels or intravaginal rings (IVRs). Most microbicide studies in macaques utilize SHIV models because the viral protein targets of microbicides (thus far predominantly RT and Env) differ enough in genetic sequence between HIV and SIV making HIV-specific inhibitors less effective against SIV. To study RT inhibitors, SHIV-RT is usually used (HIV RT in SIV background). To study entry inhibitors (those interfering with Env function), SHIVs expressing different HIV Envs are used with SHIV_{SF162P3} being the most common.

Macaque studies of a gel comprising 1% of the RT inhibitor tenofovir (TFV) demonstrated that this product prevented both vaginal and rectal SHIV infection, providing the data necessary to move 1% TFV into clinical trials where it was partially effective against vaginal acquisition of HIV in studies demonstrating good adherence to the regimen (Abdool Karim and Baxter 2013).

Moreover, studies with NHP models have enabled scientists to determine the strength and duration of protection of products. These characteristics may help generating a product that is somewhat independent from how it is used by individuals (adherence), a key factor in the success of microbicide strategies. By challenging with high doses of virus and with viruses of varying virulence, it is possible to gauge the limit of protection. To establish the window of protection, animals are challenged at different times following vaginal or rectal application – i.e., does a product have to be applied just prior to exposure or could it be applied up to a day (or days) before, and can it be used repeatedly and still remain safe and effective? The ultimate goal is to develop products that can be applied under diverse scenarios that appeal to the women and men using them and offer the same level of protection (e.g., sporadic use, long-lasting protection, lack of toxicity if used frequently, etc.). For example, these types of studies were used to demonstrate that a promising microbicide gel, MZC (containing the anti-retroviral drug MIV-150, zinc acetate, and the

seaweed derivative carrageenan developed by Population Council), protects against vaginal SHIV-RT challenge providing up to 8 h of full protection when used once or daily for 2 weeks (Kenney et al. 2012). They also showed that MZC prevents rectal SHIV-RT infection but only when it is applied within an hour of challenge as protection against rectal infection wanes quickly with increasing time between application and challenge.

ARV-based microbicide approaches are dependent on the presence of therapeutic levels of functional drug in the mucosal epithelia. Pharmacokinetics (PK) and pharmacodynamics (PD) studies are crucial for identifying the presence of drug in vivo (PK studies) and its activity against virus (PD studies) in order to draw correlations between drug level/activity and protection. Although PK studies testing for API in the blood can be carried out easily in humans, tissue PK and PD studies are more invasive, and the macaque model enables extensive testing. Moreover, tissues can be collected for ex vivo PD analysis. However, while informative, there are some limitations to the ex vivo approaches since perfect mimics of in vivo efficacy are hard to establish (i.e., there is no dynamic environment; continued drug delivery postexposure cannot be mimicked).

By targeting specific steps in the viral life cycle, microbicides can cause the virus to develop or select for drug resistance mutations. This is of particular concern if an infected person unaware of her infection status uses the product. In these individuals the virus would be replicating under constant drug pressure. Drug resistance studies are carried out in macaques treated with different microbicides under a variety of conditions (e.g., infected animals vs. uninfected animals) to determine the likelihood that resistance will develop.

More Opportunities, Problems, and Pitfalls

In light of the complexity of the circumstances in which transmission can occur in humans and the consequent differences in susceptibility to HIV infection, new NHP models of transmission are

being developed. These include models of coinfection with other STIs and, more recently, models that try to mimic the hormonal environment of women at different stages of the menstrual cycle or women who use different contraceptive strategies. Although it has been known for several years that sex hormones influence the susceptibility to vaginal (and possibly also rectal) transmission, our understanding of the mechanism and degree of the hormones-linked increased risk of infection is lacking. This is particularly relevant for the widespread use of hormonal contraceptives by women in developing countries and especially those in groups already at risk of HIV acquisition. To evaluate the role of hormones in NHPs, progestins, estrogens, or combinations of these two hormones that mimic specific contraceptive strategies or different stages of the menstrual cycle are injected into NHPs. Ovariectomized animals can be used to isolate the effect of the single hormones and mimic the postmenopausal condition.

However, although particularly useful, NHP models of HIV transmission have several limitations especially in testing the safety and the efficacy of prevention strategies. On the one hand, macaques are a better species in which to test vaccines than other mammals. The structure of their Abs is very close to that of humans, enabling the animals to develop the types of Abs that have been shown to have the best neutralizing activity. Nevertheless, the immune system of macaques is not identical to the human immune system, and several vaccines that elicited protective immune responses in macaques did not demonstrate the same efficacy in humans. Subtle differences may prove to be important in developing a vaccine that confers complete protection.

Importantly, in the case of microbicide testing, macaque studies cannot predict adherence to a product and a regimen. Therefore, NHP studies need to be complemented with behavioral studies to identify the vehicle and administration strategy that promises to be most widely used.

Finally, the substantial differences in the menstrual cycle of macaques and humans render particularly challenging the studies that aim to understand the effect of hormones on susceptibility to sexual transmission. They impair studies of microbicides

and vaccine efficacy since monkeys breed seasonally, their susceptibility to infection can be heavily influenced by the season in which the study is performed. Moreover, the differences between humans and macaques in their menstrual cycle substantially limit the ability to test products with dual function as contraceptives and microbicides.

The difficulty in interpreting the results of macaque studies is evident when considering that they have already failed to predict the results of several clinical trials.

Conclusion

Although not perfect, NHP models are the best tool scientists have to study how the virus penetrates mucosal barriers, how it establishes infection, and what are the correlates of susceptibility and protection. Ultimately NHP models constitute the best system to test prevention strategies. Moreover, the data generated with these models have helped our understanding of the immune response to pathogens other than HIV and ultimately will guide more innovative strategies to tackle the virus at its portal of entry.

(IDU) involves piercing through the skin into the body with a needle and a syringe. IDU may be intravenous, intramuscular, or subcutaneous. NIDU may involve prescription medications such as opioids or illicit drugs like alkyl nitrite (“poppers,” most often amyl nitrites), marijuana, crack or powdered cocaine, methamphetamines, and multiple drugs (Qian et al. 2011). Excessive alcohol consumption is often referred to separately from NIDU but is clearly in the same category. Also associated with disinhibition and high-risk sexual behavior is the frequent use of erectile dysfunction (ED) drugs, popular among men who have sex with men and other men who may seek multiple partners and commercial sex workers.

NIDUs may be defined as individuals who have a history of non-injection use of any of the abovementioned substances but no history of IDU (the latter would hierarchically preempt NIDU since its HIV risk is higher and since IDU almost invariably are also NIDU). Hence, persons who do not inject drugs and are recognized to use substances with or without dependence, and/or have entered any drug or alcohol rehabilitation program, and/or have any medical, legal, or social problems due to drug or heavy alcohol use, can be classified as NIDU (Qian et al. 2011).

Epidemiologic Overview

According to *World Drug Report 2013* (United Nation Office on Drugs and Crime 2013), the prevalence of illicit drug use in 2010 was between 3.6% and 6.9%, representing 167–315 million people aged 15–64 who used illicit substances at least once in 2010. Data suggested that the estimated number of drug-related deaths was 211,000, occurring mostly amid the younger population. Illicit drug use continues to jeopardize the health and welfare of populations all over the world, and HIV/AIDS is typically overrepresented in this population. Although having apparently declined a bit compared to 2008, an estimated 1.6 million people between 15 and 64 years of age are still using illicit drugs while living with HIV/AIDS. Evidence suggests that

Non-injecting Drug Users, Epidemiology of HIV/AIDS

Yu Liu¹ and Sten H. Vermund²

¹Vanderbilt Institute for Global Health, Vanderbilt University, Nashville, TN, USA

²Yale School of Public Health, New Haven, CT, USA

Definition

Non-injection drug use (NIDU) is a term used to describe substance use through oral ingestion or nasal inhalation. In contrast, injection drug use

IDU accounts for an increasing proportion of new HIV cases in Eastern Europe, South America, and East and Southeast Asia (Mathers et al. 2008). NIDU is common among HIV-infected individuals and may contribute to a substantial proportion of new HIV cases worldwide through sexual disinhibition (Kipp et al. 2011). Whether the drugs contribute to HIV risk behavior or whether drug use is simply a component of a high-risk lifestyle that would be extant even in the absence of drug availability has been debated.

HIV and Drug Use Pattern by Continent

Africa

Over a third of the infected persons globally live in just ten nations of southern Africa, by far the worst afflicted region. South Africa, for example, was the world's 25th most populous nation with 49 million persons in mid-2009 (U.S. Census Bureau 2014). Yet it ranked first for the number of persons living with HIV/AIDS with an estimated 5.6 million persons (range 5.4–5.9 million) in 2009. The sub-Saharan African epidemic is mainly driven by heterosexual contact (Vermund et al. 2009; Eyawo et al. 2010). Injection drug use (IDU) and male-to-male sexual contact may be increasing and represent future risk (Vlahov et al. 2010; McCurdy et al. 2010; Smith et al. 2009; Baral et al. 2011; Rispel et al. 2011; Merrigan et al. 2011; Johnston et al. 2010; UNAIDS 2014).

In West Africa, HIV prevalence is lowest in Senegal and highest in Nigeria. Compared to South Africa's adult HIV prevalence (17.3%), Nigeria's is much lower (3.7%). Yet as Africa's most populous nation, Nigeria has Africa's second largest number of people living with HIV. A principal driver of infection in the region may be commercial sex. Non-injection drug use, such as cocaine, is increasing with traffickers who traverse West Africa also marketing their drugs locally in the transit cities. For example, reports from Dakar, Senegal, indicate that consumption of cocaine and crack has increased, even as heroin use had declined since 2000.

In East Africa, HIV infection prevalence is moderate to high. Heroin is the most commonly

used substance with an especially severe problem in Zanzibar. Other commonly used substances include cannabis and alcohol (United Nation Office on Drugs and Crime 2013). The East Africa epidemic is similar to southern Africa, largely driven by heterosexual transmission (with accompanying maternal-to-child transmission). The epidemic in Central Africa is not as robust, also driven by heterosexual transmission. The role of unsafe needle/syringe or razor reuse by allopathic or traditional health personnel is also potentially contributing to transmission in sub-Saharan Africa. Alcohol use is prevalent and associated with increased risk taking.

In North Africa and the Middle East, sexual transmission among MSM accounts for a majority of HIV infections (Mumtaz et al. 2010). Information on drug use is available from Algeria and Morocco; prevalence of drug use is low in Algeria, but a documented increase in cocaine use has been noted in Morocco (United Nation Office on Drugs and Crime 2013). Iran has the region's highest injection heroin problem, and there are many non-injection heroin users as well (Khajehkazemi et al. 2013; Navadeh et al. 2013; Malekinejad and Vazirian 2012; Zamani et al. 2010; Farnia et al. 2010).

Americas

The HIV epidemic in North America has been driven by MSM, illicit drug use, and, to a lesser extent, heterosexual transmission (Vermund and Leigh-Brown 2012). Sexual risk taking is documented to be higher in persons using alcohol and/or illicit drugs proximate to sexual activity, including receptive anal intercourse (Shoptaw and Reback 2007; Colfax and Shoptaw 2005; Miller 2003). Party drugs such as nitrates, amphetamines, and cocaine have been associated with higher-risk sexual activity, an observation dating from very early in the HIV/AIDS epidemic (Goedert 1984; Drumright et al. 2006; Wooff and Maisto 2009). Persons addicted to crack-cocaine and methamphetamine may practice high-risk sex, and both women and men may sell sex for drugs or money to support drug habits (Wilson and DeHovitz 1997; Corsi and Booth 2008; Zierler and Krieger 1997; Norris et al.

2004). Adolescents are vulnerable to peer pressures to have sex and use drugs (Senf and Price 1994; Fortenberry 1998).

There is diversity in the south and Central American epidemic, but the dominant mode of transmission seems to be anal sex among MSM (McGowan et al. 2007; Caceres 2002; Coplan et al. 1996; McCarthy et al. 1996; Bastos et al. 2008). PWID contributes substantially in some regions such as urban Brazil but is a less common risk factor than in North America, Europe, or Asia (Lima et al. 1994; Hacker et al. 2005; Rodriguez et al. 2002; Caiaffa et al. 2003; Khalsa et al. 2003; Mesquita et al. 2003). Alcohol and non-injecting drug use fuel unsafe sexual behaviors (Bastos et al. 2007; Damacena et al. 2011; Cortez et al. 2011; Anastario et al. 2011; Bassols et al. 2010; von Diemen et al. 2010). Heterosexual transmission occurs and bisexual men are thought to be an important bridge population (Ramirez et al. 1994; Konda et al. 2011). Perinatal transmission is less common with most antenatal programs in endemic areas offering HIV testing and ART, albeit imperfectly (D'Ippolito et al. 2007; Read et al. 2007).

The Caribbean is the region with the second highest prevalence rates in the world, after sub-Saharan Africa (Figueroa 2003, 2004, 2008; Calleja et al. 2002; Inciardi et al. 2005). Heterosexual transmission, homosexual transmission, and illicit drug use (particularly IDU in Puerto Rico) are all dominant factors for the HIV epidemic in this region (Castro and Farmer 2005; Pape and Johnson 1993; Dorjgochoo et al. 2009). It is not known the extent to which non-injected drugs that are used with high prevalence may contribute to sexual risk, such as marijuana, but alcohol use in the context of "sun-and-fun" tourism cultures are very likely to increase sexual risk taking.

Europe

Non-injection drug use is prevalent in Europe, and its contribution to HIV spread is, as elsewhere, thought to be mediated by sexual disinhibition. People who inject drugs (PWID) may use non-injection drugs as well, such that sexual risk may persist even as IDU-related risk reduction

progresses. Eastern European countries, notably Russia, that have taken a punitive approach to IDU without concomitant public health (needle exchange) and medical (opiate substitution therapy) approaches continue to have growth in their epidemics, even as prevalence rates stabilize or even decline elsewhere in the world (Kelly and Amirkhanian 2003). Except for the prevalence of heroin use which is estimated to be 1.2% of the adult population, other patterns and types of illicit drug use in Eastern Europe are lower compared with global levels (United Nation Office on Drugs and Crime 2013).

Male homosexual transmission has been a principal driver of the epidemic in Western Europe, but IDU has also been a major contributor, particularly in Southern and Eastern Europe (Mathers et al. 2010). The HIV epidemic in Western Europe is similar to that in North America in many ways, though it is less intense, possibly due to more aggressive public health responses to HIV early in the epidemic (Vermund and Leigh-Brown 2012). The use of all illicit substances in Western Europe is higher than the average for the rest of the world, particularly with use of methamphetamine and cannabis (7.6% of the adult population). The proportion of persons using cocaine in a year was 1.2%, nearly threefold the global average (United Nation Office on Drugs and Crime 2013).

Asia

The HIV epidemic in East and Southeast Asia, and other parts of the region, is a complex one. While less intense than in Africa, the Asian epidemic remains intractable with persistent transmission in vulnerable populations. In Southeast Asia and Indonesia, heterosexual, MSM, and PWID transmission are all prevalent (Vlahov et al. 2010; van Griensven and de Lind van Wijngaarden 2010; Sharma et al. 2009; Ruxrungtham et al. 2004; Couture et al. 2011). In countries like Thailand and Cambodia, successes are notable in reducing transmission among PWID and heterosexual transmission with needle exchange and universal condom advocacy, respectively (Park et al. 2010; Ainsworth et al. 2003; Celentano et al. 1998). China has had some progress in addressing its

serious problem of HIV among PWID, but the epidemic among MSM is rising; fortunately, heterosexual spread is not common in the world's most populous nation, even among sex workers (Wu et al. 2007; Xiao et al. 2007; Tucker and Cohen 2011). In South Asia, India has experienced a substantial heterosexual epidemic concentrated in its southern states, with PWID-related transmission in northeastern states; the northern states have much lower incidence and prevalence (Chandrasekaran et al. 2006). Despite prevalence rates far lower than in sub-Saharan Africa, India, the second most populous nation on the globe, ranks just behind South Africa and Nigeria for the highest number of HIV-infected persons (about 2.5 million in 2009) living in the nation (Dandona et al. 2006). MSM are at risk throughout South Asia, including *hijras*, who are men who dress as women and have a long-standing cultural niche in such nations as India, Pakistan, and Bangladesh (Siddiqui et al. 2011; Sahastrabuddhe et al. 2012; Shaw et al. 2011; Phillips et al. 2010; Solomon et al. 2010; Verma et al. 2010). In Central Asia, the pattern of HIV transmission is similar to Eastern Europe, which is mostly through IDU, though homosexual and heterosexual also account for HIV epidemic in this region (Mathers et al. 2010).

Little is known about the role of non-injection drug use in Asia in driving the HIV epidemic. Countries like Thailand that have had tremendous reductions in HIV spread among both PWID, and high-risk heterosexuals still have large epidemics among MSM. It is likely that non-injection drug use helps fuel high-risk behaviors, including alcohol use.

Australia and Oceania

Australia has had a persistent and aggressive risk reduction program from the early days of their epidemic (Mao et al. 2011; Kang et al. 2010; Jones et al. 2010; Minichiello et al. 2001). Their widespread and "user-friendly" approaches to clean needle exchange and availability of opiate substitutions therapy through primary care practitioners are credited for keeping HIV rates exceedingly low (Miller et al. 2009; Falster et al. 2009; Maher et al. 2007; Dolan et al. 2003). MSM is a

principal challenge in parts of the region, though Oceania and New Zealand confront pockets of heterosexual transmission (Vallely et al. 2010; Washington et al. 2008; Vanualailai et al. 2003; Corner et al. 2005). The prevalence of the use of most illicit drugs remains relatively high in the Oceania region, especially in Australia and New Zealand. High prevalence of some non-injecting drugs was reported in this region, for example, cannabis (10.9%), "ecstasy" (2.9%), and cocaine (1.5%) (United Nation Office on Drugs and Crime 2013).

Drug Use, HIV Risk, and HIV Disease Progression

PWIDs are at substantial risk of contracting HIV from the transmission of blood-borne HIV via needle sharing (Mathers et al. 2008). Non-injecting users increase their HIV infection risk via several mechanisms: (1) Impairing decision-making may result in high-risk sexual behaviors (Kipp et al. 2011; Cook and Clark 2005); (2) trading sex for drugs or for money to buy drugs may result in unprotected sex; (3) the immune-modulating effects of drugs may increase HIV viral load among infected persons and decrease host defenses to viral exposure among uninfected persons, which would upregulate HIV-specific cellular receptors (Kipp et al. 2011; Astemborski et al. 1994; Brewer et al. 2007; Cabral 2006; de Souza et al. 2002; Edlin et al. 1994; Ramirez-Valles et al. 2008). Extant literature has indicated that, specifically among crack-cocaine users, non-IDUs may experience elevated risk of STI and HIV compared with other drug use group, and IDUs, explicitly due to increase in numbers of sexual partner and sex trade, engagement in complex sexual networks, decrease in condom use, and having multiple concurrent partnerships (Khan et al. 2013; Celentano et al. 2008; Ross and Williams 2001). In addition, global evidence suggests alcohol use among MSM is particularly high in many venues, though not all (Deiss et al. 2013; Balan et al. 2013; Wirtz et al. 2013; Bruce et al. 2013; Newcomb 2013; Grov 2012; Liu et al. 2014). Like heterosexuals, MSM may use alcohol

for sexual arousal in anticipation of subsequent sex (Woolf-King and Maisto 2011). MSM may also experience stigma, psychological, and social-legal problems (Yu et al. 2013; King et al. 2008), for which alcohol may be used for relief or coping (Dyer et al. 2012, 2013; Jeffries et al. 2013; Gorbach et al. 2009).

Interesting to note is the literature on marijuana use. Cannabinoid agonists actually have anti-HIV properties and have been proposed as salutary immune modulators for infected persons, though the quality of evidence from human studies is inadequate to judge its merit (Hu et al. 2013; Lutge et al. 2013; Rom and Persidsky 2013; Kaplan 2013). At the same time, marijuana may be a sexual disinhibitor associated with higher risk.

Illicit drug use among people living with HIV/AIDS (PLWHA) is a medical and public health concern. HIV-infected drug users may not fully benefit from combination antiretroviral therapy (cART) (Kipp et al. 2011). Drug abuse comorbidities are associated with delayed access to, or reduced uptake of, treatment (Spire et al. 2007); worse adherence compared to HIV-infected subgroups (Hinkin et al. 2007); and inferior virologic and clinical outcomes (Cook et al. 2008). Most published studies included PWIDs and clearly identify a positive association between drug use and adverse HIV disease progression outcomes (Spire et al. 2007; Grigoryan et al. 2009; Lert and Kazatchkine 2007). Non-IDU drug abusers may share similar biologic, social, and behavioral consequences (Kipp et al. 2011). However, data on non-IDU and HIV disease progression remain limited, and the findings are mixed. Non-IDU drug use has been associated with higher AIDS and all-cause mortality (Baum et al. 2009). Use of crack-cocaine independently predicts AIDS-related mortality, upregulation of immunologic and virologic markers of HIV disease progression, and more AIDS-defining illnesses among women (Cook et al. 2008). Crack-cocaine users have also been demonstrated to have more aggressive HIV disease progression and lower rates of cART adherence with postulated cocaine-related up-modulation of viral activity (Arnsten et al. 2002). However, an MSM study did not find any association between marijuana

and other recreational non-IDU drugs with HIV disease progression (Di Franco et al. 1996).

Conclusion

Non-injecting drug use is associated with an increased number of sexual partners. It is presumed that disinhibition contributes to this, but an alternative explanation is that persons seeking higher-risk sex are more likely to use drugs, when available, such that the behaviors are associated, but not causally. Clearly, persons addicted to drugs may be more vulnerable to HIV via trading sex or drugs or money for drugs and can be engaged by clients in especially risky sexual behaviors (Khan et al. 2013). Non-IDUs comprise a variety of populations, particular young adults, MSM, and sex workers. In the USA, racial and ethnic patterns have not suggested one group having much higher non-IDU than another. In a study in Atlanta, Georgia, for example, black MSM had even lower numbers of sexual partners and use of non-injection drugs than white MSM, even though MSM had higher HIV prevalence (Sullivan et al. 2014). While the patterns of non-IDU and their relative contributions to HIV transmission risk differ by regions and socio-demographic characteristics globally, research suggests that interventions to reduce non-IDU drug use could play a role in reducing subsequent HIV exposure. The NIH has highlighted a need to (a) reduce risk of drug-associated and sexual transmission HIV among injecting and non-injecting users; (b) develop and refine primary and secondary interventions for HIV-infected drug users; and (c) develop interventions to overcome structural and community-level barriers to accepting and implementing effective HIV prevention strategies (NIAIDS 2014). Comprehensive HIV prevention interventions for drug users must provide the information, skills, and support necessary to reduce the drug-related and behavioral risk. The effort requires cross-disciplinary partnerships including community health workers, government officials, policy makers, peers and peer organizations, and public health authorities to dissemination of prevention

interventions and evaluate their effectiveness (Khan et al. 2013).

Non-neutralizing Antibody Responses and Protection Against HIV-1

George K. Lewis

Division of Basic Science and Vaccine Research, Institute of Human Virology, University of Maryland School of Medicine, Baltimore, MD, USA

Definition

Non-neutralizing antibodies against conserved regions of the HIV-1 envelope glycoprotein (Env) appear early after infection, preceding neutralizing antibodies, and appear to persist for the life of the infected individual. Some non-neutralizing antibodies recognize internal Env epitopes that never become antibody accessible during either virus acquisition or virus production. Such antibodies are of no consequence to protective immunity against HIV-1. By contrast, it is clear that other non-neutralizing antibodies recognize Env epitopes that become antibody accessible during viral acquisition, virus production, or both. In this case, non-neutralizing antibodies can theoretically block transmission by several mechanisms including aggregation of virions, blocking epithelial transport of virions, Fc-mediated effector function, complement-mediated lysis, or various combinations of these mechanisms. A growing body of literature suggests that these responses contribute to protective immunity against HIV-1 transmission.

Neutralizing Versus Non-neutralizing Antibodies

There is strong evidence from passive immunization studies in nonhuman primates (NHPs) that antibodies can protect against transmission by neutralization alone, although protection can be stronger if Fc-mediated effector function is also present (Hessell et al. 2007; Burton et al. 2011).

Similar compelling evidence from passive immunization studies in NHPs is lacking for non-neutralizing antibodies. By contrast, the RV144 vaccine trial provides evidence that non-neutralizing antibodies specific for the C1 region of the outer envelope glycoprotein, gp120, of HIV-1 contributed to against HIV-1 transmission, possibly by antibody-dependent cell-mediated cytotoxicity (ADCC) (Haynes et al. 2012). Before going further, it is important to operationally define neutralizing and non-neutralizing antibodies. Neutralizing antibodies block infection of susceptible target cells *in vitro* without any additional cellular effector function, such as phagocytosis or ADCC. The mechanism may be the simple stoichiometric blocking of virion binding to the target cell or by interfering with virus entry at a post-binding step. By contrast, non-neutralizing antibodies fail to neutralize consistently by these mechanisms using standardized target cells. If they are protective, non-neutralizing must be capable of mediating effector activities such as virion aggregation, blocking virion transcytosis across epithelial cells, phagocytosis, ADCC, complement-mediated lysis and opsonization, or a combination of these mechanisms. There can be great variation among neutralization assay formats but there are now standardized, validated assays that provide good discrimination between neutralizing and non-neutralizing antibodies. Further, neutralizing antibodies can also possess effector activities, such as ADCC or phagocytosis, whereas non-neutralizing antibodies must rely solely on one or more effector functions for protection, which is a fundamental distinction between these two categories of antibody. The following section describes the sites at which non-neutralizing antibodies need to work and the range of effector mechanisms that can be tapped at these sites to prevent the transmission of HIV-1.

Where Do Non-neutralizing Antibodies Work?

It is useful to consider the general anatomical locations where non-neutralizing antibodies need

to work while recognizing that the distinct micro-environments will dictate the specific effector mechanisms required for protection. There are four routes of HIV-1 infection, parenteral, largely through injection drug use; vaginal and anal, through sexual intercourse; and oral or gastrointestinal, through breast-feeding. Surprisingly little attention has been paid over the years to the mechanisms of parenteral infection and this area is in need of renewed scrutiny. For this reason, this route will not be considered further. The other three routes share the commonality of being mucosal and they will be discussed with respect to their shared features.

To a first approximation, each route can be considered as a two-compartment system with a lumen, lined by an apical epithelial surface, and a submucosal lamina propria, lined by the basolateral surface of the same epithelium. When HIV-1 enters the lumen of each of these tissues, it first encounters mucus of varying compositions depending on the precise site. In an immune individual, the mucus will also contain antibodies that can bind free virions. This can be because the antibodies recognize native Env on the virions or because they recognize mis-folded Env that is usually present (Moore et al. 2006). Thus, virion aggregation is potentially the first line of defense by a non-neutralizing antibody, possibly also with contributions from luminal mucus. If a virion makes it past this initial barrier, its next barrier to hurdle is the intestinal epithelium itself where the virion is actively transported from the apical to the basolateral surface. Antibodies can interdict this step (Bomsel et al. 1998). If a virion makes it across the epithelium into the lamina propria, non-neutralizing antibodies must rely on Fc-mediated effector functions or complement activation to prevent an established infection. These functions include phagocytosis, ADCC, or its related function antibody-dependent cell-mediated viral inhibition (ADCVI) (Forthal et al. 2007), and complement-mediated lysis of antibody-coated virions. Any or all of these mechanisms may be operative but they all involve the recognition of antibody-coated virions or infected target cells by either Fc receptors on the effector cells or by complement components. In addition

to the proximal effector sites, non-neutralizing antibodies can exert activity at systemic sites, but, by the time that HIV-1 infects CD4+ cells in secondary lymphoid tissues, it is likely to have too strong of a foothold to be eradicated, although the infection could still be blunted. There are significant variations among the local humoral microenvironments, effector cell types, and Fc-receptor expression patterns that are particular to the anatomical locus, but each route of transmission holds these steps in common.

Mechanisms by Which Non-neutralizing Antibodies Might Block Transmission

Virion Aggregation

Circulating antibodies are bivalent (IgG, IgE, and monomeric IgA), tetravalent (dimeric IgA), or decavalent (IgM) and can cross-link multivalent antigens such as bacteria and virions. Additionally, humans have two forms of IgA, IgA1 and IgA2, which differ in hinge length, IgA1 being the longer. Thus, IgA1 might have a greater ability to cross-link virions and confer protection. This was confirmed recently in a passive immunization study using a neutralizing antibody (Watkins et al. 2013). Although it has never been formally demonstrated, it is possible that aggregated HIV-1 virions are less infectious than single virions. This is because the interior virions in a large aggregate will not have the same access to susceptible CD4+ target cells as the same number of free virions. Regardless of whether this is so, large virion-antibody complexes will certainly have decreased diffusion coefficients relative to individual virions, possibly with increased retardation by mucins (Shukair et al. 2013). Thus, virion aggregation by antibodies is potentially a first line of defense in the luminal sites of mucosal tissues. In this regard, a recent passive immunizations study using non-neutralizing anti-gp41 monoclonal antibodies showed a statistically significant postinfection control of SHIV162p3 viremia (Moog et al. 2013), and, among other activities, these monoclonal antibodies (mAbs) efficiently aggregated infectious virions in vitro (Moog et al. 2013).

Virion Transport Across Epithelial Layers (Transcytosis)

HIV-1 must pass from the apical surface to the basolateral surface of luminal epithelia to gain entry to the lamina propria and susceptible CD4+ target cells. This process is termed transcytosis. At this site, non-neutralizing antibodies can possibly exert two antagonistic activities. First, mucosal epithelial cells have the neonatal Fc receptor that binds IgG with high affinity at luminal pH favoring the trans-epithelial transport of IgG-virion complexes. In the case of a non-neutralizing antibody-virion complex, the virion could theoretically retain infectivity and such a complex would favor transmission rather than protection, although this has not been demonstrated in vivo. Second, some non-neutralizing antibodies can clearly block virion transcytosis (Matoba et al. 2008). Thus, non-neutralizing antibodies that bind to virions can potentially block the transcytosis of HIV-1 from the luminal to the basolateral surface of mucosal epithelium in vivo. On the other hand, depending on specificity and isotype, virion binding by non-neutralizing antibodies could also favor transcytosis providing access to susceptible CD4+ target cells in the lamina propria. The relative ability of HIV-1 to pass across mucosal epithelia is likely to be determined by a balance between these two activities.

Phagocytosis

Once HIV-1 passes the mucosal epithelium, Fc-mediated effector functions become prime mechanisms through which non-neutralizing antibodies might block transmission. Antibody-virion complexes can be phagocytosed by a number of different cell types including monocytes, macrophages, dendritic cells, neutrophils, and mast cells. Presence of these cells at the sites of HIV-1 entry varies with the mucosal tissue under consideration as well as the local microenvironment (normal or inflammatory). However, each cell type shares the common features of bearing Fc receptors and being phagocytic. In contrast to other Fc-mediated effector functions, phagocytosis is less studied in the context of HIV-1 infection, although it is known that monocytic cell lines can be infected with HIV-1 and that non-

neutralizing antibodies can block this infection (Moog et al. 2013). This observation correlated with protection in the recent passive immunization study discussed above (Moog et al. 2013). Additionally, there appears to be an inverse relationship between antibody-mediated phagocytosis and disease progression in HIV-1 infected individuals (Dugast et al. 2011), but the precise role of phagocytosis in preventing HIV-1 acquisition is not known.

ADCC and ADCVI

Three lines of evidence suggest that ADCC or ADCVI plays a role in preventing acquisition in humans (Forthal et al. 2007; Haynes et al. 2012; Mabuka et al. 2012). First, there was a significant inverse relationship between ADCVI titers specific for clinical strains and reduced infection risk for a subset of volunteers in the VAX 004 Phase III gp120 vaccine trial in which there was no overall efficacy (Forthal et al. 2007). In that study, each 10% increase in ADCVI activity correlated with a 6.3% decrease in the hazard rate of infection (Forthal et al. 2007). Alleles of the Fc γ RIIa and Fc γ RIIIa receptors influenced this relationship, strongly implicating an *in vivo* role for Fc-mediated effector activity. The precise specificities of the antibodies mediating these effects were not determined, and it is possible that both neutralizing and non-neutralizing antibodies made contributions.

Second, the RV144 vaccine trial, in which modest efficacy was observed after immunization with a combination of membrane-anchored gp120 delivered by canarypox and two Clade B gp120 proteins, was the first to indicate a role for non-neutralizing antibodies in the prevention of HIV-1 acquisition (Haynes et al. 2012). In that study, immune correlates analysis showed that infection risk varied inversely with titers of anti-V1/V2 antibodies and directly with IgA titers against gp120, specifically the C1 region. Secondary analyses in which the top third tier of individuals mounting IgA anti-gp120 titers were excluded, a significant inverse correlation emerged between ADCC, measured by two independent methods, and infection risk. This finding

suggested the possibility that the IgA antibodies specific for the C1 region of gp120, which don't mediate ADCC in the assay formats employed in that study, competitively inhibit ADCC mediated by IgG antibodies specific for this region that is a known potent target for ADCC in infected individuals. This hypothesis was confirmed using matched pairs of IgA and IgG mAbs of the same specificity from the RV144 trial (Tomaras et al. 2013). This study provided the first evidence suggesting that non-neutralizing antibodies of defined specificity play a role in the prevention of HIV-1 acquisition via Fc-mediated effector function.

Third, a role for Fc-mediated effector function in preventing HIV-1 acquisition was indicated by a study in which ADCC activity in breast milk correlated with decreased perinatal transmission by breast-feeding (Mabuka et al. 2012). Although the precise specificities of the antibodies that mediate ADCC in this study were not determined, the decreased transmission did not correlate with neutralization of autologous or circulating HIV-1, suggesting that non-neutralizing antibodies are playing a role in protection against acquisition due to breast-feeding (Mabuka et al. 2012).

Complement-Mediated Lysis and Opsonization

Although HIV-1 virions can bind and activate complement directly, there is clear evidence that complement activation by antibody-coated virions results in virion lysis and/or opsonization (Sullivan et al. 1996). Thus, non-neutralizing antibodies can theoretically block HIV-1 transmission by direct viral lysis or increasing phagocytic activity via opsonization. Although a role for complement in passive protection of NHPs against a SHIV virus challenge by a neutralizing antibody has been questioned (Hessell et al. 2007), there is evidence that complement plays a protective role in HIV-1 infection (Huber et al. 2006). It should also be recognized that complement-mediated opsonization by non-neutralizing antibodies can enhance HIV-1 infection *in vitro* (Willey et al.

2011), which indicates that complement activation is potentially a double-edged sword with regard to HIV-1 transmission. The degree to which complement activation by antibody-coated virions favors protection versus increased acquisition of HIV-1 is currently unknown.

Conclusion

Largely through passive immunization studies in nonhuman primates, it is well accepted that neutralizing antibodies will block HIV-1 acquisition (Hessell et al. 2007; Burton et al. 2011). By contrast, similar compelling evidence is absent for non-neutralizing antibodies. Two passive immunization studies in nonhuman primates have shown that non-neutralizing antibodies can impact the postinfection control of viremia (Burton et al. 2011; Moog et al. 2013), but there is no evidence that such antibodies can block the acquisition of model AIDS viruses in challenge studies. Against this backdrop, three studies in HIV-1 transmission cohorts suggest that non-neutralizing antibodies can block acquisition, possibly by an Fc-mediated mechanism. First, an inverse correlation between infection risk and antibody-dependent cell-mediated viral inhibition was noted for a subset of volunteers in the VAX004 vaccine trial, for which overall efficacy was absent (Forthal et al. 2007). This correlation was influenced by Fc-receptor genotype (Forthal et al. 2007), further indicating a role for Fc-mediated effector function in protection. Second, an inverse correlation between reduced infection risk and antibody-dependent cell-mediated cytotoxicity mediated by non-neutralizing antibodies against epitopes in the N-terminal region of gp120 was found for a subset of volunteers in the RV144 vaccine trial, for which modest efficacy was reported (Haynes et al. 2012). Third, an inverse correlation was found between antibody-dependent cell-mediated cytotoxicity titers in breast milk and risk of transmission to infants of HIV-1 infected mothers by breast-feeding (Mabuka et al. 2012). Taken together, these correlations imply a role of non-neutralizing

antibodies in protection against HIV-1 infection. Although the correlations are provocative, confirmation of this hypothesis awaits definitive passive immunization studies in nonhuman primates showing that non-neutralizing antibodies can block the transmission of model AIDS viruses.

Non-Nucleoside Reverse Transcriptase Inhibitors for Treatment of HIV Infection

Francine Touzard Romo and Karen T. Tashima
The Miriam Hospital, Providence, RI, USA
Department of Medicine, The Warren Alpert
Medical School of Brown University, Providence,
RI, USA

Definition

Non-nucleoside or nucleotide reverse transcriptase inhibitors (NNRTIs) are a class of antiretroviral drugs that inhibit the reverse transcriptase enzyme and are used in the treatment of the human immunodeficiency virus type 1 (HIV-1) infection.

Introduction

Treatment of HIV is based on blockage of the different stages of the HIV life cycle. Twenty eight drugs classified into six different classes (nucleoside-analog reverse transcriptase inhibitors [NRTIs], non-nucleoside reverse transcriptase inhibitors [NNRTIs], integrase inhibitors, protease inhibitors [PIs], fusion inhibitors, and CCR5 coreceptor antagonists) are currently available for HIV treatment (Pau and George 2014). Initial antiretroviral therapy (ART) consists of a combination of two NRTIs plus either a NNRTI, a PI, or an integrase inhibitor (Panel on Antiretroviral Guidelines for Adults and Adolescents 2015).

NNRTIs affect viral replication by inhibiting the reverse transcriptase (RT) enzyme, responsible for the conversion of viral RNA to complementary viral DNA. Unlike NRTIs, NNRTIs are chemically diverse compounds that non-competitively bind to the same site in the RT enzyme. The binding site is a hydrophobic pocket located near the enzyme's catalytic site in the p66 subunit that induces a conformational change of the amino acid side chains towards the catalytic

Non-Nucleoside Reverse Transcriptase Inhibitors for Treatment of HIV Infection, Table 1 Summary of NNRTIs formulations, characteristics and clinical use

NNRTIs	Formulation	Taken with Food	Available as single tablet ART	Adverse events	Clinical use
Nevirapine	Tablet (200 mg and 400 mg XR) Suspension (50 mg/5 ml)	No	No	Rash hepatotoxicity	Prevention of mother to child HIV transmission
Delavirdine	Tablet (100 mg and 200 mg)	No	No	Rash; CNS side effects	Rarely used
Efavirenz	Tablet (50, 200 and 600 mg) Suspension (30 mg/ml)	No ^a	Yes (Atripla [®])	Rash; CNS side effects	Preferred “single pill” regimen in resource limited settings
Etravirine	Tablet (100 and 200 mg)	Yes	No	Rash; diarrhea headache	Effective as salvage regimen for NNRTI resistant virus
Rilpivirine	Tablet (25 mg) Long Acting IM ^b (300 mg/ml)	Yes	Yes (Complera [®])	Nausea dizziness transaminitis	Active against K103N mutant virus Less CNS side effects Pregnancy category B

site affecting its activity (Kohlstaedt et al. 1992; Hsiou et al. 1996).

NNRTIs were the third class of antiretrovirals identified for the treatment of HIV. The first drug in the class, nevirapine, was approved by the US Food and Drug Administration (FDA) in 1996. At present, there are five NNRTI drugs available for HIV treatment in the United States. They are all selectively active against HIV-1, but are not active against HIV-2 or animal retrovirus. In addition, NNRTIs do not require additional intracellular phosphorylation to become active and are metabolized to some degree by the cytochrome P450 enzyme. Despite sharing the same mechanism of action, each NNRTI has a unique chemical structure and characteristics and selection of the drug will depend on the HIV resistance pattern, toxicity profile, and drug interactions. In this review, we will describe each drug from the NNRTI class, focusing on their pharmacokinetics, resistance, side effects, and clinical use. Table 1 summarizes key characteristics of each NNRTI drug.

First Generation NNRTIs

The discovery of the 1-(2-(2-hydroxyethoxy-methyl)-6-(phenylthio) thymine (HEPT) and tetrahydroimidazo [4,5,1-jk][1,4]benzodiazepin-2(1H)-one and -thione (TIBO) in the early 1990s as the first compounds to inhibit the RT enzyme led to the development of NNRTI drugs (Baba et al. 1991; Pauwels et al. 1994). Soon after, dipyridodiazepinones, bis(heteroaryl)piperazines and benzoxazinones were used as compounds for the first generation NNRTI. Three first generation NNRTI drugs have been FDA approved: nevirapine in 1996, delavirdine in 1997, and efavirenz in 1998.

- Nevirapine (NVP)
 - Description: NVP is a dipyridodiazepinone derivative discovered in 1990 by researchers at Boehringer Ingelheim (Fig. 1). Oral bioavailability is above 90% and the drug can be administered with or without

Non-Nucleoside Reverse Transcriptase Inhibitors for Treatment of HIV Infection, Fig. 1 Chemical structure and molecular formula of NNRTIs

food. It is highly lipophilic and 60% is bound to proteins allowing penetration of the blood–brain barrier and placenta. NVP has a long half-life of approximately 25–30 h and effective dosing regimen is 200 mg daily for 14 days followed by 200 mg twice a day (or 400 mg daily of the extended release formulation). It is metabolized in the liver and induces the CYP3A4 and 2B6 isoenzymes. Eighty percent of the drug is excreted in the urine and 10% in the feces.

- Resistance: Development of resistance is common with monotherapy or non-adherence. The most common selected mutation is Y181C, which also confers cross-resistance to other NNRTIs.
- Adverse events: Severe hypersensitivity reactions (including Stevens-Johnson

syndrome and toxic epidermal necrolysis) and hepatotoxicity have occurred with NVP. These adverse events are more common in women with CD4 cell counts above 250 cells/mm³ and in men with CD4 cell count above 400 cells/mm³. These adverse events usually manifest during the first 8 weeks of therapy and can be fatal if not recognized. It has been assigned category B for pregnancy and has been used extensively to prevent mother to child HIV transmission.

- Drug–drug interactions: As a CYP3A4 substrate and inducer, NVP can interact with other isoenzyme substrates. NVP has been shown to decrease the serum levels of drugs such as ketoconazole, voriconazole, methadone, carbamazepine, diltiazem, and amiodarone. Other CYP3A4 inducers may

also decrease NVP serum levels. St. John's wort has been shown to significantly reduce NVP serum levels and coadministration should be avoided.

- Clinical trials: The efficacy of NVP is comparable to efavirenz and ritonavir-boosted protease inhibitors when taken with two NRTIs in individuals with HIV infection who are treatment-naïve or have limited exposure to ART. The open label randomized 2NN trial compared efavirenz vs. nevirapine in combination with two NNRTIs (stavudine and lamivudine in treatment-naïve HIV-infected individuals) (van Leth et al. 2004). Results revealed similar efficacy between both NNRTIs but higher treatment failures were observed in patients taking NVP with CD4 cell count <250 cell/mm³ or plasma RNA >100,000 copies/ml as well as higher rates of adverse events. Similarly, the ARTEN and the NEWART studies demonstrated that NVP was noninferior to atazanavir/ritonavir when taken in combination with tenofovir and emtricitabine with comparable rates of adverse events (Soriano et al. 2011; Dejesus et al. 2011).
- Delavirdine (DLV)
 - Description: DLV belongs to the family of bishetero-arylpiperazine compounds (*N*-[2-(4-[3-(propan-2-ylamino) pyridin-2-yl] piperazin-1-yl carbonyl)-1H-indol-5-yl] methanesulfonamide) discovered by researchers at Upjohn Laboratories, now Pfizer (Fig. 1). It has a high oral bioavailability of 85% and is unaffected by food, however it has a short half-life of 5.8 h and requires a dosing of 400 mg every 8 h. DLV is highly protein bound and has a low penetration into the CNS. Metabolism occurs primarily in the liver by the CYP3A4 enzyme. Forty-four percent of the drug is eliminated in the feces and 51% in the urine.
 - Resistance: Resistance to DLV emerges rapidly when used as monotherapy or in sub-optimal regimens. Resistance mutations at codon position 103 [lysine to asparagine (K103N)] and 181 [tyrosine to cysteine (Y181C)] are the most commonly encountered mutations and confer resistance to first generation NNRTIs. Mutation P236L confers high-level resistance to DLV but causes hyper susceptibility to other NNRTIs.
 - Adverse Events: The most common adverse events seen with DLV include skin rash, CNS side effects and gastrointestinal symptoms. The skin rash can be severe and in rare instances erythema multiforme and Stevens-Johnson's syndrome may develop. Headache, anxiety, depressive symptoms and insomnia are the predominant CNS adverse events. DLV has been designated pregnancy category C by the FDA.
 - Drug-Drug Interactions: Unlike other NNRTIs, DLV inhibits the CYP3A4 enzyme thereby increasing the serum level of the enzyme's substrates. Lovastatin, simvastatin, rifabutin, rifampicin, sildenafil, ergot derivatives, quinidine, midazolam, carbamazepine, phenobarbital or phenytoin should be avoided when using DLV. Antacids, histamine-2 receptor antagonists, or proton pump inhibitors may reduce the absorption of DLV.
 - Clinical trials: Early studies using DLV combined with a single NRTI (zidovudine or didanosine) resulted in greater decreases in plasma HIV viral load than did NNRTI monotherapy. Triple therapy combinations of DLV with zidovudine and didanosine showed greater reduction in HIV plasma viral loads and sustained improvements in CD4 cell counts compared to dual therapy, however these differences were not consistent nor statistically significant (Friedland et al. 1999). In a randomized study of treatment-experienced individuals, the addition of DLV to a PI-based regimen showed short-term virologic benefit which did not persist at 48 weeks (Gulick et al. 2000). Due to insufficient evidence supporting DLV's virologic efficacy in combination therapy and availability of better antiretroviral agents, DLV is "not recommended" as a component of antiretroviral regimens for initial treatment of HIV

infection (Panel on Antiretroviral Guidelines for Adults and Adolescents 2015).

- Efavirenz (EFV)

- Description: EFV is a benzoxazinone derivative ((*S*)-6-chloro-4-(cyclopropylethynyl)-1,4-dihydro-4-(trifluoromethyl)-2H-3,1-benzoxazin-2-one) discovered by Merck researchers (Fig. 1). EFV's oral bioavailability is 40–45% and increases in the setting of a high-fat meal so it is recommended to take the drug on an empty stomach. EFV is highly protein bound (>99%) and is excreted as an unchanged drug primarily in the feces (16–61%) and in the urine as hydrolyzed metabolites (14–34%). As other NNRTIs, EFV is metabolized by CYP3A4 and 2B6 iso-enzymes. Its long half-life (40–55 h) allows for once daily dosing of 600 mg and it was incorporated in the first single tablet formulation in combination with tenofovir disoproxil fumarate and emtricitabine. EFV is the most widely used NNRTI, nonetheless given availability of newer agents with less adverse events and superior efficacy it is now listed as an alternative drug for HIV treatment in ARV naïve individuals.
- Resistance: Like the other NNRTIs, EFV has a low genetic barrier to resistance and selects for HIV-1 reverse transcriptase amino acid substitutions that will lead to resistant mutants. K103N mutation is the most characteristic, which also confers resistance to NVP and DLV. Other mutations such as L100I, K103N, V108I, V179D, Y181C also affect susceptibility to EFV.
- Adverse events: EFV is usually well tolerated but rash and CNS side effects can be significant. Rash has been reported in about 26% of patients and usually resolves on its own without requiring discontinuation. Rare cases of Steven Johnson's syndrome have been reported. Approximately 25–77% of patients on EFV have reported CNS side effects and neuropsychiatric side effects such as headache, dizziness, insomnia, abnormal dreams, impaired concentration, agitation, depression, amnesia, fatigue

and hallucinations. Analyzed data from four AIDS Clinical Trials Group (ACTG) on HIV treatment naïve individuals showed that initial treatment with an efavirenz-containing antiretroviral regimen was associated with a twofold increased hazard of suicidality (suicidal ideation, attempted or completed suicide) compared to a regimen without efavirenz (Mollan et al. 2014). A genetic polymorphism of CYP2B6 has been associated with higher plasma concentrations of EFV and higher risk of CNS adverse events (Ribaudo et al. 2010). EFV should be administered at bedtime and on an empty stomach to minimize the risk of these side effects. CNS side effects usually dissipate within the first 4 weeks of therapy but in certain patients symptoms can persist and discontinuation of therapy should be considered (Clifford et al. 2005). Other less common adverse events include hepatotoxicity, nausea, dyspepsia, lipodystrophy, dyslipidemia, gynecomastia, myopathy, and tinnitus.

- Drug–Drug interactions: Like other NNRTIs, EFV has the potential to cause drug–drug interaction by inducing the CYP3A4 enzyme. Concomitant use with voriconazole should be avoided as EFV significantly decreases the plasma levels of voriconazole and, paradoxically, voriconazole raises the plasma levels of EFV. EFV can also reduce the plasma levels of rifabutin, clarithromycin, atorvastatin, simvastatin, methadone, and carbamazepine. Rifampin increases the plasma levels of EFV generally requiring dose adjustment from 600 to 800 mg daily. EFV has been labeled category D for pregnancy as its use during the first trimester has been associated with neural tube defects in both primates and humans.
- Clinical Trials: Large randomized trials in HIV treatment-naïve patients have demonstrated potent and durable viral suppression when treated with combination ART regimens including EFV and two NRTIs (Gulick et al. 2004). EFV has been shown to have comparable HIV antiviral activity

to nevirapine, lopinavir/ritonavir, and atazanavir/ritonavir based regimens (van Leth et al. 2004; Daar et al. 2011; Riddler et al. 2008), In treatment-experienced HIV-infected individuals with viral suppression, the switch to a single pill fixed dose combination of EFV/emtricitabine/tenofovir disoproxil fumarate was effective in maintaining viral suppression at 96 weeks (DeJesus et al. 2009). Lower dose EFV of 400 mg in combination with emtricitabine and tenofovir disoproxil fumarate was confirmed to be noninferior to the standard dosing of 600 mg with fewer EFV-related adverse events (Study Group 2015). Compared to rilpivirine, a newer NNRTI, EFV has shown to be noninferior with less virologic failure among patients with pre-ART plasma viral load >100,000 copies/ml but with higher rates of therapy discontinuation related to adverse events (Molina et al. 2011; Cohen et al. 2011). When compared to integrase inhibitors, EFV has been shown to be noninferior to the elvitegravir/cobicistat/TDF/FTC combination but raltegravir and dolutegravir have demonstrated superiority to EFV in randomized controlled trials based primarily on discontinuation related to adverse events (Wohl et al. 2014; Lennox et al. 2009; Walmsley et al. 2013).

Second Generation NNRTIs

The need for NNRTIs with a better resistance profile led to the development of the second generation NNRTIs. Second generation NNRTIs currently include etravirine and rilpivirine. These NNRTIs have a higher genetic resistance barrier and can be used in most patients who have HIV-1 virus with resistance to the first generation NNRTIs.

- Etravirine (ETR):
 - Description: ETR was approved in January 2008 by the FDA as a salvage treatment for HIV treatment-experienced individuals.

It belongs to the family of di-aryl-pyrimidine (DAPY) compounds (Fig. 1). ETR's chemical name is 4-[6-amino-5-bromo-2-(4-cyanoanilino) pyrimidin-4-yl]oxy-3,5-dimethylbenzonitrile and this structure allows it to bind to the RT enzyme in more than 1 distinct mode based on changes in the NNRTI-binding pocket. ETR is taken with meals as oral absorption increases by 50% when administered with food. The drug's half-life is approximately 41 h and it is administered at a dose of 200 mg every 12 h. It is highly protein bound (>99%) primarily to albumin and α 1-acid glycoprotein. ETR is metabolized in the liver to mostly inactive metabolites through methyl hydroxylation, glucuronidation, and aromatic hydroxylation. Elimination occurs primarily in the feces (94%), followed by the bile (11%) and to a much smaller degree in the urine (1%).

- Resistance: Unlike other NNRTIs, ETR requires multiple mutations for the development of resistance. In addition, it retains activity against HIV-1 despite emergence of the traditional NNRTI mutations K103N and Y181C. A number of NNRTI mutations including V90I, A98G, L100I, K101E, K101P, V106I, V179D, V179F, Y181C, Y181I, Y181V, G190A, and G190S have been shown to decrease susceptibility to ETR. A score of mutations has been developed to assess the effect of mutations on the activity of ETR. A score of 0–2 confers a 74% response rate (highest response); a score of 2.5–3.5 confers a 52% response rate (intermediate response); and a score of ≥ 4 confers a 38% response rate (reduced response) (Vingerhoets et al. 2010). The E138K mutation, which usually develops after erratic use of rilpivirine, also confers resistance to ETR.
- Adverse Events: ETR is usually well tolerated with rare grade 3 or 4 adverse events leading to drug discontinuations. The most common reported side effects include rash, diarrhea, nausea, and headache. Hyperglycemia and hypercholesterolemia

have also been reported. It does not cause significant CNS side effects as seen with EFV. ETR is a pregnancy category B drug, however due to insufficient data its use is not recommended in pregnancy unless other alternatives are not available. In addition, its safety profile in elderly, individuals with renal or hepatic dysfunction is unknown.

- Drug–Drug Interactions: ETR is a substrate and an inducer of CYP3A4 and an inhibitor of CYP2C9 and CYP2C19. It can decrease the levels of several medications such as antiarrhythmics (disopyramide, lidocaine, quinidine), antineoplastics (vinca alkaloids, docetaxel, paclitaxel), benzodiazepines, calcium channel blockers, 3-hydroxy-3-methylglutaryl-coenzyme A reductase inhibitors, immunosuppressive agents (cyclosporine, tacrolimus), sildenafil, and tricyclic antidepressants. ETR can also interact with other ART drugs; EFV, nevirapine, ritonavir, and tipranavir can significantly reduce the plasma concentrations of ETR and ETR can lower the concentrations of unboosted PIs, maraviroc, and raltegravir.
- Clinical Trials: Unlike other NNRTIs, ETR was first evaluated in treatment-experienced individuals. The DUET-1 and -2 trials, phase III blinded randomized trials in which highly treatment-experienced individuals with NNRTI mutations were assigned to ETR or placebo in addition to an ART regimen that included darunavir/ritonavir, optimized NRTI combinations, and optional enfuvirtide, demonstrated viral suppression compared to placebo (55 vs. 33%). These studies demonstrated the effectiveness of adding ETR to regimens for individuals who had HIV-1 virus resistant to other NNRTIs (Madruga et al. 2007; Lazzarin et al. 2007).
- Rilpivirine (RPV)
 - Description: RPV is a diarylpyrimidine added to the NNRTI class after its FDA approval on August 2011. Its chemical structure 4-[[4-[[4-(E)-2-cyanoethenyl]-2,6-dimethylphenyl]amino]-2-pyrimidinyl]

amino]benzotrile monohydrochloride allows deeper attachment to the NNRTI binding pocket (Fig. 1). Solubility and systemic absorption are pH-dependent, so RPV has to be administered with a meal at a dose of 25 mg once a day. Antacids and high protein drinks significantly reduce RPV absorption. It is the second NNRTI coformulated with 300 mg of tenofovir and 200 mg of emtricitabine into a single pill form known commercially as Complera. After oral administration RPV reaches peak plasma levels after 4–5 h and the half time to elimination is approximately 50 h. It is highly protein bound (99%), mainly to albumin, and is excreted in the feces (85%) to a lesser extent in the urine.

- Resistance: RPV is active against K103N mutant HIV-1 virus. Fifteen NNRTI mutations have been associated with decreased susceptibility to rilpivirine: K101E, K101P, E138A, E138G, E138K, E138Q, E138R, V179L, Y181C, Y181I, Y181V, H221Y, F227C, M230I, and M230L. The E138K mutation is known to confer resistance against all members of the NNRTI family including RPV and ETR.
- Adverse Events: RPV is generally well tolerated. Nausea and dizziness are the most common adverse events associated with RPV. A lower incidence of rash, neuropsychiatric symptoms, and lipid abnormalities are seen with RPV compared to EFV (Cohen et al. 2012). Depressive disorders have been reported in 4–9% of RPV recipients. Transaminitis can occur and is the most common reason for drug discontinuation (Pozniak et al. 2010). QTc prolongation have been seen with RPV at higher doses but rarely at 25 mg daily. RPV has been classified into a pregnancy category B by the US Food and Drug Administration (FDA); this means that animal studies have failed to demonstrate a risk to the fetus but there are no adequate and well-controlled studies available in pregnant women.
- Drug–Drug Interactions: RPV is primarily metabolized in the liver by CYP3A enzyme;

its plasma concentration may be affected in the presence of CYP3A inhibitors or inducers. Coadministration with anticonvulsants (carbamazepine, oxcarbazepine, phenobarbital, phenytoin), antituberculous drugs (rifampin, rifapentine), proton pump inhibitors, systemic dexamethasone, or St John's wort should be avoided.

- Clinical Trials: Three randomized trials compared RPV with EFV in combination with two NRTIs for treatment-naïve individuals. ECHO and THRIVE showed that RPV met noninferiority criteria at 96 weeks when compared with EFV (Cohen et al. 2013), except in patients with pre-ART plasma viral load of >100,000 copies/ml and CD4 cell count <200 cells/mm³ where higher rates of virologic failure were documented in the RPV group. Fewer drug discontinuations and serious adverse events were observed with RPV compared to EFV. The STaR trial compared the fixed-dose combinations of RPV/TDF/FTC vs. EFV/TDF/FTC and showed that the RPV combination was superior to EFV in patients with pre-ART viral loads ≤100,000 copies/ml (Cohen et al. 2014).

Investigational Agents

New NNRTIs in clinical trials include doravirine and long acting injectable rilpivirine. Doravirine has pharmacologic advantages over other NNRTIs and activity against NNRTI resistant virus. Rilpivirine is being tested in a long acting formulation allowing intermittent dosing by injection. In clinical trials, this drug is being tested for both treatment of chronic HIV infection (in combination with an injectable long acting integrase inhibitor) and for prevention of HIV infection using the long acting rilpivirine injection alone.

- MK 1439 (Doravirine)
 - Description: Doravirine is a potent investigational nonnucleoside inhibitor of HIV-1 reverse transcriptase under development

by Merck & Co., Inc. It is primarily metabolized by oxidation via CYP3A4 and is a P-glycoprotein substrate in vitro. Doravirine may be affected by CYP3A4 inhibitors or inducers but has a low potential to cause drug–drug interactions. The terminal half-life of 12–21 h supports once daily dosing. Administration of 50 mg doravirine with a high-fat meal was associated with slight elevations in AUC_{0-∞} and C_{24hr} with no change in C_{max}. PK was similar between HIV-infected patients and healthy subjects. Doravirine can be dosed without regard to food (Anderson et al. 2015a).

- Resistance: In vitro, doravirine inhibits wild type HIV virus and K103N, Y181C, and K103N/Y181C mutant virus.
- Adverse events: In clinical trials, at doses between 25 and 200 mg, doravirine was well tolerated. There were fewer CNS side effects seen with doravirine compared with efavirenz in a randomized trial (Gatell et al. 2014).
- Drug–drug interactions: Coadministration of ritonavir increases doravirine AUC_{0-∞} 3.5-fold and C_{24hr} 2.9-fold, but increased C_{max} only 30%. Tenofovir had no meaningful effect on doravirine PK (Anderson et al. 2013). Doravirine can be coadministered with dolutegravir and a ketoconazole study showed that strong CYP3A inhibitors can be administered with doravirine (Anderson et al. 2015b, c). However, strong CYP3A inducers should not be administered with doravirine.
- Clinical Trials: In a dose ranging (25–200 mg) PK study in HIV-infected subjects, there was no exposure-response relationship between doravirine plasma levels and both viral load and proportion of subjects with undetectable viral load at week 48 (Gatell et al. 2014). Phase 3 trials are on-going with the 100 mg daily dose.
- Long acting rilpivirine (RPV-LA)
 - RPV-LA is a nanosuspension developed for intramuscular injection. A 300 mg/ml

nanosuspension has been chosen for further investigation. Single dose injections of either 600 or 300 mg RPV-LA given to healthy volunteers showed a median half life of 2.2 and 1.3 months, respectively. Although no serious AEs were reported, grade 1 events included short-lasting pain at the injection site and stiffness of the extremities. A compartment study of RPV-LA demonstrated rilpivirine presence after a single 600 mg IM injection in plasma, rectal fluid and rectal tissue, and in women in cervicovaginal fluid (Jackson et al. 2014). In a healthy volunteer study, RPV-LA and long-acting cabotegravir (GSK1265744) showed that injections were safe and generally well-tolerated (Spreen et al. 2014). A phase 2b study is ongoing in ARV-naïve subjects testing the two injections given every 4 or 8 weeks, after a 24 week induction period with oral daily cabotegravir plus abacavir and lamivudine (Healthcare ViiV 2012).

Clinical Use

First generation NNRTIs EFV and NVP have treated HIV infection successfully for nearly 20 years, most commonly in combination with 2NRTIs for initial infection. EFV with tenofovir and lamivudine (or emtricitabine) is currently considered to be the preferred regimen for initial therapy of adults and adolescents in the developing world (World Health Organization (WHO) 2013). EFV can have significant CNS side effects and therefore some guidelines for resource rich countries list an EFV regimen as an alternative option after first line integrase inhibitor-based or darunavir/ritonavir-based regimens (Panel on Antiretroviral Guidelines for Adults and Adolescents 2015). NVP with zidovudine/lamivudine or tenofovir/lamivudine (or emtricitabine) are alternative regimens after the EFV regimen in WHO guidelines for adolescents and adults. This is due to the higher rate of serious adverse events (rash

and liver toxicity) associated with NVP. EFV based regimens are now considered safe to use in pregnancy (even in first trimester) per WHO guidelines despite many years of concern over fetal neural toxicity. In resource rich areas, other regimens are preferred above one containing EFV, but EFV regimens should be continued if a woman becomes pregnant while taking EFV provided the regimen is well tolerated and achieves virologic suppression. In 2006, a coformulated pill of EFV plus tenofovir and emtricitabine became available, giving patients a one pill once a day option thereby revolutionizing HIV treatment.

Second generation NNRTIs are active against virus with first generation NNRTI mutations and are better tolerated. RPV was coformulated with tenofovir and emtricitabine into a one pill daily regimen in 2011. Higher virologic failure rates were seen in patients with baseline viral loads $>100,000$ or baseline CD4 counts <200 cells/mm³. Emtricitabine/rilpivirine/tenofovir disoproxil fumarate is not recommended for patients with high baseline viral loads. ETR is approved for treatment-experienced patients with NNRTI resistant virus. ETR is not likely to be active for a patient experiencing virologic failure on a RPV regimen due to mutations conferring reduced susceptibility to both drugs.

Doravirine is being studied in phase III trials and appears to be effective, well tolerated, and has minimal potential for drug interactions. A long acting injectable formulation of RPV (given with at least one other injectable ARV) is being tested in phase II studies and, if the study outcomes are favorable, will give patients the option of infrequent dosing.

Conclusion

The NNRTIs are a highly effective and generally well tolerated class of medications, particularly used in treatment-naïve patients. EFV and RPV can be taken in one pill once daily regimens, increasing the ease of administration and

adherence. Doravirine and a long acting injection of RPV may improve treatment options for patients with HIV-1 infection.

Nonpathogenic SIV Infection of Sooty Mangabeys

Steven E. Bosinger

Division of Microbiology and Immunology,
Yerkes National Primate Research Center, Emory
University, Atlanta, GA, USA

Definition

Nonhuman primates (monkeys) are the most widely used experimental animal model for the study of HIV infection and AIDS. While rhesus macaques are the workhorse system used in the majority of vaccine and pathogenesis studies, significant insight into how AIDS causes immune dysfunction has been made by examining simian immunodeficiency virus (SIV) infection in non-macaque species of monkeys that do not develop disease during SIV infection, referred to as “natural host species.” The purpose of this entry is to highlight the most important findings to come out of research using the sooty mangabey monkey, one of the best studied natural host species, and how these findings have shaped contemporary thinking about HIV infection and AIDS.

Overview: Pathogenic versus Natural Infection of Monkeys with SIV

The use of monkeys as an animal model for the study of AIDS is widely known; however, the particular species used for this research warrant introduction in a more specific manner. The most broadly used species for AIDS vaccine and pathogenesis research is the rhesus macaque (*Macaca mulatta*). Rhesus and other species within the *Macaca* genus ranges are predominantly in Asia, although some macaque species range into northern Africa and southern Europe. The virus used to infect rhesus in this experimental system is the simian immunodeficiency virus (SIV), which is highly related to HIV. SIV infection of rhesus macaques shares similar hallmarks with HIV infection of humans: loss of CD4⁺ T cells,

disruption of lymph node architecture, weight loss, diarrhea, and susceptibility to opportunistic infections. SIV infection of other species within the *Macaca* genus, the best studied being pig-tailed macaques and cynomolgus macaques, also displays AIDS-like symptoms. Prior to the advent of antiretroviral therapy, the time-to-death for an HIV-infected person was estimated to be 10–12 years; in comparison, rhesus macaques typically succumb to AIDS-related complications in 6 months to 2 years, a time frame that is convenient for their use as an experimental model system.

SIV was originally discovered in rhesus macaques within several US primate research centers. Shortly after reports of AIDS in humans had surfaced, a similar disease was noted in captive rhesus colonies in the USA. Subsequent work demonstrated that the etiologic agent responsible for this “simian-AIDS” (sAIDS) was a virus sharing seroreactivity and a high degree of nucleotide sequence similarity with HIV. Surprisingly, similar viruses were also found at a high prevalence in captive sooty mangabey monkeys that did not display AIDS-like symptoms (Murphey-Corb et al. 1986). Follow-up studies showed that the SIVmac strains of SIV viruses (the suffix “mac” given for their origin in rhesus macaques) that infect macaques and cause AIDS could not be found in wild macaque monkeys. Instead, the source of the SIVmac virus was determined to be cross-species transmission of SIVs from sooty mangabeys (referred to as SIVsmm) (Hirsch et al. 1989) that occurred in captivity. Thus, the strains of SIV that are most commonly used for preclinical AIDS vaccine testing in monkeys are not found in the wild naturally, but are in fact a by-product of a zoonotic jump during captivity.

HIV-1, HIV-2, SIV, and the Origins of HIV-Related Immunodeficiency Viruses

HIV-1, HIV-2, and Their Origins in Monkeys

The search for SIV in the wild that occurred in the late 1980s set the groundwork for later research that would identify the origins of HIV and define how it entered the human population. A full

discussion of this topic is not the focus of this entry, but it warrants explanation to avoid confusion. The human immunodeficiency virus can be classified into two major types: HIV-1 and HIV-2. There are four subtypes of HIV-1: M, N, O, and P. HIV-1M is by far the predominant agent responsible for the majority of worldwide infections and main cause of the AIDS epidemic. In contrast, infections with subtypes N, O, and P have only been described in people residing or originating in West Africa. Phylogenetic evidence indicates that each HIV-1 subtype entered into the human population as a result of an independent cross-species transmission event. HIV-1M is thought to have originated from cross-species transmission of SIVcpz, which infects chimpanzee subspecies in West Africa. The other SIV subtypes are thought to originate from either SIVcpz or SIVgor (from lowland gorillas). Molecular dating studies have indicated that HIV-1 likely crossed into the human population as a result of the hunting and consumption of chimpanzee bushmeat at the end of the nineteenth century or early twentieth century.

HIV-2 is endemic to people in West Africa, with the highest prevalence being found in people of Senegal and Guinea Bissau. Typically, the course of infection of HIV-2 is much milder than that of HIV-1, with lower viral loads and less dramatic CD4⁺ T cell depletion. The majority of those infected do not progress to AIDS, but those who do experience similar symptoms to HIV-1 infected patients. At least eight sub-lineages of HIV-2 have been found in people, and each one is likely the result of an independent cross-species transmission. The primary source of most strains of HIV-2 is thought to be from cross-species SIVsmm, from African sooty mangabeys.

SIVcpz Versus SIVsmm and “Natural” SIV Strains

Strains of SIV have been identified in at least 40 different nonhuman primate species in Africa. These monkey species do not display any signs of AIDS when infected with their endemic virus. The majority of SIVs that are found in species such as sooty mangabey, African Green monkeys, and

others have a high degree of similarity with each other and with HIV-2. In contrast, the SIVcpz and SIVgor strains are highly atypical compared to most SIVs, containing different accessory genes and considerable divergence at the nucleotide level. SIVsmm and other “typical” SIV strains have infected their host species for millions of years and are maintained within species at high prevalence. SIVcpz is thought to be the result of recombination of two different strains of SIV in more recent evolutionary history.

In striking contrast to most SIVs, which are benign in their natural hosts, recent evidence indicates that SIVcpz infection in chimpanzees in the wild is, in fact, associated with disease and lower life expectancy.

The considerable divergence between HIV-1 and the SIVmac and SIVsmm strains used for vaccine experiments in rhesus had led to some efforts in the 1990s to develop a chimpanzee model that used HIV-1, with the rationale that it would provide a platform for testing vaccines that could be directly translated into human clinical trials (i.e., without the need to re-engineer from SIV antigens to HIV antigens). While chimpanzees were capable of infection, they did not show an observable disease, and this model failed to gain traction. Recent ethical restrictions on invasive biomedical research performed on chimpanzees have effectively ended any potential use of chimpanzees for this purpose in the foreseeable future.

The goal of this section was to provide the reader with an overview of the different types of HIV and SIV, their animal reservoirs, and the historical and biological reasons underlying the use of different SIVs in contemporary research. Further, the evolutionary history of SIV within their respective species provides perspective on why these “natural” infections are no longer pathogenic. For more detailed information on the origins of immunodeficiency viruses and the molecular mechanisms that affect their cross-species transmission, the reader is directed to an excellent review by Sharp and Hahn (2011). The remainder of this entry will focus on SIV infection of sooty mangabeys and related natural hosts.

Clinical Features of SIV Infection in Sooty Mangabeys

The sooty mangabey (*Cercocebus atys*) is an old-world monkey that ranges in West Africa (Fig. 1). They are notable in that they harbor a strain of SIV, SIV_{smm}, that is the most likely origin of most HIV-2 cross-species transmission events and is the source of the SIV_{mac} strain of viruses, the most widely used strain in monkey (rhesus) vaccine studies. However, the most biomedically important aspect of SIV infection in sooty mangabeys (SMs) and other natural host species of monkeys is that they do not develop any observable signs of AIDS when infected with SIV. It should be noted that although this entry deals specifically with SIV infection of sooty mangabeys, our understanding of natural host/SIV interactions is complemented by studies of SIV infection in other African monkeys; in fact, several of the key findings in SMs have been contemporaneously shown in African green monkeys, which has helped the interpretation of the results. In this regard, within this entry, findings derived equally from natural hosts models will be lumped together; conversely, unique properties of each species will be specifically mentioned. Lastly, should the reader require more in-depth information, they are directed to two

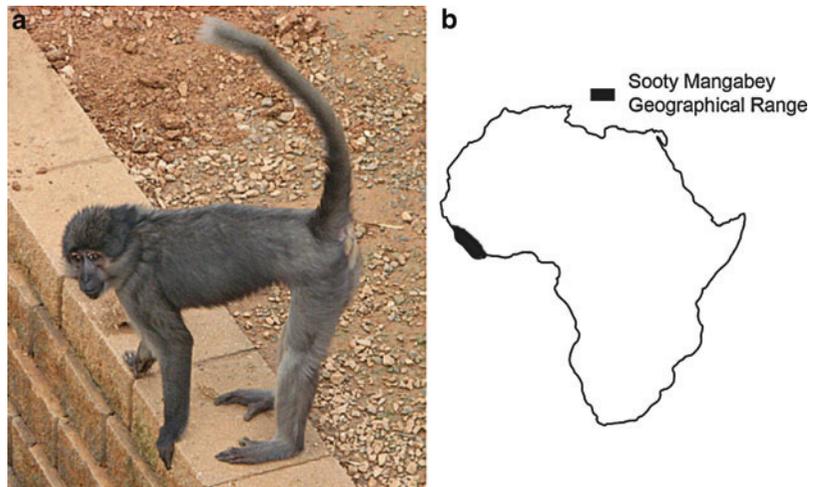

comprehensive recent reviews by Chahroudi et al. (2011) and Sodora et al. (2009).

SIV-Infected Sooty Mangabeys Maintain High Levels of Plasma Virus

Despite the disparity in disease course, nonpathogenic infection of SMs shares many similarities with pathogenic HIV/SIV infection; differences and similarities are summarized in Table 1. Both SMs and pathogenic hosts exhibit high levels of virus in the plasma, at average level of 10^5 RNA copies per ml of plasma. This observation has several important implications for HIV research. First, the observation that SMs (and >40 other African natural host species of NHPs) have, over millennia, evolved to coexist with SIV infection, and have not evolved immune mechanisms that control or eradicate infection, is a sobering lesson for the considerable challenges that need to be surmounted in the development of a vaccine that prevents against HIV transmission. Second, it highlights the contrast between the mechanisms maintaining non-pathogenesis seen in SMs compared to humans that naturally control virus. This rare population of patients, termed long-term non-progressors (LTNPs), comprises <1% of HIV-infected persons and maintains low levels of HIV by immune control mediated by CD8+ “killer T cells.” A graphical comparison of viral

Nonpathogenic SIV Infection of Sooty Mangabeys, Fig. 1 (a) Photograph of a sooty mangabey monkey at the Yerkes National Primate Research Center. (b) Geographical range of sooty mangabeys within West Africa

Nonpathogenic SIV Infection of Sooty Mangabeys, Table 1 Clinical features of SIV infection in natural and pathogenic hosts

Phenotype	Pathogenic hosts (humans, rhesus)	Natural hosts (sooty mangabeys, African green monkeys)
AIDS	Yes	No
Peripheral blood CD4+ T cells	Depleted	Unaffected
Viral load	High	High
Mucosal CD4+ T cells	Progressively depleted	Depleted initially, then stable
Microbial translocation	Yes	No
Immune activation	Perpetual	Acute phase only
CD4+ T cell memory cell infection	Tcm > Tem	Tem > Tcm
Mother-to-child transmission	Frequent:	Rare:
	Humans (~40%)	Sooty (~7%)
	Rhesus (25–75%)	

loads in various HIV and SIV infection settings is shown in Fig. 2. The high levels of plasma viremia are strong evidence that “non-pathogenesis” is not due to an enhanced ability of the immune system in sooty mangabeys to control virus. Nevertheless, to rule out this possibility, follow-up experiments showed that sooty mangabeys do not have superior antiviral CD8+ T cell responses nor more effective antibodies against SIV compared to rhesus macaques. Another early hypothesis to explain the lack of disease in natural hosts proposed that the SIV_{smm} strain was less pathogenic than HIV or SIV_{mac239}. However, infection of sooty mangabeys with the SIV_{mac239} isolate did not cause disease. Additionally, mathematical modeling experiments of SIV_{smm} kinetics in the plasma of sooty mangabeys treated with antiretroviral drugs showed that the mangabey virus replicated in cells with a high turnover rate (i.e., CD4+ T cells) in a manner indistinguishable from HIV infection. Overall, these experiments provided powerful evidence that the lack of disease in sooty mangabeys was not due to a more

Nonpathogenic SIV Infection of Sooty Mangabeys, Fig. 2 Viral loads within models of HIV and SIV infection. During the common course of HIV infection, most patients will experience progressive disease which, left untreated, would result in eventual AIDS. These patients (chronic progressors) typically maintain viral loads in the plasma or 10^4 – 10^5 RNA copies/ml. In contrast, a limited number of patients control virus to varying degrees and are able to maintain stable numbers of CD4+ counts for several years called long-term non-progressors which can be

subclassified based on their plasma virus levels: patients with lowered but detectable virus in the range of 10^2 copies per ml are viremic controllers, and patients that completely suppress virus are elite controllers. In comparison, the plasma viral loads of rhesus macaques, which develop disease, and sooty mangabeys, which remain AIDS-free, are similar to the virus levels in chronic progressors. This suggests that immune control is not likely a mechanism by which SIV-infected sooty mangabeys avoid disease

effective immune response or to defective properties of the SIV_{smm} strain.

Sooty Mangabeys Maintain Blood CD4+ T Cells but Lose Gut CD4+ T Cells During SIV Infection

A key difference that distinguishes SIV infection of sooty mangabeys from pathogenic infections is the absence of depletion of peripheral blood CD4+ T cells, which is the defining clinical feature of HIV infection. Data from SIV + sooty mangabeys at the Yerkes National Primate Research Center have documented infection of more than 200 SMs, many of which have been infected for over 20 years, in which the decline of blood CD4+ T cells does not differ perceptibly from age-matched controls (Taaffe et al. 2010). It should be noted that there is a minor exception to this general observation: depletion of CD4+ T cells was observed in a handful of SMs that were experimentally infected with an atypical strain of SIV_{smm} that utilized the CXCR4 coreceptor (rather than CCR5, which is the most commonly observed tropism in SIV and HIV strains during initial infection) (Milush et al. 2011). Remarkably, despite being CD4 low for many years, the SMs remain disease-free. While the ability of SMs to maintain their peripheral blood CD4+ T cell levels during SIV infection has been firmly established, the immunological mechanism by which this occurs remains elusive and one of the priorities of research into this species.

While the vast majority of SIV-infected SMs maintain stable levels of peripheral blood CD4+ T cells, they undergo a profound depletion (50–90%) of CD4+ T cells in the rectal mucosa within days of infection (Gordon et al. 2007), and similar findings have been shown in natural host African green monkeys. Pathogenic infection of humans and RMs also causes a rapid and severe loss of mucosal-associated CD4+ T cells. Although mucosal CD4+ T cell loss is observed in both nonpathogenic and pathogenic infections, there are, in fact, several features that differ: (1) whereas CD4+ T cell loss in RMs is continual, the levels stabilize in natural hosts; (2) the “quality” of gut CD4+ T cell loss differs – sooty mangabeys maintain a subpopulation of CD4+ T cells

called “CD4+ Th17” cells that are uniquely configured to combat gut infections and maintain the integrity of the gut epithelial barrier; and (3) while the causative link has not been established, the depletion of mucosal CD4+ T cells coincides with a breakdown of mucosal barrier continuity in SIV-infected rhesus macaques, whereas SMs maintain an intact mucosal epithelium even in the face of mucosal CD4+ T cell loss. The consequence of breaches in the mucosal barrier is the appearance of particles from resident flora entering into the systemic circulation. SIV-infected rhesus and HIV-infected humans have been shown to have an accumulation of LPS, a structural component of gram-negative bacteria, in the blood, and blood LPS levels correlate with pathogenic immune activation. This phenomenon, coined “microbial translocation,” has emerged as a major hypothesis to explain the pathogenic immune activation observed in HIV infection. Importantly, no evidence of microbial translocation has been shown in SIV-infected SMs. The ability of SMs to keep their gut architecture intact may allow them to limit the entry of microbial flora to the systemic circulation, thus avoiding immune activation. This hypothesis is an active area of research at present.

SIV-Infected Sooty Mangabeys Avoid Chronic Immune Activation

In the late 1990s, a series of large-scale clinical studies of untreated HIV-infected patients demonstrated that the strongest predictor of time-to-death was not plasma levels of virus or CD4+ T cell counts, but instead was the level of activation markers such as CD38 or HLA-DR on the surface of CD4+ and CD8+ T cells. These studies were important milestones for HIV pathogenesis because they indicated that the loss of CD4+ T cells and the destruction of immune structures were not simply a consequence of the death of infected cells, but rather due to the unrelenting “over-activation” of the immune system. This concept was supported by the observations that: (1) only a small minority of CD4+ T cells are productively infected relative to the number of dying cells and (2) sooty mangabeys did not show disease despite high viral loads. In 2003, a seminal study demonstrated that SMs chronically

infected with SIV did not exhibit any signs of CD4⁺ or CD8⁺ T cell activation (Silvestri et al. 2003). The lack of immune activation in SMs despite high viral loads was compelling evidence that the driving mechanism for CD4⁺ T cell depletion in HIV-infected humans was due to unabated activation, and not due to direct cytopathic effects of virus infecting CD4⁺ T cells. This study further established the utility of using SMs and other natural host species in combination with pathogenic hosts for comparative studies of the immune response to SIV infection to dissect “normal” responses to viral infection from “abnormal” responses that cause disease. The remainder of this entry will focus on studies that have been based on using this comparative approach.

The lack of immune activation observed in early studies suggested that SMs “ignored” the immune stimuli provided by high levels of SIV, and initial follow-up studies supported this view. However, later data demonstrated unequivocally that SMs have a widespread innate and adaptive response to the virus that is rapidly controlled within approximately 30–60 days after infection. Currently, there are several hypotheses to explain the ability of SMs to limit immune activation to the acute phase of infection.

One model proposes that the innate response to SIV is attenuated in an active manner by immunoregulatory genes that arise during the transition to chronic infection and is based off of genome-wide studies of the gene expression that occurs during SIV infection of SMs and AGMs (Bosinger et al. 2009). In these experiments, SIV infection of SMs caused a widespread induction of a class of genes known as “interferon-stimulated genes” (ISGs). Hundreds of diverse genes have been classified as ISGs and are related primarily by (1) having antiviral activities and (2) being turned on by the interferon alpha and beta cytokines. Elevated ISG expression has been detected in rhesus macaques even at 1 year post-infection, but abated quickly in sooty mangabeys and in African green monkeys, coinciding with the upregulation of immunoregulatory genes. In a follow-up experiment, exogenous interferon was administered to sooty mangabeys, and ISG expression was quickly muted, and while there

were changes in immune activation, they were transient (Vanderford et al. 2012). A long-standing hypothesis to explain AIDS pathogenesis is that the continual production of interferon in HIV infection contributes to the disease process, and the observation that both sooty mangabeys and African green monkeys shut off this response has provided additional evidence to this concept.

A second model postulates that the limited immune activation in natural hosts is due to cellular functions of the viral SIV Nef protein. Nef is highly related to disease in SIV and HIV; deletions of the *Nef* gene from the SIV genome render the virus largely apathogenic. One of the many functions of the Nef protein is to lower the amount of CD4⁺ molecule from the surface of T cells. The Nef protein in SIV_{smm} is considerably more efficient than Nef from HIV-1 (Schindler et al. 2006), allowing SIV_{smm} to cause less activation at the cellular level than HIV-1. This hypothesis is currently being tested by infecting NHPs with recombinant SIV viruses that contain the human *Nef* gene.

The models discussed above propose that the ability to resolve immune activation in natural host species is due to either direct immunoregulatory mechanisms by the host or virus. However, as will be discussed below, other recent data suggests that the lack of chronic immune activation in natural hosts is a secondary effect, due to the ability of SMs to avoid microbial translocation and/or by the ability of SMs to sequester viral replication in a manner that minimizes its impact on immune activation.

Sooty Mangabeys Compartmentalize SIV Replication in Different Immunological Niches Compared to Pathogenic Hosts

In both HIV and SIV infection, the primary cellular target of viral infection is CD4⁺ T cells. HIV and SIV both utilize the CD4 molecule as their primary receptor for cellular entry. The viruses also have secondary requirements for fusion, referred to as a “coreceptor”. In HIV/SIV infection the predominant coreceptor is the chemokine receptor CCR5, although other chemokine

receptors are also utilized albeit at a much reduced level. The CD4⁺ T cell population has been demonstrated to be the predominant target cell for HIV/SIV replication in humans and in both pathogenic and natural primate hosts. The primary function of CD4⁺ T cell within the mammalian immune system is to provide “help” to other effector cells of the immune system, such as antibody-secreting B cells and killer CD8⁺ T cells, which kill virally infected cells. Advances in our understanding of CD4⁺ T cell biology over the decade have shown that the CD4⁺ T cell compartment is in fact made up of multiple lineages phenotypically defined by their own distinct pattern of surface markers, residing in diverse anatomical niches and each providing a unique role within a functioning immune system. Simply put, all CD4⁺ T cells are not “equal.” In the sections below, the different classes of CD4⁺ T cells will be reviewed. The subsequent sections will describe how natural and pathogenic hosts differ in the subclasses of CD4⁺ T cells in which SIV is found, and the impact of this different pattern of infection on the function of the immune system.

Basic CD4⁺ T Cell Biology

The progenitors of CD4⁺ T cells move from the bone marrow to the thymus, where they undergo development from immature precursors and emerge as naïve cells. Naïve cells patrol peripherally and migrate throughout inductive secondary lymphoid organs such as lymph nodes until they come into contact with their specific antigen, displayed by MHC II molecules on the surface of antigen-presenting cells (APCs). Interaction of the T cell receptor with its cognate antigen/MHC II complex with appropriate co-stimulatory signals will activate naïve T cells, driving them to proliferate, upregulate cell-surface levels of maturation markers, and, most importantly, differentiate into non-naïve antigen-experienced effector and memory cells. CD4⁺ T cells can be classified in two fundamental ways: (1) according to their exposure to antigen and differentiation (i.e., “memory status”) and (2) based on their specialization to conduct an array of different immune activities (i.e., “functional status”).

Memory Status of CD4⁺ T Cells

During the initial period of an infection, the antigen-exposed pool of CD4⁺ T cells is predominantly comprised of effector cells that produce cytokines that provide “help” to other arms of the immune system, such as enhancing the phagocytic activity of macrophages, enabling the maturation of antibody-producing B cells, or directing the activation of antigen-specific CD8⁺ killer T cells. When the offending pathogen is cleared and the antigenic burden is removed, the pool of antigen-specific effectors rapidly contracts as the cells die. In their stead, a heterogeneous population of memory cells remain, and in the event of a secondary infection by the same pathogen, these pathogen-specific memory cells are capable of activation, expansion, and differentiation to effector cells in a manner much more rapid than naïve cells (hence they provide “memory” of a previous infection).

The memory cell populations are defined in three lineages: effector memory (Tem), central memory (Tcm), and a newly described population, stem-cell memory (Tscm). The populations differ in their anatomic location and regenerative potential and are defined from one another by distinct expression of cell-surface markers. Effector memory CD4⁺ T cells are typically found in peripheral tissues. Accordingly, they lack expression of molecules that drive migration to the lymph nodes (CCR7 and CD62L). They tend to express high levels of the chemokine receptor CCR5 that promotes chemotaxis to peripheral sites (i.e., skin, lung, mucosa) where they reside and can provide an early line of defense against infection by rapidly differentiating into effectors. Effector memory cells are relatively short lived and are capable of differentiating into effector cells with limited self-renewal. In contrast, central memory T cells (Tcm) are long-lived, multipotent cells that are enriched in secondary lymphoid tissues. Reciprocal to effector memory cells, Tcm cells are defined by expression of CD62L and CCR7. Tcm can maintain long-term immunological memory of antigen through their ability to stably self-renew. Upon the reappearance of antigen, Tcm can also divide very rapidly into effector memory cells. Because of their propensity for

self-renewal, T_{cm} are critical for maintaining a stable pool of antigen-specific CD4⁺ T cells. A recently described memory subset of T cells, termed “stem-cell memory” (T_{scm}), are extraordinarily long-lived. T_{scm} share many similar characteristics and surface markers with T_{cm}, however also maintain cell-surface markers associated with naïve cells. T_{scm} are a very small proportion of the overall T cell pool and their function overlaps somewhat T_{cm}, however they maintain a high proliferative capacity similar to naïve cells.

Functional Classes of CD4⁺ T Cells

Whereas memory status reflects the state of maturation, i.e., how far down the maturation path a T cell has gone after coming contact with its cognate antigen, CD4⁺ T cells also differentiate into specialized functional subsets that reside in different anatomical locations and carry out distinct immunological tasks. Functional subsets have been traditionally defined by the major cytokines they produce; however, improved characterization has now identified transcription factors and/or surface markers that discriminate these subsets. The classification of CD4⁺ T cells has yielded a steadily increasing number of functional lineages, and a full description is beyond the scope of this entry; instead the most well-established subsets affected by SIV infection will be discussed.

For many years, CD4⁺ T cells were thought to be polarized into two functional classes: (1) T-helper type 1 (Th1), which function to support the cell-mediated arm of the adaptive immune system by the production of cytokines such as IL2 and IFN γ that enhance the functions of macrophages and cytotoxic/killer CD8⁺ T cells, and (2) T-helper type 2 (Th2) that improve the humoral response (i.e., antibody-mediated response via B cells) through the production of cytokines such as IL4, IL5, IL10, and others. However, novel, more specialized subclasses of CD4⁺ T cells have recently been described. One such subset is CD4⁺ T follicular cells (T_{fh}), which are memory cells that are defined by the surface markers CXCR5 and PD1. These cells colocalize with B cells within the germinal centers

in lymph nodes, and their function is to enhance the antibody response by facilitating class-switching and somatic hypermutation of immunoglobulin genes that improve the affinity and avidity of the resultant antibodies.

Another recently described functional subclass of CD4⁺ T cells are Th17 cells, which were briefly introduced in a preceding section of this entry. While a definitive set of surface markers for this subset have not been described, Th17 are defined by high production of IL17 and IL22 and expression of the transcription factor ROR γ . A major function of Th17 is to provide immunity against fungal and bacterial pathogens; they also support the proliferation of mucosal epithelial cells via the production of IL22, and dysregulation of these cells has been associated with intestinal autoimmune disorders.

Lastly, CD4⁺ T regulatory cells (Tregs) are defined by their immunoregulatory activities, primarily secretion of the suppressive cytokines IL10 and TGF β . The best characterized subset of Tregs are defined by surface expression of the CD25 markers and the transcription factor FOXP3.

Sooty Mangabeys and Natural Hosts Exhibit a Differential Pattern of SIV Infection in CD4⁺ Subsets Compared to Pathogenic Hosts

As new lineages of CD4⁺ T cells were described in mice and humans, research into their depletion, activation status, and in vivo infection within macaques and SMs have yielded important observations that help to explain the natural host phenotype. These results have clearly established that natural hosts are able to maintain SIV replication in a different pattern of cells compared to non-natural hosts. Sooty mangabeys maintain a lower frequency of SIV-infected CD4⁺ T_{cm} when compared to infected RMs (Paiardini et al. 2011). This observation is important because several studies have shown that, consistent with their crucial role in maintaining CD4⁺ T cell homeostasis, depletion of CD4⁺ T_{cm} in RMs predicts the rate of disease progression. The limitation of infection in CD4⁺ memory cells appears to be a consistent theme in natural host infection, as African green monkeys also have limited infection in

their Tcm and Tem compartments. Visualization experiments have shown that SIV infection also differs at the anatomical level; in sections of lymph nodes taken from SIV + RMs and HIV-infected subjects, infected cells were detected at high frequencies in B cell follicles, but were absent from these areas in SMs; instead infected cells were detected in extrafollicular T cell zones. Consistent with anatomical location data, higher levels of cell-associated SIV have been observed in CD4+ Tfh cells from rhesus macaques compared to SMs. The collective observation of natural hosts minimizing infection in vulnerable subsets of CD4+ T cells has led to a model to explain non-pathogenesis in SMs termed the “target restriction hypothesis.” Under this model, natural host shifts the majority of the burden of viral replication away from cell subsets critical for homeostatic maintenance of the CD4+ T cell pool and favors replication in cells such as effector memory cells that are short-lived and, while they are needed to combat infection, are ultimately dispensable.

Sooty Mangabeys Have a Significantly Low Rate of Mother-to-Child Transmission of SIV

Of the 30 million people infected with HIV worldwide, an estimated 3.3 million are children. Mother-to-child transmission (MTCT) accounts for an estimated 370,000 pediatric infections annually. Antiretroviral regimens administered to pregnant mothers have been one of the victories of HIV prevention research, reducing transmission from an estimated 40% to below 5%. Unfortunately, in resource-limited settings, access to ART during childbirth is still underutilized, and thus understanding the mechanisms by which MTCT can be limited immunologically is important. In this regard, natural hosts provide an interesting model. In macaques, the rate of perinatal transmission has been estimated to be 25–75% in various studies; in SMs the rate is significantly reduced at 7% (Chahroudi et al. 2012). Studies of mandrills and African green monkeys have shown that they have similarly low transmission rates.

Interestingly, SMs that are infected by vertical transmission have plasma viral loads that are approximately two orders of magnitude lower than animals acquiring SIV later in life. Research into the mechanisms underlying limited MTCT in SMs is still in early stages. Comparison of SMs and RMs has not observed any differences in the level or infectivity of virus in the breast milk between species. However, infant SMs have a drastically reduced expression of the SIV entry receptor CCR5 on CD4+ cells in tonsils, esophagus, and mucosal lymphoid tissue, suggesting that the low transmission rate may be due to a lower number of potential targets for viral infection/replication. The observation of low CCR5 in both infant and adult natural hosts suggests that modulation of entry receptors may be an evolutionary adaptation that allowed natural hosts to reduce infection. Given the low rate of vertical transmission but the high population prevalence of SIV in wild mangabeys (estimated at approximately 70%), it is likely that the majority of transmission events occur by sexual contact. Overall, this would restrict most transmissions until child-bearing years and limit the impact of SIV infection on the fitness of the species as a whole.

Lessons from Genetic and Genomic Studies of Sooty Mangabeys

The use of natural hosts for detailed immunological comparative studies has been conducted for a little over a decade, but has already proven a useful tool to identify components of the immune system critical to avoiding pathogenic disease. The advent of high-throughput genomic technology should allow for greater insight in coming years. Already, microarray analysis of the immune response to SIV detectable in blood identified the ability of SMs and African green monkeys to resolve immune activation. Currently, two large-scale studies utilizing next-generation sequencing technology to study SMs and natural hosts are underway: (1) the first is using RNA-Seq technology to characterize genome-wide level in multiple classes of immune cells, including the CD4+ T cell memory subsets described here, and

(ii) sequencing of the DNA genome of sooty mangabeys for comparison with human, rhesus and cynomolgus macaques, and African green monkeys to identify potential immune modulating genes under recent evolutionary selection. The unraveling of the genome and transcriptome of SMs will be exciting advances because they will provide the power to examine natural host biology in the absence of preformed hypotheses. Thus, genomic information can be a “roadmap” that leads us to important differences unique to natural hosts.

Other recent studies have not performed genome-wide characterization, but have sequenced individual genes within the majority of animals in the sooty mangabey colony. One such study examined the protein coding regions of IRF7, a signaling molecule that regulates interferon production: these results showed that IRF7 was not appreciably different from human or rhesus IRF7 and likely not responsible for differences in disease. In contrast, the reduced expression of CCR5 in SMs and other natural host species provided a strong rationale for the sequencing of this gene across the colony. Compellingly, approximately 8% of sooty mangabeys are homozygous for one of two mutations in CCR5 (CCR5 Δ 2 and CCR5 Δ 24) that abrogates its ability to be expressed on the cell surface (Riddick et al. 2010). In comparison, an analogous mutation in human CCR5 that provides resistance to infection, named CCR5 Δ 32, is present in homozygosity at about 1% in the Caucasian population. The enrichment of CCR5-null mutations in the species provides a compelling argument for a central role of this coreceptor in dictating pathogenesis. Interestingly, homozygote CCR5-null sooty mangabeys are not infected at lower prevalence, and plasma viral load is only marginally lower (although statistically significant) compared to wild-type animals. This observation, in combination with other studies, have shown that sooty mangabeys have the ability to permit infection by cellular coreceptors other than CCR5. The permissiveness of CCR5-null animals provides another line of evidence that an evolutionary “strategy” employed by sooty mangabeys is to “shunt” infection into dispensable targets,

rather than to block infection altogether. While this “strategy” has the disadvantage of allowing infection, the advantage is that it removes selective pressure for the virus to evolve in unpredictable ways which may ultimately become pathogenic. A compelling line of evidence supports the concept for a central role in CCR5 in permissiveness and disease in HIV infection: the continued, successful “functional cure” (defined as the absence of detectable viremia despite cessation of antiretroviral therapy) for over 5 years of an HIV-positive patient receiving a bone marrow transplant from a donor homozygous for the null CCR5 Δ 32 mutation, known as the “Berlin Patient.” Thus, therapies aimed at reducing the ability of HIV to utilize CCR5 via genetic targeting or pharmacological manipulation may hold real promise for reducing disease in HIV infection. The association between low levels of CCR5 on target cells and reduced MTCT in sooty mangabeys suggests that reduction of CCR5+ targets in viral inductive sites may be a viable strategy for preventative modalities.

Concluding Remarks

Significant progress has been made in characterizing SIV infection in the context of nonpathogenic infection. Despite a wealth of data, the field has not been able to definitively demonstrate that modulation of an immunological pathway can “break” the sooty mangabey phenotype and cause AIDS. This is likely due to the inherent technical difficulties in conducting in vivo interventions in monkeys and the multifactorial nature of the phenotype. Of importance, recent studies have identified a population of HIV-infected patients that recapitulate the natural host phenotype. These patients, termed “viremic non-progressors,” maintain high levels of virus from many years without appreciable CD4+ T cell loss and share many immunologic and transcriptomic features with SIV+sooty mangabeys. The identification of VNPs is strong evidence that research into the natural host model is more than an intellectual curiosity, and will have direct relevance for human health.

NRTIs

David Sears and Eric S. Daar
Division of HIV Medicine, Department of
Medicine, Harbor-UCLA Medical Center,
David Geffen School of Medicine at UCLA,
Torrance, CA, USA

Definition

Nucleoside and nucleotide reverse transcriptase inhibitors (NRTIs) are a class of antiretroviral (ARV) medications primarily used to treat HIV infection. Two NRTIs (often referred to as the ARV “backbone”) are commonly included as part of a three- or four-drug treatment regimen. The NRTI class comprises one nucleotide analogue, tenofovir disoproxil fumarate (DF), and six nucleoside analogues: abacavir, didanosine, emtricitabine, lamivudine, stavudine, and zidovudine. These medications act to inhibit the active site of the enzyme reverse transcriptase, which is necessary for the synthesis of viral complementary DNA (cDNA) from viral RNA as part of the HIV replication cycle. Zalcitabine, a nucleoside analogue, was previously used in clinical practice but has since been discontinued by its

manufacturer. A new nucleotide analogue, tenofovir alafenamide (AF), is in phase III clinical trials and has been submitted for approval to regulatory agencies in the United States and Europe.

Mechanism of Action

Each NRTI is an analogue of one of the four nucleosides found in DNA: adenosine (didanosine), cytidine (lamivudine and emtricitabine), guanosine (abacavir), and thymidine (stavudine and zidovudine). Tenofovir, with a chemical structure that includes a phosphate group, is an analogue of the nucleotide adenosine monophosphate. Owing to the poor oral bioavailability of tenofovir, the prodrug tenofovir DF is used clinically.

As a class, NRTIs have activity against both HIV-1 and HIV-2. NRTIs block the activity of the viral enzyme reverse transcriptase, a DNA polymerase that synthesizes viral cDNA from HIV RNA. In order to effectively inhibit reverse transcriptase, NRTIs must first be phosphorylated by intracellular kinases into an active triphosphate form. While NRTIs target viral reverse transcriptase, these drugs have variable affinity for native DNA polymerases, especially mitochondrial DNA polymerase- γ . Inhibition of mitochondrial activity is thought to be responsible for most of the toxicity observed in the earlier medications in this drug class, such as lipoatrophy, peripheral neuropathy, and lactic acidosis.

History

The first five ARVs approved by the United States Food and Drug Administration (FDA) for the treatment of HIV infection were from the NRTI class: zidovudine (1987), didanosine (1991), zalcitabine (1992), stavudine (1994), and lamivudine (1995). The FDA later approved abacavir (1998), tenofovir DF (2001), and emtricitabine (2003). The sale and distribution of zalcitabine was suspended in 2006, owing to comparatively poor efficacy and high rates of toxicity.

NRTIs were initially approved for use as monotherapy against HIV infection, and expert

guidelines recommended zidovudine as first-line therapy for patients with symptomatic HIV infection or CD4+ T-cell counts of less than 200–500/ μ L. Drug-related adverse events complicated the use of the first generation of NRTIs, such as bone marrow suppression from zidovudine and mitochondrial toxicity – primarily from didanosine, zalcitabine, and stavudine – leading to lactic acidosis, peripheral neuropathy, myopathy, hepatic steatosis, and lipoatrophy. While zidovudine monotherapy was shown to reduce HIV mortality, high rates of HIV disease progression and death led many providers to prescribe dual NRTI therapy in the early and mid-1990s. Dual NRTI therapy often delayed disease progression, yet various combinations of early drugs proved problematic due to overlapping toxicities (particularly from didanosine with stavudine) and in vivo antagonism (zidovudine with stavudine). The approval of lamivudine in 1995, however, demonstrated the promise of dual NRTI therapy as combination treatment with zidovudine slowed HIV progression more than either agent alone and was associated with a favorable tolerability profile. The approval of the first drugs in two new classes of ARV medications – protease inhibitors (PIs), saquinavir, indinavir, and ritonavir (1995–1996), and non-nucleoside reverse transcriptase inhibitors (NNRTIs), nevirapine (1996) and efavirenz (1998) – paved the way for triple therapy that included combinations from different drug classes. Early clinical trials of a PI combined with two NRTIs showed improved efficacy when compared to NRTI mono and dual therapy. The first United States Department of Health and Human Services (DHHS) *Guidelines for the Use of Antiretroviral Agents in HIV-Infected Adults and Adolescents* in 1998 recommended the combination of one PI and two NRTIs over two NRTIs alone.

The FDA approval of abacavir, tenofovir DF, and emtricitabine was based upon virologic efficacy as well as substantially less toxicity when compared to older NRTIs. Improved tolerability to these medications created renewed interest in combination NRTI therapy alone, this time in the form of three-drug combinations. Clinical trials, however, were disappointing as

combination therapy with abacavir-lamivudine-zidovudine (Gulick et al. 2004) and abacavir-lamivudine plus tenofovir DF (Gallant et al. 2005) demonstrated inferiority to therapy with two NRTIs plus efavirenz. Consequently, clinical practice has continued to favor the inclusion of two NRTIs as the “backbone” of ARV therapy with partner drugs from either the NNRTI, PI, or more recently the integrase strand transfer inhibitor (INSTI) class and occasionally an additional medication to serve as a pharmacologic booster. Many pairs of NRTIs are also available as fixed-dose combinations to improve the convenience

of medication administration. Some combinations also include the partner drug or drugs so that a complete ARV regimen may be taken in a single tablet.

Individual NRTIs and Combination Pills

Individual NRTIs and combination pills, along with key characteristics, are listed in Table 1. Each NRTI is subsequently described with a focus on important toxicities and key clinical features.

NRTIs, Table 1 Nucleoside and nucleotide reverse transcriptase inhibitor (NRTI) characteristics^a

Drug (abbreviation)	Trade name	Year of FDA approval	Usual adult dose	Route(s)	Form(s)
<i>Single NRTIs</i>					
Abacavir (ABC)	Ziagen [®]	1998	600 mg once daily or 300 mg twice daily	Oral	Tablet, suspension
Didanosine (ddI)	Videx [®] , Videx EC [®]	1991	400 mg once daily	Oral	Powder, capsule
Emtricitabine (FTC)	Emtriva [®]	2003	200 mg once daily	Oral	Capsule, solution
Lamivudine (3TC)	Epivir [®]	1995	300 mg once daily or 150 mg twice daily	Oral	Tablet
Stavudine (d4T)	Zerit [®]	1994	30 mg or 40 mg twice daily	Oral	Capsule, liquid
Tenofovir disoproxil fumarate (TDF)	Viread [®]	2001	300 mg once daily	Oral	Tablet, powder
Zalcitabine (ddC) ^b	Hivid [®]	1992	0.75 mg thrice daily	Oral	Tablet
Zidovudine (AZT, ZDV)	Retrovir [®]	1987	300 mg twice daily	Oral, IV	Tablet, capsule, syrup, vial
<i>Co-formulated ARVs with NRTIs</i>					
3TC/AZT (150 mg/300 mg)	Combivir [®]	1997	1 pill twice daily	PO	Tablet
ABC/3TC (600 mg/300 mg)	Epzicom [®] , Kivexa [®]	2004	1 pill daily	PO	Tablet
ABC/3TC/AZT (300 mg/150 mg/300 mg)	Trizivir [®]	2000	1 pill twice daily	PO	Tablet
ABC/3TC/DTG (600 mg/300 mg/50 mg)	Triumeq [®]	2014	1 pill daily	PO	Tablet
TDF/FTC (300 mg/200 mg)	Truvada [®]	2004	1 pill daily	PO	Tablet
TDF/FTC/EFV (300 mg/200 mg/600 mg)	Atripla [®]	2006	1 pill daily	PO	Tablet
TDF/FTC/RPV (300 mg/200 mg/25 mg)	Complera [®]	2011	1 pill daily	PO	Tablet
EVG/Cobi/FTC/TDF (150/150 mg/200 mg/300)	Stribild [®]	2012	1 pill daily	PO	Tablet

DTG dolutegravir, EFV efavirenz, RPV rilpivirine, EVG/COBI elvitegravir/cobicistat

^aThe dosage and use of these medications should be in direct consultation with a medical practitioner

^bWithdrawn from the market

Abacavir

Abacavir is currently one of the most commonly prescribed NRTIs. In contrast to tenofovir DF, abacavir does not have significant adverse effects on renal function or bone mineral density. The primary toxicity related to abacavir is a hypersensitivity reaction characterized by fever and a combination of symptoms that may include rash, gastrointestinal upset, headache, dyspnea, and cough. Continued use of abacavir despite a hypersensitivity reaction (or re-challenge following the reaction) can be fatal. Abacavir hypersensitivity reaction is strongly associated with human leukocyte antigen (HLA) B*5701 allele, and therefore HLA-B*5701 testing is recommended prior to use. Patients who test positive for HLA-B*5701 should avoid abacavir, while those testing negative are at very low risk of having a hypersensitivity reaction. In addition to the risk of hypersensitivity reaction, abacavir use has been complicated by a controversial association with increased cardiac events. This association was first discovered in an analysis of the D:A:D collaboration (an international group of 11 prospective cohorts of HIV-infected patients), which demonstrated an approximately two-fold increased risk of cardiovascular events in those who had recently taken or were currently receiving abacavir (D:A:D Study Group et al. 2008). Although the relative risk for such events was increased in all patients, the absolute risk was highest for those with multiple cardiovascular risk factors. Subsequent observational studies, randomized controlled trials (RCTs), and case-control studies have produced conflicting results with two meta-analyses of multiple RCTs not revealing an association between abacavir and an increased risk for cardiovascular events. Given the discrepancy in results and the lack of an adequately powered RCT, many practitioners avoid the use of abacavir in patients at high risk for cardiovascular events.

Didanosine

The clinical use of didanosine is limited due to the development of other NRTIs with more favorable side effect profiles. Didanosine use has been complicated by gastrointestinal upset, dose-dependent

peripheral neuropathy (17–20% of patients), dose-dependent pancreatitis (1–7%), lipoatrophy, lactic acidosis, and non-cirrhotic portal hypertension. Concomitant administration of didanosine and stavudine greatly increases the rate and severity of these side effects due to the overlapping toxicities of both medications.

Lamivudine and Emtricitabine

Lamivudine and emtricitabine are discussed together as they are structurally similar, inhibit viral reverse transcriptase in the same manner, and have similar side effect profiles. Both drugs are well tolerated, do not affect mitochondrial function *in vitro*, and demonstrate side effect profiles comparable to placebo. Resistance mutations, however, can develop rapidly on therapy, particularly when the ARV regimen has suboptimal potency. Inclusion of one of these drugs is recommended in all first-line ARV regimens for treatment-naïve patients, although they should never be used together. Lamivudine and emtricitabine both have activity against hepatitis B virus (HBV), as does tenofovir DF with which emtricitabine is co-formulated. Inclusion of emtricitabine-tenofovir DF is recommended as part of the ARV regimen of all patients with HBV coinfection in the absence of any contraindications. This co-formulation has also demonstrated clinical benefit when taken as pre-exposure prophylaxis (PrEP), a key HIV prevention measure for high-risk uninfected individuals.

Stavudine

Much like didanosine, stavudine is rarely used due to the development of other NRTIs with more favorable side effect profiles. Stavudine use has been complicated by gastrointestinal upset and mitochondrial toxicity manifesting as dose-dependent peripheral neuropathy (8–21% of patients), dose-dependent pancreatitis, lipoatrophy, and lactic acidosis. Concomitant administration of stavudine and didanosine also exacerbates these side effects due to the overlapping toxicities of both medications.

Tenofovir DF

Tenofovir DF is well tolerated, efficacious, and recommended as part of most first-line ARV

regimens for treatment-naïve patients. Side effects due to mitochondrial toxicity are rare in comparison to earlier NRTIs. Like lamivudine and emtricitabine, tenofovir DF has activity against HBV and is recommended as part of the ARV regimen of all coinfecting patients, barring any contraindications. As above, the co-formulation of emtricitabine-tenofovir DF has demonstrated clinical efficacy when taken as PrEP. Tenofovir DF has the added benefit of improving the lipid profile of patients although the clinical significance of this finding is unclear. The two principal toxicities of tenofovir DF are renal damage and increased loss of bone mineral density. Tenofovir DF-mediated renal toxicity (<5% of patients) comes in the form of proximal tubular dysfunction, acute kidney injury, and chronic kidney disease, most frequently after long-term use and in patients with preexisting kidney disease or those taking concurrent nephrotoxic medications. Early drug withdrawal leads to partial or complete reversal of renal toxicity in many, but not all, patients. Due to this toxicity, tenofovir DF is not recommended for those with an estimated glomerular filtration rate (eGFR) <60 mL/min/1.73 m² or those who experience a >25% decline in eGFR while taking the medication. An accelerated reduction in bone mineral density, relative to other NRTIs, also complicates long-term tenofovir DF use. While fragility fractures have been reported, it is uncertain to what degree tenofovir DF affects fracture risk and long-term bone health. Regardless, this drug should be used with caution in those patients at high risk of fragility fractures.

Zalcitabine

Zalcitabine was approved in 1992 but removed from the market in 2006 due to toxicity and poor data on virologic efficacy. In addition to the host of side effects mediated by mitochondrial toxicity, zalcitabine was associated with aphthous stomatitis.

Zidovudine

The first approved NRTI, until recently, zidovudine had been widely used in clinical practice. This drug, however, is no longer recommended for most patients because it is less convenient than

other options (dosing is twice daily) and, even more importantly, it is associated with an increased risk of adverse events including hematologic (anemia and neutropenia) and mitochondrial toxicity. While zidovudine is no longer recommended as part of first-line therapy for treatment-naïve patients, it does have a role in the prevention of mother to child transmission, given the extensive clinical experience in this setting. Zidovudine is often included in the antepartum ARV regimen of pregnant women and is given intravenously during the intrapartum period for pregnancies with a higher risk of transmission. It is also administered to newborns during the first 6 weeks of life as postexposure prophylaxis.

NRTI Resistance

Select mutations in the reverse transcriptase gene are associated with resistance to various NRTIs (Wensing et al. 2014). The reverse transcriptase mutations that are most commonly encountered and most likely to affect clinical outcomes are the thymidine analogue-associated mutations (TAMs; M41L, D67N, K70R, L210W, T215Y, K219E/Q), K65R, L74V, M184V, the 69 insertion complex, and the 151 complex.

TAMs arise after exposure to the thymidine analogues (zidovudine and stavudine). Most commonly a series of TAMs is encountered that follows either the TAM1 (M41L, L210W, T215Y) or TAM2 (D67N, K70R, K219E/Q) pathway. TAMs confer reduced susceptibility to all NRTIs, although resistance is greater with the mutations in the TAM1 pathway. The presence of T215Y may increase susceptibility to the NNRTI class.

The M184V mutation is frequently the first mutation seen in patients failing a regimen that includes lamivudine or emtricitabine. This mutation confers outright resistance to both medications, while also reducing susceptibility to abacavir, particularly if at least one TAM is present. The M184V mutation, however, does lead to enhanced susceptibility to zidovudine, tenofovir DF, and stavudine and is associated with a decrease in viral fitness. These benefits, coupled with the fact that lamivudine and emtricitabine are

extremely well tolerated, means that one of these drugs is often continued in treatment-experienced patients who have the M184V mutation as a way of maintaining selection pressure for this mutation.

When emtricitabine is combined with tenofovir DF as first-line therapy, the K65R mutation is often the next NRTI mutation to appear after M184V. The K65R mutation confers reduced susceptibility to abacavir, didanosine, emtricitabine, lamivudine, stavudine, and tenofovir DF. Zidovudine susceptibility is preserved. Patients on lamivudine with abacavir often develop the L74V mutation following M184V and this mutation reduces susceptibility to both abacavir and didanosine.

An insertion complex is when two or more amino acids are inserted at a particular codon. The 69 insertion complex consists of T69S with an additional amino acid added to serine. The 69 insertion complex is typically part of a pattern of mutations that may include A62V and any TAMs (except D67N). In the presence of at least one mutation from the TAM1 pathway, the 69 insertion complex is associated with resistance to all NRTIs. The 151 complex comprises Q151M with up to four other mutations (A62V, V75I, F77L, F116Y). When Q151M is present, there is reduced susceptibility to all NRTIs except tenofovir DF.

Use of NRTIs in Current Clinical Practice

Due to excellent virologic efficacy, tolerability, and the convenience of fixed-dose combinations and single tablet regimens, tenofovir DF with emtricitabine and abacavir with lamivudine are the NRTI backbones of choice for most treatment-naïve patients. The role of abacavir with lamivudine was established in 2004 from the results of a randomized, double-blind non-inferiority trial in treatment-naïve patients. In this trial – where both arms were also given the NNRTI efavirenz – once-daily abacavir with lamivudine demonstrated non-inferior virologic efficacy when compared to twice-daily zidovudine with lamivudine (DeJesus et al. 2004). Two years later, in an open-label non-inferiority treatment-naïve trial also involving

efavirenz, the combination of once-daily tenofovir DF with emtricitabine was found to have superior efficacy and a more favorable side effect profile than zidovudine with lamivudine (Gallant et al. 2006).

When considering tenofovir DF with emtricitabine versus abacavir with lamivudine for treatment-naïve patients, the selection of the optimal NRTI backbone typically depends upon HLA-B*5701 testing, the presence of comorbidities, the partner drug, and the pretreatment plasma HIV RNA level. Among patients with the HLA-B*5701 allele or HBV, and perhaps those with multiple cardiovascular risk factors, tenofovir DF with emtricitabine is favored. In contrast, among patients with chronic kidney disease or osteoporosis, abacavir with lamivudine may be favored.

In the absence of specific comorbidities, clinical trials with different partner drugs can inform the best approach to selecting between tenofovir DF with emtricitabine and abacavir with lamivudine as the NRTI backbone. When these two combinations have been compared in RCTs, results have varied depending on the partner drug and study design. In the first double-blind non-inferiority trial of treatment-naïve patients comparing both combinations, they were found to have comparable virologic efficacy, safety, and tolerability when given with the PI lopinavir with ritonavir (Smith et al. 2009). A later trial compared both combinations with either efavirenz or atazanavir plus ritonavir. Among patients with pretreatment plasma HIV RNA levels of greater than 100,000 copies/mL, the time to virologic failure was shorter in patients receiving abacavir with lamivudine irrespective of the partner drug (Sax et al. 2009). In contrast, there was no difference in time to virologic failure among patients with a pretreatment plasma HIV RNA level of less than 100,000 copies/mL (Sax et al. 2011). The difference in the results between the studies may reflect the difference in the partner drugs used, such as lopinavir and ritonavir in one study and efavirenz and atazanavir plus ritonavir in the other, or study design differences. As a result of these studies, tenofovir DF with emtricitabine is the NRTI backbone of choice when used with

NRTIs,

efavirenz or atazanavir plus ritonavir, particularly in patients with a pretreatment plasma HIV RNA of greater than 100,000 copies/mL.

While tenofovir DF with emtricitabine was the superior NRTI backbone for some regimens, the partner drug plays an important role. For example, the single tablet regimen (STR) tenofovir DF with emtricitabine and the NNRTI rilpivirine was inferior to the STR tenofovir DF with emtricitabine and efavirenz in a subgroup analysis of patients with pretreatment plasma HIV RNA levels greater than 100,000 copies/mL (Cohen et al. 2013). In addition, abacavir with lamivudine is a highly effective NRTI backbone when paired with the INSTI dolutegravir, available as a STR. This three-drug combination was superior to the STR tenofovir DF with emtricitabine and efavirenz in another RCT of treatment-naïve patients regardless of baseline plasma HIV RNA (Walmsley et al. 2013).

Informed in large part by these studies, first-line regimens for treatment-naïve patients (irrespective of pretreatment plasma HIV RNA) from three expert panels are summarized in Table 2. Of note, the most recent World Health Organization guidelines recommend tenofovir DF with emtricitabine (or lamivudine) and efavirenz as first-line therapy for adults in resource-limited settings.

Among patients who have failed first-line therapies, the role of NRTIs is complicated and depends on resistance mutations, medications

involved in the failing regimen, ARV treatment history, and comorbid conditions. In two RCTs of patients who failed therapy with NRTIs and an NNRTI, treatment with lopinavir plus ritonavir and two to three new or recycled NRTIs achieved rates of virologic suppression comparable to lopinavir plus ritonavir and the INSTI raltegravir, despite the presence of substantial resistance to some of the selected NRTIs (SECOND-LINE Study Group et al. 2013; Paton et al. 2014). One of these studies (Paton et al. 2014) also included a study group treated with only lopinavir plus ritonavir. This study group was inferior to the PI with NRTIs study group, suggesting that the NRTIs are an important part of the regimen despite the presence of resistance to multiple drugs in the class. As seen in these trials, the need for NRTIs depends upon how many other active drugs are in the regimen. Similar to the effectiveness seen with the PI plus INSTI study arms, another study demonstrated that if there are more than two fully active drugs used in highly treatment-experienced patient populations, overall efficacy is not impacted by the addition of NRTIs (Tashima et al. 2013).

Future Directions

Despite the successes of NRTIs, bone and renal toxicity (tenofovir DF), hypersensitivity reactions and associations with increased risk of

cardiovascular events (abacavir), and a low barrier to drug resistance (lamivudine and emtricitabine) all provide compelling reasons to develop new NRTIs and to investigate the role for NRTI-sparing regimens. The only NRTI currently in phase III clinical trials is tenofovir AF, another tenofovir prodrug. Compared to tenofovir DF, tenofovir AF achieves higher intracellular concentrations of tenofovir, allowing for reduced dosing and resulting in lower circulating plasma levels. Initial studies of tenofovir AF have demonstrated equivalent virologic efficacy, potentially less renal toxicity and smaller declines in bone mineral density, with a somewhat less favorable lipid profile when compared to tenofovir DF (Sax et al. 2015). Tenofovir AF activity against HBV is being studied. If approved by the FDA, tenofovir AF could be co-formulated with many of the same medications as tenofovir DF, and a new STR with tenofovir AF, emtricitabine, darunavir, and cobicistat is currently under investigation.

Regimens that spare all NRTIs, or at least abacavir and tenofovir DF, have demonstrated favorable results in initial studies, but are not commonly used in clinical practice due to limited data. For example, an RCT of treatment-naïve patients compared ritonavir-boosted darunavir with either raltegravir or two NRTIs. This study demonstrated that NRTI-sparing regimen was less effective in those with fewer than 200 CD4+ T-cells or plasma HIV RNA levels greater than 100,000 copies/mL at baseline (Raffi et al. 2014). Another study of treatment-naïve patients showed that lopinavir plus ritonavir was just as efficacious when given with lamivudine alone as with two NRTIs (Cahn et al. 2014). There are several switch studies that are also pursuing treatment that spares tenofovir DF and abacavir, such as the SALT study where suppressed patients were switched to ritonavir-boosted atazanavir with lamivudine alone or with two NRTIs. Outcomes were similar in both arms (Perez-Molina et al. 2015). In current clinical practice, these NRTI-sparing regimens are mostly used in those for whom there is concern regarding the use of abacavir and tenofovir DF. Further studies will be needed to determine if regimens such as these are appropriate for other patients who are

treatment naïve, desiring a switch to a new regimen or failing therapy.

Conclusions

NRTIs are a vital component of all first-line ARV regimens and many second-line and salvage regimens. As the oldest class of ARV medications, there is a wealth of clinical experience and well-designed RCTs to support the use of NRTIs to treat HIV infection. While the use of the earlier NRTIs such as zidovudine, stavudine, and didanosine were limited by safety and tolerability, relatively newer medications – lamivudine, emtricitabine, abacavir, and tenofovir DF – have markedly improved side effect profiles while retaining excellent virologic efficacy. Current expert guidelines recommend either the combination of tenofovir DF with emtricitabine or abacavir with lamivudine as the NRTI backbone in all treatment-naïve patients. The selection between these two options depends on HLA-B*5701 testing, the presence of comorbidities, the partner drug, and the pretreatment plasma HIV RNA levels and CD4+ T-cell counts. Despite the successes of ARV therapy involving an NRTI backbone, clinically significant toxicities and tolerability issues remain and are the impetus for the development of better medications in the class or regimens that avoid NRTIs entirely.

Nuclear Import: HIV-1 Goes NUPs

Cora L. Woodward¹, Jonathan Wu² and Samson A. Chow²

²Department of Molecular and Medical Pharmacology, UCLA AIDS Institute, UCLA School of Medicine, Los Angeles, CA, USA

Definition

A key feature of human immunodeficiency virus type 1 (HIV-1) and other lentiviruses is their

ability to traverse an intact nuclear envelope and productively infect nondividing cells. The nuclear import mechanisms of HIV-1 appear to involve interactions with several nucleoporin members, the constituent building blocks of nuclear pore complexes that span across the nuclear envelope.

Transport Pathways Between Nuclear and Cytoplasmic Compartments

Eukaryotic cells segregate their genomic information from the cytoplasmic milieu by sequestering the genome within the nuclear envelope, thereby defining the boundaries of the nuclear and cytoplasmic compartments of the cell. The presence of the nuclear envelope necessitates that eukaryotic cells maintain a continuous exchange of proteins and other macromolecules between these distinct cellular compartments to sustain proper cellular function. For example, transcription factors must reach their appropriate gene targets in the nucleus, and mRNA transcripts must locate to the cytoplasm for translation by the protein synthesis machinery.

The regulation of information exchange between the nucleus and cytoplasm must balance the need for high specificity with the need for rapidity and efficiency during transport. This can be exemplified by the rapid transduction of extracellular stimuli into a specific response from the cellular transcription machinery. To achieve this important regulatory balance, eukaryotic cells have evolved an elaborate pathway to mediate appropriate nucleocytoplasmic transport (reviewed in Terry et al. 2007). Key features of the regulatory pathway mediating nucleocytoplasmic transport include peptide signal sequences, or nuclear localization sequences (NLS), that identify proteins as appropriate substrates for transport into the nucleus. Nuclear import receptors belonging to the importin family of proteins recognize and bind to NLS to form complexes competent for nuclear transport. The directionality of importin-mediated nuclear transport is determined by a gradient of nucleotide-bound Ran across the nuclear envelope. High levels of Ran bound to GDP (RanGDP) are maintained in the cytoplasm by a RanGTPase-

activating protein (RanGAP) together with the Ran-binding protein 1 (RanBP1). These proteins enhance the GTPase activity of Ran in the cytoplasm leading to accumulation of RanGDP. Conversely, in the nucleus high levels of Ran bound to GTP (RanGTP) are maintained by the exclusively nuclear guanine nucleotide exchange factor (RanGEF) known as regulator of chromosome condensation 1 (RCC1). When GDP is exchanged for GTP on Ran in the nucleus, disassembly of transport complexes occurs due to the increased binding affinity of RanGTP for importin, effectively displacing the import cargo from the receptor. This entry restricts discussion on pathways pertinent to HIV-1. A more complete discussion on nuclear import pathways can be found elsewhere (Terry et al. 2007).

Bi-directional transport between the nucleus and cytoplasm takes place through the nuclear pore complex (NPC), a large macromolecular complex that forms an aqueous channel that spans the nuclear envelope (Tetenbaum-Novatt and Rout 2010). The NPC functions as the gateway between the nuclear and cytoplasmic domains of the cell by serving as a molecular sieve that allows the passage of small molecules (with a cutoff of approximately 50 kDa) but imposes a strict requirement of active transport on larger molecules (Terry et al. 2007). The structural organization of the NPC is central to its role in nuclear transport. While structural nuclear pore proteins (nucleoporins, NUPs) anchor the NPC in the nuclear envelope, NUPs containing phenylalanine-glycine repeat domains (FG-NUPs) organized at the cytoplasmic face and along the aqueous channel of the complex serve as contact points for assembled transport complexes during translocation through the NPC (reviewed in Terry and Wentz 2009). Models describing the role of FG repeats during transport include “selective gating” where FG-repeat domains provide a transient but specific binding platform for import complexes during passage through the NPC, while function concurrently as a physical barrier to restrict passage of macromolecules in the absence of import receptor binding. Alternatively, the “selective phase” model proposes that FG-repeat domains form a gel-like

barrier through which only receptor-associated cargos can dissolve. In both models, the FG-NUPs present a formidable entropic barrier for entry into the nucleus (reviewed in Tetenbaum-Novatt and Rout 2010).

While receptor-mediated transport of proteins bearing a canonical signal sequence represents the classical nuclear import pathway, non-conventional nuclear import pathways also exist (reviewed in Wagstaff and Jans 2009). These import pathways largely comprise proteins that enter to the nucleus via a receptor-independent mechanism. A common characteristic among proteins that transport via this mechanism is the ability to interact directly with components of the NPC. Specifically, the FG-NUPS, such as NUP62, NUP358 (also known as RanBP2), NUP98, and NUP153, are NPC constituents that facilitate receptor-independent nuclear transport by interacting directly with cargo proteins (Sharma et al. 2012). Proteins that undergo receptor-independent transport are often transcription factors that are released from cytoplasmic retention following a specific signal cascade and then migrate to the nucleus to mediate gene expression in response to the signaling event (reviewed in Wagstaff and Jans 2009).

Exploitation of Nuclear Transport Pathways by Viruses Obligated to Carry Out Replicative Steps in the Nucleus

The nuclear envelope imposes a physical barrier to not only cellular components that carry out necessary processes in the nucleus but also for those microbes that are obligated to carry out part of their lifecycle in the nucleus. For viruses that encode their genomes as single- or double-stranded DNA or utilize a DNA intermediate (retroviral cDNA), access to the nucleus is usually required during replication unless the virus encodes its own RNA polymerase (e.g., poxviruses; reviewed in Cohen et al. 2011). For most RNA viruses, nuclear localization is not necessary for replication except in the case of influenza A. Influenza must transport its segmented genome into the nucleus due to its dependence on the host

splicing machinery. How viruses subvert the restriction of regulated nuclear transport and deliver their genomes into the nucleus is reviewed in detail elsewhere (Cohen et al. 2011). Briefly, five proposed nuclear transport mechanisms account for the diverse strategies employed by viruses: (1) nuclear entry during mitosis when the nuclear envelope is disassembled [murine leukemia virus (MLV)], (2) viral genome release into the cytoplasm followed by nuclear import of the genome through the NPC (influenza A), (3) viral capsid docking at the NPC followed by genome release (adenovirus), (4) nuclear entry of intact capsids (hepatitis B virus), and (5) nuclear entry via virus-induced disruption of the nuclear envelope (parvovirus). These mechanisms indicate that viruses obligated to enter the nucleus during replication have evolved and thus committed valuable genomic resources for the purpose of either interacting with the cellular nuclear transport machinery or manipulating it for their own gain.

HIV-1 Infection and Nuclear Import

Since retroviruses, like HIV and MLV, form a double-stranded DNA copy (cDNA) of the single-stranded RNA genome that must be integrated into the host cell chromosomes for productive replication, these viruses are required to import their genomes to the nucleus. After cell entry and reverse transcription, the viral cDNA is assembled together with viral and cellular proteins into a large nucleoprotein complex termed the pre-integration complex (PIC). Although similar in their requirement for nuclear access, HIV-1 and MLV utilize distinct nuclear import pathways to transport their PICs into the nucleus. For MLV, a member of the *Gammaretrovirus* subfamily of retroviruses, mitosis and dissolution of the nuclear envelope precede PIC nuclear import. In contrast, HIV-1, a member of the *Lentivirus* subfamily of retroviruses, can achieve nuclear import independent of mitosis. Transport of the viral PIC across the interphase nuclear envelope is a distinguishing characteristic shared by all members of the *Lentivirus* subfamily examined thus far and implies

that these viruses have evolved a way to transport their genomes across an intact nuclear envelope. Given the size of the viral genome together with associated proteins, it is assumed that the lentiviral PIC is imported to the nucleus by means of an active nuclear import mechanism.

The significance of the ability of HIV-1 to transport its genome across an intact nuclear envelope is manifold. For example, during transmission to a new host, initial cell targets for HIV-1 infection are macrophage, a terminally differentiated and nondividing immune cell that carries out immune surveillance in the mucosa. Productive infection of macrophage affords the virus a stable foothold in the newly infected host. Importantly, infected macrophage represents a stable, persistent reservoir of virus, facilitating dissemination of the virus across the blood-tissue barrier and into diverse compartments of the host, including the lymphoid tissues where large populations of CD4+ T cells localize.

Current Models of HIV-1 Nuclear Import

Although nuclear transport of the genome is a key feature of the HIV-1 lifecycle, the mechanism that accounts for the delivery of the genome into the nucleus remains poorly understood. It is generally assumed that the large size of the PIC necessitates that the complex be able to engage the cellular nuclear import machinery to achieve active transport into the nucleus. For this reason, considerable effort has been made to characterize the karyophilic determinant in the PIC that would confer this property to the virus. Viral proteins that comprise the PIC, including matrix (MA), Vpr, and integrase (IN), as well as the triple-stranded cDNA reverse transcription intermediate, the central cDNA-flap, have been examined for their ability to mediate nuclear import of the PIC. A detailed discussion of this area of research is beyond the scope of this article, and is referred to a review on this topic (Suzuki and Craigie 2007). To briefly summarize, importin- α family members have been shown to interact directly with PIC constituents, such as MA, and were thus proposed to mediate a functional interaction

between the viral complex and cellular import pathways. However, follow-up studies have failed to support a definitive role for importin- α and MA during PIC transport. Similarly, the central cDNA-flap was shown to have an effect on the steps preceding integration, but whether it functions as a karyophilic determinant is inconclusive. Another candidate viral factor responsible for the nuclear import of the HIV-1 PIC is Vpr, which possesses unique karyophilic properties and is able to interact with components of the NPC (reviewed in Kogan and Rappaport 2011). Vpr has been reported to bind to the central, non-FG region of NUP153, as well as the non-FG region of the nucleoporin hCG1 (Kogan and Rappaport 2011). However, an essential role for Vpr in HIV-1 nuclear import has not been confirmed, and the interaction between Vpr and the NPC may not be essential but serve instead to modulate efficiency of PIC import in certain cell types by promoting PIC association with the NPC.

Two other viral proteins implicated to function as major determinants of HIV-1 nuclear import are Capsid CA and IN. Since the entry mechanism involving either CA or IN during nuclear import of HIV-1 appears to be tightly linked to their interactions with NUPs, the roles played by CA and IN are discussed below under their corresponding NUPs.

Role of NUPs Involved in HIV Import

The potential role of the NUPs in the active transport of the PIC remained largely unknown until recently. Large-scale small interfering RNA (siRNA) screens to identify cellular cofactors for HIV-1 replication have provided important insight to the function of cellular proteins during viral replication and have underscored the pivotal role of the NPC during the step of nuclear transport (Brass et al. 2008; Konig et al. 2008; Zhou et al. 2008). Three such studies identified a total of 842 cellular genes as encoding cofactors for HIV-1 replication. Due to differences in experimental parameters (i.e., cell types, filtering thresholds, timing, and readout), there is little overlap in the identity of cellular proteins identified by these

studies (Bushman et al. 2009). Among all proteins identified within the three studies, eleven were NUPs. The identified NUPs include both structural NUPs (NUP85, NUP107, NUP133, NUP155, and NUP160) and FG-containing NUPs (NUP50, NUP62, NUP98, NUP153, NUP214, and NUP358). Among the 34 proteins identified in two or more of the studies are NUP153 and NUP358 (RanBP2). The fact that multiple NUPs have been identified in separate studies as essential host factors underscores the importance of this supramolecular complex in the HIV-1 lifecycle. The identification of NUP153 and NUP358 by two separate studies further suggests that these NUPs in particular are central to the role of the NPC in mediating nuclear transport of HIV-1. Indeed, subsequent studies have corroborated the importance of the NPC, and both NUP153 and NUP358 (Woodward et al. 2009; Matreyek and Engelman 2011; Schaller et al. 2011; Di Nunzio et al. 2012; Koh et al. 2012; Matreyek et al. 2013), during HIV-1 replication. The remainder of this entry will summarize those studies and extend their importance to not only nuclear import but also ► [integration](#) and viral gene expression.

NUP153

As discussed earlier, many proteins can be transported into the nucleus via direct interaction with the NPC, bypassing the classical nuclear import pathways (Ball and Ullman 2005; Wagstaff and Jans 2009). In the absence of strong evidence supporting a role for importin- α and the classical receptor-mediated nuclear import pathways during HIV-1 replication, the role of NPC for transporting HIV-1 PICs has been investigated. The initial report found that the C-terminal domain (amino acid residues 896–1475) of NUP153, which is rich in FG repeats, binds directly with HIV-1 IN, but not FIV IN (Woodward et al. 2009). In cultured cells, overexpression of the NUP153 C-terminal domain inhibits nuclear import of IN and reduces HIV-1 infectivity by interfering with the nuclear translocation of the viral cDNA. Knockdown studies using siRNA also show the requirement of NUP153 for HIV-1 infection (Brass et al. 2008; Konig et al. 2008; Lee et al.

2010) and nuclear entry of HIV-1 cDNA (Matreyek and Engelman 2011). Further analyses suggest that NUP153 functions downstream of NUP358 and synergistically with transportin-3 (TNPO3/TRN-SR2) (Matreyek and Engelman 2011; Schaller et al. 2011). Importantly, wild-type HIV-1 depleted of cyclophilin A (CypA), a cytoplasmic peptidyl-prolyl isomerase required for optimal viral core stability (Briones et al. 2010), and HIV-1 CA mutants N74D and P90A are insensitive to NUP153 knockdown (Matreyek and Engelman 2011; Schaller et al. 2011). These results suggest that CA is a major determinant of HIV-1 nuclear entry, and NUP153 dependency is linked to uncoating of the viral core. Subsequent studies show the N-terminal domain of CA binds directly to the FG-rich C-terminal domain of NUP153 (Di Nunzio et al. 2012; Matreyek et al. 2013). NUP153 also plays a subsidiary role in targeting HIV-1 PICs to transcriptionally active regions of chromosomes (Koh et al. 2012).

NUP358

A recent study concluded that HIV-1 PICs use NUP358 (RanBP2) and CypA to access the cellular genome and target favored chromosomal regions for integration (Schaller et al. 2011). The way by which the entry pathway is engaged is through the HIV-1 CA. Besides NUP153, HIV-1 CA binds directly to CypA, as well as NUP358. HIV-1 CA-NC complexes assembled *in vitro* can also bind to NUP358 (Di Nunzio et al. 2012). In wild-type cells, CypA molecules are specifically incorporated into virions through CA interactions. The CypA-bound PIC interacts with NUP358, and the complex is then channeled through a specific nuclear entry mechanism involving NUP153 and TNPO3 (Schaller et al. 2011). Under conditions wherein CypA is depleted or inhibited or the infection is done in wild-type cells with CA mutants defective in binding NUP358, NUP358 usage is impaired and the nuclear entry of such PICs becomes less dependent on NUP153 and TNPO3 (Schaller et al. 2011). Importantly, the study shows that the choice of import pathways not only alters HIV-1 viral integration frequency but also affects the targeting preference of HIV-1 to specific genomic regions for integration (Schaller et al. 2011).

The effects of NUP358 and TNPO3 on HIV-1 integration targeting are consistent with the results from an earlier report (Oecwieja et al. 2011). The interaction between HIV-1 cores and NUP358 may form the mechanistic basis for the binding that NUP358 mediates during HIV-1 docking at the nuclear pore (Di Nunzio et al. 2012).

In addition to nuclear import of HIV-1 PICs, NUP358 has been associated specifically with HIV-1 Rev import. Rev is a sequence-specific viral RNA-binding protein that is required for the nuclear export of unspliced or partially spliced viral RNA. Rev shuttles between the nucleus and cytoplasm with its nuclear localization signals and nuclear export signals. These signals utilize typical cellular pathways to enter and exit the nucleus. Depletion of NUP358 led to a dramatic re-localization of Rev to the cytoplasm (Hutten et al. 2009). Moreover, the import rates of several other transportin-dependent proteins are also reduced when NUP358 is depleted (Hutten et al. 2009), suggesting a general role of NUP358 in nuclear import.

NUP98

Results obtained from experiments using vesicular stomatitis virus matrix protein (VSV-M), which binds within residues 66–515 of NUP98 (encompassing most of the FG repeats) and is a specific inhibitor against NUP98, and siRNA have shown that NUP98 has a definite role in HIV-1 nuclear import (Ebina et al. 2004). Expression of VSV-M in infected cells decreases the levels of integrated provirus and 2-long-terminal repeat (LTR) circle formation, an indicator of HIV-1 nuclear entry, but has no effect on full-length cDNA synthesis. The VSV-M-induced impairment of proviral and 2-LTR DNA can be restored by ectopic overexpression of NUP98 (Ebina et al. 2004). HIV-1 infection of NUP98-depleted cells using siRNA also demonstrates a reduction of proviral and 2-LTR DNA but not full-length cDNA (Ebina et al. 2004). The data indicate that NUP98 directly participates in the nuclear import of HIV-1 cDNA following viral entry. However in a separate study, NUP98 can interact with HIV-1 CA-NC complexes, depletion of NUP98 by shRNA only causes a

slight defect in HIV-1 integration (Di Nunzio et al. 2012, 2013).

In contrast to NUP358, NUP98 plays a major role in the export of HIV-1 Rev (Zolotukhin and Felber 1999). Rev actively recruits NUP98 to the nucleolus (Zolotukhin and Felber 1999). As NUP98 can associate with Rev outside of the NPC, this implicates that NUP98 is not solely stationary in the nuclear pore. Treatment of cells with actinomycin D, a polypeptide antibiotic that inhibits transcription and can affect the localization of several shuttle proteins, causes NUP98 to translocate to the cytoplasm in the absence or presence of translation inhibitor cycloheximide (Zolotukhin and Felber 1999) but has no effect on the localization of either NUP153 or NUP214. The result further supports NUP98 acting as a soluble factor (Zolotukhin and Felber 1999). Whether or not NUP98 can engage the PIC in the cytoplasm and affect the nuclear import process requires further investigation.

It is important to note that, in addition to NUP98, Rev export can similarly affect the sub-cellular localization of NUP214 (Zolotukhin and Felber 1999). Although NUP214 has been identified as one of the eleven NUPs important for HIV-1 replication, the role of NUP214 in nuclear import of HIV-1 has not been shown thus far. In fact, depletion of NUP214 may indirectly reduce HIV-1 infectivity by inhibiting general RNA export (Di Nunzio et al. 2012).

NUP62

NUP62 has been shown to be incorporated into HIV-1 and involved in viral RNA genome export, viral gene expression, and infectivity (Monette et al. 2011). A recent study has shown that NUP62 is a chromatin-bound protein that can interact with HIV-1 IN (Ao et al. 2012). Knockdown of NUP62 using short hairpin RNA significantly impairs IN-chromatin interactions and reduces viral DNA integration. Importantly, NUP62 knockdown does not inhibit appreciably HIV-1 cDNA nuclear import. In addition to knockdown, overexpression of the IN-binding region of NUP62 inhibits HIV-1 infectivity by interfering the IN-chromatin association (Ao et al. 2012). Various working models postulate that NUP62 provides the

PIC a direct link from the NPC to the chromosomal DNA. Since HIV-1 prefers to integrate into regions rich in actively transcribed genes, this would suggest the existence of complex communications occurring among NUPs to facilitate shuttling between the nuclear pore and intranuclear transcription sites. Due to NUP62's association to chromatin and transcriptionally active genes, it is hypothesized that IN recruits NUP62 to facilitate chromatin targeting and integration of HIV-1 cDNA (Ao et al. 2012).

It is worth noting that NUP62 knockdown does not completely eliminate IN-chromatin association in HIV-1-infected cells, suggesting that other viral or cellular factors play a similar role in chromatin targeting.

Conclusion

Overall, several NUPs, including NUP153 and NUP358, have been identified as being crucial for HIV-1 infection. How these different NUPs may function together in the context of the macromolecular structure of the NPC to mediate nuclear import of the HIV-1 PIC remains to be elucidated. In fact, the role of the NPC in HIV-1 replication may extend beyond that of nuclear import. The ability of multiple viral proteins to interact with diverse NUPs suggests that the biological properties of the complex are important to other replication steps such as uncoating (Schaller et al. 2011) and viral cDNA integration (Ao et al. 2012; Di Nunzio et al. 2012; Koh et al. 2012). Such a role for the NPC in these distinct replication steps is not surprising given that the complex functions to regulate not only nucleocytoplasmic trafficking but also the structure and organization of genomic DNA and cellular transcriptional activity (Capelson et al. 2010). One possible model that considers the interplay of NUPs with different viral factors proposes that interactions between NUP358 and CA associated with the incoming viral particle allows the docking of the core at the NPC and may cue the virus to uncoat, or functionally alter its CA content, within a specific context in preparation for nuclear transport (Schaller et al. 2011, Di Nunzio et al. 2012).

NUP358-dependent docking and uncoating may then result in interactions between the partially uncoated core, NUP153, and presentation of PIC-associated IN to function as the karyophilic determinant of the viral complex. The reported interaction between the C-terminal domain of NUP153, HIV-1 CA and/or IN would then function to deliver the PIC across the NPC (Woodward et al. 2009; Di Nunzio et al. 2013; Matreyek et al. 2013). After traversing the NPC, NUP153 and NUP62 may provide chaperone activity for the PIC and facilitate chromatin association and integration through its interaction with IN- and chromatin-binding properties (Ao et al. 2012; Di Nunzio et al. 2013; Koh et al. 2012).

Dependency on NUP153 for delivery of the PIC into the nucleus may have important consequences for the integration of the viral DNA into the chromosome. Cellular transcription induces both the dynamic association of NUP153 with the NPC and conformational changes in NPC-associated NUP153 (Ball and Ullman 2005). The dynamic properties of NUP153 may enable contacts with the uncoated viral complex at the cytoplasmic face of the NPC and then facilitate its transport through the aqueous channel of the NPC. Such a transport mechanism would preferentially target the PIC to transcriptionally active regions of the genome. Import of the PIC into genomic regions that are transcriptionally active may offer the advantage of encountering a chromosomal environment that will optimally support both integration and viral gene expression. This model would predict that changing how the virus interacts with the NPC would also change the chromosomal environment into which the virus integrates. Support for this hypothesis comes in the form of integration site analyses carried out after depletion of NUP153, NUP358, and TNPO3 (Ocwieja et al. 2011; Schaller et al. 2011; Di Nunzio et al. 2013; Koh et al. 2012); under these conditions, integration site selection is shifted to genomic regions with low gene density and activity.

Similarly, changes in viral proteins that impact NUP interactions also affect nuclear transport of the virus. CA mutations that result in loss of nuclear import are well documented and may reflect changes in core stability (Dismuke and

Aiken 2006). Some CA mutant can also modulate nuclear import pathways to produce altered integration target site selection. For example, the CA mutant N74D demonstrates impaired use of NUP358 and NUP153 (Schaller et al. 2011) but increases dependency on NUP155 and NUP160 during translocation (Lee et al. 2010). Interestingly, N74D also results in integration into genomic areas of low gene density (Schaller et al. 2011; Koh et al. 2012). Summarily, these findings demonstrate that alterations in the interaction between HIV-1 and NUPs impact the genomic integration site selection and modulate this important step in the viral lifecycle. Therapeutic interventions that target these interactions may represent legitimate goals for drug development.

The extent to which the NUPs play similar roles in the replication of other lentiviruses remains to be fully explored. The CAs of several primate lentiviruses and equine infectious anemia virus also interact directly with the C-terminal domain of NUP153, and NUP153 knockdown reduces their infectivity (Matreyek et al. 2013). Feline immunodeficiency virus (FIV) has neither the same sensitivity to NUP153 knockdown (Matreyek and Engelman 2011; Matreyek et al. 2013) nor the same binding characteristics with NUP153 (Woodward et al. 2009). In still another study (Lee et al. 2010), FIV demonstrates dependency on NUP155 and NUP160 for replication but not NUP153. It is worth noting that the NUP requirements of FIV are similar to that of the HIV-1 CA mutant N74D. Collectively, these findings suggest that lentiviruses have evolved diverse strategies for utilizing the NPC and specific NUPs to mediate this essential step in the viral lifecycle. Deletion of key factors or inhibition of steps along the default pathway of nuclear import opens up HIV-1 for other routes of nuclear entry. These observations emphasize the redundant mechanisms employed by HIV-1 to complete this essential replication step.

Nurse-Delivered Interventions for Adherence

Nancy R. Reynolds
Yale University, West Haven, CT, USA

Definition

Adherence is key to achieving and maintaining virological suppression in HIV-infected patients in order to achieve optimal health outcomes.

However, not all patients adhere to their medication regimens. In that adherence is a multifaceted behavior, a substantial portion of the literature focuses on interventions delivered by nurses; this chapter offers an overview of nurse-delivered care and its relationship to adherence to antiretroviral medication.

Introduction

Advances in combined antiretroviral therapy have dramatically improved the clinical outcomes and life expectancy of persons living with HIV. These medicines not only enable people living with HIV to live longer and healthier lives but also help to prevent new HIV infections. Yet, these benefits cannot be realized without consistent adherence to maintain drug exposure at levels necessary to achieve durable virologic suppression and to maximize the availability of future therapeutic options.

Adherence has long been recognized as a primary determinant of virological success. Maintaining sufficient levels of adherence to antiretroviral medications has proved to be challenging for many people living with HIV. Although today's regimens are more convenient and better tolerated than those prescribed in the early years, suboptimal adherence with resulting treatment failure is still common. It is therefore essential that measures to support and sustain patients' adherence are a standard component of HIV clinical care.

Maximizing adherence and achieving the full potential of the antiretroviral therapies require attention to complex behavioral issues that compromise the success of HIV therapies. Nurses are well positioned to provide and coordinate adherence care. Since the beginning of the HIV epidemic, nurses have played a critical role in caring for persons with HIV, both as members of care teams and as primary HIV care providers. Nurses are increasingly recognized throughout the world as a significant, largely underutilized asset to health service delivery by virtue of their numbers, distribution in urban and rural areas, educational preparation which emphasizes an integrated

consideration of the patient's physical and psychosocial health-care needs, competence, and their ability to deliver safe and high-quality patient care.

Nurse-Delivered Antiretroviral Adherence Interventions

Numerous behavioral change interventions designed to improve adherence to antiretroviral medications have been tested in randomized controlled trials. Among strategies that have been examined are psychoeducational counseling approaches (e.g., motivational interviewing, behavioral skills development/problem solving), cue-based reminders (e.g., short message prompts via MEMS, text messaging), antidepressant therapy, social support/"buddy systems," directly observed therapy, and reward systems (e.g., payment). Interventions are commonly delivered in 1:1 counseling or group sessions in clinic settings, methadone maintenance programs, at the patient's home or by phone, and computer-assisted or video instruction.

Nurses have delivered the antiretroviral adherence interventions in several of the studies as summarized in Table 1 (Berrien et al. 2004; de Bruin et al. 2010; DiIorio et al. 2008; Holstad et al. 2011; Holzemer et al. 2006; Koenig et al. 2008; Reynolds et al. 2008; Simoni et al. 2011; Wang et al. 2010; Williams et al. 2006). Most of the nurse-delivered adherence interventions have been implemented in HIV clinic settings (de Bruin et al. 2010; DiIorio et al. 2008; Holstad et al. 2011; Holzemer et al. 2006; Koenig et al. 2008; Simoni et al. 2011). A few have been delivered through home visits (Berrien et al. 2004; Wang et al. 2010; Williams et al. 2006), by phone (Reynolds et al. 2008), or through a combination of face-to-face visits and phone calls (Holzemer et al. 2006; Koenig et al. 2008; Wang et al. 2010).

The antiretroviral adherence interventions delivered by nurses have been guided by different theoretical frameworks (e.g., self-regulation, theory of planned behavior, health belief model, and information, motivation, and behavioral (IMB) model). However, each has used a

multicomponent psychoeducational counseling approach that generally involves a combination of tailored knowledge development, motivation, skills building, problem solving, and/or social support. Two have also used electronic feedback (de Bruin et al. 2010) or reminders (Simoni et al. 2011). The frequency of the nurse-delivered adherence intervention sessions has ranged from just a few sessions (de Bruin et al. 2010) to as many as 24 sessions delivered over 12 months (Williams et al. 2006).

The nurse-delivered adherence interventions have shown varying degrees of success. Most have shown some improvement in adherence behavior. Several have demonstrated a significant improvement in adherence behavior (de Bruin et al. 2010; Koenig et al. 2008; Reynolds et al. 2008; Wang et al. 2010; Williams et al. 2006) or a trend toward improved adherence (Berrien et al. 2004; DiIorio et al. 2008; Holstad et al. 2011; Simoni et al. 2011). An effect on viral outcomes has been demonstrated less frequently (de Bruin et al. 2010; DiIorio et al. 2008; Reynolds et al. 2008).

Available evidence suggests that nurse-delivered adherence interventions with even modest effectiveness are likely to provide long-term survival benefit to patients and to be cost-effective. Using data from a randomized controlled clinical trial as input to a computer-based simulation model of HIV disease, the cost-effectiveness of a nursing intervention on antiretroviral adherence was examined by Freedberg and colleagues (Freedberg et al. 2006). Implementing the nursing intervention in addition to standard care yielded a 63% increase in virological suppression at 48 weeks. This produced an increase in expected survival (from 94.5 to 100.9 quality-adjusted life months) and estimated discounted direct lifetime medical costs (\$253,800–\$261,300). The incremental cost-effectiveness ratio for the intervention was \$14,100 per quality-adjusted life year gained compared with standard care.

The relative efficacy of the different nurse-delivered strategies has not been examined. Further, the mechanisms by which the interventions promote adherence are not clear. While delivery

Nurse-Delivered Interventions for Adherence, Table 1 Summary of nurse-delivered antiretroviral adherence interventions

Author (Year) Country	Study population	Mode of delivery	Guiding theory/ mechanism of change	Outcomes	Main findings
Berrien et al. (2004) US	HIV+ children (N = 37) N = 20 intervention N = 17 control	Home visits; individual; 8 structured psycho- educational sessions by registered nurses over 3 months	Health belief model; designed to improve knowledge and identify and resolve barriers to adherence	Adherence – self- report Adherence – pharmacy refill CD4 T-cell count Viral load	Trend (NS) toward better adherence; no difference biologic outcomes
De Bruin et al. (2010) Netherlands	HIV+ adult (N = 133) N = 66 intervention N = 67 control	Clinic based; individual; 2 tailored, psycho- educational and EDM-feedback sessions by clinic nurses	Theory of planned behavior and self- regulation theories; designed to increase knowledge and promote motivation	Adherence – EDM Viral load	Significantly better adherence and viral load
DiIorio et al. (2008) U.S.	HIV+ adults (N = 213) N = 107 intervention N = 106 control	Clinic based; individual; 5 counseling sessions by registered nurses over 3 months	Motivational interviewing; designed to build confidence, reduce ambivalence, and increase motivation	Adherence – EDM CD4 T-cell count Viral load	Trend toward better adherence and viral load
Holstad et al. (2011) US	HIV+ adult women (N = 207) N = 104 intervention N = 103 control	Clinic based; group; 8 counseling sessions led by nurse	Motivational interviewing; designed to empower women in decision- making, use strategies to improve adherence/ risk taking behaviors, reduce resistance/ ambivalence	Adherence – EDM CD4 T-cell count Viral load	Trend (NS) toward better adherence and viral load
Holzemer et al. (2006) US	HIV+ adults (N = 243) N = 118 intervention N = 122 control	Clinic based with phone calls; individual; 3 tailored, nurse- delivered psychoeducational counseling sessions and up to 3 booster phone sessions	Ickovics and Meisler adherence framework, nursing process, tailored health communication; designed to assess areas of adherence risk and target with nursing interventions	Adherence – self- report Adherence – pharmacy refill Adherence – pill count Adherence – EDM	No significant difference in adherence
Koenig et al. (2008) US	HIV+ adults (N = 266) N = 116 intervention N = 120 control	Clinic based with phone calls and support partner; individual and group; 5 nurse-delivered psycho-educational individual sessions over 5 months and 1 booster session at 6 months/5 phone calls/2 group educational sessions/ support partner	Problem-solving theory, five-stage model of problem solving, self- determination theory, social support theory; designed to be tailored, multi-level, multifaceted approach targeting individual and socio-contextual barriers to adherence and enhance social support	Adherence – EDM Viral load	Significantly better adherence. Viral load outcomes inconclusive

by nurses appears feasible generally, this research does not demonstrate whether delivery by the nurses contributes uniquely to the efficacy of the intervention. Nurse communication, nurse-patient relationship, and patient responses have not been explicitly examined as potential active ingredients over and above the a priori hypothesized mechanisms of action.

Nurse-Managed Care and Adherence Outcomes

In other research, the quality of nurse-managed HIV care has been compared to physician-delivered care. Adherence and viral load outcomes are among outcomes that have been examined as quality indicators in these studies.

Global efforts to improve HIV care through prevention and decentralized treatment have led to implementation of models of care that rely heavily on nurses with specialized training. The impetus to use nursing personnel with specialized training in extended roles has developed, in a large part, because several assessments have shown only limited capacity to scale up physician-oriented HIV service models, particularly in settings with low ratios of physicians to population and high rates of attrition among medical staff. The World Health Organization has estimated that there are 57 countries facing critical shortages of health workers. Over half of them are in Africa.

In an effort to reduce dependence on highly trained physicians, many countries now use nurses to undertake a wide range of interventions in community-based primary care settings, including central roles in HIV prevention and treatment. For example, in ART center settings in countries such as Lesotho, Malawi, Kenya, and Rwanda, nurses are routinely trained to provide services that were previously delivered by doctors, such as diagnosis and treatment of opportunistic infections, clinical monitoring, responding to new signs and symptoms, and, in some circumstances, initiating first-line ART regimens in patients who do not have complicating conditions. In such models of care, nurses generally perform tasks customarily provided by physicians per standardized protocols under district medical officers' supervision. They refer patients to medical clinicians when treatment does not seem to control the disease, if the patient experiences severe medication toxicity, or to manage complex and serious conditions.

Use of nursing personnel with specialized training in extended roles is also a reflection of their ability to perform in the roles effectively. The educational preparation of nurses emphasizes autonomous and collaborative care of individuals of all ages, families, groups and communities, sick or well, and in all settings. Nursing includes the promotion of health, prevention of illness, and the care of ill, disabled, and dying people. Advocacy, promotion of a safe environment, research, participation in shaping health policy and in patient and

health systems management, and education are also key nursing roles that equip nurses to be ideal vehicles for medication adherence interventions. Nurses are also educated to provide palliative care, manage clinics, and supervise staff and outreach workers.

Nevertheless, the transition to nurses in expanded roles in HIV care has been accompanied by questions about the safety, competence, and effectiveness of nurses in comparison with physicians. A number of studies have thus been conducted to address this concern. Findings from this body of work provide a substantial, unfailingly positive, evidence base that clearly demonstrates the effectiveness of nurses in these roles.

For example, Humphreys et al. examined the effectiveness of nurse-led care in comparison with usual hospital care in a typical rural sub-Saharan African setting (Humphreys et al. 2010). Clinically stable adults with a CD4 count of less than 100 cells/ μ L and on antiretroviral treatment for at least four weeks at the district hospital were assigned to either nurse-led primary care-based antiretroviral treatment care or usual hospital care. Findings showed that those receiving primary care based on nurse-led care treatment were less likely to miss an appointment compared with those continuing to receive hospital care (RR 0.37, $p < 0.0001$), were more likely to be satisfied in the ability of staff to manage their condition (RR 1.23, $p = 0.003$), and average travel cost was half that of those receiving hospital care ($p = 0.001$). Further, there was no significant difference in loss to follow up and health-related outcomes were equivalent. The authors observed that the patients who received services in the nurse-led primary care setting were more satisfied in the ability of staff to manage their condition in the local clinic setting than the hospital setting in spite of the lack of diagnostics, such as radiology, or medical opinion available on demand. Reasons for satisfaction with the nurse-led clinic included reduced cost, being nearer to home, a shorter queue, being treated better by staff, receiving better care, and "not be talked about at the clinic."

Likewise, in a randomized, non-inferiority trial (Sanne et al. 2010), the health outcomes of nurse-managed ART were compared with physician-

managed ART (Sanne et al. 2010). No significant differences were found. HIV-positive individuals with a CD4 cell count of less than 350 cells/ μ L or WHO stage 3 or 4 disease were randomly assigned to nurse-monitored ART care (N = 404) or doctor-monitored ART care (N = 408) and followed for a median follow-up of 120 weeks (IQR 60–144). Among the patients that reached an endpoint of treatment failure (N = 371), 192 (48%) were in the nurse group and 179 (44%) in the doctor group (hazard ratio 1.09, 95% CI 0.89–1.33). Deaths (10 vs 11), virological failures (44 vs 39), toxicity failures (68 vs 66), and program losses were also similar in nurse and doctor groups (70 vs 63), respectively.

Findings from an observational cohort study (Cohen et al. 2009) conducted in rural Lesotho lend additional support for community-based, nurse-driven ART management for adults and children. Despite a lack of resources for health, Lesotho implemented state-of-the-art antiretroviral treatment guidelines and nurse-initiated and managed HIV care (including ART management) at the primary health-care level. The study found that between 2006 and 2008, the annual enrollment more than doubled for adults and children, with no major external increase in human resources. The proportion of adults arriving sick (CD4 < 50 cells/mm³) decreased from 22.2% in 2006 to 11.9% in 2008, and at 12 months, 80% of adults and 89% of children were alive and in care (loss to follow up, 8.8%), and at 24 months, 77% of adults remained in care.

Consistent with findings from these individual studies, a meta-analysis comparing nurse-initiated and managed ART to physician-initiated and managed ART (Emdin et al. 2013) also found that adherence, viral failure, and mortality outcomes were similar between nurses and physicians.

Conclusions

Nurses offer a valuable, but often underutilized, resource for providing care to support adherence to antiretroviral therapy and strengthen HIV prevention and treatment delivery. Nurses have educational preparation that provides them with a

range of health-care competencies (e.g., therapeutic communication skills, knowledge about psychosocial and pathophysiologic aspects of illness) to deliver comprehensive, theory-based adherence intervention approaches with fidelity. Further, their presence in most health-care settings is an advantage. The available body of evidence shows that safe and effective management of HIV can be provided at the primary care level by nurses in expanded roles. Taken together, the evaluations of nurses in adherence counseling and expanded HIV patient care roles demonstrates that the use of nurses in expanded HIV patient care roles is feasible and well accepted by patients; nurses can provide a range of services safely and effectively (e.g., initiating and managing ART to adults and children, patient education, and adherence counseling); outcomes (e.g., adherence, treatment failure, mortality, toxicity, loss to follow up, patient satisfaction) of nurse-led management of uncomplicated HIV adults and children are as good as doctors and sometimes better. While nurse-delivered adherence interventions have demonstrated efficacy, the relative efficacy of the different nurse-delivered strategies has not been examined, and the mechanisms by which the interventions promote adherence are not clear.

Definition

HIV-1 displays a high genetic diversity that can be classified into clades, called subtypes. HIV-1 subtypes represent separate epidemics with independent evolutionary histories that occasionally overlap to generate recombinant forms. The stratification of HIV-1 strains into subtypes and circulating recombinant forms (CRFs) is useful to study the impact of HIV-1 genetic diversity on pathogenesis, disease progression, treatment including resistance development, molecular epidemiology, and vaccine design. Furthermore, such a classification provides a way to monitor

the evolution of different subtype epidemics, its geographic distribution, and its spread across countries, continents, and risk groups.

HIV Genetic Diversity

HIV accumulates mutations at an alarming rate, mainly due to its error-prone replication cycle, vast virus burden, and high recombination rate. This fast evolution allows the virus to adapt quickly upon attack by the immune system and to resist drug treatment and, thus far, prevents successful vaccine development. However, such a fast evolution greatly facilitates understanding the details about how HIV spreads, providing a window on potential means to better contain the pandemic. No two infected individuals have the same virus, and divergence has accumulated to such an extent that the pandemic HIV-1 group M can be subdivided in different lineages, called subtypes. Each of these subtypes has their own history and epidemic peculiarities, and the accumulating divergence within each subtype allows a fine-grained tracking of the movement of the virus.

Origin and Dissemination of HIV Types and Groups

Immediately after the discovery of the etiological agents of AIDS, HIV, it was clear that there were two forms of AIDS, one associated with a relatively fast progression caused by HIV-1 and the

other associated with a much slower progression caused by HIV-2. The genetic divergence between these two AIDS-causing viruses was so huge, and their geographic and risk group association so different, that it soon became clear that these were two different epidemics. Later, after the discovery of the different simian origins of HIV-1 (acquired from chimpanzees and/or gorillas) and HIV-2 (acquired from sooty mangabeys), different groups within each type were further identified, each resulting from a separate zoonotic transmission event. Thus, the large genetic diversity within AIDS-causing viruses is in a large part inherited from its distinct zoonotic origins.

Four different groups have currently been identified within HIV-1 (M, N, O, and P), originating from separate transmission events from chimpanzees and/or gorillas. The close relatedness of groups M and N to SIVcpz from *Pan troglodytes troglodytes* (a subspecies of chimpanzees from Central Africa) indicates that this is the subspecies from which humans have acquired these viruses. The fact that phylogenetic HIV-1 groups M and N cluster separately among SIVcpz strains attests that they arose from two separate zoonotic transmissions from this central subspecies of chimpanzee. The origin of group O is however more dubious. HIV-1 group O-like infections found in wild gorillas (SIVgor) suggest that this clade may have been originated from gorillas (Peeters and Delaporte 2012). The fourth group P is even more closely related to SIVgor, making the case stronger that humans can get infected from gorillas. These gorilla strains are however nested inside an SIVcpz clade, suggesting that most probably gorillas got their infection also from chimpanzees. Where and how some of these zoonotic events turned into human epidemics is expanded elsewhere (Sharp and Hahn 2011).

The current pandemic is almost entirely linked to HIV-1 group M. The ancestral SIVcpzPtt strain that crossed the chimpanzee-human barrier and gave rise to HIV-1 group M belonged to a viral lineage that still persists today in *Pan troglodytes troglodytes* living in southeastern Cameroon. Hunting and butchering chimpanzees for the “bushmeat” market are

currently considered the most probable and parsimonious explanation for the zoonotic transmission of SIVcpz to humans. From southeastern Cameroon, HIV-1 appears to have made its way via the Sangha River (or other tributaries) south to the Congo River and on to Kinshasa where the group M pandemic was probably spawned (Sharp and Hahn 2011).

HIV-1 group N (non-M, non-O) was first identified in 1998 in a Cameroonian woman. Until 2011, only 12 cases of group N infections had been identified exclusively in patients living in Cameroon. However, in that year, a new case of a patient probably infected in Togo was identified in Paris indicating a possible dissemination across borders. Even though group N is also associated with AIDS, if it were not for the HIV-1 group M pandemic, this group N might never have been discovered. HIV-1 group O, on the other hand, causes thousands of infections and AIDS cases in West-Central Africa, especially in Cameroon, and its epidemic spread, including to a limited extent to Europe, is of concern. Group P has only been identified in two humans originating from Cameroon, suggesting that its dissemination in humans is rare and not of epidemic potential (Mourez et al. 2013).

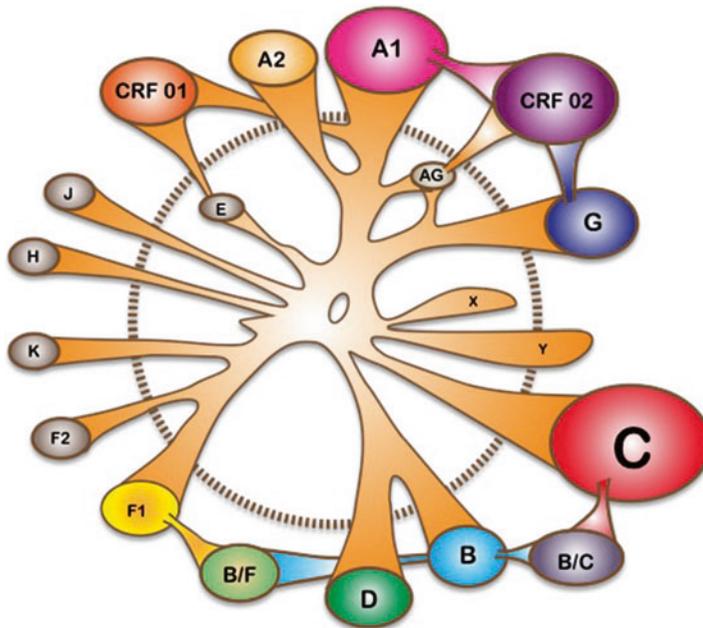

The timing of the origin of different HIV types and groups is still a matter of discussion but different studies and methods have generated a rough time frame. These estimates are based on phylogenetic molecular clock calculations, extrapolating back in time beyond the earliest documented strain. Overall, group N seems to be the youngest clade, having crossed to humans around the 1960s. Going further back in time, the two major HIV-2 clades, HIV-2A and HIV-2B, both arose a few decades earlier around the 1930s/1940s. Perhaps a decade earlier, HIV-1 group O arose around the 1920s (Mourez et al. 2013). The common ancestor of HIV-1 group M has been traced back to the beginning of the twentieth century (Faria et al. 2014). If both HIV-1 group P strains are descendent from the same interspecies transmission, then this is the oldest clade surviving today, with an estimated date of origin of its tMRCA to have occurred in the second half of the nineteenth century (Mourez et al. 2013).

The AIDS Pandemic and HIV-1 Group M

The AIDS pandemic, with an estimated number of 60 million cumulative infections, is caused almost exclusively by HIV-1 group M. The enigma why so many decades passed between the cross-species transmission from simians to humans and the discovery of AIDS has still not been resolved satisfactorily, and only now the factors involved in the early establishment and spread of the HIV-1 pandemic are being uncovered (Sharp and Hahn 2011; Pepin 2011). The earliest serologically and genetically confirmed HIV-1 group M infection has been found in an archival sample from 1959 belonging to an adult Bantu male, with a sickle-cell trait and a glucose-6-phosphate-dehydrogenase deficiency, living in Leopoldville, Belgian Congo (now Kinshasa, Democratic Republic of Congo, DRC). In addition, molecular epidemiological studies have indicated that all of the known HIV-1 group M subtypes, as well as

additional lineages that have remained restricted to this area, circulated in Kinshasa in the mid-1980s. Together, these findings have been taken as evidence that most of the early diversification of HIV-1 group M occurred in and around Kinshasa, making Kinshasa the most probable location of the early HIV-1 group M epidemic.

From the Congo Basin, the virus spread successfully around the world, accumulating significant genetic variability. Nine different, so-called pure lineages have formed, representing the subtypes (A, B, C, D, F, G, H, J, and K). Their variability and relationship can conveniently be illustrated by a phylogenetic tree (Fig. 1). Such a phylogenetic analysis reveals three levels of classification, based on the clustering and distances in the phylogenetic tree and on the recombination patterns: *subtypes*, *sub-subtypes*, and *circulating recombinant forms (CRFs)* (Robertson et al. 2000).

Origin and Distribution of HIV-1 Subtypes, Fig. 1 Phylogenetic origins of HIV-1 group M subtypes and circulating recombinant forms (CRFs). The *dashed circle* differentiates old and contemporary sequences. Inside the *circle*, the old sequences, such as the subtype E clade, may no longer exist in the current epidemic. The ancient presence of subtype E based on CRF01_AE is inferred, a recombinant between subtypes

A and E. “X” represents a hypothetical extinct strain, and “Y” represents a hypothetical old strain that is still circulating in the current epidemic but has not been identified. CRF02 is an old recombinant derived from both old and contemporary subtypes A and G. BF recombinants in South America and BC in China are new, as their parents are contemporary sequences (Adapted from Zhang et al. 2010)

Subtypes refer to the major clades, which supposedly have evolved independently from each other. These form distinct clusters with inter-subtype genetic distances ranging from 25% in *env* (Robertson and et al. 1999) to between 5% and 30% (nucleotide divergence), depending on the genes compared. Continuing evolution has as consequence that diversity keeps increasing over time and slightly differently so for the different subtypes as their evolutionary rates are different.

Sub-subtypes refer to distinct lineages that are very closely related to each other. Subtype A is divided in at least two distinct sub-subtypes (A1 and A2) and subtype F has two sub-subtypes (F1 and F2). From the point of view of genetic distance, subtypes B and D could be considered sub-subtypes rather than different subtypes; however, epidemiological argumentation as detailed below has maintained their status as different subtypes until now.

CRFs represent inter-subtype recombinant lineages that play an important role in the pandemic. Inter-subtype recombinants can form when two epidemics that initially evolved separately meet each other again. When a single individual becomes infected with two viruses from the two epidemics, some cells will be dually infected and spawn inter-subtype recombinants in the next replication round. When such inter-subtype recombinants perpetuate in the epidemic, many strains share an identical mosaic structure; since they are descended from the same recombination event(s), they achieve the CRF status, whereas many others will just disappear and represent unique recombinant forms or URFs. Currently, there are 55 different CRFs described in the Los Alamos database (<http://www.hiv.lanl.gov/content/sequence/HIV/CRFs/CRFs.html>), although most of them have not really taken epidemic proportions. Together, all CRFs account for approximately 20% of all HIV-1 infections. However, CRF01_AE and CRF02_AG are the most important for the world pandemic, causing a significant number of infections in Asia and West Africa, respectively. For this reason, a separate section will be included for these two CRFs.

Clinical and Epidemiological Importance of Subtyping

HIV-1 subtypes have been shown to be highly compartmentalized between risk groups and geographic regions. A study in patients newly diagnosed in Europe between 2002 and 2005 showed a stratification of HIV-1 subtypes according to gender, risk group, and patients' country of origin: subtype B is more prevalent in men who have sex with men (MSM), while most other subtypes are more prevalent in heterosexuals. The fact that HIV-1 subtypes have a different prevalence in different risk groups could suggest that they diverged because of differences in transmission potentials depending on the mode of transmission in risk groups involved. For example, subtype B may have adapted to anal sex practiced by MSM, while other subtypes may be more easily transmissible by vaginal sex in heterosexuals. Subtype C seems particularly adapted to heterosexual transmission. Alternatively, the different prevalence in the different risk groups could simply be a stochastic event, a founder effect and lack of mixing of the different risk groups. Until now, no study has refuted any of these hypotheses and it may be that both are valid.

Some evidence might point toward adaptation to risk groups. For example, the evolutionary rate differs between HIV-1 subtypes. CRF02_AG and subtype G were found to have higher rates, while subtype D had lower rates than the other subtypes. In addition, evolutionary rate is linked to the speed of transmission of the epidemic, i.e., when HIV-1 infections are transmitted faster, HIV-1 evolves slower and vice versa. The speed of transmission is in turn linked to the risk group, for example, HIV spreads much faster by needle sharing than by sexual contact. The differences in evolutionary rate between subtypes were not only at nucleotide but also at amino acid level, varying in roughly similar ways. This could be attributed to both differences in selective pressures (amino acid level) potentially associated with a particular mode of transmission and risk behavior, but also to differences in replication dynamics (nucleotide level) (i.e., mutation rate or generation time) of the strains potentially associated with speed of transmission.

The evidence supporting the founder effect is much stronger and an entire next section below is dedicated to these founder effects. Therefore, although the strongest contributing factor may be founder effects, the jury is still out on whether the mode of transmission has also shaped the genetic divergence among subtypes. Perhaps distinct founder effects were at the origin of the different HIV subtypes, and these genetic clades might have later adapted to the way they were transmitted in the infected population where they were first introduced.

HIV-1 Subtypes and Disease Progression

Several studies in Uganda, Kenya, and Tanzania have compared the disease progression of HIV-1 subtypes A and D, the most prevalent subtypes in that region. The prevalence of other subtypes included in such cohorts is small making it difficult to draw conclusions about the disease progression of other subtypes. All studies agree that people infected with subtype D have a higher risk of progressing to AIDS and to death than people infected with subtype A. One study also found that infection with subtype D, with multiple subtypes (probably subtypes A and D, given the geographic range of the study), and with A/D recombinant viruses resulted in significantly faster progression to AIDS and to death than did infection with subtype A only. Studies also agree that the observed differences in rates of disease progression are most likely explained by differences in coreceptor tropism: in the course of HIV-1 infection, the emergence of CXCR4 (X4) tropic viruses is associated with a more rapid decrease in the CD4⁺ cell count, and subtype D has been shown to have a higher frequency of syncytium formation and X4 tropism compared with subtype A. Another study indicated that Africans infected with subtypes C, CRF02_AG, A, and G had slower disease progression before commencing treatment than Haitians and Canadians infected with subtype B.

Response and Resistance to Antiretroviral Drugs

In terms of response to antiretroviral therapy, one large study indicated that current combination

therapies are very effective regardless of the infecting subtype. The recovery of the immune system and the hazard of therapy failure were similar across subtypes. Despite the many nucleotide and amino acid differences, most resistance mutations are similar across subtypes. However, several differences have been noted in the mutational pathways to resistance development. These differences could be explained through a combination of several factors (Camacho and Vandamme 2007).

Inter-subtype amino acid differences are involved in minor structural changes in the targets of therapy. The presence of such polymorphisms can influence the emergence of drug resistance mutations. Different mutations can emerge under the same drug pressure. Sometimes, different mutations arise in different subtypes. Different and mutually exclusive pathways to the development of resistance to the protease inhibitor nelfinavir occur in subtypes B and G or C. While subtype B preferentially develops the mutation D30N, subtype G strains exclusively and C strains preferentially develop the mutation L90M.

On the other hand, inter-subtype differences in codon usage result in differences in nucleotide and mutational motifs that may affect the genetic barrier to resistance. The number of mutations or whether transitions or transversions are needed to develop resistance to antiretroviral drugs all contribute to the genetic barrier for resistance development. An example is the development of the resistance mutation V106M in the reverse transcriptase of subtype C strains due to the usage of codon GTG (the mutation is GTG to ATG) as opposed to other subtypes that more frequently use the GTA codon and therefore evolve more easily to the V106A mutation (the mutation is GTA to GCA). Other such positions include protease codon 82 where subtypes C and G have an increased genetic barrier to the development of the resistance mutation V82A when compared to subtype B and protease codon 89 where the subtype B wild-type 89L develops few mutations, while subtypes C, F, and G use wild-type 89M and frequently develop 89I/V mutations (Santoro and Perno 2013).

Another result from such differences in mutational motifs is the type of mistakes made by replication enzymes. Some common mistakes by the viral reverse transcriptase favor the development of particular drug resistance mutations. For example, the K65R mutation that confers resistance to tenofovir is more frequent in subtype C than in subtype B, and D67N, contributing to the resistance to several nucleoside reverse transcriptase inhibitors, occurs more often in subtype B than in subtype C. This seems to be due to the nature of the subtype C RNA template. Differences in nucleotide sequence in this region cause a difference in RT pausing which in turn results in different errors made (Santoro and Perno 2013).

Most of these differences can be related to genetic differences between subtypes. However, genetic differences also exist within a subtype where slighter differences in evolutionary pathways to develop drug resistance seem to occur.

Vaccine Development

Several factors pose important obstacles in the development of an effective preventive HIV-1 vaccine, most notably the high degree of antigenic and genetic viral diversity and the capacity to quickly develop mutations that allow HIV-1 to escape neutralization by antibodies. In fact, a successful vaccine against HIV-1 needs to target a quasispecies of viruses and antigens that are constantly changing and not a single or a small number of viral proteins. In addition, an effective vaccine will need to target all circulating subtypes and recombinant forms simultaneously.

Currently, it is thought that a successful HIV-1 vaccine will need to elicit both humoral immune responses (Env-specific neutralizing antibodies) to block HIV-1 acquisition and cellular immune responses through Gag-specific CD8 T cells to control viral replication for breakthrough HIV-1 infections. However, it is not clear which antigens should be used to deal with HIV-1 sequence diversity. Major strategies have been proposed that include the design of (1) vaccines specific for each geographic region that include antigens matching local circulating strains and (2) a single vaccine broadly neutralizing all subtypes that could either target highly conserved epitopes

shared by all subtypes or elicit highly diverse HIV-1-specific responses (Stephenson and Barouch 2013).

Independently of the strategy followed, vaccine trials have shown very discouraging results. Some optimism returned with the RV144 trial that used a vaccine candidate based on a recombinant viral vector boosted with a protein-based vaccine VaxGen gp120 including subtype B and CRF01_AE immunogens. In this trial, a significant but modest and transient 31% reduction in HIV-1 acquisition was observed. However, the latest large-scale clinical study HVTN505, which tested a multiclade HIV-1 DNA plasmid (EnvA, EnvB, EnvC, gagB, polB, nefB) boosted by a recombinant adenovirus vector (Ad5 EnvA, EnvB, EnvC, gag/polB), was interrupted because the vaccine regimen did not prevent HIV infection nor reduce viral load (the amount of HIV in the blood) among vaccine recipients who became infected with HIV (Kwong et al. 2012) (<http://www.niaid.nih.gov/news/newsreleases/2013/Pages/HVTN505April2013.aspx>).

Recent studies on neutralizing antibodies are again encouraging. Broadly neutralizing antibodies have been found in the sera of some HIV-1-infected individuals. Monoclonal antibodies generated with peripheral blood B cells from donors with potent serum neutralizing antibodies were found to broadly neutralize currently circulating HIV-1 isolates. These antibodies are being used to design an effective vaccine eliciting protection against most HIV-1 variants. Vaccine efforts are now directed more at developing therapeutic than preventive vaccines, although not all hope for a protective vaccine has been lost yet (Klein et al. 2013).

Vaccine efforts used to be the major driving force behind subtyping efforts, while nowadays most subtyping is done in the context of drug resistance testing and epidemiological monitoring.

The Origin of HIV-1 Group M Subtypes

It might not seem logical to call the firstly discovered HIV-1 clade subtype B, while subtype A was only discovered in 1990. However, at that time the term subtype was not yet in use. Gerald Myers and

collaborators at the Los Alamos database (currently <http://www.hiv.lanl.gov/>) were the first to group the growing divergence of HIV-1 into subtypes, and they happened to have started the nomenclature following the appearance of the five main clades of that time in a phylogenetic tree, subtypes A through E (Myers et al. 1992). Subsequently, newly discovered subtypes had consecutive letter codes, while subtypes E and I were later renamed when they were identified as CRFs.

It is currently commonly agreed that subtype clusters are in a large part the result of a combination of incomplete sampling and founder effects. Incomplete sampling because samples from West and Central Africa have been collected that fall between subtypes and bridge the divergence between clusters (Rambaut et al. 2004). Founder effects because of different studies on the origin of the most important HIV-1 subtypes, B and C, indicate that the burst of those subtype epidemics occurred after migration out of the Congo Basin.

Postcolonial circumstances were responsible for the migration of at least one subtype D strain out of the Congo Basin into Haiti, where it diverged into an early subtype B clade around 1962–1970, before a single branch dispersed to the USA around 1966–1972 and from there globally. One study also showed that the spread of this epidemic was driven essentially by bottlenecks, chance events, and ecological interactions, rather than driven by evolutionary changes associated with selection (Rambaut et al. 2004). Historical information supports that hundreds of Haitian teachers and doctors were actively recruited after the independence of the DRC in July 1960 to fill in the gaps left by the previous Belgian rulers. Whereas at that time the virus might have been mainly spreading in heterosexuals, the only successful (from the point of view of the virus) link between Haiti and the USA was gay sex tourism (Vangroenweghe 1997), which seems to have ignited the “gay” AIDS disease that was discovered in the early 1980s in the USA (Centers for Disease Control (CDC) 1981). In most countries worldwide, HIV-1 subtype B still predominantly infects MSM.

According to recent data, subtype C originated around the 1950s in the southern DRC and subsequently dispersed south and east along the

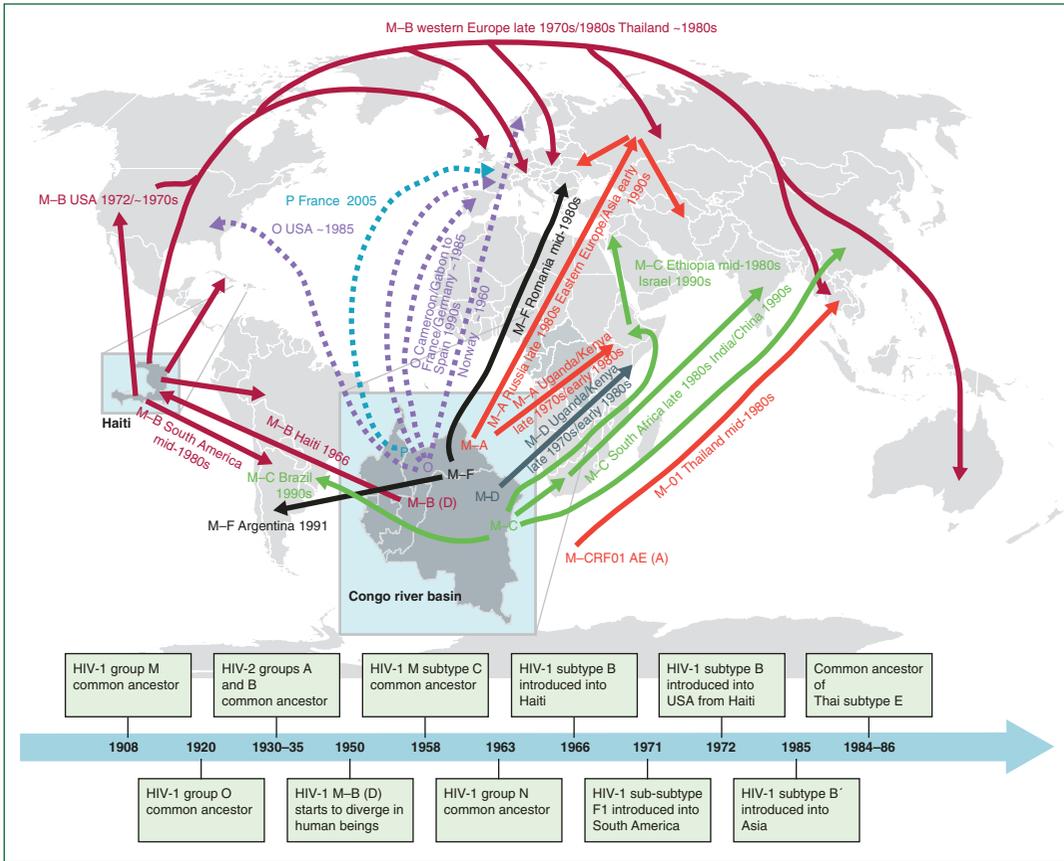

Copperbelt corridor (Faria et al. 2014). Phylogenetic analysis indicated that for several of the well-supported African subtype C clusters, there is a match with specific geographic regions and thus they presumably resulted from additional founder events. Also for other subtypes, further founder effects gave rise to well-supported clades linked to specific geographic regions or risk groups.

Geographic Distribution of Different Subtypes

Subtype A

Subtype A is divided in two sub-subtypes. Sub-subtype A1 originated around the 1950s with a local epidemic in West-Central Africa, followed by an exponential growth phase around the 1970s and a leveling off period during the mid-1980s/early 1990s. It has spread worldwide, causing a significant burden in Africa, Europe, and Asia (Hemelaar et al. 2011). It is currently thought that sub-subtype A1 was exported from the Congo Basin to Uganda and Kenya around the 1980s, to Russia in the late 1980s, and from there to Eastern Europe and Asia in the early 1990s (Tebit and Arts 2011) (Fig. 2). Sub-subtype A2, on the other hand, is limited to West and Central Africa.

In the 2004–2007 period (Hemelaar et al. 2011) (Fig. 3), HIV-1 sub-subtype A1 caused 12% of all HIV-1 infections worldwide, with its highest proportion among HIV-1 infected in Eastern Europe and Central Asia (up to 80%) and in East Africa (up to 50%). It can be found however throughout the entire Africa. In a cohort of newly diagnosed patients from Western Europe, sub-subtype A1 was found to cause 6.9% of infections in patients newly diagnosed between 2002 and 2005. In West and East Africa, subtype A infections are linked to heterosexual transmission. On the other hand, in Eastern Europe and Central Asia, injecting drug use is the main route of transmission for subtype A. As a consequence of the co-circulation of subtypes A1 and B in Eastern Europe and Central Asia, a recombinant form of these subtypes (CRF03_AB) circulates in injecting drug users in this geographic region (Bobkov et al. 2004).

Origin and Distribution of HIV-1 Subtypes, Fig. 2 Global spread of HIV outside its heartlands. In the upper part, arrows denote the pathways, along with estimated dates of introduction, of HIV-1 groups M, N, O, and P subtypes and circulating recombinant forms (CRFs) from the Congo River Basin to elsewhere. In the lower

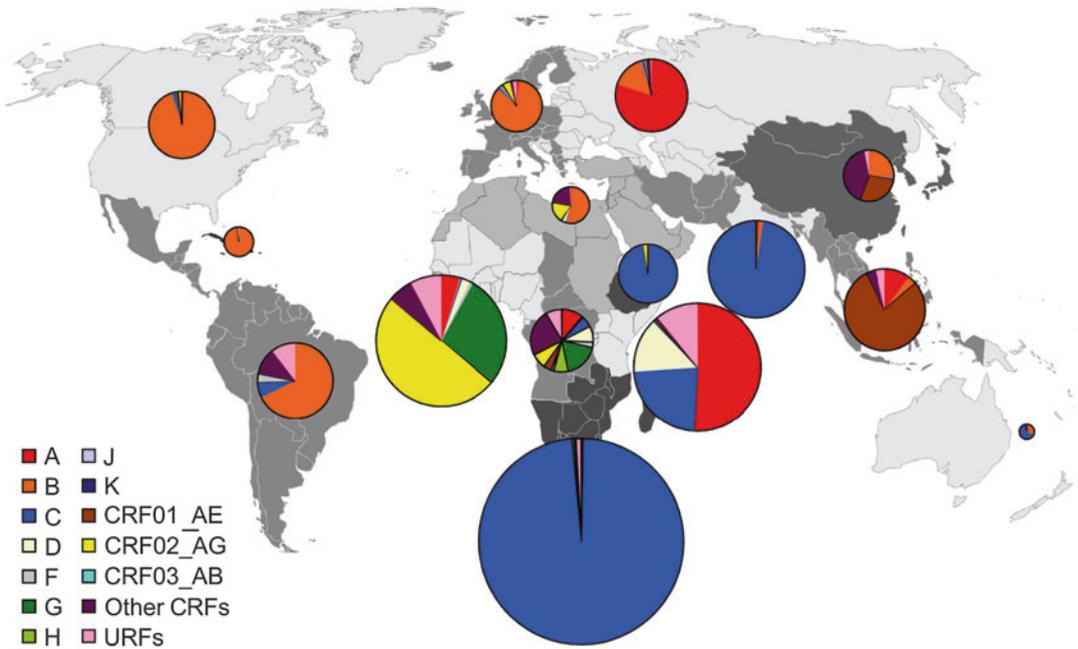

part, a time line of the estimated common ancestors of HIV-1 and HIV-2 groups, together with estimated introductions that subsequently led to some of the main circulating subtypes, is shown (Adapted and reproduced with permission from Tebit and Arts 2011)

Sub-subtype A1 infections have recently spilled over to the MSM risk group, and this is taking epidemic proportions in Greece.

Subtype B

Subtype B was the first variant of HIV-1 that was identified. It was initially found in homosexual men in San Francisco and New York and soon after in MSM and intravenous drug users (IVDUs) in Europe (Centers for Disease Control (CDC) 1981). As described above, it is now known to be an expansion of a subtype D strain that was exported from Africa to Haiti and from there to the USA in the 1970s (Fig. 2). From the USA, subtype B was exported to Western Europe and

Thailand in the 1970s/1980s and to South America somewhere in the mid-1970s. The subtype B strain that circulates in Asia has been named “B” because of its clear distinction from the “American” subtype B, another example of a founder effect followed by geographic separation. Although subtypes other than B were unknown for some time after the discovery of HIV-1 and despite the fact that it was virtually the only subtype circulating in developed countries for some years, this subtype causes only 11% of infections worldwide (Hemelaar et al. 2011). Subtype B is the main genetic form in North America (95% of all infections) and the Caribbean (98%), Western and Central Europe (85%), Latin America (68%),

Origin and Distribution of HIV-1 Subtypes, Fig. 3 Distribution of HIV-1 subtypes and recombinant forms per global region (2004–2007). Countries belonging to the same region are shaded identically. Pie charts represent the proportion of infections caused by

subtypes, circulating recombinant forms (CRF), and unique recombinant forms (URFs), as indicated in the legend on the left, during 2004–2007 in each geographic region (Reproduced with permission from Hemelaar et al. 2011)

and Middle East and North Africa (54%) (Fig. 3). In these geographic regions, this subtype infects all risk groups, with a predominance for MSMs and IDUs. It is also common in several countries of Eastern Europe and Central Asia (15%) and East Asia (26%), where it infects mostly IDUs. Finally, it causes 31% of HIV-1 infections in Oceania.

Subtype C

HIV-1 subtype C was first noticed in East Africa; however, recent findings show that subtype C arose from a founder effect from the Congo Basin into the Copperbelt of Southern and Eastern Africa (Faria et al. 2014). The subtype C epidemic then invaded Ethiopia, and from there it spread to Israel along with the return of “the lost tribe,” and that is the reason why Israel has two HIV-1 epidemics of almost equal proportion, one of subtype B mainly in Caucasians and one of subtype C mainly in black Africans. The virus also spread

from Eastern Africa to Brazil (possibly through the UK) and then to Argentina and Uruguay (Fig. 3). The epidemic has also spread to South and Central China, India, and Brazil. There is significant evidence of overall geographic clustering but no evidence of geographic clustering within South Africa. Significant clusters from a single geographic region are from Ethiopia, South America, India, and Botswana.

Subtype C is the most prevalent subtype worldwide. It causes 48% of all HIV-1 infections. This high prevalence is caused by its predominance in countries where the prevalence of HIV-1 is extremely high, such as Southern Africa, India and Ethiopia, where it causes over 95% of all local infections. It is transmitted almost exclusively by heterosexual transmission. It is also increasingly prevalent among heterosexuals in other world regions, such as Western Europe, Oceania, and Latin America. Subtype C recently entered the MSM population in the UK.

Subtype D

HIV-1 subtype D is only a minor player in the pandemic, even though it was at the origin of subtype B. This may be related to its higher malignancy compared to other subtypes, giving its host fewer opportunities to spread the virus. Between 2004 and 2007 (Hemelaar et al. 2011), subtype D accounted for only 2% of worldwide infections. These infections were spread mainly over East Africa (13.8% of local infections), Central Africa (8.5%), West Africa (1.5%), and Middle East and North Africa (2.2%) (Fig. 3). A higher proportion is found in Sudan and Uganda (up to 50%). In competition with other subtypes, subtype D seems to lose foot, for example, its proportion in Uganda decreased by 8% in 8 years (between 1994 and 2002). Also, in East Africa, a 3% decrease in proportion was observed between 2000 and 2007.

Subtype F

Subtype F causes only 0.45% of all HIV-1 infections, distributed mostly between South America (3.53%), Eastern Europe (1.14%), and Central Africa (2.69%) (Fig. 3). Except for Central Africa, where there was a small increase in the proportion of infections caused by this subtype, in the other geographic regions, its prevalence decreased between 2000 and 2007 (Hemelaar et al. 2011).

Subtype F is divided in two sub-subtypes: F1 and F2. However, only sub-subtype F1 was exported from Africa to other geographic regions. Sub-subtype F2 is restricted to Cameroon, with very few cases outside Africa and some cases found in West and Central Africa (Equatorial Guinea, Gabon, DRC, Central African Republic).

Sub-subtype F1 on the other hand has been widely exported from the Congo Basin to Eastern Europe (around 1985) and to South America and was introduced in Argentina around 1991 and in Brazil in the late 1970s (Bello et al. 2007) (Fig. 2). In Romania, the first HIV-1 cases were reported in 1985 and were followed by a dramatic increase in the number of infections primarily in children. These infections, caused by nosocomial transmission, were largely caused by sub-subtype F1 strains. F1 is still the most prevalent subtype in Romania, although newly diagnosed patients in 2007 were more infected by other subtypes than

by sub-subtype F1. In other Balkan countries, such as Bulgaria, Slovenia, and Hungary, a small proportion of infections are also caused by sub-subtype F1. However, as opposed to what happens in South America and Italy, F1 does not seem to have spawned BF-related CRFs in the Balkan epidemic. In Italy, sub-subtype F1 accounts for 2.7% of local infections and BF recombinants are also described in 1.1% of infections.

From all South American HIV-1 sequences deposited in the Los Alamos database, sub-subtype F1 amounts for 7.4% of strains and BF recombinants account for 16% of all sequences. This bias in the public database is related to intensive HIV and AIDS research in Brazil, where F1 infections and BF recombinants are major players in the epidemic, including in the surrounding countries (Paraguay, Bolivia, Uruguay, Argentina, and Chile). While sub-subtype F1 is contributing at a high proportion to infections in Brazil, this is based on partial genomic fragments, and one study with full genomes found that very few isolates were full-length subtype F: most of them had some B and C fragments and were thus in fact recombinant strains. The reported prevalence of subtypes does indeed depend on the genetic region analyzed, and full genomes are rarely sequenced to verify the claims. The BF recombinant pattern seems to increase the epidemic fitness of the virus, and this may explain its success.

Subtype G

Subtype G accounted for 4.6% of worldwide infections between 2004 and 2007. Subtype G is a typical West and Central African virus where it accounts for 27.6% and 18.2% of infections, respectively (Hemelaar et al. 2011). In Europe, subtype G is found in Western and Central European countries where it causes around 1% of local infections, with the exception of Portugal, where it has spread substantially causing a local epidemic. This epidemic was probably caused by an importation of a strain from West Africa to a network of Portuguese IVDUs that propagated the epidemic in the 1980s/1990s. Nowadays, subtype G circulates also among Portuguese heterosexuals. In 2003 it already accounted for nearly 30% of new infections. CRF14_BG originated

from this epidemic around 1990 and circulates in Portugal and Spain. A similar but much smaller subtype G epidemic among IVDUs has also been identified in Italy and Spain.

Subtype G causes substantial epidemics in many Central and Western African countries: Cape Verde (48% of HIV-1 infections), Nigeria (39%), Republic of Congo (21%), Togo (12%), Gabon (10%), Cameroon (4.5% in blood donors), Cote D'Ivoire (4%), and Chad (4%). Despite its low proportion in Cameroon, genome segments of subtype G are present in 67% of all infections and 80% of infections are due to inter-subtype recombinant strains.

CRF01_AE

CRF01_AE is a recombinant form for which the parental "subtype E" has never been identified. Globally, it causes an estimated proportion of 5% of all infections; however, in Southeast Asia it causes 79% of infections. It is now also spreading in East Asia, with the last estimate being 27.6% (Hemelaar et al. 2011). Phylogenetic studies have shown that CRF01_AE originated in Central Africa in the 1970s and spread to Thailand in the 1980s through heterosexual transmission. It was first identified among female sex workers in Northern Thailand in 1989. Later, it expanded to Southeast and East Asia and to other risk groups. It was introduced in China in the 1990s through multiple strain introductions in different risk groups and geographic regions. In a nationwide survey in 2006, CRF01_AE was found to cause 28% of infections in China. A study based on PRO-RT sequencing in Northern Thailand identified 95% of infections as CRF01_AE. Other studies, also based on PRO-RT sequences, found 98% of CRF01_AE in Vietnam and in Malaysia 57% of infections. However, based on the PRO-RT genomic region, it is not possible to discriminate CRF15_01B from CRF01_AE. In Vietnam, CRF01_AE was found in 96% of patients from Jakarta based on *gag* and *env* sequences.

CRF02_AG

CRF02_AG causes 5.5% of all HIV-1 infections worldwide. These infections occur mainly in West Africa, where it causes 50.1% of infections, and in

Middle East and North Africa with 18.1% of infections (Hemelaar et al. 2011). One study indicated that CRF02_AG diverged in the DRC around 1973, although CRF02_AG infections in this country are rare, and the predominance of this clade in Cameroon is related with at least two chance exportations of the virus from DRC to Cameroon.

Studies have shown a predominance of CRF02_AG in Cameroon (~58%), Cote D'Ivoire (82%), Senegal (64%), Togo (~50%), Burkina Faso (~50%), Benin (39–66%), Equatorial Guinea (54–64%), Gabon (~47%), Gambia (47%), Ghana (66%), Guinea (89%), Mali (~70%), Niger (54%), and Nigeria (~45%). All these studies indicate the importance of CRF02_AG in the HIV-1 epidemic in West and Central Africa.

In Northern Africa, in Libya, despite the lack of molecular epidemiology studies, CRF02_AG sequences were found to be responsible for the outbreak of nosocomial HIV-1 infections that occurred in Libya in 1998. This HIV clade is also present in Algeria, especially in the southern part of the country, probably due to importation events from West African countries.

Out of Africa, CRF02_AG has had an increasing impact in Western and Central Europe, where it caused 4.5% of infections between 2004 and 2007. These infections occurred mostly in the heterosexual risk group and in people originating from Africa. According to a recent survey, the European countries with the highest prevalence of CRF02_AG are Belgium and the Netherlands.

One study in Central Asia indicated 4.7% of HIV-1 infections in Kazakhstan were caused by CRF02_AG and these strains clustered with sequences from Uzbekistan, where 9.2% of infections were caused by this CRF, reflecting its spread in this geographic region.

Also in the Balkans CRF02_AG has been found: one study indicated that it causes 6.8% of infections in heterosexuals and IVDUs from Bulgaria and 9% of infections in heterosexuals from Croatia.

Other Subtypes/CRFs

Subtype H, J, and K infections are mainly restricted to the DRC and other West/Central

African countries (Fig. 3). Yet, as only very few full-genome sequences are available for these subtypes, it is not known if many of the identified sequences are pure subtypes H and J or descendant recombinant sequences. As these subtypes do not cause HIV-1 epidemics in other countries, they cannot be considered taking part in the pandemic. These subtypes are however included in the genomic structure of several recombinant forms, such as CRF04_cpx and CRF06_cpx.

Importantly, the global proportion of all CRFs combined increased by 4.5% between 2000–2003 and 2004–2007. Some cause epidemics in a specific geographic region. For example, CRF06_cpx is a complex recombinant that includes genomic segments of subtypes A, G, J, and K. It mainly circulates in Western Africa and is the predominant clade in Burkina Faso where it accounts for 40–50% of HIV-1 infections. This country seems to have been the main hub for the CRF06_cpx dissemination at regional level, continuously exporting the virus to other countries in West and West-Central Africa. Other neighboring countries have a lower proportion: 10–15% in Mali and Niger; 3–8% in Benin, Ghana, Côte d'Ivoire, Nigeria, Senegal, and Togo; and 1% or less in Guinea-Bissau and Guinea-Conakry. CRF06_cpx has been exported to Europe, mainly to Russia, and probably from there it has found its way during the 1990s into the IVDU population in Estonia, where it is now causing a major epidemic.

In South America, several recombinant forms originated from the co-circulation of subtypes B and F. CRF12_BF was first identified in Argentina and Uruguay, and other isolates have been identified in South America, Spain, and Italy. Other BF recombinant forms are currently circulating worldwide, albeit causing epidemics of limited proportions. These include CRF17_BF that has been isolated in Argentina; CRF28_BF, CRF29_BF, CRF39_BF, and CRF40_BF that have been identified in Brazil; CRF38_BF in Uruguay; CRF42_BF in Luxembourg; CRF44_BF and CRF46_BF in Chile; and CRF47_BF in Spain.

More recently, recombinants between subtypes B and C were found to circulate in Brazil. The

analysis of HIV-1 strains from Southern Brazil found that many presented the same genomic structure, with a 240-base pair fragment of subtype B in the middle of the reverse transcriptase pol region. This CRF (CRF31_BC) accounted for 11% of infections in the south of Brazil, indicating an important role in the epidemic.

The co-circulation of CRF01_AE and subtype B in Southeast Asia since the early 1990s already generated several CRFs. CRF15_01B was initially identified in heterosexuals from Thailand, but it was soon found to be circulating also in IVDUs. Its genomic structure includes a subtype B *env* and the rest of the genome is CRF01_AE. CRF33_01B was identified in Malaysia. In this chimera, two short subtype B segments are inserted into the gag-RT region in the backbone of CRF01_AE. By 2006, the proportion of CRF33_01B in Kuala Lumpur was 19.0%. Although its proportion was particularly high among IVDUs (42.0%), it was also detected in a substantial proportion of homo-/bisexual males (18.8%) and heterosexuals (9.8%). CRF34_01B was identified in 2007 in IVDUs from Northern Thailand, CRF48_01B in Malaysian IVDUs, CRF 51_01B in Singapore, CRF52_01B in Thailand and Malaysia, CRF53_01B and CRF54_01B in Malaysia, and CRF55_01B in MSMs from China. In China, also CRF07_BC and CRF08_BC were found to circulate among local IVDUs and are an important part of the local epidemic.

CRF03_AB represents a subtype A/B recombinant that was first found in Kaliningrad and is circulating in Russian and Ukrainian cities, primarily in IVDUs. The circulation of this strain appears to have been accelerated by intravenous injection of a locally produced opiate contaminated with HIV-infected blood.

Finally, different recombinant forms between subtypes B and G have been identified in Portugal and parts of Spain, due to the simultaneous epidemics caused by these two subtypes in these countries. The most important of these is CRF14_BG, first identified by Delgado et al. (2000) in IVDUs from Galicia (a Spanish region bordering Portugal). This CRF circulates widely in these two countries and other

recombinant forms including fragments of CRF14_BG have been identified subsequently. Other BG recombinant forms (CRF20_BG, CRF23_BG, and CRF24_BG) have been identified in Cuba, where subtypes B and G also co-circulate.

Many unique recombinant forms (URFs), recombinants that were not found to infect three epidemiologically unlinked individuals, have also been found in distinct geographic regions.

What Is a “Pure” Lineage and What Is a CRF?

There is some discussion on whether the so-called “pure” lineage classification of subtype G and the CRF classification of CRF02_AG are in fact justified. It is true that both have been discovered around the same time, and originally there was some doubt whether subtype G was indeed a “pure” subtype since it had several regions that were rather closely related to subtype A (Robertson et al. 2000). Later on, an in-depth analysis of the diversity within subtype G and within CRF02_AG suggested that subtype G was in fact the circulating recombinant form (including also fragments that were closest related to subtype J), while CRF02_AG could be considered a divergent lineage within subtype A - (Abecasis et al. 2007). Later this was again refuted (Zhang et al. 2010). Also, the fact that CRF01_AE and other complex CRFs were discovered soon after the initial discovery of HIV, and that sometimes the parent subtypes have actually never been sampled, clouds the early history of subtype origins. Moreover, in the Congo Basin, HIV-1 group M diversity is so large, and many strains do not belong to any pure subtype (some with and some without recombination signal), suggesting that the early history of subtype origins may not properly be represented by separate lineages. In fact, it is possible that HIV-1 group M was diverging and recombining locally in the Congo Basin, and what are known today as pure subtypes did not exist up until the exportation of distinct clades out of their epicenter, possibly Kinshasa, after the 1960s (Kalish et al. 2004; Rambaut et al. 2001). As argued above, subtypes are the result of a migration event to a new susceptible population, and one should not try to “enforce”

treelike behavior to this early period of the epidemic. The classical phylogenetic analysis software has no proper way of displaying this initial history of HIV-1 group M before subtypes arose. Perhaps it is better to leave this early divergence period as an unresolved network or cloud, as was done in Fig. 1.

Now that the different HIV-1 subtypes and CRFs are co-circulating in various countries as described above, the number of new CRFs and URFs is increasing. Some of these CRFs are difficult to discriminate from their founder “pure” subtype or CRF, especially in genetic regions where there is no recombination breakpoint. Reporting of subtypes and CRFs is therefore becoming confusing. Robust classification of HIV-1 divergence into distinct CRFs may gain a higher resolution once full-genome sequencing becomes an affordable standard, for example, in drug resistance testing practice. Another issue is that some subtypes are diverging to such an extent, such as sub-subtypes A1 and A2, that it can be disputed whether some of them should be renamed as separate subtypes. It is thus already clear that the existing subtype and CRF nomenclature might not be sufficiently flexible to accommodate the global diversity of currently circulating strains and that perhaps molecular epidemiologists should start talking about “phylotypes,” naming only those phylotypes that have a serious impact on the HIV-1 pandemic.

How to Subtype?

Given the clinical and epidemiological importance of HIV-1 subtypes, and despite the rising confusion about subtypes and CRFs, it remains useful to subtype HIV-1 isolates. The general principle to subtype HIV-1 sequences is to compare the query sequences to a set of reference sequences that includes representatives of all HIV-1 subtypes and/or CRFs. To guarantee that possible recombination events are detected, sequences are split in segments of ~400 base pairs and each one of these segments is compared to the positional homologous segment of the reference sequences. The analysis then moves in steps of around 50 base pairs to find another

sequence fragment that is compared again to the reference set. This procedure is followed for the whole length of the sequences and the results are summarized. If across the genome all sequence fragments are similar to only one reference subtype, then this query sequence corresponds to a pure subtype. If, on the other hand, some sequence fragments are similar to one subtype and others are similar to another subtype and at a certain point in the genome an abrupt and significant drop in the support for belonging to one subtype and a rise in the support for another subtype are detected, then this genomic region most likely corresponds to a recombination breakpoint, and the sequence is either a CRF or a URF.

Ideally, HIV-1 sequences should be subtyped using phylogenetic analysis of the full genome of the query sequences compared to reference sets. This type of analysis includes building phylogenetic trees and making bootscanning analysis across the full genome of the query sequences (Salminen et al. 1995). However, due to the scarcity of full-genome sequences and the high number of sequences that are subtyped, this approach is not practical. Often, and because a large number of pol sequences are generated for HIV-1 drug resistance testing, subtyping is only performed for this genomic region, and assignments are based on automated subtyping methods available in different software packages. Methods available for automated subtyping include similarity-based tools (NCBI subtyping tool, Stanford, Geno2pheno, and EuResist) (http://engine.euresist.org/data_analysis/viral_sequence/new), statistical-based tools (COntext-based Modeling for Expeditious Typing (COMET) which uses partial matching compression algorithms, STAR which uses position-specific scoring matrices, and jumping profile Hidden Markov Models (jpHMM)), and phylogenetic-based tools (REGA and Subtype Classification Using Evolutionary ALgorithms (SCUEAL)). A recent comprehensive comparison between these methods suggests that there is no single method that outperforms all others for all potential uses. Rather, a combination of two well-performing methods can be advised, such as COMET and REGA.

Conclusion

Several studies have shown the importance of taking HIV-1 genetic diversity into account while investigating its clinical and biological properties. There is substantial difference in disease progression among patients infected with different subtypes. Despite reported differences in the pathways to the development of antiviral drug resistance, overall response to treatment seems not to vary between HIV-1 subtypes. Vaccine development, on the other hand, has been severely compromised by the high level of HIV-1 genetic diversity, with several clinical trials showing very low levels of protection against infection. To understand and take into account these differences, it is important to look at the origin of subtypes. After the establishment and early spread of HIV-1 group M in the Congo Basin, different subtypes arose through independent exportation events. This fact generated a disparate prevalence and distribution of HIV-1 subtypes in different geographic regions. The distribution of HIV-1 subtypes is also highly compartmentalized among risk and demographic groups. Although HIV-1 subtype B is historically the best characterized because it was the first clade to be identified in the Western world, it is subtype C that is the most prevalent subtype worldwide, causing around 50% of global infections, most of these in South Africa and India where the prevalence of HIV-1 is now extremely high. Because of the general interest in subtypes for huge datasets, automatic tools have been developed, which are however less accurate than classical manual analysis.

Definition

- ▶ **Human papillomavirus (HPV)** has been recognized as an etiologic agent in malignancies at several anatomic sites, including the oropharynx and the penis. The overwhelming majority of oropharyngeal and penile cancers are squamous cell carcinomas. It is estimated that approximately two-thirds of oropharyngeal cancers and half of penile cancers can be attributed to HPV infection. The incidence of HPV-associated oropharyngeal cancers is rapidly increasing in developed

countries. Penile cancer remains rare in developed countries but constitutes a major cancer burden among men in developing countries. Compared with the general population, patients with HIV/AIDS are at increased risk for HPV-associated cancers, including oropharyngeal and penile cancers.

Introduction

► **Human papillomavirus (HPV)** is the cause of 5.2% of cancers worldwide and has been identified as an important etiologic agent by the International Agency for Research on Cancer (Chaturvedi 2010; Gillison 2008). Virtually all ► **cervical cancers** are attributable to HPV infection, as are 90–93% of anal cancers, 12–63% of oropharyngeal cancers, 36–40% of penile cancers, 40–64% of vaginal cancers, and 40–51% of vulvar cancers; HPV16 is the main viral type involved in carcinogenesis (Chaturvedi 2010). The main risk factors for HPV-positive compared with HPV-negative noncervical cancers are high-risk sexual behaviors, immunosuppression (including immunosuppression due to HIV and immunosuppressive drugs required after organ transplant), and a prior HPV-associated cancer (Chaturvedi 2010). HPV-positive noncervical cancers tend to be diagnosed at earlier ages than HPV-negative noncervical cancers (Chaturvedi 2010). The ratio of noncervical to cervical HPV-associated cancers differs by geographical region. Developed countries with established ► **cervical cancer** screening programs in place have higher proportions of noncervical than cervical HPV-associated cancers, while developing countries without such programs have a high burden of ► **cervical cancer** that far outweighs the burden of other HPV-associated cancers (Chaturvedi 2010).

Oropharyngeal Cancer

The oropharynx contains the tonsils and base of tongue (lingual tonsil) and refers to the mid-portion of the pharynx immediately behind the

oral cavity and above the larynx. Along with smoking and alcohol use, HPV is a major etiologic agent of oropharyngeal cancer, and oropharyngeal cancers may arise from either of two distinct etiologic pathways, one associated with HPV and one associated with tobacco exposure (Gillison 2009; Sturgis and Ang 2011). The incidence of oropharyngeal cancer is increasing in the United States despite a decrease in smoking prevalence (Sturgis and Ang 2011). The prevalence of HPV in oropharyngeal cancer has increased significantly over time to the current prevalence of 70–80% (Sturgis and Ang 2011). HPV16 is the chief type of HPV associated with oropharyngeal cancer, and more than 90% of HPV-positive oropharyngeal cancers are positive for HPV16 (Sturgis and Ang 2011).

Approximately 60–80% of HIV-positive individuals smoke compared with fewer than 20% of individuals in the general population. Between 25% and 40% of HIV-positive individuals have a prevalent oral HPV infection, compared with only 5–10% of individuals in the general population (Gillison 2009; Gillison et al. 2012). However, it remains unclear what proportion of oropharyngeal cancers among HIV-positive individuals should be attributed to HPV and what proportion should be attributed to smoking and alcohol use.

HPV-positive oropharyngeal cancer is often of nonkeratinizing histology (basaloid, lymphoepithelial, or poorly differentiated carcinoma), and patients typically present with late-stage disease characterized by small primary tumors and advanced nodal metastases (Gillison 2009; Sturgis and Ang 2011). These patients also have distinct demographic characteristics: compared with patients with HPV-negative oropharyngeal cancer, patients with HPV-positive oropharyngeal cancer typically present at younger ages and are more likely to be white men of high socioeconomic status (Gillison 2009; Sturgis and Ang 2011). Sexual behaviors, including younger age at first sexual intercourse, a history of sexually transmitted diseases, and high number of sex partners have all been associated with increased risk of HPV-associated oropharyngeal cancer. High number of oral sex partners is particularly strongly associated with HPV-positive cancers (Gillison

2009). In addition to distinct demographic, behavioral, and clinical characteristics, patients with HPV-positive oropharyngeal cancer have outcomes not typical of those in patients with HPV-negative oropharyngeal or other head and neck cancers. In particular, patients with HPV-positive oropharyngeal cancer have much better overall, disease-specific, recurrence-free, and second primary tumor-free survival rates than those with HPV-negative cancer (Sturgis and Ang 2011). Additionally, when recurrences do occur in patients with HPV-positive oropharyngeal cancer, these recurrences are more commonly distant recurrences rather than local-regional recurrences, which are more typical in patients with head and neck cancer.

The increasing incidence of oropharyngeal cancer in the United States is limited to the tonsils and base of the tongue, oropharyngeal sites typically associated with HPV (Sturgis and Ang 2011). From 1973 to 2004, the age-adjusted incidence of oropharyngeal cancer at HPV-associated sites (base of the tongue/lingual tonsil and tonsils) increased significantly, and this increase was especially pronounced from 2000 to 2004, when the annual percent change was 5.22% ($p = 0.016$) (Chaturvedi et al. 2008). Conversely, the incidence of cancers at sites not associated with HPV (oral cavity) remained stable through 1982 (annual percent change, 0.82%; $p = 0.186$) and decreased from 1983 to 2004 (annual percent change, -1.6%; $p < 0.001$) (Chaturvedi et al. 2008).

That the increase at sites associated with HPV is in fact due to an increase in the prevalence of HPV infection has recently been confirmed using oropharyngeal cancer tumor tissue from participants in the Surveillance, Epidemiology, and End Results Residual Tissue Repositories Program (Chaturvedi et al. 2011). In this study, the prevalence of HPV in oropharyngeal tumors increased from 16.3% in the 1980s to 72.7% in the 2000s, and between 1988 and 2004, there was a 225% increase in the incidence of HPV-positive oropharyngeal cancer (from 0.8 cases per 100,000 individuals to 2.6 per 100,000), accompanied by a 50% decrease in the incidence of HPV-negative oropharyngeal cancer (from 2.0 cases per 100,000 individuals to 1.0 per 100,000) (Chaturvedi

et al. 2011). If these trends continue, it is expected that HPV-positive oropharyngeal cancer cases will constitute the majority of head and neck cancers in the next few decades and that the number of HPV-positive oropharyngeal cancer cases will surpass the number of ▶ [cervical cancer](#) cases by 2020 (Chaturvedi et al. 2011).

It is estimated that the odds ratio (OR) for HPV-positive oropharyngeal cancer among individuals with a prevalent oral HPV infection ranges from 3.6 to 230. Studies measuring evidence of a previous HPV infection as indicated by HPV seropositivity have reported odds ratios (ORs) in the range of 2.3–182 for HPV16 L1 antibodies and ORs in the range of 9.2–231 for HPV16 E6/E7 antibodies (Chaturvedi 2012). In contrast to the understanding of cervical HPV infections, large prospective studies confirming these risk estimates for oropharyngeal cancer are lacking, as is documentation of the natural history of oral HPV infections with data on clearance, reinfection, and malignant conversion. Additionally, identification is still awaited of a precursor HPV-positive oropharyngeal lesion analogous to cervical or anal intraepithelial neoplasia, which would allow for screening for oropharyngeal cancer as well as early diagnosis and treatment.

Penile Cancer

Penile cancer is relatively rare in developed countries, where incidence rates range up to 1.5 cases per 100,000 men per year, but is much more common in developing countries, where incidence rates reach 4.4 cases per 100,000 men per year in Uganda and as high as 6.8 cases per 100,000 men per year in Brazil (Anic and Giuliano 2011; Backes et al. 2009; Bleeker et al. 2009). Penile cancer accounts for less than 1% of cancers in adult men in Europe and North America and up to 10% of cancers in adult men in less developed regions (Anic and Giuliano 2011; Bleeker et al. 2009; Miralles-Guri et al. 2009). Penile cancer is usually diagnosed among older men; the mean age at diagnosis is 60 years, and incidence is highest at 70 years (Bleeker et al. 2009). It is estimated that about 40% of

penile cancers can be attributed to HPV, and HPV16 accounts for 63% of HPV-positive cases (Backes et al. 2009; Miralles-Guri et al. 2009).

As with oropharyngeal cancer, penile cancer is thought to arise from either of two distinct etiologic pathways, one related to HPV and one related to other factors. Risk factors for penile cancer include higher number of sex partners and a history of sexually transmitted diseases, factors that are also associated with HPV infection (Bleeker et al. 2009). Other risk factors for penile cancer include smoking, lack of circumcision, poor penile hygiene, phimosis, and inflammation (Backes et al. 2009; Bleeker et al. 2009). HPV-associated penile cancer is thought to follow the same carcinogenic pathway as ► [cervical cancer](#), including a persistent infection with high-risk HPV and genetic alterations necessary for malignancy to develop in an HPV-infected cell (Bleeker et al. 2009). However, the lower incidence rates and later age at onset of penile cancer compared with ► [cervical cancer](#) suggest that tissue- and hormone-specific differences may exist between cancers at the two sites (Bleeker et al. 2009).

Virtually all (95%) penile cancers are squamous cell carcinomas, which can be further classified into at least four histological subtypes, keratinizing, basaloid, warty, and verrucous, with the keratinizing type being the most common (50–60%) (Backes et al. 2009; Miralles-Guri et al. 2009). Several retrospective reviews have estimated the prevalence of HPV and the distribution of HPV types in invasive penile cancer (Backes et al. 2009; Bleeker et al. 2009; Miralles-Guri et al. 2009). These studies found that almost half of invasive penile cancer cases were associated with HPV and that the prevalence of HPV infection differed by histologic subtype (Backes et al. 2009; Miralles-Guri et al. 2009). The highest HPV prevalence was found among basaloid and warty types and the lowest prevalence among verrucous types. Miralles-Guri et al. estimated that 76% of basaloid, 59% of warty, 44% of keratinizing, and 25% of verrucous types were HPV positive (Miralles-Guri et al. 2009). Backes et al. found that keratinizing tumors had an HPV prevalence of 48% and that

warty/basaloid types were 3.5 times as likely as keratinizing tumors and verrucous types were less than half as likely as keratinizing tumors to be associated with HPV (Backes et al. 2009). Although HPV prevalence differed by geographical region, at least 40% of all cases in all regions were positive for HPV (Backes et al. 2009; Miralles-Guri et al. 2009). The most common HPV types found in penile cancer were HPV16 (75%), HPV18 (12%), and HPV6/HPV11 (5%) (Backes et al. 2009; Miralles-Guri et al. 2009).

Genital HPV infection in men is common: prevalence estimates range from 1.3% to 72.9% (most >20%), with the most common types detected being HPV6 and HPV16 (Anic and Giuliano 2011). Higher prevalence rates are reported in studies using more sensitive sampling techniques (i.e., a prewetted Dacron swab) and when multiple anatomic sites are sampled (Anic and Giuliano 2011). A US study reported higher prevalence rates in samples taken from the shaft (50%), glans (36%), and scrotum (34%) than in samples taken from the perianal area (20%), anal canal (18%), urethra (10%), and semen (5%) (Anic and Giuliano 2011).

Penile intraepithelial neoplasia (PIN) is heterogeneous, and without histological confirmation, benign conditions are often misclassified as PIN (Anic and Giuliano 2011). It is estimated that 60–100% of PIN lesions are HPV positive, and one large case series reported prevalence rates of 41% for HPV16, 22% for HPV6, 15% for HPV52, and 4% for HPV11 (Anic and Giuliano 2011). High-grade PIN is considered penile carcinoma in situ, and development to this stage of PIN is rare; however, whereas the risk of progression to invasive disease in patients with cervical and anal intraepithelial neoplasia is known, the risk of progression to invasive penile cancer once high-grade PIN occurs is still unknown (Anic and Giuliano 2011).

Increased Risk of HPV-Associated Cancers Among Patients with HIV/AIDS

HIV-positive patients have an increased risk of HPV-associated cancers, including oropharyngeal

and penile cancers, compared with the general population. Moreover, the risk of these cancers appears to increase with time since AIDS onset. The increased risk is consistent with the increased incidence, prevalence, and persistence of HPV infections and increased smoking prevalence among HIV-infected individuals.

Analysis of more than 300,000 patients with HIV/AIDS from the AIDS-Cancer Match Registry documented that these individuals have an increased risk of HPV-associated cancers (Frisch et al. 2000). Patients with HIV/AIDS were seven times as likely as those in the general population to have HPV-associated cancers, and this risk increased significantly with time since AIDS onset. For invasive cancers, the risk of tonsillar cancer among men with HIV/AIDS was 2.6 times higher than among men in the general population, while no cases occurred among women with HIV/AIDS. The risk of penile cancer was almost four times as high among men with HIV/AIDS as among men in the general population, and the risk was especially elevated among men younger than 30 years (in situ penile cancer, relative risk [RR], 16.1; 95% CI, 4.4–41.2 and invasive penile cancer, RR, 37.2; 95% CI, 7.7–108.6) (Frisch et al. 2000). Furthermore, the risk of both in situ and invasive penile cancer was higher among Blacks and Hispanics with HIV/AIDS, while the risk was not statistically elevated among Whites. When individuals were stratified by HIV-exposure category, the risk of invasive penile cancer was highest among intravenous drug users (RR, 7.1; 95% CI, 2.8–14.6) and only slightly elevated among homosexual men (RR, 2.8; 95% CI, 1.0–6.1) (Frisch et al. 2000).

Engels et al. found that among HIV-positive individuals, the overall standardized incidence ratio (SIR) for oral cavity/pharynx cancer was 1.7 (95% CI, 1.1–2.5) and for penile cancer was 5.4 (95% CI, 1.1–16) (Engels et al. 2008). Furthermore, the risk for oral cavity/pharynx cancer increased after diagnosis with AIDS (RR, 3.6; 95% CI, 1.6–8.2). There were too few cases to evaluate incidence trends for penile cancer (Engels et al. 2008). These results were

confirmed in a study by Chaturvedi et al. that included almost 500,000 individuals diagnosed with AIDS during 1980–2004 (Chaturvedi et al. 2009). The SIR for invasive oropharyngeal cancer was 1.6 (95% CI, 1.2–2.1), but no significant increase in SIR was found with time since AIDS diagnosis. The SIRs for both in situ and invasive penile cancers were elevated (SIR, 19.7; 95% CI, 13.2–28.3 and SIR, 5.3, 95% SIR, 3.2–8.2, respectively), and there was a significant increase in in situ cancers (but not for invasive cancers) since time of AIDS diagnosis ($p < 0.001$) (Chaturvedi et al. 2009). When patients were stratified by HIV-exposure category, the risk of invasive oropharyngeal cancer was highest among heterosexual men (RR, 3.2; 95% CI, 1.6–5.7), followed by intravenous drug users (RR, 2.1; 95% CI, 1.3–3.2). For penile cancer, the risk of in situ cancer was elevated among men who had sex with men, intravenous drug users, and heterosexual men (RR > 20 for all subgroups), and the risk of invasive cancer was elevated among men who had sex with men (RR, 4.4; 95% CI 1.9–8.7) and heterosexual men (RR, 14.7; 95% CI, 4.8–34.5) (Chaturvedi et al. 2009).

It is unclear to what extent immunosuppression plays a role in progression of HPV-associated cancers in patients with HIV/AIDS (Chaturvedi et al. 2009; Frisch et al. 2000). While the risk of in situ cancers appears to increase with time since AIDS diagnosis, such an increase was generally not seen for invasive cancers. This may signify that immune suppression facilitates the progression of premalignancies but is not relevant in later progression to invasive cancer (Chaturvedi et al. 2009; Frisch et al. 2000). Progression of disease may be due to other factors among individuals with HIV/AIDS that are as yet unknown (Frisch et al. 2000).

The incidence of HPV-associated cancer among people with HIV/AIDS remains high even after the use of highly active antiretroviral therapy (HAART). One possible explanation may be that HAART may not influence immunity to HPV or that immunologic control of HPV-related tumors is exerted only at early stages of tumor development

(Chaturvedi et al. 2009). At the same time, the longer life expectancy of individuals in the HAART era may also lead to an increased risk of HPV-associated cancer because individuals with HIV/AIDS now live long enough to develop these cancers (Chaturvedi et al. 2009; Gillison 2009).

Opportunities for Prevention

HPV16 and HPV18 are responsible for 70% of ► [cervical cancers](#) and 90% of noncervical cancers. There are currently two HPV vaccines approved by the US Food and Drug Administration to protect against these types. Cervarix (GlaxoSmithKline) is a bivalent vaccine that protects against HPV16 and HPV18, while Gardasil (Merck) is a quadrivalent vaccine that protects against these and two additional viral types, HPV6 and HPV11. Because of the high global burden of HPV-positive cervical lesions and ► [cervical cancer](#), initial clinical trials were limited to women; however, the vaccines have more recently been shown to be highly efficacious in preventing anogenital warts in males and anal precancer in men and women, and the vaccines are expected to prevent HPV-positive oropharyngeal cancer as well.

Initial results from population-based studies are encouraging. Significant reductions in the incidence of genital warts have been observed in Australia, where 65% of eligible girls have been vaccinated. Among women aged 12–26 years, there was a 59% reduction in the incidence of genital warts between 2004 and 2009. Concomitantly, there was a significant 39% reduction in the incidence of genital warts among men aged 12–26 (Donovan et al. 2011). Herd immunity confers protection to heterosexual boys in areas where vaccine coverage is high (e.g., Australia); however, this is not observed when vaccination rates are low and may not extend to homosexual men, unless a substantial percentage of men are vaccinated (Brisson et al. 2011).

The US Food and Drug Administration approved Gardasil for routine use in girls and young women aged 9–26 years in 2006 and for use in boys in 2011. Unfortunately, the US

Centers for Disease Control and Prevention estimates that in 2011, only about half of girls in the United States of the targeted age range had received at least one dose, and only 35% had received all three doses of the vaccine. Among boys in the United States, 8% had received at least one dose, while only 1% had received all three doses (CDC 2011). It is imperative that both boys and girls be vaccinated since HPV-associated disease occurs among both men and women, and in this decade, HPV-positive oropharyngeal cancer is expected to surpass ► [cervical cancer](#) as the most common HPV-related cancer in the United States. In addition, vaccination programs ignoring boys will leave some men outside the proposed protective effect of herd immunity and at risk for oropharyngeal, penile, and ► [anal cancers](#).

Conclusion

HPV is the cause of approximately two-thirds of oropharyngeal cancers and half of penile cancers. The incidence of HPV-associated oropharyngeal cancer is increasing, especially among middle-aged white men, and is expected to surpass the incidence of cervical cancer in this decade. The incidence of penile cancer is rare in developed countries but is high in areas where the burden of cervical cancer is high. Patients with HIV/AIDS are at increased risk for HPV-associated cancers compared with the general population. The HPV vaccine offers an opportunity for prevention of HPV-associated disease, including oropharyngeal and penile cancer; however, it is imperative that both boys and girls be vaccinated to protect all persons at risk.

Overcoming the Transcriptional Block: The HIV-1 Tat Auxiliary Protein

Lavina Gharu and Alessandro Marcello
Laboratory of Molecular Virology, International Centre for Genetic Engineering and Biotechnology (ICGEB), AREA Science Park, Trieste, Italy

Definition

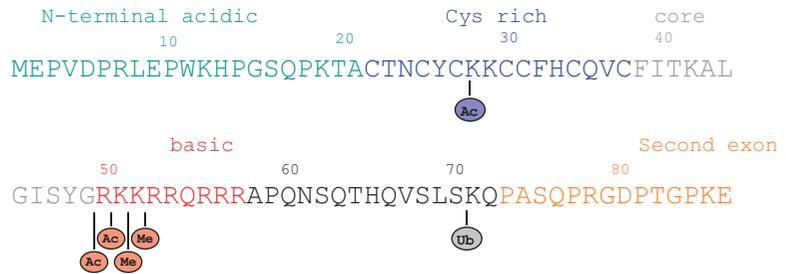

The human immunodeficiency virus type 1 (HIV-1) encodes for the auxiliary protein Tat (*trans*-activator of transcription). Tat is expressed early following HIV-1 infection and dramatically increases the level of transcription from the integrated viral promoter. Before Tat expression, only few RNA transcripts are completed, allowing also for the production of Tat itself. Tat then functions as an adaptor for the binding of cellular proteins to viral RNA, which boosts transcription in a positive feedback cycle. Tat is an essential protein for HIV-1 pathogenesis and for reactivation from post-integrative latency following antiretroviral therapy.

The Tat Polypeptide

HIV-1 is a retrovirus that integrates a DNA copy of its RNA genome into the host chromatin. The HIV-1 promoter is embedded in the long terminal repeat (LTR) of the virus and contains several upstream DNA regulatory elements that act as binding sites for cellular transcription factors. The core promoter includes three binding sites for the SP1 (specificity protein 1) activator plus a TATA box to facilitate RNA polymerase II (RNAPII) transcription. The enhancer region, located upstream of the SP1 binding sites, is formed by two binding sites for NF- κ B (nuclear factor kappa-light-chain-enhancer of activated B cells), which act in concert with Sp1 to stimulate basal transcription following diverse stimuli. However, the unique feature that distinguishes the

Overcoming the Transcriptional Block:

The HIV-1 Tat Auxiliary Protein, Fig. 1 The HIV-1 Tat polypeptide (86 aa) with indicated residues modified by acetylation (Ac), methylation (Me), or ubiquitylation (Ub)

HIV-1 LTR from a cellular promoter is its regulation by the viral transactivator Tat. Essentially, Tat establishes a feedback loop to stimulate HIV-1 transcription. Tat is a small polypeptide (101 amino acids for most primary isolates, 86 amino acids for some laboratory-adapted strains), which is transcribed from a spliced transcript of the HIV-1 genome that overlaps with viral *env* and *rev* genes. Tat is a nuclear protein, but is also secreted as an active polypeptide able to transactivate the viral LTR of neighboring cells. Indeed, Tat-derived peptides are highly efficient in delivering proteins across cellular membranes. The amino acid sequence of Tat comprises four regions in the first exon: the amino-terminal acidic domain (aa 1–21), a domain containing 7 cysteines (aa 22–37), a core region (aa 38–48), and a basic domain enriched in arginine and lysine amino acids, which is highly conserved among different strains (aa 49–57) (Fig. 1). The first exon contains all the minimal functional domain of the protein. The second exon starts at amino acid position 73 and has a relatively more variable sequence. Being dispensable for the transcriptional functions of Tat, the second exon has been largely overlooked, although its conservation points to a specific role in the life cycle of HIV-1 *in vivo*. HIV-1 Tat interacts with a *cis*-acting RNA element (*trans*-activation-responsive region; TAR) present at the 5' end of each viral transcript (nucleotide position +1 to +59 counting from the transcription start site). The basic domain of Tat is a nuclear localization signal but is also required for TAR binding. Through this interaction, the protein promotes the assembly of transcriptionally active complexes at the LTR by multiple protein-RNA and protein-protein interactions. Tat is considered an intrinsically unfolded protein that does

not allow its structure to be easily determined. However, when bound to host factors such as P-TEFb (see below), Tat adopts a resolvable structure that is complementary to the surface of the partners (Tahirov et al. 2010).

Remodeling of Chromatin

Following infection, reverse-transcription, and nuclear translocation of the pre-integration complex, the viral cDNA is spliced into host chromatin. The choice of the integration site is quasi-random, with a preference for actively transcribing genes and highly dependent on the conformation of chromatin (Dieudonne et al. 2009; Marcello et al. 2010). However, independently of the integration site, nucleosomes in the 5' LTR are precisely positioned with respect to *cis*-acting regulatory elements (Van Lint et al. 1996). Nucleosomes form the fundamental repeating units of eukaryotic chromatin, which are used to pack the DNA into the nuclei while regulating accessibility. Nucleosomes carry epigenetically inherited information in the form of covalent modifications such as phosphorylation, ubiquitylation, acetylation, or methylation of their core histones (Jenuwein and Allis 2001). Nucleosome nuc-1, located immediately downstream of the transcription start site, is critical for the control of HIV-1 transcription being specifically remodeled through posttranslational covalent modifications of histone tails and through remodeling complexes that require energy (ATP) to function. In conditions of transcriptional repression, this area of the promoter is enriched with histone deacetylases (HDAC) and with histone methyltransferases (HMT), which actively deacetylate or methylate specific lysine

residues in histone tails, respectively. As a result, chromatin is more compact and less accessible to the RNAPII complex. When the cell is exposed to external stimuli, certain inducible host transcription factors, such as NF- κ B, NFAT (nuclear factor of activated T cells), and AP-1 (activator protein 1), translocate into the nucleus and bind the viral LTR to initiate the transcription cycle and the expression of the first molecules of Tat. Tat is able to recruit to the LTR specific histone acetyltransferases, such as the cAMP-responsive element binding factor (CREB) binding protein (CBP)/p300 and the p300/CBP-associated protein P/CAF (Benkirane et al. 1998; Lusic et al. 2003; Marzio et al. 1998). In addition to acetyltransferases, Tat recruits also the SWI/SNF remodeling ATPase components BRM and BRG1, which contribute to the final remodeling of chromatin at the integrated LTR (Treand et al. 2006). The ability to modulate early events in chromatin remodeling at the viral promoter is at the basis of the most recent attempts to cure the disease. Although combined antiretroviral therapy (cART) is highly efficient in reducing the levels of circulating virus, it is not able to eradicate the infection from cells carrying a transcriptionally silent provirus. Hence, several inhibitors of HDACs or activators of the transcription factors are being tested to drive the virus out once and for all (see paragraph six). These approaches leverage essentially on triggering Tat expression because, once Tat is available, transcription proceeds *sine impedimenta*.

Tat and Elongation

In the presence of suboptimal levels of the viral transactivator Tat, basal transcription from the viral LTR leads to pausing of RNAPII after synthesis of a short RNA that includes the TAR element. Promoter-proximal pausing of RNAPII is a widespread negative regulatory mechanism of gene expression, which is controlled by negative (NTEF) and positive (P-TEFb) transcription elongation factors. A wealth of literature is available on this topic extensively reviewed elsewhere (Marcello 2006; Ott et al. 2011). In the paused state, RNAPII is found associated to the promoter

and to nascent RNA together with the NTEF composed of the negative elongation factor (NELF) multisubunit complex and the 5,6-dichloro-1 β -D-ribofuranosylbenzimidazole sensitivity-inducing factor DSIF, which is a heterodimer, composed of Spt4 and Spt5. Regulation of transcriptional pausing is actively being investigated and has been recently shown to involve RNA-dependent premature termination as well as the integrator complex (Stadelmayer et al. 2014; Wagschal et al. 2012). In order to overcome RNAPII pausing and to enter transcription elongation, P-TEFb is recruited to the promoter-proximal region and phosphorylates NELF, which dissociates from RNAPII, and Spt5. Additionally, P-TEFb phosphorylates the C-terminal domain (CTD) of the RNAPII largest subunit (RPB1), which consists of multiple heptad repeats of the consensus sequence YSPTSPS and serves as a platform for the binding of factors required for the expression of RNAPII-transcribed genes. P-TEFb is composed of the cyclin-dependent kinase Cdk9 associated with cyclin T1 or with one of the other related members of the cyclin T family, including cyclin T2a or T2b. A fraction of nuclear P-TEFb is found in an inactive complex containing proteins such as HEXIM1 (or the homologous HEXIM2), La-related protein 7 (LARP7), and the 7SK-specific methyl-phosphate-capping enzyme (MePCE) associated to the noncoding 7SK RNA (Nguyen et al. 2001; Yang et al. 2001). In physiological conditions, P-TEFb is released from this reservoir and bound by the bromodomain-containing protein 4 (Brd4) to activate genes when cells are exposed to hypertrophic or stress signals. Tat usurps this pathway by competing with Brd4 for P-TEFb binding and its recruitment to the LTR. Whether Tat extracts P-TEFb from the nuclear soluble fraction or from a preloaded fraction on the chromatin at the integrated provirus, or both, remains to be established (D'Orso and Frankel 2010). Tat is such an effective elongation factor because, in addition to P-TEFb, it is able to recruit the so-called super elongation complex (SEC) (He et al. 2010; Sobhian et al. 2010). SEC components such as ELL1 and ELL2 are well-characterized transcription elongation factors that act in concert with P-TEFb to stimulate the

same RNAPII. Tat interacts also with the 19S PAAF1 component of the proteasome to increase transcription in a non-proteolytic mode (Lassot et al. 2007).

Posttranslational Modifications of Tat

Tat functions essentially as a promiscuous adaptor. Not surprisingly, Tat can be post-translationally modified at various residues, thereby creating a variety of configurations for different interacting partners (Fig. 1). Lysine acetylation at Lys28 allows high-affinity binding to P-TEFb (Bres et al. 2002; Kiernan et al. 1999). Lys28 acetylation is reversed by HDAC6 (Huo et al. 2011). Acetylation at Lys50/51 leads to the dissociation of Tat from TAR and promotes the association of the P/CAF acetyltransferase (Bres et al. 2002; Col et al. 2001; Dorr et al. 2002; Kaehlcke et al. 2003; Kiernan et al. 1999; Ott et al. 1999). Lys50 acetylation generates an interaction surface also for the SWI-SNF chromatin-remodeling complex (Mahmoudi et al. 2006). Deacetylation of Tat is mediated by SIRT1 and possibly controls a late step in Tat transcriptional activity, allowing the recycling of the deacetylated protein for next rounds of transcription (Pagans et al. 2005). Lys51 is also methylated by the monomethyl-transferase Set7/9 and demethylated by the action of LSD1 (Pagans et al. 2010; Sakane et al. 2011). Interestingly, both activities are required for Tat function, possibly controlling different steps of process. Finally, polyubiquitination of Lys71 mediated by the proto-oncoprotein Hdm2 does not induce proteasome-dependent degradation but has an activating effect on Tat (Bres et al. 2003).

The Transcriptional Cycle of Tat

Tat is an essential switch that converts inefficient abortive transcription from the viral promoter into a highly robust platform for viral RNA production. The viral promoter appears generally poised for transcription, with a paused RNAPII that is converted to a highly processive enzymatic

complex by Tat-mediated recruitment of P-TEFb and SEC. Control of viral transcription is essential for the success of the infection being post-integration latency a critical step of the virus life cycle, which allows long-term survival also in the presence of cART. In addition to a number of chromatin features at the site of integration and to the spatial positioning of the integration site within the nucleus, triggering of feedback loop of Tat is the final step of the process. In fact, stochastic fluctuations of Tat have been proposed to be sufficient to control HIV gene expression (Weinberger et al. 2005). In excess of Tat, the viral LTR is extremely productive, independently of the site of integration, with an extremely high velocity of RNAPII measured by a fluorescent recovery after photobleaching (FRAP) assay in living cells (Maiuri et al. 2011). FRAP analysis of HIV transcription allowed also the calculation of the dwell time of the various components present at the HIV-1 transcription site: Tat and Cdk9 behaved similarly, while RNAPII remained on the gene for the time required to reach the end of the gene (Boireau et al. 2007; Molle et al. 2007). These data support the idea that Tat and P-TEFb remain associated in the elongating complex, rather than Tat alone being transferred to the elongating polymerase, but that the complex dissociates from RNAPII before termination of transcription.

Pharmacological Modulation of HIV-1 Transcription for Therapeutic Purposes

Due to the emergence of multidrug resistant HIV-1 strains and the inability of cART to completely eradicate HIV-1 from infected patients, there is an urgent need to identify new compounds that act on alternative steps of the viral replicative cycle. To this end Tat-mediated transactivation has been explored as an alternative target for inhibition. Two approaches have been proposed: (i) targeting cellular factors involved in HIV transcription or (ii) inhibition of the Tat/TAR axis.

The principal target for the first approach is the P-TEFb complex. Inhibitors that block CDK9

kinase activity are flavopiridol and derivatives, indirubin-3'-monoxime, DRB, roscovitine, or the R-enantiomer of roscovitine (seliciclib or CYC202). A new class of nontoxic anti-CDK9 compounds based on the 2-phenylquinazolinone scaffold has been recently reported to interfere with Tat-mediated transactivation of the viral promoter and in the inhibition of HIV-1 reactivation from latently infected cells (Sancineto et al. 2013). CDK2 is another potential therapeutic target to inhibit Tat transactivation. CDK2 is reported to phosphorylate CDK9 on Ser90 and thereby contributes to HIV-1 transcription, and this could also provide a new strategy for activation of latent HIV-1 provirus (Breuer et al. 2012). Known CDK2 inhibitors are CYC202, Alsterpaullone, and small peptide inhibitors. Antihuman cyclin T1 intrabodies were also proposed as new agents for HIV-1 gene therapy as they are reported to target cyclinT1/Tat interaction, thereby blocking Tat-mediated transactivation and HIV-1 replication (Bai et al. 2003). However, their delivery represents an unresolved issue.

Quinolone derivatives have been shown to control the latent reservoirs through the inhibition of Tat-mediated HIV-1 transcription. One such molecule is naphthyridone 3 (HM13N), which showed improved solubility and very potent and selective anti-HIV activity in acutely, chronically, and latently infected cells (Massari et al. 2010). To overcome the drawbacks of cART therapy, a valid alternative would be a single molecule able to inhibit multiple viral targets. For instance, a recent study showed that WM5, a quinolone derivative previously identified as HIV Tat-mediated transcription inhibitor, combined either with the tricyclic core of nevirapine or with BILR 355BS (BILR) non-nucleoside reverse transcriptase inhibitors resulted in a hybrid molecule which was sufficient to inhibit both Tat transactivation and reverse transcriptase activity resulting in selective inhibition of HIV-1 reactivation from latently infected cells (Sancineto et al. 2014). Finally, recent work suggested that inhibition of the heat-shock protein 90, a protein chaperone required for the correct folding of client proteins, resulted in inhibition of HIV-1 reactivation from

latency (Anderson et al. 2014). Interestingly, several inhibitors of HSP90 are readily available for testing because of their extended clinical testing for the treatment of certain cancers.

However, once integrated in the host genome, replication-competent viral DNA can become quiescent, with its expression durably suppressed and insensitive to inhibitors. The goal of induction and clearance strategies, which are also known as “kick and kill” strategies, is to induce transcription of these quiescent, replication-competent HIV proviruses (the “kick”), making them susceptible to immune clearance and the effects of cART (the “kill”). Several compounds are being studied that reactivate Tat-mediated transcription of HIV-1 through a variety of mechanisms extensively reviewed in Van Lint et al. (2013). HDACs are implicated in maintaining a quiescent provirus, and their inhibitors (HDACi) are primary candidates for the “kick.” HDACi including valproic acid (VPA), trichostatin A, vorinostat (VOR or suberoylanilide hydroxamic acid or SAHA), sodium butyrate, oxamflatin, belinostat, givinostat, entinostat, and panobinostat have been all reported to activate latent HIV in cell lines and primary cells. Initial results from HDACi clinical trials are promising, although they may not be sufficient for complete reactivation. In addition to HDACi, activation of signaling pathways such as protein kinase C (PKC) and NF- κ B induces expression of quiescent proviruses. Once activated, PKC phosphorylates I κ B α (inhibitor of NF- κ B), which results in the release of NF- κ B. Free NF- κ B then translocates to the nucleus, where it binds to HIV LTR and promotes transcriptional activation. Drugs targeting these pathways, such as tumor necrosis factor- α , prostratin, and bryostatins, are currently under study for the treatment of latent HIV infection. Prostratin, for example, a phorbol ester that targets both PKC and NF- κ B pathways, activates HIV transcription in several models of latency. In addition, prostratin along with HDACi increases the amount of virus produced from cells carrying a quiescent provirus demonstrating the necessity of combining multiple drugs with different targets for improved efficacy. Hence, there is a continuous effort to find novel molecules and targets. For

example, hexamethylene bisacetamide (HMBA) reactivates viral production in stable cell lines as well as in primary infected cells via transient activation of the P13K/Akt pathway, which results in HEXIM1 phosphorylation allowing the recruitment of released P-TEFb to HIV promoter to stimulate transcription. Disulfiram (DSF), an inhibitor of acetaldehyde dehydrogenase that is used for the treatment of alcoholism, was shown to reactivate latent HIV-1 expression in a primary cell model of virus latency and is currently being assessed in a clinical trial for its potential to deplete the latent HIV-1 reservoir in patients on combination antiretroviral therapy. DSF reactivates latent HIV-1 expression via the Akt signaling pathway through depletion of PTEN (phosphatase and tensin homolog) protein level. JQ1, an inhibitor of Brd4, is reported to reactivate latent HIV-1. Brd4 is shown to competitively block the Tat-super elongation complex (SEC) interaction, and this interaction is essential to overcome the limitation imposed by RNAPII pausing at the HIV promoter. JQ1, in contrast, dissociates Brd4 to enable Tat to recruit SEC to stimulate RNAPII elongation and thus enhances transcription.

Conclusions

The study of HIV-1 transcription and the function of Tat have been the subject of intense investigation over the years. In the wake of the AIDS epidemic, research on HIV-1 transcription has become essential to understand the post-integration latency mechanisms that make the virus undetectable by the immune system and insensitive to cART. Current approaches aiming at eradicating viral reservoirs from infected individuals are all based on triggering transcription and derived from basic mechanistic studies. However, the importance of investigating HIV-1 transcription extends far beyond virology into our understanding of cellular pathways of gene expression control. It is expected that such studies will contribute also to uncover disease-related dysregulation of cellular processes.

Overview of HIV CNS Infection

Nisha S. Bhatia¹ and Richard W. Price²

¹Department of Neurology, University of California San Francisco, San Francisco, CA, USA

²Department of Neurology, UCSF School of Medicine, San Francisco General Hospital, San Francisco, CA, USA

Definition

Infection of the central nervous system (CNS) is a nearly universal facet of systemic HIV type 1 infection that begins during initial systemic viremia and continues through the subsequent course of chronic untreated infection. Importantly, the character and neurological consequences of this infection vary considerably among individuals and evolve over a protracted chronic course, changing from subclinical, seemingly innocent meningitis in most individuals to severe encephalitis in a substantial minority late in the course of systemic infection. Antiretroviral therapy (ART) is usually effective in suppressing CNS HIV infection and preventing its more severe neurological consequences, though milder neurological

impairment may persist in an appreciable number of patients and, rarely, isolated CNS treatment failure may present with more severe neurological disease.

Introduction

HIV infection can be complicated by an array of neurological diseases afflicting the central nervous systems (CNS) that include not only important opportunistic pathologies (e.g., cryptococcal meningitis, cerebral toxoplasmosis, progressive multifocal leukoencephalopathy, and primary CNS lymphoma) but CNS dysfunction that relate more fundamentally to HIV infection itself rather than another etiology (Del Valle and Pina-Oviedo 2006). However, the connection between HIV CNS infection and disease is complex, involving not only exposure of the brain to HIV but likely changes in the genetic and pathogenic character of virus populations within the individual host along with alteration in host defenses and reactions caused by systemic HIV infection that, in turn, determine CNS disease susceptibility and development. This short review provides an introduction to the general character of untreated CNS infection, its clinical consequences, and the impact of antiretroviral therapy (ART).

Untreated CNS HIV Infection

Untreated HIV infection exhibits three important characteristics: (1) it is a nearly constant facet of systemic infection; (2) its character can change over time as systemic disease progresses; and (3) it has the potential to cause CNS injury, most severely in the context of late systemic disease when blood CD4⁺ T cell counts are low. Much of what we know about CNS infection, particularly in a longitudinal context, has been defined by studies of cerebrospinal fluid (CSF) in which the virus can be measured along with local inflammatory responses and brain injury using biomarkers of these processes. This review therefore draws largely on CSF studies.

Evolution of CNS HIV Infection

HIV RNA can be detected in the CSF of virtually all viremic patients, usually at about one-tenth the concentration of HIV RNA in blood, though the quantitative relation of CSF to blood virus varies among individual patients. General exceptions to this average ratio include both patients studied within the first year of infection and those seen late in disease when blood CD4 T cell counts are below 50 cells per μL ; in both these groups, the CSF HIV RNA concentrations are relatively lower compared to blood, closer to 1:100 copies per μL (Price et al. 2014). While mild CSF lymphocytic pleocytosis is very common in untreated patients, it is usually asymptomatic without headache or other signs of meningitis (Spudich et al. 2005).

However, in some patients, the character and consequences of infection can be more severe, and CNS infection can be invasive with frank HIV encephalitis that presents clinically as HIV-associated dementia (HAD) with debilitating cognitive and motor deficits and high mortality. How can the same CNS virus infection range in its clinical consequences from no symptoms to severe encephalopathy? The answer to this fundamental question is not fully understood in detail, but important factors include the evolution of viral populations within individual patients so that, despite the seeming similarities in CSF viral profiles, the character of the underlying infection likely differs. Changes in the host immune cell responses as systemic disease advances also are likely important in facilitating the different disease outcomes, and indeed virus and host factors are interdependent and likely evolve hand in hand.

For simplicity, Table 1 compares some salient characteristics of typical early and late chronic CNS HIV infections. While CSF HIV may be detected in similar concentrations in these two settings, underneath the seeming similarity are important genetic and biological differences. During *early* chronic systemic infection when blood CD4 T cell counts are high, infection in the CSF generally has two important characteristics. First, the CSF HIV populations are genetically similar to those in blood and referred to as *equilibrated* or *non-compartmentalized*. Thus, if one examines

Overview of HIV CNS Infection, Table 1 Two hypothesized CNS infection prototypes

Timing	Anatomic location	Virus populations	Cell tropism	CSF HIV treatment decay
Early (CD4>350)	Meninges	Equilibrated	T-tropic	Rapid
Late (CD4<200)	Brain (encephalitis)	Compartmentalized	M-tropic	Slow

HIV envelope (*env*) RNA sequences of CSF and blood populations, they are similar, and phylogenetic comparisons show an admixture of related genotypes across the two fluids (Schnell et al. 2011). This implies that CSF HIV populations are recently derived from systemic sources. One explanation for this is that blood lymphocytes traffic into the CSF space (leptomeninges) and release progeny viruses which undergo only limited local replication in uninfected lymphocytes without local evolution. In some of these patients, there may be evidence of limited compartmentalization related to a burst of clonal expansion but without further sustained local evolution. *Second*, when examined for cell tropism determined by their *env* sequences, these CSF viruses, like those in blood, are T-lymphocyte-tropic (T-tropic, requiring high cell CD4 surface concentrations for infection), consistent with this blood origin (Schnell et al. 2011).

By contrast, *late* chronic infection in patients with low CD4 counts more often includes CSF HIV populations that are genetically distinct from those in plasma or *compartmentalized*, indicating independent evolution within the CNS that diverges genetically from blood populations. Additionally, these CSF viral populations show macrophage tropism (M-tropic, able to infect cells expressing low concentrations of CD4) (Schnell et al. 2011). The local selection and expansion of these M-tropic viruses likely are important in the development of frank HIV encephalitis with its characteristic infection of perivascular and parenchymal macrophages and microglia – the main pathological substrate of HAD (Burdo et al. 2013)

These two types of infection are not mutually exclusive within an individual patient, but likely frequently coexist in various mixtures. Because of this variability, CSF HIV isolates vary in their correlation with brain infection and CNS injury,

and the CSF HIV RNA concentration alone does not provide a quantitative index of the severity of neuropathic CNS infection. It remains to be seen if molecular analysis of CSF HIV genotypes and phenotypes (including cell tropism) will prove more helpful indicators of the character of underlying brain infection.

A second major component of the pathogenesis of brain injury and dysfunction relates to the mechanisms that link infection to brain injury. Since productive CNS infection, as outlined above, is confined to lymphocytes in the meninges during early infection and to cells of monocyte lineage within the brain (including the perivascular spaces) in HAD, neuronal injury appears to involve “indirect” mechanisms, whereby intermediary signals and toxic products derived from infected and uninfected (chiefly myeloid) cells impact on neuronal function and, eventually, viability. A number of different molecular mechanisms mediating neurotoxic effects have been described and are reviewed (Spudich and González-Scarano 2012). It should be also added that astrocytes may be infected by HIV, though infection of these cells is generally restricted in its gene expression and does not produce progeny (Dewhurst et al. 1987). Astrocytes therefore do not seem to sustain active infection or viral evolution within the CNS though this has been difficult to examine in detail. However, widespread astrocytic infection could theoretically contribute to brain dysfunction by altering the functions of these important glial elements.

This general picture of CNS infection and neuropathogenic mediation derives mainly from studies focused on more severe infection with HIV encephalitis and HAD. Less well defined are the mechanisms underlying milder CNS dysfunction, so-called asymptomatic neurocognitive impairment (ANI) and mild neurocognitive disorder (MND). While these clinical forms may involve milder forms of the same processes

causing HAD, this has not yet been clearly established by focused clinical-pathological and clinical-virological correlations.

Treatment of CNS HIV Infection

While the remarkable development of contemporary combination ART has occurred largely without special consideration of the particular effects on CNS infection or disease, treatment has nonetheless had a major impact on brain infection and its consequences. Most notably, the incidence of HAD is now markedly reduced in places where ART usage is widespread to the point that HAD is now uncommon and largely a disease of individuals who are outside the envelope of treatment because of psychiatric, social, or economic obstacles. Unfortunately these same background factors can make diagnosis difficult by obscuring the effects of CNS infection. Thus, in the developed world, contemporary treatment undeniably has had a profound preventative effect on the severe neurological diseases that were common in the early AIDS epidemic and that still linger in resource-poor areas (Chan and Brew 2014). Case studies and common clinical experience also demonstrate a therapeutic effect of ART on HAD with patients improving neurologically after treatment initiation.

However, despite these favorable observations, there are a number of important issues regarding CNS treatment that remain to be addressed. These include question regarding the efficacy of ART in preventing or treating milder neurocognitive impairment which has been reported to remain common in treated populations (Heaton et al. 2011). Also, it is uncertain when and how strategies to treat or prevent CNS infection and dysfunction might diverge from those for systemic infection.

Effect of ART on CNS Infection

The effect of treatment on CNS infection has been examined using CSF HIV RNA as an indicator, and, in general, combination ART has proved very effective in suppressing virus measured in CSF. Most patients with plasma viral suppression

below the clinical detection limits (usually 40–50 copies of HIV RNA per mL) exhibit parallel suppression of CSF HIV (Price and Staprans 1997). Only a small minority of patients may show asymptomatic CSF “viral escape” despite plasma suppression. For example, in one cross-sectional study, CSF escape was detected in about 10% of neurologically asymptomatic subjects undergoing lumbar puncture in the context of cohort studies (Eden et al. 2010). Emerging data suggest that asymptomatic low-level CSF HIV escape is common, characteristically transient, and accompanied by a minor inflammatory response but not by detectable immediate CNS injury or progressive local infection. The lack of symptoms in these individuals suggests that these asymptomatic elevations in CSF HIV RNA may be equivalent to plasma “blips” and not indicative of ongoing CNS viral replication. The low levels of virus in these individuals make studies of genetic evolution difficult, and thus this type of escape has not been characterized in molecular terms.

CSF studies have also examined the dynamics of CSF reduction (decay) with treatment initiation and noted that in some patients CSF decay is rapid and similar to the rapid decay of HIV RNA in plasma, while in others it is considerably slower than that of plasma. This difference supports the concept of different cell sources for CSF HIV (Table 1) with fast decay related to lymphocytic replication, like that of plasma virus in which the rate is determined by the short half-life of lymphocytes (Haas et al. 2003). In contrast, the slow CSF decay is thought to relate to the longer survival of infected macrophages, supporting the presence and importance of the cellular substrate of CNS infections. Patients with lower blood CD4 cells and HAD are more likely to exhibit this slow decay.

In those individuals with undetectable CSF HIV RNA, one study of 45 individuals using the sensitive single-copy assay to measure CSF and HIV RNA down to levels of less than one copy of HIV RNA per mL found that CSF HIV could be detected in some of these individuals but with a lower frequency than that of plasma detection and at lower levels of “residual” virus (Dahl et al. 2014). Together these observations show

that CSF HIV is generally lower than that detected in plasma, with exceptions largely seeming to be transient and with uncertain clinical significance. An important exception to this, neurosymptomatic CSF HIV escape is discussed below.

Effect of Different ART Regimens on CNS Dysfunction

One of the most controversial aspects of treating the CNS revolves around the issues of when and how to optimally target CNS HIV infection. This has been studied more extensively in relation to neurological outcomes assessed by neuropsychological test performance. Most of these studies are retrospective and examine cohorts treated with a variety of regimens. Because of the treatment heterogeneity and the changes in favored drug regimens over time as new drugs are introduced, a common approach in these studies has been to group regimens based on an aggregate “CNS penetration-effectiveness” (CPE) score (Letendre et al. 2008). This approach involves assigning a score, in its present iteration from 1 to 4, to each component drug based on available data regarding CNS pharmacokinetics (mainly of CSF drug concentrations) and virological efficacy (generally sparse since there are few rigorous studies of CNS efficacy that allow one to pick out effects of individual drugs on CSF HIV RNA). While the scale involves some tenuous assumptions and is not strictly quantitative, its great advantage is to provide an easy reference regarding each drug’s CNS pharmacology. A number of studies suggest that higher CPE score is associated with better neuropsychological test outcomes (Fabbiani et al. 2015), though a general difficulty is that the supporting studies are not randomized or prospective; as a result they do not balance potential CNS effects with other properties of the regimens important for systemic efficacy, including potency, tolerability, side effects, and convenience that favor adherence (Libertone et al. 2014).

The importance of this issue has become moot in recent years as newer regimens now suggested for initial therapy also have pharmacological properties that favor CNS drug exposure. For example, among the “Recommended” regimens in the 2015 DHHS Guidelines are two containing

dolutegravir, one with raltegravir, and one with darunavir which have relatively favorable CSF pharmacokinetics (<http://aidsinfo.nih.gov/guidelines>). The relative value of the two nucleoside “backbones,” tenofovir disoproxil fumarate/emtricitabine and abacavir/lamivudine, for CNS treatment remains uncertain. With these choices for the naïve patient beginning treatment, the clinician now does not face a major dilemma of whether to treat the body or the mind, and more than one of these regimens can be recommended for newly presenting HAD.

Neurosymptomatic CSF HIV Escape

An uncommon, but clinically important, exception to the high CNS effectiveness of ART is a syndrome characterized by “discordant” elevations of CSF in relation to plasma HIV RNA in patients presenting clinically with overt neurological symptoms and signs, referred to here as *neurosymptomatic CSF escape*. This was first clearly outlined in a case reported by Canestri and colleagues (Canestri et al. 2010), subsequently confirmed by a second case series and by a number of individual reports (for review, see Ferretti et al. 2015). Some of these cases present an important argument for the need for antiviral drugs to achieve therapeutic levels within the CNS. Dissociation between CSF and plasma virus concentrations is the hallmark of this disorder and indicates that these are examples of isolated CNS treatment failure in the face of systemic success. In those with plasma HIV RNA levels below detection limit, CSF levels >100 copies/mL may be present, while in those with low but measurable plasma VLs, levels at least twice as high are characteristic. Neurological presentations vary and may include focal or non-focal neurological symptoms and signs. Two factors, often in combination, appear to contribute to this: (1) drug resistance within the CNS and (2) poor penetration of drug. Either alone or in combination can lead to antiviral drug concentration inadequate to suppress CNS infection but able to suppress systemic infection. While other factors may also be important (including establishment of latent CNS infection during untreated nadir and CD8+ T cell immunopathology), the inadequacy of local drug

effectiveness seems paramount and supported by reversal of the syndrome when treatment is changed to overcome these two factors.

CNS as an HIV Reservoir

Long-term infection established in the CNS but suppressed by ART may also have implications for HIV cure strategies that are now receiving increased attention. Because of the barriers to drug entry into the CNS and because CNS infection may be supported within myeloid cells (macrophages and related cells) rather than lymphocytes, current cure efforts may not be as effective in reducing or eliminating a CNS HIV reservoir than the systemic lymphocytic reservoir (Fois and Brew 2015).

Conclusions

CNS exposure and infection by HIV is a nearly ubiquitous facet of systemic infection that may evolve in parallel with systemic infection but may also pursue an independent course that eventuates in CNS injury and neurological dysfunction. As antiretroviral treatment has become increasingly effective in suppressing plasma and CSF HIV RNA, current interest has turned to newer concepts of CSF escape, CNS as a reservoir, and ongoing cognitive decline as important areas of investigative and clinical interest.

Overview: Immunopathogenesis

Mathias Lichterfeld
 Infectious Disease Division, Brigham and
 Women's Hospital, Boston, MA, USA

Definition

HIV-1 infection causes a chronic disease of the immune system, and almost all clinical HIV-1 disease manifestations stem from immune pathology or immune dysfunction. While initially largely regarded as a disease that primarily affects CD4 T cells and cellular immunity, it is now clear that HIV-1 infection represents a systemic immune disorder that involves almost all innate and adaptive components of the immune system, although they can play diverse and partially opposing roles in disease pathogenesis. This overview briefly discusses four distinct aspects of HIV-1 immune pathogenesis: HIV-1 immune activation, HIV-1 immune defense mechanisms, HIV-1 immune dysfunction, and immune cells that serve as target cells and cellular reservoirs for HIV-1. A detailed discussion of these specific areas is provided in dedicated entries of this encyclopedia.

HIV-1-Associated Immune Activation

Initial infection of the human body with HIV-1 leads to massive, uncontrolled viral replication in lymphoid tissues and causes excessive activation of the immune system that involves stimulation of innate and adaptive effector cells, release of cytokines, and induction of a proinflammatory condition in tissue microenvironments (Appay and Sauce 2008). HIV-1-associated immune activation likely stems from multiple different underlying mechanisms: Persistently elevated levels of circulating HIV-1 antigen can directly stimulate T cells via TCR-dependent immune recognition, and non-HIV-1-specific T cells can be activated via bystander activation (Bangs et al. 2009). In addition, HIV-1 can activate innate immune cells through interactions with pattern recognition receptors, such as Toll-like receptors or cytosolic receptors for HIV-1 DNA or RNA (Beignon et al. 2005; Doitsh et al. 2014). Moreover, HIV-1-associated damage of the enteric immune system can increase microbial translocation and lead to elevated levels of circulating bacterial antigens, which also stimulate and activate the immune system (Brenchley et al. 2006). While possibly playing some role in host protection against HIV-1 progression during early stages of infection, it is now clear that this massive immune activation contributes to disease pathogenesis by increasing cellular susceptibility to HIV-1, inducing exhaustion and accelerated senescence of immune cells, and stimulating fibrotic transformation in lymphoid tissues (Zeng et al. 2012). As such, HIV-1-associated immune activation is responsible for many HIV-1-associated disease manifestations and represents an independent and more accurate predictor of clinical HIV-1 disease progression than levels of HIV-1 replication measured in the blood. Interestingly, immune activation persists at abnormally elevated levels when viral replication is effectively suppressed with antiretroviral combination therapy (Hunt et al. 2003) and seems to be responsible for many clinical problems of HIV-1 patients treated with antiretroviral therapy, including increased frequencies of cardiovascular diseases, accelerated aging, alterations in the bone, lipid and

carbohydrate metabolism, and neurocognitive deficiencies. Abnormally elevated levels of immune activation are also encountered in elite controllers, a group of patients who naturally achieve undetectable levels of HIV-1 replication in the absence of treatment (Hunt et al. 2008). The decisive impact of immune activation on HIV-1 disease progression is highlighted by specific non-human primates who are fully susceptible to infection with simian immunodeficiency virus (SIV) and develop high levels of SIV replication, but do not show signs of SIV-associated immune activation and fail to exhibit clinical signs of HIV/SIV disease typically encountered in humans (Chahroudi et al. 2012). Aspects of HIV-associated immune activation are discussed in the following entries:

Immune Responses Against HIV-1

The human immune response to HIV-1 involves a complex network of innate and adaptive immune cells, but is unable to protect against HIV-1 disease progression in most infected persons. T cell-mediated immune responses represent a principal element of the adaptive immune response against HIV-1 and are generated early during the disease process, typically at a time when the viral load declines to the set point (Walker and McMichael 2012). While there is evidence that cellular immune responses against HIV-1 can contribute to relative control of HIV-1 replication, particularly during early stages of the disease and in carriers of protective HLA class I alleles, the efficacy of HIV-1-specific T cell responses is generally limited by viral escape mutations, which

occur frequently in untreated patients and contribute to shaping viral sequence evolution (Goulder and Watkins 2004). Antiviral activity of HIV-1-specific T cell responses is further limited by T cell dysfunction that likely results from exhaustion and accelerated senescence of cells (Tsoukas 2014). Neutralizing antibodies generated by HIV-1-specific B lymphocytes represent a major aspect of the humoral immune response against HIV-1, but their ability to inhibit HIV-1 replication is also reduced by viral escape mutations in targeted epitopes. Innate immune responses, mediated by, e.g., NK cells, NKT cells, $\gamma\delta$ T cells, macrophages, and interferon-secreting plasmacytoid dendritic cells may also contribute to HIV-1 immune defense in some individuals, and their precise antiviral effects represent an area of active research (Silvin and Manel 2015). Notably, activation of antiviral effector cells can in many cases enhance cellular susceptibility to infection and contribute to viral dissemination and long-term persistence. As such, the physiologic immune response to HIV-1 may paradoxically increase host vulnerability to HIV-1 and may in some aspects benefit the virus more than the host. However, it is noteworthy that small groups of HIV-1-infected patients are able to naturally control HIV-1 infection and maintain undetectable or low level of HIV-1 viral loads in the absence of treatment; this is typical in individuals with strong HIV-1-specific T cell responses, which seem to represent the primary correlate of HIV-1 immune protection in these patients (Walker and Yu 2013). These individuals provide living evidence that the human immune system, at least in very special situations, is able to effectively control HIV-1 infection. Immune defense mechanisms against HIV-1 are discussed in this encyclopedia in the following entries:

Immune Cells That Serve as a Reservoir for HIV-1 Persistence

A characteristic feature of HIV-1 infection is that the virus primarily infects CD4 T cells, which play key roles in orchestrating antimicrobial immune defense. When activated during HIV-1 infection, these cells become particularly susceptible to HIV-1, leading to the observation that high levels of HIV-1 are detectable in antigen-specific memory CD4 T cells that specifically recognize HIV-1 (Douek et al. 2002). CD4 T cells infected with HIV-1 are in many cases short-lived and die fast; however, HIV-1 can also infect cells that constitutively have or revert to a functional profile with an extended lifespan and persist in these cells in a transcriptionally silent (latent) form (Finzi et al. 1999). This likely explains why HIV-1 can persist for decades despite very effective antiretroviral therapy. Moreover, studies over the last several years have revealed an enormous heterogeneity of CD4 T cells that differ by phenotype, developmental programs, and functional polarizations (Farber et al. 2014), and it is likely that these characteristics influence the ability of these cells to serve as target cells or cellular reservoirs for HIV-1. Myeloid cells, such as monocytes and macrophages, also express CD4, and many of these cells are susceptible to HIV-1 and may represent a long-term reservoir for HIV-1, although their role in this regard remains less well characterized (Kumar et al. 2014). The investigation of immune cell subsets that serve as target cells for HIV-1 and as reservoirs for HIV-1 persistence despite treatment represents a critical aspect for developing interventions that may lead to at least a transient drug-free remission of HIV-1 infection. Immune cells that serve as a reservoir for HIV-1

are discussed in the following entries of this encyclopedia:

- ▶ [Central Memory CD4 T Cells](#)
- ▶ [Macrophages in HIV Immunopathogenesis](#)
- ▶ [T Memory Stem Cells](#)
- ▶ [Post-treatment Controllers](#)
- ▶ [Immunology of Latent HIV Infection](#)

HIV-1-Associated Immune Dysfunction

The clinical hallmark of HIV-1 infection is progressive immune deficiency and immune dysfunction. The numeric decline of CD4 T helper cells was initially identified as the most visible and arguably most important aspect of HIV-1-associated immune deficiency. However, it is now clear that impaired CD4 T cell immune responses only represent one aspect of immune dysfunction during HIV-1 infection. An increasing number of studies demonstrate that during untreated HIV-1 infection, B cells (Moir and Fauci 2014), follicular T helper cells (Cubas and Perreau 2014), dendritic cells (Piguet et al. 2014), NK cells, gamma-delta T cells (Pauza et al. 2014), and many other immune cells are functionally impaired or deficient, leading to dysfunction of many, if not all, immunological networks that ensure immune surveillance and pathogen-specific immune defense. HIV-1-associated immune deficiency can occur as a direct result of viral infection, which can lead to cell death and apoptosis. However, even in patients with progressive HIV-1 infection and AIDS, only a comparatively small number of cells are impaired this way. Indirect mechanisms of HIV-1-associated immune deficiency are substantially more frequent and can result from activation-induced cell death, cellular exhaustion, upregulation of inhibitory immunoregulatory pathways, and altered cell-to-cell interactions in lymphoid tissue microenvironments. Immune dysfunction in HIV-1 infection is complicated by the fact that mechanisms for immune regeneration are impaired during the disease by mechanisms that include thymic and bone marrow dysfunction (Sauce et al. 2011). Different aspects of HIV-1-associated

immune dysfunction are discussed in the following entries:

- ▶ [Gamma Delta T Cells](#)
- ▶ [HIV and SIV, B-Cell Responses to](#)
- ▶ [HIV and SIV, CD4 T-Cell Responses to](#)

Conclusion

Infection with HIV-1 causes a complex perturbation of almost all component of the human immune system and leads to excessive immune activation, immune exhaustion, and accelerated immune senescence, all of which contribute to the typical clinical signs of immune deficiency associated with HIV-1 infection and AIDS. Substantial progress has been made over the recent years in defining and understanding cellular and molecular aspects of HIV-related immune dysfunction and antiviral immune defense, and although our current understanding of HIV-1 immune pathogenesis is far from complete, a unifying theory of how HIV-1 causes disease of the human immune system is emerging. Notably, many of the immune abnormalities observed during HIV-1 infection regress during treatment with antiretroviral agents; however, residual levels of immune dysfunction and elevated immune activation persist despite treatment and fail to normalize even after extended periods of treatment. The development of interventions that eliminate residual HIV-1 disease in patients treated with

antiretroviral agents remains a challenge for the future generation of immunologists interested in HIV-1 pathogenesis.

Definition

PD-1 (programmed death-1), also called CD279, is a receptor expressed upon activation on innate and adaptive immune cells and is encoded by the gene *Pdcd1*. It recognized two ligands, PD-L1 (programmed death-ligand 1) and PD-L2 (programmed death-ligand 2). Upon ligation of its ligand, PD-1 negatively regulates immune activation and is a key modulator of immune responses. PD-1 deficiency results in the loss of peripheral tolerance and the development of auto-immune phenotypes in mice. In humans, single mutations in *Pdcd1* are associated with autoimmune diseases. Pathogens including HIV exploit this negative regulatory pathway important for peripheral tolerance to evade immune control. Exhausted T cells during chronic infections have been shown to overexpress PD-1. In HIV infection, the inhibitory role of PD-1 has been demonstrated for both CD8 and CD4 T cells. Blockade of the interaction between PD-1 and its ligand restored the survival and proliferation of the exhausted T cells in chronic HIV infection. PD-1 expression is also a marker of ongoing immune activation, as its levels are not normalized after

control of HIV replication by antiretroviral therapy. The PD-1 molecule is therefore a potential target for therapy in HIV infection.

Introduction

PD-1 is inducibly expressed on CD4 T cells, CD8 T cells, B cells, NK cells, NKT cells, monocytes, and dendritic cells (DCs) but has been mostly studied on T cells. PD-1 belongs to the B7-CD28 family of molecules involved in regulating the activation of immune cells (Sharpe and Freeman 2002). Two classes of molecules in this family correspond to co-stimulatory and co-inhibitory molecules. The triggering of TCR concomitant with a co-stimulatory signal through CD28 leads to T cell proliferation and cytokine production. Inversely, the engagement of a co-inhibitory molecule upon TCR triggering leads to a blockade of the TCR signaling cascade and no T cell activation. The first signal through the TCR confers specificity to the response; the second signal through the co-stimulatory or co-inhibitory molecules modulates this response. The fate of the T cell response is shaped by the balance between positive and negative signals from these molecules that regulate T cell activation and tolerance. PD-1 shares structural properties with CD28 and CTLA-4. It is a transmembrane protein of 268aa composed of an extracellular IgV domain followed by a transmembrane region and an intracellular tail. PD-1 is in a monomeric form on the

cell surface as it lacks the membrane-proximal residue required for homodimerization characteristic of other members of the CD28 family. The cytoplasmic tail of PD-1 contains two tyrosine signaling motifs which can be phosphorylated upon receptor triggering. The extracellular domain recognizes two known ligands, PD-L1, also called B7-H1, or CD274 and PD-L2, also called B7-DC or CD273 (Latchman et al. 2001). These two PD-1 ligands are differentially expressed on immune cells. PD-L1 is broadly expressed on cells including B cells, T cells, DCs, and macrophages and is further expressed upon activation. This ligand is also expressed on other cell types throughout the body including parenchymal cells, vascular endothelial cells, glial cells, keratinocytes and pancreatic islet cells, but also tumor cell and virus-infected cells. PD-L2 is inducibly expressed exclusively on DCs and macrophages. The ligation of PD-1 with its ligands leads to the inhibition of T cell proliferation and cytokine production after TCR triggering (Freeman et al. 2000). The PD-1 pathway is likely to affect a large number of cell types *in vivo*. Several other inhibitory molecules besides PD-1 can also be upregulated on activated T cells including the receptors 2B4, LAG3, CD160, and TIM3 (Blackburn et al. 2009). The coexpression of several inhibitory receptors enhances the exhaustion phenotype.

Signaling of PD-1

PD-1 is induced after T cell activation and serves as a negative regulator of TCR signaling to dampen the TCR signaling cascade and prevent excessive T cell activation. PD-1 engagement with its ligands activates a signaling pathway that suppresses T cell activation by inhibiting AKT phosphorylation. During antigen recognition by a T cell, triggering of PD-1 induces the cross-linking of PD-1 and the TCR signaling complex. The cytoplasmic tail of PD-1 contains an immunoreceptor tyrosine-based inhibition motif (ITIM) and an immunoreceptor tyrosine-based switch motif (ITSM). Both motifs can be phosphorylated upon PD-1 engagement. The

phosphorylation of the ITSM motif upon PD-1 cross-linking recruits the tyrosine Src homology phosphatase SHP-2 to the cytoplasmic tail of PD-1 (Okazaki et al. 2001). The recruitment of SHP-2 leads to dephosphorylation of ZAP70 and an inhibition of the TCR proximal signal (Okazaki et al. 2013). The inhibitory mechanisms of the TCR signal by PD-1 and CTLA-4 are distinct. CTLA-4 blocks the costimulation by CD28 via its stronger affinity to B7 molecules. PD-1 does not compete for the ligands of CD28 but acts on the TCR signaling cascade. The inhibitory function of PD-1 is therefore less stringent and slower than the one exerted by CTLA-4. The inhibition of proximal TCR signal prevents CD28-mediated activation of phosphatidylinositol-3-kinase (PI3K), reduced AKT phosphorylation resulting in decrease activation, cytokine production, glucose metabolism, and cell cycle arrest.

Regulation of PD-1

The amount of antigen and the duration of antigen exposure determine the amount of PD-1 expression on the cell surface, but the molecular events that regulate the expression of PD-1 are still largely unknown. PD-1 was shown to be differentially expressed during T cell differentiation as PD-1 expression was higher in early and intermediate CD8 T cell subsets and downregulated in later stages of differentiation (Sauce et al. 2007). PD-1 expression is associated with the expression of other activation markers. Transient PD-1 expression is important to limit excessive immune response during acute infection and might be important for avoiding tissue damage due to the exacerbated immune responses during the acute phase of infection. PD-L1-deficient mice infected with LCMV clone 13 succumb to severe liver damage. PD-1-dependent inhibitory role is important in later phases of the immune response such as sustained activation or secondary responses. However, persistent expression of PD-1 in chronic immune responses has a negative impact on the disease progression. PD-1 is expressed on a significant fraction of CD4 and CD8 T cells under physiological conditions. Common gamma chain

cytokines IL-2, IL-7, IL-15, and IL-21 as well as inflammatory cytokines differentially regulate PD-1 expression on CD4 and CD8 T cells (Kinter et al. 2008). Some transcription factors have been shown to modulate PD-1 expression. The basic leucine zipper transcription factor ATF-like (BATF) has been shown to be upregulated in exhausted CD8 T cells. BATF is a negative regulator of AP-1 activity and is sufficient to inhibit proliferation and cytokine production (Quigley et al. 2010). The B lymphocyte-induced maturation protein 1 (BLIMP-1) transcription factor has been shown to repress PD-1 expression through a feedforward repressive loop regulating PD-1 directly and by repressing NFATc1 expression, an activator of PD-1 expression (Lu et al. 2014). Epigenetic modifications can also modulate the expression of PD-1. The upregulation of PD-1 transcriptional expression during the differentiation of PD-1 from naïve to effector cells is associated with transient DNA demethylation of the PD-1 locus, then remethylation in memory cells when the antigen is cleared. The high expression of PD-1 during chronic HIV infection has been associated with the irreversible demethylation of CpG dinucleotides in the *Pdcd1* promoter due to chronic exposure to viral antigens (Youngblood et al. 2011, 2013). A decrease of viremia results in reduced PD-1 expression, but does not cause a remethylation of the PD-1 locus. The unmethylated locus of PD-1 reaches maximal PD-1 expression much faster than fully functional memory CD8 T cells with a methylated PD-1 locus.

Role of PD-1 in Chronic Viral Infections

During chronic infections, as the virus is not cleared, the continuous exposure to the viral antigens leads to an exhaustion of the CD8 T cells that lose their capacity to proliferate, survive, and exert effector functions. The upregulation of PD-1 expression on exhausted CD8 T cells was first described in the lymphocytic choriomeningitis virus (LCMV) model of chronic infection in mice (Barber et al. 2006). When comparing

functional and exhausted LCMV-specific CD8 T cells in that model, PD-1 mRNA was found to be highly upregulated in exhausted T cells. PD-1 was only transiently expressed in acute infection on effector CD8 T cells when LCMV was controlled. In contrast, PD-1 was sustained and expressed at high levels on virus-specific CD8 T cells in mice with chronic LCMV infection. When LCMV-infected mice were injected with antibodies to block the PD-1/PD-L1 pathway, virus-specific CD8 T cells were enhanced demonstrating the role of this pathway in mediating the dysfunction during chronic infection. After PD-1/PD-L1 blockade, virus-specific CD8 T cells regained proliferative capacity and effector function resulting in a decrease in viral load. Following the LCMV study demonstrating the role of PD-1 in mediating CD8 T cell dysfunction, several studies demonstrated the role of PD-1 in mediating CD8 T cell exhaustion chronic infections in humans such as HIV or Epstein-Barr Virus (EBV).

Role of PD-1 in HIV Infection

PD-1 on CD8 T Cells

Defective HIV-specific CD8 T cell responses are suspected to be a major factor in the lack of immune control in HIV infection. Of note, during chronic HIV infection, PD-L1 is expressed at higher levels on antigen-presenting cells than in noninfected individuals. Three studies demonstrated the role of the PD-1/PD-L1 pathway in the exhaustion of HIV-specific CD8 T cells during chronic HIV infection (Day et al. 2006; Petrovas et al. 2006; Trautmann et al. 2006). They showed that PD-1 was highly upregulated on HIV-specific CD8 T cells during chronic HIV infection. The degree of PD-1 expression was associated with the level of CD8 T cell dysfunction. PD-1 expression was associated with lower proliferation of HIV-specific CD8 T cells. Its levels also correlated with viral load, loss of CD4 T cells, and disease progression. The blockade of the PD-1/PD-L1 interaction in vitro restored the proliferation and survival of these cells as well as their effector functions. PD-1 triggering increased apoptosis in

the CD8 T cells expressing high levels of PD-1. HIV-specific CD8 T cells were shown to have shortened telomeric DNA and a reduced telomerase activity. Blocking the PD-1/PD-L1 pathway increased telomere length and telomerase activity that may contribute to the recovery of T cell functions (Lichterfeld et al. 2008). PD-1 upregulation was also shown on the total CD8 T cell population and was not restricted to HIV-specific CD8 T cells. Viral load and CD4 T cell loss both correlated negatively with the expression of PD-1 on total CD8 T cells. PD-1 expression was found to be higher in lymph nodes and in gut-associated lymphoid tissues than in the peripheral blood. Control of viral load after treatment initiation resulted in decreased PD-1 levels on HIV-specific CD8 T cells. Levels of PD-1 expression correlated with the presence of antigen as they decrease after antiretroviral treatment or on HIV-specific CD8 T cell responses directed against epitopes that undergo mutational escape. In a minority of HIV-infected individuals that control HIV replication called HIV controllers, HIV-specific CD8 T cells are functional, have a preserved proliferative capacity, and express low levels of PD-1. The role of PD-1 expression on HIV-specific CD8 T cells also varies for different epitopes in a given individual. HLA-B-restricted CD8 T cell responses express lower levels of PD-1 and exhibit higher functionality compared to HLA-A-restricted CD8 T cell responses.

PD-1 on CD4 T Cell

One subset of CD4 T cells expresses high levels of PD-1 within the germinal centers: the follicular helper T cells (T_{fh} cells) defined by CXCR5+ PD-1^{hi} FoxP3⁻ (Locci et al. 2013). PD-1 expression on CD4 T cells is involved in the regulation of class-switch recombination and somatic hypermutation of activated B cells. In HIV infection, T_{fh} cells are elevated probably because of the increase in germinal center formation due to extensive viral replication (Lindqvist et al. 2012; Cubas et al. 2013). However, recent evidence suggested that these T_{fh} cells are impaired and are unable to provide B cell help, in part due to PD-1 ligation to PD-1 ligands on germinal center B cells (Cubas et al. 2013). Interestingly, it has

been further shown that T_{fh} CD4 T cells harbor HIV DNA and can serve as HIV reservoir in lymphoid tissues (Perreau et al. 2013). Levels of PD-1 are higher on HIV-specific CD4 T cells in chronic HIV infection and have been shown to correlate with levels on HIV-specific CD8 T cells. As for CD8 T cells, the blockade of PD-1/PD-L1 pathway by monoclonal antibodies was also able to restore the proliferation of HIV-specific CD4 T cells (Porichis et al. 2011). In non-treated HIV-infected individuals, PD-1 is also upregulated on total CD4 T cells. PD-1 expression levels on CD4 T cells correlate with viral load and with loss of CD4 T cells. High levels of PD-1 on CD4 T cells appear to predict suboptimal CD4 T cell recovery after long-term ART (Grabmeier-Pfistershammer et al. 2011).

Therapies Targeting PD-1

The PD-1/PD-L1 pathway has been shown to be critical in tumor-induced dampening of the immune response. As in chronic infections, blockade of the PD-1/PD-L1 interaction resulted in tumor eradication in various cancer models. These results served as basis to develop a fully humanized monoclonal antibody against PD-1 (nivolumab also called NON4538, MDX-1106, or BMS-936558). The phase I clinical trial using nivolumab reported high response rates for several cancers, non-small cell lung cancer, melanoma, and renal cell carcinoma (18–28%) (Topalian et al. 2012). Another phase I clinical trial using a monoclonal antibody against PD-L1 (BMS-936559 or MDX-1105) demonstrated similar response rates (6–17%) (Brahmer et al. 2012). The PD-1/PD-L1 blockade used in these trials resulted in the highest rate of antitumor activity of the many immunotherapeutic approaches tested over the past 30 years. These treatments showed better tolerance than CTLA-4 blockade, even though autoimmune side effects did occur in some subjects. Several groups are conducting safety and efficacy studies with PD-1-blocking antibodies in the simian immunodeficiency virus (SIV) rhesus macaque model (Velu et al. 2009; Amancha et al. 2013). Treatment with PD-1-blocking antibodies resulted

in expansion of SIV-specific CD8 T cells and increase in cytotoxic function of these cells and led to a reduction in viral load. The treatment resulted in expansion of memory B cells and an increase in antibodies against SIV envelope (Titanji et al. 2010). The treatment also showed increased survival and evidence of restoration of the mucosal barrier integrity. These preclinical studies provide the rationale for initiating human clinical trials targeting PD-1 in HIV infection. Future clinical trials in humans will determine if blockade of the PD-1 pathway is capable of improving T and B cell responses beyond what is achievable with ART.

Conclusion

PD-1 is a critical regulator of the balance between tolerance and T cell activation. Studies have demonstrated that exhausted T cells overexpress PD-1 during chronic HIV infection, but blocking the PD-1/PD-L1 pathway leads to an enhancement of T cell survival, proliferation, and function. These studies provided the basis for the development of humanized antibodies that block the PD-1/PD-L1 interaction to enhance immune effector functions for the eradication of tumors and chronic diseases including HIV. The use of PD-1 blockade has been initiated in cancer immunotherapy and led to promising results. The PD-1 pathway might be of interest for intervention strategies in HIV infection as well. PD-1 is an attractive potential target as it is not only responsible for HIV-specific T cell impairment but plays a wider role in HIV pathogenesis.

Definition

Peer-based intervention approaches use community members, as opposed to highly trained specialists, to provide HIV care and prevention services.

Review of Peer-Based Approaches

Since the onset of the HIV epidemic, people living with HIV/AIDS (PLWHA) and those directly affected by it such as high-risk groups and family caregivers of PLWHA, have been an indispensable component of HIV prevention, care, and treatment. Yet it has not been until recently that efforts have been made to systematically define peers, describe their roles, and evaluate the efficacy of their contributions.

Simoni et al. (2011a) offer the following comprehensive definition of “peers”: individuals who (a) share key personal characteristics, circumstances, or experiences with the people they serve; (b) contribute services whose value emanates from the peers’ status as a peer; (c) lack

formal expertise but may have short-term and competency-based training; and (d) provide services according to standard protocols, rather than as a natural result of informal social engagement.

Peers can function as leaders of formal meeting/structured groups, in one-on-one interactions, as opinion leaders, and in outreach activities. Formal meetings/structured groups typically range from 1 to 12 sessions and involve a manualized curriculum led by one or two peers. One-on-one interventions are often scripted but have the flexibility to be more individually tailored and run anywhere from 1 to 12 sessions. Peer opinion leaders are taught to endorse risk-reduction behaviors through casual, one-on-one conversations with members of their own social network in the hopes of changing community norms around HIV risk behaviors. General peer outreach interventions typically involve teaching a group of peers specific talking points and giving them educational material to take into the community.

Peer-based interventions are often targeted at specific at-risk populations such as men who have sex with men (MSM), school-based youth, non-school based youth, sex workers, substance users, people living with HIV/AIDS, and at-risk women. Outcomes typically targeted and assessed include sexual risk behaviors, substance use, HIV knowledge, and attitudes and cognitions, while biomarkers and other non-self-reported outcomes (e.g., condom distribution counts, needles exchanged) are much less frequently targeted or assessed.

Two reviews have systematically evaluated the efficacy of peer-based interventions in the area of HIV/AIDS (Medley 2009; Simoni et al. 2011b). These reviews collectively assessed the efficacy of peer-based interventions from 147 studies in developing and developed countries. Both of these reviews concluded that while peer-based interventions had moderate effects on behavioral outcomes, including increasing HIV knowledge, reducing equipment sharing among injection drug users, decreasing sexual risk behavior, and decreasing substance use, they were not associated with any changes in biological outcomes (e.g., sexually transmitted infection rates) or other non self-reported outcomes (e.g., condom

distribution counts, needles exchanged), which are perhaps capable of offering a less subjective, more rigorous test of efficacy. These findings suggest that peer interventions to promote the health and well-being of persons living with or at risk for HIV/AIDS are widespread and potentially efficacious. Unfortunately the majority of current research lacks a rigorous study design, limiting the extent to which causality can be inferred. Further, work in this area often lacks a clear theoretical basis for the use of peers in these interventions, limiting our understanding of why and under what circumstances peers may be useful.

Simoni et al. (2011a) have argued that optimal integration of peers into health-related interventions requires a consideration of how and why they might be helpful. Specifically, they outline a two-step process involving, first, specification of the main goal of the intervention and, next, identification of a theory that justifies the use of peers to attain that goal and might explain the specific impact of the peers. Below is a list of potential targets and theories that might justify the choice of peers as interveners.

Most peer-based interventions involve peer education and communication to affect HIV/AIDS related attitudes and knowledge, which are thought to influence behavior change. Multiple health behavior, social impact, and social comparison theories posit that peers may be particularly effective communicators of information, primarily because of their similarity to targeted individuals. For example, Dynamic Social Impact Theory (DSIT) emphasizes that the success of communication about behavior change relies on the communicator being similar and credible; that the communication occur at critical high-risk moments (e.g., immediately following an HIV diagnosis or in high-risk situations such as those involving drug use); and that the new behavior is communicated by multiple persuasive sources. Peers are well suited to provide communication in such a fashion.

A second common intervention using peers attempts to bolster social support, which has been shown to help people cope with stressful events, improve physical health, and increase beneficial health behaviors. In addition to DSIT and

social comparison theories, mutual support group and self-help theories provide a conceptual basis for the potential efficacy of peers as resources of support. Specifically, peers are posited to be particularly good resources of support because of their shared identity, experiences, and/or social capital. For example, sharing personal experiential knowledge concerning safe sex and substance use practices when providing social support is likely to increase the credibility of the peer, the sense of closeness felt between the peer and the person or people they are supporting, and the perceived strength of the social support which in turn can help improve health related outcomes.

Peers have also been used to change perceived social norms associated with high HIV risk behaviors. Such interventions are often grounded in the theory of reasoned action, which posits that perceived social norms are powerful predictors of health related behaviors. Social network theories argue that the social capital of peer opinion leaders in high-risk communities is crucial to their success in modeling safer sex and HIV-prevention behaviors.

Peers have also been used in interventions targeting individuals' self-efficacy or perceived ability to execute desired health behaviors. Self-efficacy has been shown to be a powerful predictor of engagement in healthy behaviors. The rationale for using peers to influence self-efficacy is based in social cognitive theory, which proposes that self-efficacy develops through mastery experiences, vicarious or observational learning, and social persuasion, each of which is amenable to peer-based approaches. Peers can provide realistic opportunities for individuals to practice skills and gain mastery, model self-efficacy for desired health behaviors, and cultivates an environment in which individuals perceive support and encouragement with regard to their abilities to change their behaviors.

Peers have also been used to promote advocacy interventions, which are targeted at empowering traditionally marginalized, stigmatized, and oppressed populations – those generally at higher risk for HIV/AIDS. They aim to engage targeted populations in participatory learning processes to

empower them and enable them to promote their collective health interests beyond a specific behavior change. Based on empowerment theory's focus on societal-level factors and connections with others, peers are optimally suited to empower others, helping to foster self-development, decisions-making skills, and a sense of community. Further, a supportive peer relationship can also allow for the development of a more critical understanding of how individuals are personally connected to social and political struggles, which may proactively enhance social justice and enact social change.

Successful implementation of peer-based approaches into HIV care and prevention requires careful consideration and systematic application. On the one hand, peers must be comprehensively trained; on the other hand, organizations must be ready to embrace trained peers into a multi-disciplinary structure of care and prevention intervention delivery. Various successful initiatives to adopt peer-based approaches have revealed several essential lessons learned ([Peer Education and Evaluation Resource Center 2012](#)). First, to integrate peers in HIV care and prevention it is important for someone within the existing organization or community to strongly believe in and champion the benefits of integrating peers into HIV care and prevention. Second, implementation strategies need to be tailored to each organization's specific needs and continuously monitored to increase the likelihood of a smooth integration. Third, it is important that the partner organization engender a supportive environment that considers peers as equal in status to other care and prevention providers, which can be accomplished through (a) the development of policies and procedures that are peer-inclusive; (b) obtaining support from existing members of the community at all levels during both planning and implementation stages; (c) training peers not just in their area of focus, but also in their role as peers within the organization; and (d) providing supervision for peers and monitoring their progress. Fourth, systematic evaluation of the peer implementation initiative is crucial to fully understand the contribution to service provision. Lastly, focusing on

program sustainability through obtaining consistent funding, creating an ongoing network of shared resources to improve learning, and provision of supportive tools, will allow for maximum success of a peer-based initiative.

Conclusion

To maximize the utility of peer-interventions in the area of HIV/AIDS, it is important to understand the theoretical and conceptual justifications for using peers, ways to effectively implement and integrate peers into HIV care and prevention services, and what the current research reveals about the efficacy of peer interventions. Incorporating a clear theoretical conceptualization and rationale for an intervention before implementation allows for the examination of constructs that might explain its effect, such as increased self-efficacy, empowerment, improved knowledge, or skills acquisition. Furthermore it is important to learn from previous work in this area both in terms of the logistical aspects of effective and efficient implementation and also what types of peer-based interventions have proven to be effective in the past. Peers are increasingly recognized as potentially powerful agents in promoting health and well-being. Future research and implementation work in this area, if carefully conducted, can contribute to their success.

Definition

PIMT, *PRIP-interacting protein with methyltransferase domain*, is also known as trimethylguanosine synthase (TGS1), nuclear receptor coactivator six interacting protein (NCOA6IP), hepatocellular carcinoma-associated antigen 137 (HCA137), and CLL-associated antigen KW-2. PIMT catalyzes two serial methylation steps for the conversion of the 7-methylguanosine (m7G) RNA cap to a 2,2,7-trimethylguanosine (TMG) cap. PIMT was first isolated as a peroxisome proliferator-activated receptor interacting protein (PRIP) (Zhu et al. 2001). PIMT contains a methyltransferase motif (9-amino acid VVDAFCGVG) and an invariant segment (GXXGXXI) found in K-homology motifs of RNA-binding proteins (Zhu et al. 2001; Misra et al. 2002). The PIMT gene is localized on human chromosome 8q1, spans more than 52 kb, and contains 11 exons; it is conserved in human, chimpanzee, rhesus monkey, dog, cow, rat, chicken, zebra fish, mosquito, and *Saccharomyces cerevisiae*. The PIMT mRNA is ubiquitously expressed, with high expression in heart, skeletal muscle, kidney, liver and placenta.

Organization of the PIMT Protein

The PIMT human cDNA encodes an approximately 90 kDa protein of 853 amino acids (<http://www.uniprot.org/uniprot/Q96RS0>). PIMT/Tgs1 proteins in human and other metazoan cells are much larger (e.g., varying from 491 aa in *Drosophila* 889 aa in chicken) than the corresponding Tgs

enzymes of yeast, *Saccharomyces cerevisiae*, and *Giardia* (315 and 239 amino acids, respectively), which mainly contain a C-terminal methyltransferase catalytic domain (Mouaikel et al. 2002) (<http://www.ncbi.nlm.nih.gov/homologene/32608>). The N-terminal extension of PIMT/TGS1 found in higher eukaryotes contains an RNA-binding domain and is also responsible for interactions with PRIP, CREB-binding protein (CBP), p300, and PPAR-binding protein (PBP) (Misra et al. 2002). The C-terminus of PIMT binds S-adenosyl-L-methionine (AdoMet), and mutagenesis of PIMT shows that the C-terminus spanning amino acids 504–853 are sufficient for its methyltransferase activity (Misra et al. 2002; Enunlu et al. 2003; Yedavalli and Jeang 2010). Additionally, the C-terminal methyltransferase domain of human PIMT/TGS1, consisting of the amino acids 576–853, is able to complement the cold-sensitive phenotype of a yeast *tgsl*Δ strain, demonstrating that the human TGS1 methyltransferase domain is a true functional ortholog of the yeast enzyme (Hausmann et al. 2008). PIMT/TGS1 in human cells is distributed diffusely in the cytoplasm and is also found in the nucleus, where it is concentrated in Cajal bodies (Yedavalli and Jeang 2010); however, in yeast cells, it has been reported that TGS1 localizes to the nucleolus (Mouaikel et al. 2002). There is evidence that PIMT/TGS1 in human cells is a nucleocytoplasmic shuttling protein, which uses a CRM1 (see ► CRM1)-dependent nuclear export pathway to exit the nucleus; indeed, treatment of HeLa cells with leptomycin B (LMB – a potent inhibitor of CRM1-mediated nuclear export of proteins) was found to result in nuclear accumulation of PIMT (Yedavalli and Jeang 2010).

Other motifs found in human PIMT include a classical AdoMet-binding site composed of ⁶⁹⁴VVDAFCGVGGN⁷⁰⁴ and ⁷¹⁷IAIDI⁷²¹ and a m⁷G-binding site comprised of ⁷⁶³SPPWGG⁷⁶⁸ (Misra et al. 2002; Hausmann et al. 2007, 2008; Monecke et al. 2009).

Functions of PIMT/TGS1

Two roles ascribed to PIMT are those of a transcriptional cofactor (Zhu et al. 2001; Misra

et al. 2002) and a trimethylguanosine synthase (Zhu et al. 2001; Mouaikel et al. 2002; Enunlu et al. 2003; Yedavalli and Jeang 2010). PIMT was first identified as a nuclear receptor coactivator (PRIP/NCOA6)-interacting protein containing RNA binding and methyltransferase motifs suggesting dual functions in transcription and RNA hypermethylation (Zhu et al. 2001). Little more is known about the role of PIMT/TGS1 in transcription, other than its interaction and regulation of PRIP, CBP/p300, and PBP (Misra et al. 2002). However, the identification of trimethylguanosine synthase activity for PIMT and yeast TGS1 has spawned additional studies exploring its functions as an RNA trimethylguanosine transferase. In eukaryotes, an m⁷G cap is added to newly transcribed RNA polymerase II (RNAP II) transcripts (Topisirovic et al. 2011). A subset of RNAP II-transcribed cellular RNAs, including small nuclear RNA (snRNA), small nucleolar RNA (snoRNA), and telomerase RNA (TLC1), acquires two additional methyl modifications to the m⁷G cap at exocyclic N₂ position to form the TMG cap (Mouaikel et al. 2002; Maxwell and Fournier 1995; Gallardo and Chartrand 2008). In yeast, deletion of the *TGS1* gene abolishes the conversion of the m⁷G to TMG caps for both snRNA and snoRNA (Mouaikel et al. 2002; Hausmann et al. 2007).

In genetic screens of yeasts, *Tgs1* was shown to be nonessential for growth of budding and fission yeasts (Mouaikel et al. 2002; Topisirovic et al. 2011). This result is surprising given that TMG capping is found on so many important yeast cellular RNAs including snRNA, snoRNA, and telomerase-associated TLC1 RNA. The *tgsl*Δ *Schizosaccharomyces pombe* grows normally, notwithstanding the absence of TMG caps on its U1, U2, U4, and U5 snRNAs (Mouaikel et al. 2002; Hausmann et al. 2007). The equivalent *tgsl*Δ mutation of *S. cerevisiae* causes a growth defect at cold temperatures, although *tgsl*Δ cells grow as well as TGS1 cells at 34 °C. Additionally PIMT/Tgs1 depletion by RNA interference in HeLa cells, which have reduced Tgs1 mRNA levels to 8% of the control value and Tgs1 protein levels to below the limit of detection, had no effect on cell growth (Lemm et al. 2006), suggesting that

mammalian somatic cells, like fungi, do not require TMG modifications for viability (Mouaikel et al. 2002; Hausmann et al. 2007; Lemm et al. 2006). However, TMG synthesis plays an essential role during *Drosophila* and mouse development (Komonyi et al. 2005; Jia et al. 2012). Mutations in the PIMT/Tgs1 methyltransferase active site caused lethality at the early pupal stage, which is consistent with findings seen upon the depletion of TMG-containing RNAs in *Drosophila* (Komonyi et al. 2005). Also embryonic lethality at E3.5 was observed in mice disrupted for PIMT gene with failed development around the blastocyst stage and at time of uterine implantation (Jia et al. 2012). These embryos show reduced expression of Oct4 and Nanog transcription factors with a failure to form an inner cell mass (Jia et al. 2012).

The 7-Methylguanosine Cap of HIV-1 Unspliced RNA is a Substrate of PIMT

The capping of viral RNAs has not been investigated as extensively as that of cellular RNAs. It has been generally assumed that, like cellular mRNAs, many viral RNAs have a 5' m7G cap, and viruses that replicate in the nucleus use the cellular capping machinery while viruses that replicate in the cytoplasm encode their own capping enzymes (Banerjee 1980; Ferron et al. 2012). However, the limited number of viral RNA capping studies point to a surprisingly diverse range of cap modifications (Yedavalli and Jeang 2010; Banerjee 1980; Ferron et al. 2012; HsuChen and Dubin 1976; van Duijn et al. 1986).

HIV-1 expresses both unspliced and spliced RNAs (see ► [HIV-1 Rev Expression and Functions](#)). The export of spliced and unspliced HIV-1 RNAs from the nucleus to the cytoplasm is a complex process, because eukaryotic cells normally choose to retain unspliced RNAs in the nucleus. To overcome this retention, HIV-1 encodes a Rev protein (see ► [HIV-1 Rev Expression and Functions](#)) that participates in the export of unspliced/partially spliced viral RNAs from the nucleus to the cytoplasm by binding to a cis-RNA element (RRE, *Rev response element*), which is present in unspliced (9 kb) and partially spliced

HIV-1 transcripts (4 kb) but is not found in spliced (1.8 kb) viral RNA. Several cellular factors including CRM1 (see ► [CRM1](#)), Ran, FG-repeat nucleoporins, RIP/RAB protein, DDX3, DDX1, RNA helicase A (RHA), and matrin 3 cooperate with Rev/RRE to facilitate the export of unspliced/partially spliced transcripts (see ► [DDX3, Cofactors, and RNA Export](#)) (Nekhai and Jeang 2006; Yedavalli and Jeang 2011). It was recently reported that PIMT hypermethylates selectively the RNA cap of unspliced and partially spliced HIV-1 transcripts to increase their cytoplasmic distribution (Yedavalli and Jeang 2010). PIMT is recruited by Rev to RRE-containing transcripts and then the Rev-recruited PIMT hypermethylates the m7G cap on these RNAs to a TMG cap. The activity of PIMT appears to be selective for only RRE-containing HIV-1 RNAs, while fully spliced viral transcripts, which do not contain the RRE sequence, are not TMG capped. How the TMG cap acts to facilitate the cytoplasmic expression of the RNA remains not understood, but one suggestion is that the TMG cap may be recognized by CRM1 which along with PHAX (Yedavalli and Jeang 2010; Gallardo and Chartrand 2008; Yedavalli and Jeang 2011), then directs the transcript for nuclear export. CRM1 and PHAX are involved in the nucleocytoplasmic and intranuclear trafficking of TMG cap-containing RNA, the nuclear export of snRNA and TLC RNA, and the nucleolar localization of snoRNA (Gallardo and Chartrand 2008; Yedavalli and Jeang 2011; Verheggen and Bertrand 2012). Multiply spliced HIV-1 RNAs, rather than using the CRM1-dependent route, exit the nucleus through the NXF1/TAP pathway.

Conclusion

The study of PIMT has added to the understanding of the complex nucleus to cytoplasm export processes for HIV-1 unspliced and partially spliced RNA. The recognition of m7G cap by eIF4E is a requirement for mRNA-ribosome association and the translation of the mRNA (Topisirovic et al. 2011). PIMT has been shown to increase the expression of proteins encoded by

HIV-1 unspliced transcripts such as RRE-containing HIV-1 Gag mRNA. Additional published data suggest that TMG capping per se is not a barrier to ribosome translation of RNAs (Yedavalli and Jeang 2010; Banerjee 1980; Ferron et al. 2012; Van and Hirsh 1990; Maroney et al. 1995) and that mechanism(s) may exist for translating TMG-capped RNA. More recently it was found that translation of HIV-1 unspliced and partially spliced RNA is sustained under conditions which suppress the expression of cellular and viral spliced transcripts (Sharma et al. 2012). Thus, HIV-1 unspliced and partially spliced transcripts predominantly associate with nuclear cap-binding complex (CBC)/cap-binding protein 80 (CBP80) in contrast to the finding that fully spliced viral and cellular mRNAs are associated with eIF4E for translation in the cytoplasm. Accordingly, PIMT-mediated TMG cap modification can provide a mechanism for HIV-1 to synthesize structural proteins during Vpr-induced suppression of eIF4E-dependent translation. One can speculate that TMG cap modification by PIMT/TGS1 provides a mechanism that can also be exploited by selected cellular mRNAs during conditions of cellular stress to bypass the down-regulation of eIF4E-dependent translation.

TMG capping of HIV-1 RNA by PIMT/TGS1 can also be a potential drug target for inhibiting HIV pathogenesis (see ► [Cellular Cofactors of HIV as Drug Targets](#)) (Ferron et al. 2012). RNA methylation inhibitors in some instances have been used successfully to inhibit the replication of herpes simplex virus, vesicular stomatitis virus, flavivirus, and other viruses (Issur et al. 2011). Emerging evidence also indicates that inhibitors of PIMT-mediated RNA cap hypermethylation can also suppress HIV-1 replication (Yedavalli and Jeang 2010).

PKR and HIV Replication

Anne Gatignol

Virus-Cell Interactions Laboratory, Lady Davis Institute for Medical Research, Montréal, QC, Canada

Departments of Medicine and Microbiology and Immunology, McGill University, Montréal, QC, Canada

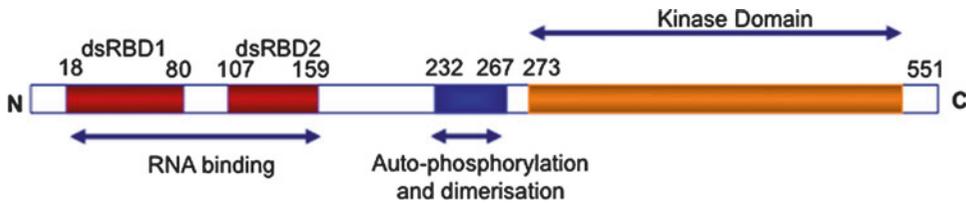

Definition

The protein kinase activated by RNA, PKR, is an interferon-induced cellular restriction factor for HIV. It phosphorylates its downstream target, the

alpha subunit of the eukaryotic translation initiation factor 2 (eIF2 α), which blocks translation initiation. PKR is expressed and activated at the beginning of HIV infection, which contributes to a block in virus expression and replication. PKR is activated by low levels of the HIV transactivation response (TAR) RNA element. During HIV replication, PKR activation is counteracted in part by the viral Tat protein and by large amounts of the TAR RNA. PKR activation is also strongly inhibited by cellular factors such as the TAR RNA-binding protein (TRBP), the adenosine deaminase acting on RNA (ADAR1), and the PKR activator (PACT), which form a multiprotein complex around PKR during HIV replication.

Introduction

Following HIV infection, interferon (IFN)- α and interferon- β are produced mainly in plasmacytoid dendritic cells through innate immune detection of viral RNA. IFNs are secreted and inhibit HIV replication in primary macrophages and T cells by inducing the production of IFN-stimulated genes (ISGs), which block several steps of the viral replication cycle. PKR was originally characterized as one of these ISGs induced by viral infection (Meurs et al. 1990). It is a 551-amino-acid-long double-stranded RNA-binding protein (dsRBP) that has two dsRNA-binding domains (dsRBDs) and a serine/threonine kinase domain (Fig. 1). PKR is central to innate cellular defense strategies with strong antiviral and antigrowth activities. PKR is present in the cell as an inactive monomer. It becomes activated by autophosphorylation after binding to low levels of dsRNA through its two dsRBDs and by dimerization. Once active, PKR phosphorylates several substrates including eIF2 α . Phosphorylated eIF2 α blocks the ability of eIF2B to renew the eIF2-GTP-Met-tRNA_i ternary complex required for protein synthesis initiation and is a critical component of antiviral and cell growth pathways (Sadler and Williams 2007). Viruses and cells have evolved to counteract the PKR antiviral and antigrowth pathway by a variety of mechanisms. In the context of HIV replication, the direct

PKR and HIV Replication, Fig. 1 Schematic representation of PKR. PKR is a 551-amino-acid-long serine/threonine kinase. It has two dsRBDs, an autophosphorylation and dimerization domain and a kinase domain

activity of viral components is not sufficient to prevent PKR activation. Instead, cellular proteins and virus-induced cellular mechanisms contribute to PKR inhibition to allow HIV production (Clerzius et al. 2011).

PKR Activation During HIV Replication

PKR is transcriptionally induced in lymphocytic T cells after HIV infection and activated at the beginning of an infection, but it is deactivated when the virus replicates actively (Clerzius et al. 2009, 2013). PKR is best known to be activated by dsRNAs longer than 30 base pairs, but other natural compounds like heparin, certain cytokine mRNAs, and its activator PACT also induce its phosphorylation. In the cell, PKR acts as a dsRNA sensor in response to viral infection. Low amounts of dsRNA promote PKR dimerization, autophosphorylation, and activation of the kinase function. Activated PKR subsequently phosphorylates several targets, including eIF2 α , whose phosphorylation on serine 51 prevents its recycling for ongoing translation (Sadler and Williams 2007).

In cell culture, PKR overexpression blocks HIV expression and viral replication very effectively, which shows its activity as a restriction factor (Benkirane et al. 1997; Adelson et al. 1999; Daher et al. 2001). HIV mRNAs all start with the structured stem-bulge-loop TAR RNA at their 5' end. PKR is activated by low amounts of the TAR RNA *in vitro*, whereas high concentrations inhibit its kinase function (Bannwarth and Gatignol 2005). Astrocytic brain cells provide an example of cells that do not replicate HIV efficiently due in part to a

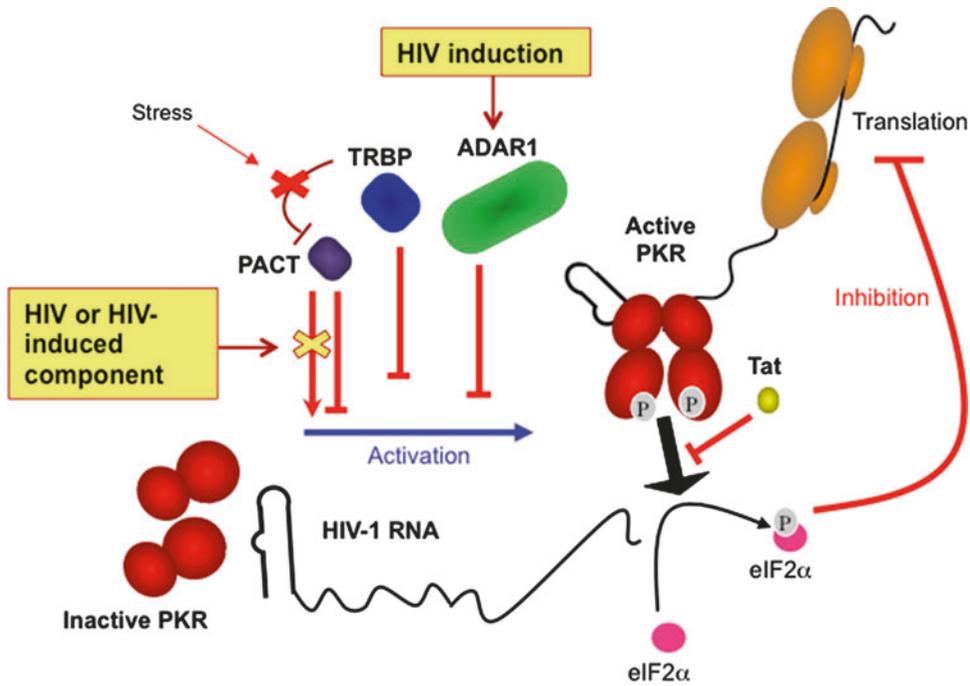

heightened PKR activation caused by the weak expression of PKR inhibitors (Ong et al. 2005). Despite PKR activation by the TAR RNA, HIV replicates efficiently in many permissive cell lines, including lymphocytes and monocytes. Various mechanisms leading to specific counteractions of PKR activation by viral and cellular proteins in permissive cells have been elucidated (Fig. 2).

Control of PKR Activation by the Viral Tat Protein

The HIV Tat protein directly binds to PKR *in vitro* and in cells and contributes to its inhibition. The Tat amino acids sequence required for PKR interaction lies in residues 40–58 encompassing the arginine-rich region important for TAR RNA binding and for Tat function. Tat inhibits the activation of the kinase by both RNA-dependent and RNA-independent mechanisms. It sequesters dsRNA, it interacts and prevents PKR autophosphorylation, and it acts as a pseudosubstrate for PKR due to a sequence homology between an eIF2 α and a Tat motif (Bannwarth and Gatignol 2005; Clerzius et al. 2011).

Control of PKR Activation by the Cellular TRBP Protein

TRBP is a cellular dsRBP, whose cDNA was isolated based on the protein's ability to bind HIV TAR RNA. TRBP also binds small interfering (si)RNAs and is an integral part of the RNA-induced silencing complex, which mediates RNA interference (Gatignol et al. 1991; Daniels

PKR and HIV Replication, Fig. 2 Mechanisms of the inhibition of PKR activity during HIV replication. PKR is inhibited by the viral Tat, which acts as a pseudo-substrate. The cellular TRBP and ADAR1 proteins directly bind to PKR and inhibit its activation. HIV replication induces an increase in ADAR1 expression. TRBP heterodimerization with PACT prevents PACT activation of

PKR, but this is reversed by stress. HIV or an HIV-induced component changes PACT function to become an inhibitor of PKR (Adapted from Daniels and Gatignol (2012) with permission of American Society for Microbiology. Copyright © American Society for Microbiology))

and Gatignol 2012). TRBP has two dsRBDs and a KR-helix motif within dsRBD2 mediates the strongest interaction with TAR RNA. TRBP also has a third domain called Medipal, which mediates protein-protein interactions identified for Merlin, Dicer, and PACT. The dsRBDs also mediate protein-protein interactions with PKR and PACT. TRBP enhances the cellular translation of HIV RNA by relieving a block due to TAR RNA and by blocking PKR activation. TRBP inhibition of PKR occurs by direct binding, by dsRNA sequestration, and by PACT binding and inhibition (Clerzius et al. 2011; Daniels and Gatignol 2012; Burugu et al. 2014). TRBP rescues HIV expression and replication in cells where the virus was suppressed by overexpressed PKR (Benkirane et al. 1997; Daher et al. 2001).

Astrocytic cells infected with HIV provide a natural model of the direct involvement of TRBP in the counteraction of PKR activation. These

cells have a major block in the translation of HIV structural proteins and an enhanced PKR activation, which blocks HIV production. Astrocytes express a low amount of TRBP, which is not sufficient to counteract PKR activation and allow HIV production. This low TRBP expression is due to a weak activity of its promoter caused by a partial lack of specific transcription factors. Overexpression of TRBP partially rescues this block in HIV replication (Bannwarth et al. 2001; Ong et al. 2005). Silencing TRBP by siRNAs or short hairpin RNAs inhibits HIV expression and replication, suggesting that the protein is required for HIV replication as a counteracting PKR factor (Christensen et al. 2007; Eekels et al. 2011). The cell type differences lead to the conclusion that HIV has evolved to replicate in cells that express a large amount of TRBP to suppress PKR activation (Clerzius et al. 2011).

Control of PKR Activation by the Cellular ADAR1 Protein

IFNs also induce the production of ADAR1. ADAR proteins convert adenosines to inosines in a process called RNA editing, which then results in A to G mutations in RNAs. RNA editing affects transcripts and noncoding RNAs (Nishikura 2010). In addition, ADAR1 also binds to and inhibits PKR activation in the context of virus infections. Full-length ADAR1 enzymes possess two N-terminal Z-DNA-binding domains (DBDs), three central dsRBDs, and a C-terminal deaminase domain. Three related isoforms of ADAR1 are found in human cells: the IFN-inducible cytoplasmic 150-kDa protein and the constitutively expressed nuclear 110-kDa and 80-kDa proteins, which lack the first Z-DBD and both Z-DBDs plus the first dsRBD, respectively. The expression of ADAR1 is induced during HIV infection of lymphocytic cell lines and primary lymphocytes, and this induction positively correlates with the expression of HIV proteins (Clerzius et al. 2009, 2013). The 150-kDa and the 110-kDa forms of ADAR1 bind to PKR, inhibit its activity, and increase the cellular susceptibility to several viral infections. ADAR1 is present in a multiprotein complex formed around PKR during HIV infection of lymphocytes. It reverses the block in HIV expression and virus production mediated by PKR in HIV-producing cells. It also increases HIV production from a transfected HIV molecular clone in astrocytic cells, which have an increased PKR response. ADAR1 mediates PKR inhibition by direct binding through its first dsRBD (Clerzius et al. 2009, 2011). Therefore, ADAR1 contributes to the inhibition of PKR activation and consequently enhances HIV expression and production. ADAR1 expression is triggered after IFN production and is further boosted by HIV replication.

Control of PKR Activation by the Cellular PACT Protein

PACT was cloned from a cDNA library based on its interaction with a catalytically inactive PKR. It

is a cellular stress-inducible PKR activator, with proapoptotic functions in the absence of dsRNA or viral infection. PACT is 313 amino acids long with two dsRBDs, and its PKR-activating domain is located in its C-terminus between amino acids 240 and 300 (Patel and Sen 1998; Patel et al. 2000). PACT is highly homologous to TRBP but has opposite functions on PKR. PACT naturally binds to TRBP in cells where TRBP is abundant, and the heterodimer acts as an inhibitor of PKR. Indeed, PACT acts as a PKR activator in cells where TRBP is in low concentration, whereas it acts as a PKR inhibitor in cells with high amounts of TRBP. TRBP-PACT interaction occurs through the two dsRBDs and the Medipal domain in both proteins. A cellular stress dissociates TRBP-PACT heterodimers and releases PACT function as an activator of PKR. In astrocytes that have low TRBP expression, PACT activates PKR with concomitant eIF2 α phosphorylation in the absence of stress. It consequently inhibits the expression of a reporter gene produced from the HIV promoter (Laraki et al. 2008; Daher et al. 2009).

During HIV replication, PACT expression is increased when HIV is expressed at high levels and the protein is pulled down with the multiprotein complex associated with PKR, ADAR1, and TRBP. Furthermore, PACT is unable to activate PKR and becomes a PKR inhibitor in HIV-expressing cells. This change of function occurs both in cells with high or low HIV production and in cells with high or low TRBP expression. Indeed, PACT induces an increased viral expression and production with concomitant PKR and eIF2 α dephosphorylation in HIV-transfected HEK293T cells and in astrocytes (Clerzius et al. 2013). The conclusion of these observations is that an HIV component or an HIV-induced cellular protein reverses PACT activity on PKR.

Conclusion

PKR is activated and acts as a restriction factor at the beginning of HIV infection. Activation is due to low levels of the viral TAR RNA, but high

levels of TAR reverse this function. The viral transactivator Tat inactivates PKR by acting as a competitive substrate. The cellular TRBP inhibits PKR activation by direct binding and by competing with dsRNA. HIV induces the production of high levels of ADAR1, which binds to and inhibits PKR activation. Finally, HIV reverses the function of PACT, which becomes a PKR inhibitor in HIV-replicating cells. To counteract a block by PKR activation, HIV has evolved to replicate in cells that express a large amount of TRBP, it induces the production of ADAR1, and it induces mechanisms, which reverse the PACT function. These mechanisms provide tools to act on these interactions to enhance PKR activation for a better control of persistent HIV replication in replicating cells or in latently infected reservoir cells (Clerzius et al. 2011; Burugu et al. 2014).

²Department of Internal Medicine, University of California, San Diego Moores Cancer Center, La Jolla, CA, USA

Definition

Plasmablastic lymphoma (PBL) is a rare, aggressive lymphoma that is mainly seen in the human immunodeficiency virus (HIV)-positive population. It is a mature large B-cell lymphoma exhibiting plasmablastic morphology and with terminal B-cell, namely, plasma cell-like differentiation. PBL has a tendency to occur in the oral cavity; however, extraoral involvement is not infrequently encountered. While PBL shares some overlapping morphologic and immunophenotypic features with other mature B-cell lymphomas, PBL is currently classified as a distinct entity in the 2008 *WHO Classification Tumours of Haematopoietic and Lymphoid Tissues* (Delecluse et al. 1997).

Introduction

Plasmablastic lymphoma (PBL) is a rare B-cell lymphoma that predominately arises in patients with HIV infection. PBL was originally described by Delecluse et al. in 1997 (Delecluse et al. 1997). It was documented as a variant of ► **diffuse large B-cell lymphoma (DLBCL)** with distinctive immunohistological features consistent with plasmacellular differentiation; the initial cases describing PBL cells expressed VS38c, frequently stained positive for CD79a, and demonstrated monoclonal rearrangement of the immunoglobulin (*Ig*) heavy chain gene. In these first reported cases, all presented in the oral

cavity, and a majority of patients were infected with HIV. Since the initial description of PBL, a number of case reports and series have been published further describing this unique lymphoproliferative disorder, which has now been documented to occur at many other sites other than the oral cavity. While PBL shares some overlapping morphologic and immunophenotypic features with other mature B-cell lymphomas, it is currently classified as a distinct entity in the 2008 *WHO Classification Tumours of Haematopoietic and Lymphoid Tissues* (Swerdlow et al. 2008).

PBL can be a diagnostic challenge given its atypical morphology and immunohistochemical profile similar to other lymphomas with plasmablastic differentiation such as primary effusion lymphoma (PEL) and plasmablastic plasma cell myeloma (PCM). The clinical outcome is typified by a highly aggressive course. At present, there are no established standard of care treatments for PBL in the era of highly active antiretroviral therapy (HAART). In addition to specific therapy for PBL, HAART appears to be an important component of management. With increased understanding of the pathophysiology of PBL, more targeted therapy and future treatment options may be available for this unique and aggressive B-cell lymphoproliferative disorder.

Epidemiology

The relationship between PBL and immunosuppression has been clearly established. PBL is most commonly diagnosed in the setting of HIV infection, and to date, a majority of patients with PBL have concurrent HIV. PBL can be seen in HIV-negative patients as well. However, even in HIV-negative cases, immunosuppression often plays a large role in pathogenesis as a number of HIV-negative patients have immunosuppression from solid organ transplantation, steroid therapy, or concurrent malignancy (Castillo et al. 2010; Teruya-Feldstein et al. 2004; Ustun et al. 2009). Other cases of PBL occur in the setting of decreased immune surveillance, such as in advanced age (Colomo et al. 2004).

PBL accounts for 2.6% of all HIV-associated non-Hodgkin lymphomas (NHLs) (Carbone et al. 1997). Given that the majority of patients with PBL have HIV, the disease in the United States occurs predominantly in males. The median age at diagnosis in the HIV population is 38 years (Castillo et al. 2008). Due to its rarity, it is not clear as to whether there are racial or ethnic predispositions. However, PBL has been reported in Europe, Asia, Africa, Australia, South America, and North America (Castillo et al. 2012; Castillo and Reagan 2011).

Pathogenesis

PBL is, in essence, an aggressive mature large B-cell lymphoma that exhibits plasmablastic morphology and terminal B-cell, namely, plasma cell-like differentiation. The postulated normal counterpart of PBL is the plasmablast. By analyzing mutations of *Ig* variably heavy chain (*IgVH*) for somatic hypermutation and *BCL-6* genes, Gaidano et al. divided PBL of the oral cavity into at least two subgroups: a subset that carries the molecular clues of germinal center (GC) transit (hypermutated *IgVH* with a subset of which showing antigen stimulation) and thus conceivably originates from a B-cell subset corresponding to post-GC cells and another subset that appears to originate from naïve B-cells (devoid of *IgVH* mutations) (Bose et al. 2009).

Clinical Presentation

Clinical presentation of PBL is largely heterogeneous. PBL can be the initial presentation of HIV infection. PBL has a tendency to occur in the oral cavity; however, extraoral involvement is not infrequently encountered (Castillo et al. 2008). Since its initial report in the oral cavity in patients with HIV in 1997 (Delecluse et al. 1997), PBL has been found to occur outside of the oral cavity in both HIV-infected and uninfected patients. It has been reported to arise in the retro-orbital; nasal cavity; jaw; parotid gland; larynx; bone marrow; lung; gastrointestinal tract including the

esophagus, stomach, small intestine, colon, and anorectal region; liver; retroperitoneum; testis; penis; vulva; skin; and bone. Central nervous system (CNS) involvement including the orbit, leptomeninges, and parenchyma as well as peripheral nervous system involvement have been reported to occur with systemic disease at the time of diagnosis or at the time of relapse (Colomo et al. 2004; Riedel et al. 2008).

A high percentage of cases of PBL present with masses in the oral cavity. Masses in the gingiva, hard palate, and alveolar mucosa are common. PBL also may arise from areas next to the oral cavity such as the mandible. Patients typically present with symptoms localized to the disease site(s), though others may present with systemic symptoms such as fatigue, unexplained fevers, drenching night sweats, or weight loss. With CNS involvement, symptoms such as altered mental status, headaches, or blurry vision are common.

HIV-positive cases usually present either as early stage IE (extranodal) disease or advanced stage IV disease (Ustun et al. 2009). There is a paucity of data documenting associated laboratory abnormalities at times of diagnosis; however, lactate dehydrogenase (LDH) was noted to be elevated in a majority of patients in one series (Castillo et al. 2012). The CD4+ count at diagnosis varies. In a study of 112 patients spanning from the early HAART to present HAART era, the median CD4 count at diagnosis of PBL was at 178 cells/mm³ (range, 10–498 cells/mm³) (Castillo et al. 2008). The duration of HIV infection before diagnosis was 5 years (range, 0–20 years). In a smaller study of 53 patients in the HAART era, the median CD4+ count was 206 cells/mm³ (range, 5–683 cells/mm³), and the median viral load at presentation was 261,560 copies/mL (range, from undetectable to 4.7 million copies/mL) (Castillo and Reagan 2011). In this study, the duration between HIV infection and PBL diagnoses was 8.9 years.

Diagnosis and Evaluation

Clinical features are not adequate to distinguish PBL from other malignancies that arise in the oral

cavity, such as carcinoma, melanoma, and other types of lymphomas. Given extraoral involvement can occur at many other sites, the differential diagnosis can range from carcinomas to other types of lymphoma or opportunistic infections. A biopsy of the mass lesion or enlarged lymph node is needed for diagnosis. Whenever possible, an excisional biopsy of suspected lesions is needed to further define the morphologic and immunophenotypic features of PBL and distinguish it from other types of lymphomas and myeloma.

Full staging scans are indicated at the time of diagnosis. Given the rarity of the disease, the usefulness of PET scans for diagnosis and prognostication in PBL is not specifically established. There are only few case reports documenting FDG uptake in PBL of the oral cavity and metastatic lesions of PBL affecting the skin, testis, and bone. It must be noted that FDG uptake can occur in HIV-related adenopathy, and therefore false positivity with PET should be anticipated (Makis et al. 2011). Marrow involvement is not infrequent; bone marrow biopsies are recommended as for any aggressive lymphoma. Given its aggressive nature and reported cases of CNS involvement, a lumbar puncture to assess for CNS disease is appropriate as is CNS imaging in the setting of headaches or neurologic symptoms.

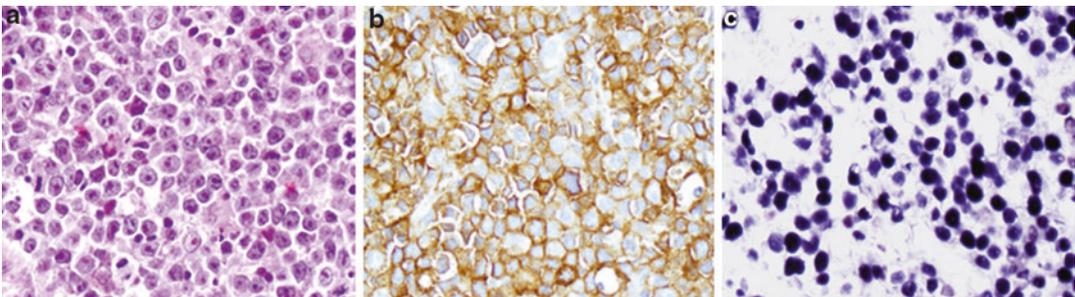

Pathologic Features

Morphology and Immunophenotype

The 2008 *WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues* (Swerdlow et al. 2008) recognizes PBL as a distinct subtype of very aggressive mature large B-cell lymphoma (Swerdlow et al. 2008). While most of PBL occur de novo, secondary/transformed PBL from low-grade B-cell lymphoma including follicular lymphoma and plasmacytoma has been described.

Histologically, PBL tends to show a diffuse and cohesive growth pattern (Swerdlow et al. 2008). Cytologically, cells from PBL are medium-sized to large cells showing a spectrum of cytology ranging from pure immunoblastic morphology to immunoblasts or plasmablasts with more plasmacytic differentiation. Typically, the lymphoma cells show centrally or slightly eccentrically located nuclei with round to oval nuclear contours, vesicular to condensed nuclear chromatin, one prominent centrally located nucleoli with or without recognizable perinuclear clearing mimicking perinuclear hof often seen in plasma cells (Fig. 1a). In addition, brisk mitoses and numerous apoptotic bodies are easily appreciated.

Immunohistochemically, the tumor cells from PBL are typically positive for plasma cell markers including CD138 and IRF4/MUM-1 and

Plasmablastic Lymphoma, Fig. 1 (a) and (b) Representative microphotographs of a plasmablastic lymphoma (PBL) from an anal fistula in a 46-year-old male with HIV infection. H&E shows the atypical lymphoid cells which are large with oval nuclear contours, vesicular nuclear chromatin, conspicuous prominent nucleoli, and relative

abundant cytoplasm (a). The lymphoma cells are positive for CD45 (b), as well as Oct2 and CD30 (not shown). These cells are negative for CD20, CD79a, and HHV-8/KSHV (not shown). (c) PBL cells from an oral cavity of a 32-year-old male are positive for EBV by in situ hybridization (EBER). All images' original magnification is 400×

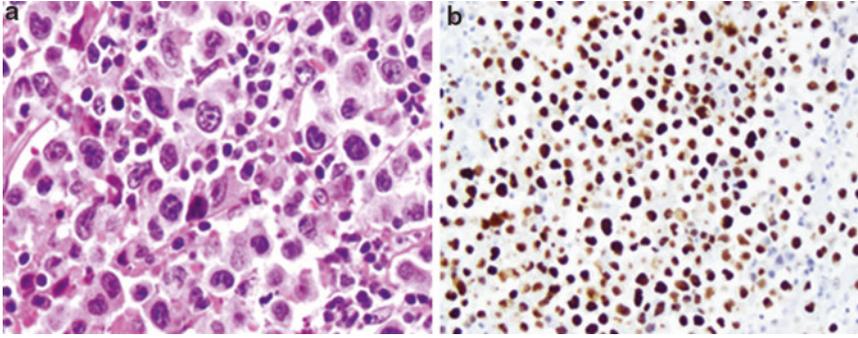

immunoglobulin light chain (kappa or lambda), activation markers such as CD30, and epithelial markers such as epithelial membrane antigen (EMA) and CD79a (Bibas et al. 2010). However, they are negative or rarely positive for mature B-cell antigens including BCL-6, CD20, CD22, CD23, and PAX-5 (Carbone et al. 1997). CD45, commonly known as leukocyte common antigen (LCA) (Fig. 1b), shows unequivocal positivity in 71% of the 14 PBL cases reported by Dong et al. (2005). The tumor cells are typically positive for ► [Epstein-Barr virus \(EBV\)](#), not by immunohistochemistry (IHC) for latent membrane protein (LMP), but by in situ hybridization to assess the expression of EBV-encoded RNA (EBER) (Fig. 1c; Dong et al. 2005).

Human herpesvirus-8 (HHV-8), also known as ► [Kaposi sarcoma herpesvirus \(KSHV\)](#), is typically absent in PBL (Carbone et al. 1997; Bibas et al. 2010), although occasional HHV-8/KSHV-positive PBL cases have been reported in the literature. For example, Dong HY et al. reported 60% (6/10) HHV-8/KSHV positivity in 10 cases of PBL in which HHV-8/KSHV status was evaluated by polymerase chain reaction (PCR); however, only 10% (1/10) showed HHV-8/KSHV positivity by IHC. Goedhals J et al. have also showed 12.5% (1/8) HHV-8/KSHV positivity in the 8 PBL cases analyzed by PCR, but none of them (0%, 0/8) was positive for HHV-8/KSHV by IHC. Therefore, it is the view of the 2008 *WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues* that HHV-8/KSHV is absent in PBL (Bibas et al. 2010). The current notion is that if a large B-cell lymphoma with plasmablastic morphology exhibits HHV-8/KSHV positivity especially by IHC then it could represent one of the following three entities: an extra-cavitary ► [primary effusion lymphoma \(PEL\)](#), a large B-cell lymphoma arising in HHV-8-associated multicentric Castlemans disease, or a yet to be defined HHV-8/KSHV(+) large B-cell lymphoma recently proposed by one of the authors.

Differential Diagnosis

Some of the lymphomas that must be distinguished from PBL include the following:

- (a) *Plasmablastic plasma cell myeloma (PCM)*
PBL shares overlapping cytomorphological and immunohistochemical features with those of plasmablastic PCM to the extent that Vega et al. claim these two entities have nearly identical immunophenotypic profiles except that EBV is absent in all 7 cases of plasmablastic PCM but is present in all 5 cases of PBL they studied. While BCL-6, CD4, CD10, CD79a, and PAX-5 were detected more often in PBL than in plasmablastic PCM, no statistical significance between PBL and PCM was seen in any of the aforementioned markers. Thus, separation of PBL from plasmablastic PCM has to be based on multiple parameters including, but not limited to, clinical history of PCM, presence or absence of paraprotein and the amount of paraprotein, lytic bone lesion, kidney function, morphology, immunophenotype, and genetics.
- (b) *Extra-cavitary ► primary effusion lymphoma (PEL)*
PBL can be confused with PEL, especially the extra-cavitary form, easily based on cytomorphological features alone; therefore, the differential diagnosis between PBL and extra-cavitary PEL has to be based on other factors such as extensive immunophenotyping and presence or absence of effusion in the body cavities. Generally speaking, the cells from PEL are larger and show more cytologic atypia (Fig. 2a). While PBL and extra-cavitary PEL share many overlapping immunohistochemical profiles, it is generally accepted that PBL is negative, but extra-cavitary PEL is typically positive for HHV-8/KSHV (Fig. 2b).
- (c) *Large B-cell lymphoma arising in HHV-8-associated multicentric Castlemans disease*
PBL should be differentiated from large B-cell lymphoma arising in HHV-8-associated multicentric Castlemans disease (MCD), which occurs more often in HIV(+) patients with MCD. While both entities display plasmablastic cytomorphology, the neoplastic cells from the large B-cell lymphoma

Plasmablastic Lymphoma, Fig. 2 Representative microphotographs of an extra-cavitary primary effusion lymphoma from an enlarged right inguinal lymph node from a 77-year-old male with HIV and TB infection. The tumor cells are large with irregular to indented nuclear

contours, relative abundant cytoplasm, and conspicuous nucleoli (a H&E, original magnification of 400×). The lymphoma cells are strongly positive for HHV-8/KSHV (b original magnification of 200×)

arising in HHV-8-associated MCD generally express HHV-8/KSHV latency-associated nuclear antigen (LANA), are typically positive for IgM and lambda-light chain restriction, and are negative for CD138.

(d) *Other aggressive large B-cell lymphomas*

DLBCL, not otherwise specified (DLBCL, NOS), occurring in HIV(+) patients often exhibit plasmacytoid features. Despite cytomorphological overlap between PBL and DLBCL, NOS in the setting of HIV infection, the latter can be easily distinguished by its expression of most of the B-lineage specific and associated antigens.

Genetic Aberrancies

C-MYC rearrangements have been reported to be the most commonly encountered cytogenetic abnormalities. For example, in a large study of oral PBLs, Boy et al. reported rearrangement of the *MYC* gene in 60% of cases with the *IgH* locus as a partner gene in 51% of cases. Similarly, Valera et al. reported *MYC* rearrangements in 49% of 41 PBL cases they studied. By using fluorescence in situ hybridization, additional genetic abnormalities such as increased copy number of cyclin D1; gains of *MYC*, *BCL-2*, *BCL-6*, *MALT1*, and *PAX-5*; and aneuploidy for *BCL-6* were observed in 41, 20, 31, 41, 33, 32, and 28% of cases, respectively. However, no rearrangements of *BCL-2*, *BCL-6*, *MALT1*

(mucosa-associated lymphoid tissue 1), or *PAX-5* were detected in any PBL cases they examined (Castillo et al. 2010; Ustun et al. 2009).

By employing array-based comparative genomic hybridization (cCGH) technology, Chang et al. reported frequent segmental gains (>40%) of 1p36.11–1p36.33, 1p34.1–1p36.13, 1q21.1–1q23.1, 7q11.2–7q11.23, 11q12–11q13.2, and 22q12.2–22q13.3, which correlated with segmental gains occurring in high frequency in DLBCL regardless of HIV status.

Treatment

A key aspect of the treatment of PBL is the use of combination cytotoxic chemotherapy, which has been shown to provide a significant increase in survival in HIV-positive patients with PBL (Castillo et al. 2010). Patients treated with combination chemotherapy have an overall response rate (ORR) to chemotherapy of 77%, with 46% of patients achieving a complete response (CR) and 31% a partial response (PR).

HAART in addition to chemotherapy and/or radiotherapy can improve the prognosis of PBL. Good responses with HAART alone have been reported, but such responses are not usually durable. Correspondingly, relapsed PBL has been documented after cessation or interruption of HAART and subsequent drop in CD4 counts and

rise in viral loads. These cases of recurrence after disruption of HAART substantiate the finding that HAART is an important cornerstone in the treatment of PBL.

Despite the wide use of combined chemotherapy, there is no standardized treatment for PBL. Many treatments have been employed including CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone), hyper-CVAD (cyclophosphamide, vincristine, doxorubicin, and dexamethasone alternating with high-dose methotrexate and cytarabine), dose-adjusted EPOCH (etoposide, doxorubicin, vincristine, cyclophosphamide, prednisone), or CODOX-M/IVAC (cyclophosphamide, vincristine, doxorubicin, methotrexate, ifosfamide, etoposide, cytarabine) (Castillo and Reagan 2011). It is not currently known whether any particular treatment is more efficacious than others. A small study did not show any survival benefit comparing CHOP with more intense treatment, although the patients who received more intensive treatment may have had higher risk and more advanced disease, biasing the results. National Comprehensive Cancer Network (NCCN) currently suggests more aggressive regimens such as dose-adjusted EPOCH, hyper-CVAD, and CODOX-M/IVAC.

Newer drugs have been used in a few cases of PBL. Drugs used in multiple myeloma therapy, particularly the proteasome inhibitor bortezomib, have been reported to be active in cases of PBL (Bibas et al. 2010; Bose et al. 2009). In a report of a case of newly diagnosed concurrent HIV and PBL, bortezomib was administered at a dose of 1.3 mg/m² intravenously on days 1, 4, 8, and 11. Bortezomib was administered because of the patient's poor hepatic performance status and inability to tolerate cytotoxic chemotherapy. The patient had a dramatic response by PET after two doses.

Radiation alone or in combination with combined chemotherapy has been utilized (Castillo et al. 2008). However, it is unknown whether radiation alone or combination of radiation and chemotherapy is better than chemotherapy alone, particularly for stage I disease.

Due to the small number of patients with PBL, there is not a wealth of data regarding the utility of

autologous stem cell transplants in PBL. A few case reports of autologous stem cell transplants in patients with HIV-positive PBL have found varying clinical outcomes. Given the few case reports of transplantation for PBL, few conclusions can be reached for this modality of treatment.

Prognosis

Prior to widespread HAART use, the prognosis of PBL was poor. HAART in addition to chemotherapy and/or radiotherapy appears to improve the prognosis of PBL. In one retrospective study of HIV-positive patients from 2000 to 2010, the median survival was 15 months (Castillo et al. 2008). However, longer survivals have been reported in the literature. In a small retrospective study examining 19 patients with central pathology review confirmation of PBL, 1-year survival was 67% for 12 newly diagnosed patients, and 2 of 6 patients with relapsed refractory disease were alive 2 years post relapse. In another review of 6 HIV-positive patients with PBL, 4 out of 6 patients had a survival of 22 months or more. Interestingly, HIV-positive patients had a better overall survival (OS) than HIV-negative patients, possibly in part explained by immune reconstitution obtained with the addition of HAART. (Castillo et al. 2010)

In a study of 53 patients by Castillo et al., ECOG status ≥ 2 , stages III–IV, age-adjusted IPI score, and MYC rearrangement were associated with a poorer OS on a univariate analysis (Castillo et al. 2012). In another study of 157 patients, age ≥ 60 , advanced stage, bone marrow involvement, lack of chemotherapy, HIV-negativity, and Ki-67 $> 80\%$ were all prognostic factors in OS. The only independent factors in OS were advanced stage and lack of chemotherapy (Castillo et al. 2010). Patients who are not treated with chemotherapy have a median survival of only 3 months (Castillo et al. 2010). Oral versus extraoral involvement has not been shown to significantly alter OS (Castillo et al. 2010). Due to the relatively few cases of PBL with CNS involvement, it is difficult to conclude whether or not CNS involvement portends a poorer survival; of

the cases reported, median OS has ranged from months to a year or more.

Conclusions

PBL makes up an infrequent but distinct type of AIDS-related NHLs. Given its overlapping cytomorphological and immunohistochemical features, it is important to distinguish PBL diagnosis from other mature aggressive large B-cell lymphomas. More data and studies are needed to further clarify clinical prognosticators and to determine the most effective treatments of PBL. Updated survival data in the age of newer and current therapy with HAART will be important to best describe PBL in the present era.

Positive Health, Dignity, and Prevention (PHDP)

Junette McWilliams and Amy Knowlton
Department of Health, Behavior and Society,
Johns Hopkins Bloomberg School of Public
Health, Baltimore, MD, USA

Definition

Positive Health, Dignity and Prevention (PHDP) is an approach to HIV prevention that focuses on people living with HIV/AIDS (PLWHA). A PHDP approach involves interventions that empower PLWHA to (1) take care of their physical and mental health and well-being, (2) adopt behaviors that reduce their risk of transmitting HIV to others, and (3) actively participate in and provide leadership in HIV prevention and advocacy activities (USAID and ProjectSEARCH 2011).

Overview and History

Previous HIV prevention approaches that have targeted PLWHA have emphasized primary prevention and the role of PLWHA in reducing HIV transmission. Prevention for PLWHA has been referred to as positive prevention, prevention for positives, prevention with positives, and prevention by positives. Founded upon a human rights framework, Positive Health, Dignity and Prevention (PHDP) can be distinguished from these previous approaches by its emphasis on promoting the dignity, well-being, empowerment, and equality of PLWHA (USAID and ProjectSEARCH 2011). PHDP encompasses a broader perspective on and multiple levels of HIV prevention because it focuses on reducing PLWHA's risk for HIV transmission (secondary prevention) as well as improving their health and well-being in living with HIV/AIDS (tertiary prevention). The PHDP approach advocates for the integration of HIV prevention, medical treatment, health promotion, and empowerment for PLWHA (USAID and AIDSTAR-One 2011). This participatory, holistic approach espouses that PHDP interventions should be designed and implemented with the meaningful involvement of PLWHA, treating them humanely and with dignity, and promoting knowledge and skills, and an array of health, human, and social services and legal support (GNP+ and UNAIDS 2011).

PHDP interventions encourage empowerment and self-determination among PLWHA, providing them with resources and support so they may be the managers of their own health and well-being, as well as valuable contributors to their communities, including their families, neighborhoods, social networks, and other affiliation-based groups (e.g., men who have sex with men [MSM] or persons who inject drugs) (GNP+ and UNAIDS 2009). A PHDP approach encourages and empowers PLWHA to: (1) take care of their physical and mental health and well-being, (2) adopt behaviors that reduce their risk of transmitting HIV to others, and (3) actively participate in and provide leadership in HIV prevention and advocacy activities (USAID and ProjectSEARCH 2011). Active participation in HIV prevention and

advocacy may include acting as informal peer educators or advocates for PLWHA in their communities or by leading or participating in HIV prevention program design, implementation, and monitoring or helping to conduct exploratory or evaluation research (GNP+ and UNAIDS 2011).

PHDP, or HIV prevention targeting PLWHA, is a relatively new approach. It is distinct from primary HIV prevention approaches focused on reducing new HIV infections by delivering messages for those presumed to be HIV-seronegative to protect themselves from HIV, which have dominated the prevention landscape since the beginning of the HIV epidemic (GNP+ and UNAID 2011). In the late 1990s, HIV prevention efforts began to be directed at PLWHA as well. PHDP has been facilitated by increased utilization of HIV testing and counseling and advances in the medical treatment of HIV. HIV-positive individuals are increasingly aware of their HIV status and are living longer, healthier, and more productive lives on antiretroviral therapy (ART) (USAID and ProjectSEARCH 2011). If PLWHA are aware of their status, adopt behaviors that reduce the risk of HIV, and access and adhere to treatment sufficient to reduce their viral load, then they will be less likely to transmit HIV to other individuals. Many PLWHA have cultivated knowledge about HIV, how it is transmitted, and the associated risk behaviors (CDC 2003). Thus, they may be uniquely qualified – and indeed in many contexts have been on the forefront of the effort – to educate others about reducing the risk of transmitting or acquiring HIV through peer-based intervention approaches (Aggleton et al. 2011).

The defining objective of PHDP interventions is to actively engage PLWHA as equal participants in potentially all aspects of HIV prevention activities (GNP+ and UNAIDS 2009). While reducing HIV transmission remains a critical objective of PHDP interventions and PLWHA are viewed as central players in reducing the spread of HIV, PHDP interventions are careful not to stigmatize or blame PLWHA for problems associated with HIV. Rather, PLWHA are seen as part of the solution, with shared responsibility in working toward curbing the pandemic and limiting its adverse impact on health and society

(USAID and ProjectSEARCH 2011). Reducing stigma and discrimination against PLWHA in the community environment is among the key objectives of PHDP interventions. In social contexts in which stigmatization of PLWHA is severe, it is challenging to implement PHDP interventions because PLWHA may not be willing to self-disclose and publicly participate in these programs (GNP+ and UNAIDS 2011). Tragically, misguided messages targeting PLWHA in some settings have had negative connotations and have further stigmatized PLWHA. Such negative messages have included “PLWHA should not have sex” or “PLWHA need to be careful,” which clearly were not intended to empower PLWHA or engender their further participation in prevention initiatives (NAM – AIDSMap 2011, p. 1). Fortunately, by now most HIV prevention programs communicating with HIV-seropositive audiences have moved away from using such alienating, stigmatizing language. Health communication messages targeting PLWHA based on the PHDP approach are positively framed and inclusive. Examples include: “We are more than patients,” “We are responsible for HIV prevention,” and “We have needs and desires to be fulfilled” (GNP+ and UNAIDS 2011, p. 10).

Current Status of PHDP Implementation

The PHDP approach has been increasingly accepted in the field of HIV prevention. Research confirms that most PLWHA express a desire to make positive contributions to their community, maintain good physical and mental health, enhance their sense of dignity, and take responsibility for preventing the transmission of HIV to others (King et al. 2009). Therefore, PLWHA are generally receptive to HIV prevention interventions embodying the PHDP approach. PHDP interventions have been implemented in many developing and more developed countries across a wide variety of social contexts and settings (PEPFAR 2011). In the past decade, various US and international agencies and groups have endorsed the use of PHDP interventions for HIV prevention, including the Centers for Disease

Control and Prevention, Health Resources and Services Administration, the National Institutes of Health, the US President’s Emergency Plan for AIDS Relief (2011), Joint United Nations Programme on HIV/AIDS, the World Health Organization, the Global Network of People Living with HIV/AIDS, and the International HIV/AIDS Alliance (GNP+ and UNAIDS 2009; International HIV/AIDS Alliance 2007).

Interventions that are illustrative of the PHDP approach to HIV prevention include the programs of the Mexican Network of People Living with HIV/AIDS and the Khmer HIV/AIDS NGO Alliance in Cambodia (International HIV/AIDS Alliance 2007). The Mexican Network of People Living with HIV/AIDS provides a wide variety of services in the setting of HIV patient care that employ PHDP strategies, including individual and group counseling to PLWHA who attend the clinic to help them address disclosure and internalized stigma; training workshops for peer educators on HIV/STI prevention; one-on-one peer counseling sessions in which peer educators employ active listening and strategic questioning while they provide information and give ongoing support for behavior change; and support groups for PLWHA to have a safe space to meet, share their experiences, and mutually provide social support. PLWHA are considered essential for effectively reaching and supporting other HIV-positive individuals and play an active role in implementing all of the HIV prevention strategies and in providing the ancillary services as well (International HIV/AIDS Alliance 2007). In Cambodia, the Khmer HIV/AIDS NGO Alliance (KHANA) offers a home care program to provide HIV prevention information and condoms for PLWHA and other community members. KHANA health workers visit the homes of PLWHA and provide HIV prevention education to the community. The home care program achieved wide reach among PLWHA, was able to earn their trust, and has improved access to HIV medical care and treatment among PLWHA in the community. The program has improved the quality of life of PLWHA, their family members, and caregivers, increased their knowledge and understanding of HIV prevention and care, reduced

stigma and discrimination toward PLWHA among their neighbors, and has offered social and economic support empowering some of the poorest and most disadvantaged individuals and families in the community (International HIV/AIDS Alliance 2007).

Research Evidence Supporting PHDP Interventions

Many studies evaluating the effectiveness of HIV prevention programs targeting PLWHA populations have been published, though most do not explicitly refer to the PHDP approach. There are now several review articles and meta-analyses that have been published on this topic (Kennedy et al. 2010; Gilliam and Straub 2009; Crepaz et al. 2006; Johnson et al. 2006). Based on these review articles, the most common PHDP interventions promote condom use and other sexual risk-reduction behaviors among HIV-seropositive individuals or serodiscordant couples. Intervention studies focused on reducing drug-related risk behaviors among HIV-seropositive persons who inject drugs are less common in the research literature (USAID and AIDSTAR-One 2011). The primary target audience of PHDP interventions is PLWHA, though some secondarily or simultaneously target their partners, family members, or the community at large. Various behavior change interventions to affect HIV risk reduction of PLWHA have been studied in both developing and more developed countries, for example, one-time individual counseling session using motivational interviewing techniques; multiple group sessions to build skills around condom negotiation and disclosing one's HIV-seropositive status; counseling following HIV testing; and educational interventions, such as videos (Kennedy et al. 2010; Gerbert et al. 2006).

There is strong scientific evidence to support the effectiveness of PHDP behavioral interventions for reducing sexual risk behaviors among PLWHA. However, there is insufficient evidence that the PHDP approach effectively reduces all HIV transmission risk behaviors or that it is equally effective across subpopulations (USAID

and AIDSTAR-One 2011). In a meta-analytic review of controlled trials with PLWHA in the United States, Crepaz and colleagues (2009) found that behavioral interventions significantly reduced the odds of PLWHA practicing unprotected sex and acquiring sexually transmitted infections (STIs). Behavioral interventions with the most documented success were theory-based; developed through formative research to appropriately frame messages; targeted specific HIV risk behaviors; delivered by healthcare providers or counselors to persons where they receive routine medical care or other services; included motivational interviewing, cognitive-behavioral counseling, and skills-building components; and addressed mental health and other challenges to medication adherence and HIV risk behavior change (Crepaz et al. 2006; Gerbert et al. 2006; Johnson et al. 2006; Gilliam and Straub 2009). Of note, the effects of these types of behavioral interventions appear to be less effective among HIV-seropositive persons who inject drugs, MSM, HIV-seronegative individuals, and HIV-serodiscordant couples (Crepaz et al. 2006; Johnson et al. 2006; Kennedy et al. 2010). The latter finding is especially relevant in sub-Saharan Africa, where heterosexual sex accounts for the vast majority of new HIV infections (Bunnell et al. 2008).

There is substantial evidence that PHDP behavioral interventions are effective for reducing sexual risk behaviors among PLWHA across a wide spectrum of cultures and contexts, particularly among HIV-seropositive heterosexual individuals. PHDP interventions have been effectively implemented in both clinic and community settings by healthcare providers, counselors, or social workers and by laypeople or peer educators, and there is evidence that these interventions are cost-effective (PEPFAR 2011).

However, evidence suggests that PHDP interventions are less effective among MSM, and there is insufficient evidence to conclude that injection drug use-related risk behaviors are reduced through PHDP approaches. Furthermore, the body of literature on PHDP-related interventions only describes the effectiveness of these

interventions for changing HIV risk behaviors; studies rarely report whether other key objectives of the PHDP approach were met by the HIV prevention interventions for PLWHA. The potential outcomes of PHDP interventions related to empowering HIV-seropositive individuals to protect their physical and mental health and well-being or engaging PLWHA in the development, implementation, and evaluation of HIV prevention programs and advocacy activities are often either not reported in the published literature or are presented only in case study format, not as part of quantitative program evaluations. More research is needed to determine whether PHDP interventions, in addition to secondary HIV prevention, are able to produce a wide array of intended outcomes. In particular, empirical evidence is needed to support the PHDP approach in: empowering PLWHA to access and optimally use healthcare and HIV treatments and other resources to improve their physical and mental health and well-being, involving PLWHA in HIV prevention program development and advocacy activities, and reducing stigma and discrimination against PLWHA.

Conclusion

The PHDP approach involves targeting PLWHA with HIV prevention interventions that emphasize the empowerment and dignity of HIV-positive individuals and may be implemented in any setting with PLWHA who are willing to actively participate in an HIV prevention program. While PHDP interventions should not be implemented instead of risk-reduction interventions targeting HIV-negative individuals or individuals whose status is unknown, they represent another critical component of a comprehensive HIV prevention strategy (CDC 2003). Although there has been increased focus and investment in prevention interventions targeting PLWHA, interventions based on a PHDP approach continue to receive less attention than they arguably deserve given their established effectiveness for reducing sexual risk behaviors (Aggleton et al. 2011).

Definition

Post-treatment controllers (PTC) are HIV-infected patients able to maintain a durable control of viremia at undetectable levels after interruption of antiretroviral treatment. Differently from natural HIV “elite” controllers (HIC), post-treatment controllers require therapeutic intervention to first reach undetectable viral loads. Post-treatment controllers still carry infected cells and, thus, are not cured but considered to be in sustained remission of HIV infection. These patients have also been termed “secondary controllers.”

Introduction

The introduction of combination antiretroviral treatment (cART) as the standard of care for HIV-infected individuals changed the face of the

AIDS epidemics. cART has drastically reduced mortality and morbidities of HIV-infected patients (Boyd 2009) and has also proven its value as a prevention tool by decreasing the risk of transmission (Cohen et al. 2011). A few years after cART was implemented, it was hypothesized that the perfectly controlled viral replication obtained with treatment may lead to the elimination of infected cells in treated patients. However, it was soon observed that HIV persists in different cell subsets, forming reservoirs that are untouched by cART (Eisele and Siliciano 2012). Infection and homeostatic proliferation of long-lived resting T cells, establishment of sanctuaries in regions not fully accessible to antiretroviral molecules, and/or residual viral replication may contribute to the persistence of HIV reservoirs in the presence of cART. Accordingly, regardless of the duration of the antiretroviral treatment, its interruption leads to prompt resumption of viral load replication to levels that are close to those observed during primary HIV infection (PHI) (Paton 2008). However, a few individuals have shown a remarkable capacity to keep efficient suppression of viremia long time after therapy discontinuation, supporting the idea that remission of HIV infection may be achievable, at least in some patients.

Early Treatment and Control of Infection

Cases of transient control after interruption of treatment initiated close to acute infection pointed to the interest of early treatment (Rosenberg et al. 2000). Indeed, analytical treatment interruption (ATI) protocols consistently reported delayed rebound of viremia and slower CD4⁺ T cell decay in some patients in whom treatment was initiated during PHI (Steingrover et al. 2008). Early treatment has been proposed to limit the establishment of viral reservoirs, reduce viral diversity and evolution, control deleterious immune activation, and preserve innate and adaptive immune responses (O'Brien and Markowitz 2012). Nevertheless, the clinical benefits of PHI treatment observed in ATI protocols often wane several months after therapy discontinuation and just a handful of patients have

been reported to extend viral control for many years (Hocqueloux et al. 2010).

The ANRS VISCONTI (Viro-Immunological Sustained CONTROL after Treatment Interruption) study reported the case of 14 post-treatment controllers who were able to keep an extremely well-controlled viremia and stable CD4+ T cell counts for more than 7 years after interruption of antiretroviral treatment (Saez-Cirion et al. 2013). These patients were not cured as they still carried infected cells, although at very low levels, and viral blips or residual replication with ultrasensitive techniques were detected at some time point for all of them. All these patients shared the characteristic of having started antiretroviral treatment within or close to PHI (before Fiebig stage VI (Fiebig et al. 2003)). Different epidemiological studies suggest that the probability of durable Post-treatment controllers may be of 5–15% among patients who initiated treatment during the first 6 months which followed contamination and kept the treatment for more than 12 months (Saez-Cirion et al. 2013; Goujard et al. 2012; Lodi et al. 2012). The ratio between the duration of the antiretroviral treatment and the immediateness of initiation of this treatment has been proposed to impact the probability to achieve durable Post-treatment controllers (Hocqueloux et al. 2010). Along this line, for the 14 patients in the VISCONTI study, the median treatment initiation delay was of 39 days after the presumed date of contamination, and the median treatment length was of 3 years (Saez-Cirion et al. 2013). Studies on non-human primate models of SIV infection have shown that treatment initiation during the very first days following contamination drastically limits the establishment of viral reservoirs (Whitney et al. 2014). However, even extremely early treatment does not suffice to prevent the seeding of the reservoir. Nevertheless, early treatment has been proposed to particularly protect long-lasting memory T cells from infection (Ananworanich et al. 2013). Longer treatment periods initiated during primary infection have been shown to have a stronger impact on viral reservoirs than the same periods of treatment initiated during chronic infection (Hocqueloux et al. 2013; Buzon et al. 2014). The questions

about the optimal treatment duration and the existence of a window of opportunity for treatment initiation are still open and require study of much larger groups of patients.

A singular case of Post-treatment controllers was reported in an in utero infected baby who started prophylactic cART 30 h post-birth and maintained the treatment for more than 15 months (Persaud et al. 2013). The viral load in the baby decreased from 19,000 RNA copies/ml of plasma to undetectable levels within 1 month of treatment. Four consecutive positive viral loads were measured during this period, confirming that the baby was infected. Weak adherence to treatment was observed from month 15, and cART was completely discontinued sometime between months 15 and 18. Viral loads were undetectable with standard techniques for over 2 years after treatment discontinuation, and HIV antibodies were negative. Traces of virus were detected with different ultrasensitive HIV-RNA and DNA determinations at months 24 and beyond, suggesting that the virus had not been completely eradicated but controlled to extremely low levels. Unfortunately, control of infection was eventually lost in this child after 2 years and a half off therapy (<http://www.niaid.nih.gov/news/newsreleases/2014/Pages/MississippiBabyHIV.aspx>). Despite this setback, this case significantly stressed the relevance of very early treatment as a starting point to achieve remission of infection in some patients and perhaps particularly in infants (Ananworanich et al. 2014; Luzuriaga et al. 2014).

Among adults, rarity of PTC might be explained by the analyses of clinical data from patients included in the French Hospital Database on HIV showing that only 2% of all the patients diagnosed close to primary infection and included in the database (>3,000 patients) underwent the therapeutic strategy that led to control of infection in the VISCONTI study (Saez-Cirion et al. 2013). Even when treatment is initiated during primary infection, the frequency of patients losing control is steep during the first months after therapy discontinuation. The patients who are able to control viremia for 12 months are likely to keep it for longer periods of time. So far, no reliable markers allow predicting which patients are more likely to

achieve a PTC status after treatment interruption. Different reports coincide to point out that patients who will control infection have lower levels of cell-associated HIV DNA at the time of treatment interruption (Hocqueloux et al. 2010; Saez-Cirion et al. 2013; Goujard et al. 2012), although low viral reservoirs alone do not suffice to ensure control of infection.

Differences Between Natural Control and Post-treatment controllers of Infection

Early treatment onset in most PTC may mask some cases of spontaneous control of infection. However, in general, many differences have been reported between PTC and HIC. In two PTC treatment initiation was due to prophylaxis after exposure (Saez-Cirion et al. 2013; Persaud et al. 2013), but in most cases treatment initiation in PTC was prompted by symptomatic primary infection accompanied by high viral loads (Saez-Cirion et al. 2013). In contrast, most HIC seem to start controlling infection very early and have weak viral loads and no symptoms during primary infection (Saez-Cirion and Pancino 2013). Natural control of infection in HIC is often associated with efficient immune responses, in particular T cell responses, which are favored by the presence of protective HLA class I alleles (e.g., HLA-B*27 and B*57) in most of these individuals (Saez-Cirion and Pancino 2013). Accordingly with their PHI profile, most PTC do not carry protective HLA class I alleles but rather neutral or high risk of progression to AIDS alleles (such as HLA-B*35 or B*07) and have very weak CD8+ T cell responses (Saez-Cirion et al. 2013). The levels of T cell activation are also higher in HIC than in PTC.

One PTC was shown to control infection of a virus that caused AIDS in his transmitting spouse (Salgado et al. 2011). Interestingly, this PTC, who initiated cART during PHI, showed a strong viral rebound when transiently discontinued treatment ~9 months after initiation. Treatment was immediately resumed and maintained for 14 additional months after which the patient was able, off

therapy, to control infection to undetectable levels for 9 years. The transient loss of control of infection in this PTC after firstly interrupting treatment further argues that Post-treatment controllers may be favored by sustained early cART in some patients non-predisposed to naturally control the virus.

PTC After Treatment in Chronic Infection

Although most PTC initiate treatment during PHI, some patients who were treated during the chronic stage of infection have been shown to control viremia after treatment interruption (Piketty et al. 2010; Van Gulck et al. 2012). It is important to differentiate these PTC, who had detectable viral loads before cART, from HIC who started treatment while keeping undetectable (or <1,000 copies) viral loads (Boufassa et al. 2014). Control of infection after interruption of cART initiated during the chronic phase of infection seems far rarer than when treatment is initiated during PHI (Saez-Cirion et al. 2013; Piketty et al. 2010). The study of a larger number of cases of PTC with sustained undetectable viremia after treatment interruption will be needed to find similarities and/or differences between chronic and PHI-treated PTC. The available reports suggest that Post-treatment controllers in patients treated during chronic infection is also associated with low levels of infected cells at the time of treatment interruption (Piketty et al. 2010; Van Gulck et al. 2012). Early initiation of treatment (with CD4+ T cell levels >500 cells/mm³) (Piketty et al. 2010) or infection with low-fitness viruses (Van Gulck et al. 2012) may have contributed to achieve PTC status in these patients.

Conclusion

In conclusion, some patients are able to keep undetectable HIV loads for long periods of time after interrupting antiretroviral treatment. In general this treatment was initiated close to the acute infection and maintained for several years before discontinuation. These patients are considered to

be in sustained remission of HIV infection: to counteract HIV replication, they needed therapeutic intervention, which interruption years later did not provoke viral rebound or progression to disease. These patients have not eliminated the virus and carry low levels of infected cells that are controlled within this remarkable status of stable remission. Although only one case of HIV eradication has been reported until now (Hutter et al. 2009; Yukl et al. 2013), the existence of several PTC cases suggests that the search for sustained HIV remission may be a more reachable goal than HIV eradication, at least in a medium term. Because of new recommendations shifting to treat HIV patients as early as possible, it is likely that more patients with favorable conditions to control infection after treatment interruption will appear over time. In this context, the priority is to identify markers that will allow the identification of patients with good probabilities to become PTC and in whom cART could be safely interrupted.

Preexposure Prophylaxis (PrEP)

 Institute School of Public Health, Washington,
 DC, USA

Definition and Rationale for Preexposure Prophylaxis (PrEP)

Traditionally, HIV prevention methods have focused on approaches such as education, evidence-based behavioral modifications, prevention with positives, harm reduction, and consistent condom use. Given that there are an estimated 7,000 new HIV infections globally each day, an estimated 48,000 new infections in the United States annually, and lack of success in developing an HIV vaccine thus far, these approaches have had a limited impact on stemming the HIV epidemic. Therefore, recent efforts have focused on the use of biomedical prevention methods to reduce HIV incidence.

Preexposure prophylaxis for HIV or “PrEP” is a biomedical prevention method that involves HIV-negative persons using oral or topical antiretroviral medications prior to sexual or parenteral exposure to prevent HIV. PrEP is seen as an intervention that should complement existing HIV prevention strategies. It is one of several biomedical prevention methods, including treatment as prevention, male circumcision, and HIV vaccine development, being used to prevent HIV transmission.

Use of PrEP

There are various routes of administration of PrEP including oral and topical PrEP. Oral PrEP involves taking a pill by mouth, whereas topical PrEP can be administered either vaginally or rectally through the use of gels containing antiretrovirals that are inserted prior to sex (precoitally) or after sex (postcoitally). These gels are often referred to as microbicides. PrEP should not be used alone but rather is intended for use in combination with other behavioral interventions including condoms, risk reduction counseling, and sexually transmitted disease (STD) testing. Preliminary guidelines for the use of PrEP include the need for baseline assessment of a person’s HIV status, frequent monitoring for side effects, frequent follow-up inclusive of routine HIV testing, and education on the importance of adherence (CDC 2011, 2012).

Biological Plausibility

The concept of using PrEP as a method for HIV prevention stems from research conducted in both animals and humans. Preexposure prophylaxis is commonly used to prevent infections with other illnesses. For example, preexposure prophylaxis with antimalarial medications is used to prevent malaria infections in people traveling and living in endemic areas. Furthermore, the use of pre- and postexposure prophylaxis in the prevention of mother-to-child transmission of HIV has been shown to dramatically reduce the risk of perinatal

transmission to newborn infants to as little as 1% (Connor et al. 1994). Similarly, the use of post-exposure prophylaxis (PEP) to reduce the risk of infection after occupational exposures and high-risk behavioral exposures has been shown to be effective with an 81% reduction in transmission among persons taking PEP (Cardo et al. 1997).

Tenofovir disoproxil fumarate (TDF, Gilead brand name Viread[®])-based regimens have been the most widely studied for use in preexposure prophylaxis for HIV. TDF, a nucleoside reverse transcriptase inhibitor (NRTI), is a well-tolerated and safe antiretroviral with minimal side effects. In recent PrEP animal studies and clinical trials, TDF with emtricitabine (FTC/TDF, Gilead brand name Truvada[®]) has shown the potential to be an even more effective medication for HIV prevention (García-Lerma et al. 2008).

Animal studies provided early evidence in support of PrEP as an HIV prevention method (García-Lerma et al. 2008; Parikh et al. 2009; García-Lerma et al. 2010; Cong et al. 2011). Studies conducted in monkeys have found high levels of protection and significant reductions in transmission when TDF was given orally, rectally, and intravenously. These unequivocal findings in animal models led to further trials in human beings. Additional animal studies are currently being conducted to identify new antiretroviral candidates for PrEP (Veazey et al. 2010; Dobard et al. 2011).

PrEP Trials Among Humans

Multiple studies among human beings, mostly in the form of phase I, II, and, III clinical trials, have been conducted on PrEP. These studies were conducted in various geographic locations and among specific high-risk populations. Descriptions of key studies and their major findings follow.

Phase I/II Clinical Trials

FHI TDF West African Trial: From June 2004 to March 2005, 936 HIV-negative heterosexual women in Ghana, Cameroon, and Nigeria were recruited into the Family Health International

(FHI) TDF West African trial (Peterson et al. 2007). This study was the first to examine the safety and effectiveness of taking once-daily oral dose of TDF to prevent HIV-1/HIV-2. The study found no significant safety outcome differences between the intervention and control arms. Insufficient follow-up time due to the premature closing of two study sites resulted in the study not being able to achieve an adequate sample size. Therefore, the investigators were not able to adequately assess the effectiveness of once-daily oral TDF as preexposure prophylaxis for HIV.

CDC 4323: Another phase II study, CDC 4323, examined the clinical and behavioral safety of daily oral TDF among men who had sex with men (MSM) in three US cities: Atlanta, Boston, and San Francisco (Grohskopf et al. 2010; CDC 2010). The 400 participants enrolled were randomized to receive either the active or placebo drug. Additionally, receipt of TDF or placebo was delayed for half of the participants in each arm in order to assess the potential behavioral effects of taking a daily medication. No significant biomedical safety concerns were discovered nor were there any significant behavioral differences identified between participants who immediately started the study drug and those with delayed initiation. CDC 4323 was not designed to examine drug effectiveness in the prevention of HIV.

IAVI E001: The International AIDS Vaccine Initiative (IAVI) conducted a phase I/II placebo-controlled trial in Kenya to evaluate the safety, acceptability, and adherence of daily versus intermittent oral FTC/TDF (IAVI E001) (Mutua et al. 2012). From October to December 2009, the study enrolled and randomized 72 MSM and female sex workers. Investigators discovered no safety concerns in either PrEP regimen compared to placebo and found few differences between the two regimens in terms of safety and acceptability. Eighty-three percent of the study participants indicated they would be willing to take PrEP if it was safe, effective, and not prohibitively expensive. The IAVI E001 study found that participants randomized to receive PrEP intermittently (twice weekly with a postcoital dose) were slightly less adherent to study medication, and from follow-up focus groups and interviews, they identified

potential adherence obstacles with the postcoital dosage, in particular (Mutua et al. 2012).

Phase IIB/III Clinical Trials

The following Table 1 presents a brief summary of major phase IIB/III PrEP clinical trials listed in chronological order of the release of study findings.

CAPRISA 004: The Centre for the AIDS Programme of Research in South Africa (CAPRISA) 004 trial assessed the safety and efficacy of a 1% vaginal gel formulation of tenofovir as PrEP among a population of 889 heterosexual South

African women (Abdool Karim et al. 2010). Participants were instructed to use one dose of the gel within 12 h prior to vaginal sex and to use a second dose within 12 h of having sex. After 30 months of follow-up, investigators found that the tenofovir gel reduced the risk of HIV-1/HIV-2 by 39% compared to those using the placebo gel. Among women with high gel adherence (i.e., taking >80% of doses) that efficacy increased to 54%. No significant safety concerns emerged and investigators concluded that tenofovir gel could prove to be an important HIV prevention tool for women who have difficulty negotiating

Preexposure Prophylaxis (PrEP), Table 1 Summary of major preexposure prophylaxis phase IIB/III clinical trials and their results

Study name (clinical trial number)	Active drug regimen	Phase	Sample size ^a	Recruitment site(s)	Study population ^b	Efficacy % (95% CI)
CAPRISA 004 (MTN 004)	Pre- and postcoital TFV	III	889	South Africa	Heterosexual women	39 (6–60)
iPrEx	Daily oral FTC/TDF	III	2,499	Peru, Ecuador, South Africa, Brazil, Thailand, the United States	MSM and transgender women	44 (15–63)
FEM-PrEP	Daily oral FTC/TDF	III	2,120	Kenya, South Africa, Tanzania	Heterosexual women	6 (–52–41) ^c
TDF2 (CDC 4940)	Daily oral FTC/TDF	III	1,219	Botswana	Heterosexual men and women	62 (22–83)
Partners PrEP	(1) Daily oral TDF (2) Daily oral FTC/TDF	III	4,758	Kenya, Uganda	Heterosexual discordant couples	TDF, 67 (44–81); FTC/TDF, 75 (55–87)
VOICE study (MTN 003)	(1) Daily TFV (2) Daily oral TDF (3) Daily oral FTC/TDF	IIB	5,029	Uganda, South Africa, Zimbabwe	Heterosexual women	TFV, 15 (–20–40) ^{c,d} ; TDF, –49 (–129–3) ^{c,d} ; FTC/TDF, –4 (–49–27) ^c
Bangkok Tenofovir Study (CDC 4370)	Daily oral TDF	III	2,413	Thailand	Injection drug users (IDU)	74 (17–94)

MTN Microbicide Trials Network, CDC Centers for Disease Control and Prevention, N/A not available, TFV 1% tenofovir vaginal gel, TDF tenofovir disoproxil fumarate, FTC/TDF TDF with emtricitabine

^cResults were not significant

^dPrematurely discontinued

monogamy or the use of condoms with their sexual partners.

iPrEx: Some of the first oral PrEP efficacy results, released November 2010, came from the Preexposure Prophylaxis Initiative (iPrEx) trial. This phase III study evaluated the effect of once-daily FTC/TDF compared to placebo among a population of 2,499 men and transgender women who have sex with men, recruited from multiple countries in the Americas, Africa, and Southeast Asia (Grant et al. 2010). A 44% relative reduction in new HIV infections was found among study participants taking daily oral FTC/TDF compared to the placebo group. Further analysis showed that strict adherence to the daily medication (i.e., taking pills on $\geq 90\%$ of days) significantly improved protection, increasing the efficacy to 73%.

FEM-PrEP: Not all phase III PrEP studies have shown a significant increase in HIV prevention, however. In the FEM-PrEP study, another investigation intended to evaluate the safety and effectiveness of daily oral FTC/TDF in the prevention of HIV acquisition; 2,120 heterosexual women from Kenya, South Africa, and Tanzania were randomized to receive either FTC/TDF or placebo drug (Van Damme et al. 2012). Preliminary analyses showed similar rates of HIV in both arms of the study (4.7 per 100 person-years in the FTC/TDF group and 5.0 per 100 person-years in the placebo group), with slightly elevated occurrences of adverse events among study participants receiving the active drug. As a result of these findings, the study was terminated early in April 2011. The study investigators proposed that the lack of significant HIV protection seen in the FTC/TDF group may have been due to poor medication adherence. Although self-reported adherence rates were high (95%) and pill count data (88%) seemed to corroborate high adherence in the study population, they found low levels of TDF in the plasma of women who became HIV positive during the study period. This implied that true adherence may have been significantly lower than suggested from either self-reports or pill count data, although a biological reason for this difference also needs to be examined.

TDF1 and TDF2: In 2005, the US Centers for Disease Control and Prevention (CDC) in cooperation with the Botswana government launched TDF1, a phase III study examining the safety and efficacy of once-daily TDF compared to placebo drug in the prevention of HIV-1/HIV-2 (Thigpen et al. 2012). After the results from animal studies were released which showed a clear advantage in using FTC/TDF over the single-drug TDF, study investigators changed the active study drug to FTC/TDF and offered TDF1 participants the opportunity to enroll in the new TDF2 study. In the TDF2 study, 1,219 heterosexual men and women were enrolled from February 2007 through October 2009 and randomized to receive either daily oral combined FTC/TDF or placebo drug. Investigators found that daily FTC/TDF reduced the likelihood of HIV by 62%. This efficacy improved to 78% when they limited analyses to only those participants who were confirmed to have received a supply of the study drug in the 30 days prior to their last visit. While minor side effects such as nausea, vomiting, and dizziness were more commonly reported among participants receiving the active study drug, the risk of serious adverse effects did not increase with FTC/TDF use. Drug resistance in one undiagnosed HIV-positive TDF2 participant who received FTC/TDF highlighted the need to closely monitor HIV seroconversion among persons taking PrEP.

Partners PrEP: From July 2008 to November 2010, investigators with the Partners PrEP study enrolled 4,758 HIV-serodiscordant heterosexual couples from Uganda and Kenya (Baeten et al. 2012). A serodiscordant couple is one in which one of the partners is HIV positive, while the other is HIV negative. One-third of the study population was randomly assigned to receive oral TDF, one-third to receive oral FTC/TDF, and one-third to receive placebo drug. All study medication was taken once daily. In July 2011, preliminary analysis showed such a significant reduction in HIV acquisition among both active study drug arms that investigators discontinued the placebo arm of the study. The final Partners

PrEP results found that daily oral TDF reduced the risk of HIV by 67% and that daily oral FTC/TDF reduced the risk even further by 75%. TDF and FTC/TDF proved to be safe and efficacious in both male and female participants.

VOICE Study: Another study with mixed results was the Vaginal and Oral Interventions to Control the Epidemic (VOICE) study, which began enrolling participants from Uganda, South Africa, and Zimbabwe in September 2009 (MTN 2011). In this phase IIB study, 5,029 young heterosexual women were randomized into one of five arms: daily 1% tenofovir vaginal gel, daily placebo vaginal gel, daily oral TDF, daily oral FTC/TDF, and daily oral placebo drug. In September 2011, the daily oral TDF arm was discontinued as preliminary analysis found that, while safe, it did not significantly reduce the risk of HIV. Similarly, the daily vaginal gel arms of the study were discontinued in November 2011 because the tenofovir gel was not shown to significantly reduce the risk of HIV. Follow-up for the daily oral FTC/TDF arm of the study was completed in August 2012 and was not shown to significantly reduce the risk of HIV compared to placebo (Marrazzo et al. 2013).

Bangkok Tenofovir Study: Launched in June 2005, the Bangkok Tenofovir Study aimed to evaluate PrEP safety and effectiveness in a population of injection drug users recruited from Thailand (Choopanya et al. 2013). Enrollment concluded in December 2010 with 2,413 participants successfully randomized to receive either daily oral TDF or placebo in a double-blinded fashion. Results from this study, released in June 2013, showed significantly lower HIV incidence rates among injection drug users who receive daily oral TDF (0.35 per 100 person-years) compared to those randomized to the placebo group (0.68 per 100 person-years). After examining tenofovir concentration levels in the plasma of seroconverted participants, investigators presented a modified efficacy estimate of 73.5%, reinforcing the findings of previous studies that medication adherence has critical impact on PrEP's ability to prevent HIV infection.

Future and Ongoing Studies

Several additional PrEP studies are ongoing or planned. These include studies that will address the use of PrEP in different populations, the long-term use of PrEP, and the effectiveness of different HIV medications and modalities for delivering these medications (Cohen et al. 2012; Underhill et al. 2010). For participants who were enrolled in some of the abovementioned trials, those who received placebo will be offered the medications, and participants will continue to be monitored to assess the long-term effectiveness and impact of PrEP on behaviors, safety, tolerability, and adherence to these medications (Cohen et al. 2012; Grant et al. 2010).

Public Health Implementation of PrEP

The results of the various PrEP clinical trials provided proof of concept that PrEP for HIV prevention could be an effective way to reduce HIV and onward transmissions. In January 2011, after the results of the iPrEx study were published, the CDC issued interim guidance on the use of PrEP among MSM (CDC 2011). In July 2012, the US Food and Drug Administration (FDA) approved the licensure of oral daily Truvada® (FTC/TDF) for use as preexposure prophylaxis in adults at high risk for HIV or who engage in sexual activity with HIV-positive partners (U.S. FDA 2012). In August 2012, the CDC issued guidance on the use of PrEP among heterosexuals at high risk for HIV (CDC 2012). Following the receipt of results from several additional PrEP clinical trials and FDA approval, final clinical practice guidance from the US Public Health Service has been published (2014).

Challenges of PrEP Use

Despite the success of many of the PrEP trials, the scalability, feasibility, and acceptability of PrEP at a population level are under much debate

(Underhill et al. 2010; Cohen et al. 2012). Many questions continue to linger regarding how best to implement, scale up, and provide PrEP in a real-world setting. Additionally, many potential issues and challenges related to PrEP use remain, including the safety and tolerability of taking antiretroviral medications on a regular basis, the optimal frequency and duration of PrEP use, the need for optimal adherence, the risk of developing drug resistance, the risk of behavioral disinhibition, the potential for PrEP use among certain high-risk populations, cost-effectiveness, and ethical concerns. These issues are discussed below.

Safety and tolerability: Research has shown that the side effects of using FTC/TDF as a prophylaxis are minimal. Those who did have side effects experienced reductions in bone mineral density, decreased renal function, and gastrointestinal upset including diarrhea and nausea. However, these side effects were not severe enough to preclude its use. Toxicities from using TDF are less likely in HIV-negative persons who are on fewer medications and are generally healthier individuals. Current guidelines for PrEP use include the routine monitoring of side effects. In order to clinically monitor for these side effects, both in short- and long-term use, it is important for persons taking PrEP to have a consistent and reliable source of medical care.

Frequency and duration of use: As taking any daily medication as prescribed can often prove difficult, the optimal frequency, dosing, and duration of PrEP use is currently under investigation. Several clinical trials will be assessing the use of both pre-coital or “on-demand” PrEP in which FTC/TDF is taken both a few hours prior to and after sexual exposure (Lorente et al. 2012), as well as intermittent dosing strategies for PrEP or “iPrEP” which might, for example, entail weekly dosing. Intermittent dosing strategies and coitally dependent dosing regimens may provide viable and effective alternatives to daily dosing.

Furthermore, unlike traditional prevention approaches, the time frame for using PrEP has not been well established. PrEP use may be continuous but the long-term effects of using antiretrovirals for HIV prevention among HIV-negative persons are not well described to

date. An alternative scenario may be that people will take PrEP for a discrete period of time (for example, during a high-risk period in their lives) and then discontinue it when they perceive their risk of HIV to be lower (for example, when they enter into a relationship with a stable partner).

Adherence: Adherence to PrEP is essential in order to achieve the maximum effectiveness and benefits of risk reduction. Studies have shown that PrEP efficacy for HIV prevention is directly affected by level of medication adherence, with significantly lower efficacy rates among those who are not fully adherent compared to those who are fully adherent (Grant et al. 2010; Thigpen et al. 2012; Choopanya et al. 2013). As previously mentioned, further research is needed to determine alternative dosing methods that may prove to be easier to follow. Additional research on adherence to PrEP and potential barriers to being fully adherent is also needed (Mutua et al. 2012).

Drug resistance: Individuals with undiagnosed HIV who are taking PrEP are at risk for developing drug resistance. For example, in the iPrEx study, two HIV-positive individuals developed resistance to emtricitabine (Grant et al. 2010). Without careful and frequent monitoring of one’s HIV status among persons on PrEP, the risk of transmitting drug-resistant virus could increase. This could potentially lead to a loss of efficacy of FTC/TDF, resulting in the need for more second-line antiretroviral therapies among these newly diagnosed individuals (Hurt et al. 2011). High levels of adherence, regular HIV testing, and the ability to detect acute infections may help to limit the development of drug resistance.

Behavioral disinhibition: One common concern regarding the use of PrEP is that individuals taking PrEP may believe that they are sufficiently protected from acquiring HIV and may start to engage more frequently in high-risk behaviors. This concept, known as behavioral disinhibition, can manifest itself in an increase of behaviors such as irregular or no condom use or increasing the number of sexual partners or risky sexual acts. Several PrEP trial studies have attempted to examine this possibility, including the iPrEx trial which reported no significant increase in sexual risk behaviors among its participants (Liu

et al. 2013). These investigations continue, and adequate and ongoing counseling regarding risk reduction will be necessary among persons taking PrEP (Cohen et al. 2012).

PrEP among other high-risk populations: Due to the conflicting results of PrEP use among high-risk women and the ongoing research among injection drug users, PrEP efficacy and use among these populations are relatively unknown. Additionally, the potential use of PrEP among serodiscordant couples is also being examined in more depth, and studies focusing on particular subpopulations such as young MSM are underway. As all of these populations are considered at high risk for HIV, this research is needed to increase understanding of the potential for PrEP as an effective prevention strategy among each of these populations.

Cost-effectiveness: To date several cost-effectiveness studies have been conducted to model the potential impact of PrEP use in different regions of the world under a variety of circumstances and assumptions. In general, these studies have concluded that PrEP use would be cost-effective and has the potential to significantly reduce HIV incidence among high-risk individuals (Paltiel et al. 2009; Walensky et al. 2012).

Ethical issues: Ethical issues regarding PrEP have also been raised, particularly in areas where there are limited resources to treat persons who are already HIV positive (Leibowitz et al. 2011). For example, in resource-limited countries, there are millions of HIV-positive persons who either cannot access and/or afford antiretroviral treatment. Similarly, in some areas of the United States, there are waiting lists for persons who need antiretroviral medications. Thus, proposals to conduct widespread implementation of PrEP in areas where medication access is already limited for HIV-positive persons present an ethical dilemma regarding the equitable allocation of antiretrovirals for treatment versus prevention.

Implementation Challenges in the United States

Several challenges have arisen as broader PrEP implementation begins. Studies are underway to

assess how best to implement PrEP in the United States in the form of demonstration projects and extensions of ongoing clinical trials. One challenge is that PrEP differs from traditional HIV prevention strategies as it requires access to a clinical setting for prescription receipt, regular HIV testing, and clinical monitoring. In addition, HIV-negative persons may not routinely seek care from infectious disease clinicians who are most familiar with prescribing antiretroviral medications. Thus, providers who are not familiar with or who do not routinely provide antiretrovirals, such as most primary care providers, will need to be trained on how to manage or appropriately refer people who are interested in taking PrEP. Lack of insurance coverage may also present an obstacle as those persons who may be at highest risk for HIV may be more likely to be un- or underinsured. Furthermore, those persons at highest risk for HIV may have limited access to care as well as awareness of PrEP as an HIV prevention method (Underhill et al. 2010).

Conclusion

Despite these challenges, preexposure prophylaxis for HIV prevention presents a novel approach to reducing HIV incidence and adds another tool to the HIV prevention toolkit. Because it is a relatively new prevention approach, there remain many unknowns regarding its prolonged use, potential side effects both biologically and behaviorally, the best methods for optimal implementation, and its cost-effectiveness in real-life settings. Despite these gaps, with additional research, careful monitoring, and education at both the patient and provider level, PrEP has the potential to play an important role in the overall strategy to reduce HIV globally.

Pregnant Women: Care and Treatment

Christina Fiske

Division of Infectious Diseases, Vanderbilt University Medical Center, Nashville, TN, USA

Epidemiology of HIV/AIDS in Women

HIV/AIDS continues to be a major global cause of morbidity and mortality in women. In 2011, more than 50% of the 34 million people infected with HIV were women (UNAIDS/WHO 2012). HIV/AIDS is the major cause of death in women of childbearing age (ages 15–49) in the developing world. The primary mode of HIV transmission in women in the United States and globally is heterosexual contact. In 2013, there were 24.7 million people living with HIV/AIDS in sub-Saharan Africa, the global region that accounts for approximately 70% of HIV/AIDS cases, and 58% of those were women. In the United States, women accounted for approximately 24% of new diagnoses of AIDS in 2012 (Centers for Disease Control 2014), and there were over 270,000 women among the 1.1 million

people living with HIV infection and AIDS in the United States as of 2013. With the increase in access to potent antiretroviral therapy (ART) in developing countries, the rates of perinatal infection have decreased from over 570,000 in 2003 to an estimated 260,000 children in 2012.

Preconception Counseling and Care for HIV-Infected Women of Childbearing Age

Surveys performed in the United States suggest that HIV-infected women have similar desires to have children as HIV-uninfected women. Pre-conceptual counseling is imperative and should include a discussion about the woman's HIV status and optimal treatment strategies for her health and strategies to decrease perinatal transmission. Discordant couples may present a particular challenge. If the potential father is HIV negative, the safest approach to conception is intravaginal or intrauterine insemination. If the potential father is HIV positive and the woman is HIV negative, the use of assisted reproductive technologies including sperm washing and in vitro fertilization techniques appears to have a low risk of horizontal transmission to the woman or vertical transmission to the developing fetus, but of course these techniques are not completely risk-free. Treatment with ART for prevention of transmission and pre-exposure prophylaxis are also strategies to permit conception without also transmitting HIV.

The goals of preconception care for women living with HIV are to prevent unintended pregnancy, optimize maternal health before pregnancy, improve maternal and fetal outcomes in pregnancy, prevent perinatal transmission, and prevent possible HIV transmission to an HIV-uninfected partner during attempts at conception (Cohn and Clark 2015). In addition to addressing fertility and reproduction, women should be counseled on safe sexual practices to prevent HIV transmission to sexual partners and to prevent sexually transmitted diseases. Because of concerns of teratogenicity of efavirenz, non-pregnant women with childbearing potential should undergo pregnancy testing before starting

efavirenz and should be counseled on risks to the developing fetus if she were to become pregnant while taking efavirenz (see below: "[Use of Antiretroviral Therapy in Pregnancy](#)").

Large studies in the developed world have failed to show worse HIV outcomes or increased rates of progression to AIDS in pregnant women. Some studies in developing countries have indicated that pregnant women with HIV progress to AIDS at a faster rate compared to nonpregnant women, but these studies could be confounded by such factors as poor nutrition, presence of other infectious diseases, and more advanced HIV disease at the time of diagnosis.

HIV infection appears to increase the risk of pregnancy-associated adverse outcomes such as preterm birth, stillbirths, small for gestational age, and neonatal death. Data on whether risk of these adverse events is higher in women on ART are conflicting (see below: "[Use of Antiretroviral Therapy in Pregnancy](#)"). The pathogenesis of premature birth is unknown for all women, and the etiology of the potential increased risk among HIV-infected women is not clear.

Perinatal Transmission

Antiretroviral medications have had a major impact on perinatal transmission of HIV. Prior to the use of antiretroviral prevention, the frequency of perinatal transmission was estimated between 15% and 45%. Effective ART for the prevention of mother to child transmission (PMTCT) reduces HIV perinatal transmission to <2% in the absence of breastfeeding and to <5% among breastfeeding infants (Ciaranello et al. 2013; WHO 2012). However, only 57% of HIV-infected pregnant women in developing countries received preventive antiretroviral medications in 2011. ART decreases maternal viral load in the blood and in genital secretions, thereby decreasing perinatal transmission. However, ART has also been shown to reduce the risk of transmission in women whose HIV RNA levels are less than 1000 copies/mL. An additional mechanism of transmission prevention may be preexposure infant prophylaxis provided by antiretroviral therapies that

cross the placenta, especially during labor when the infant is exposed to high levels of HIV in the mother's genital tract secretions.

The most important risk factor for perinatal transmission is maternal plasma or breast milk viral load. There is no "safe" level of HIV viremia as women with undetectable viral load have transmitted HIV to their infants (Mayaux et al. 1997; Sperling et al. 1996). Other associated maternal factors include CD4+ cell count, anemia, advanced WHO clinical disease stage, reproductive tract infections, mastitis, and acute maternal HIV infection during pregnancy or breastfeeding. HIV can be transmitted from mother to child during intrauterine gestation, at delivery, or in the postpartum period through breastfeeding. Infants infected in late pregnancy or at birth have a slower progression to AIDS and prolonged survival compared to infants infected in utero. Most cases of perinatal transmission are thought to occur near or during delivery. Studies performed prior to the availability of combination ART demonstrated that elective cesarean section before the onset of labor and the rupture of membranes decreased the risk for perinatal transmission of HIV-1 by 50% (The International Perinatal HIV Group 1999). The degree of protection afforded by elective cesarean in the era of combination ART is unknown. HIV-positive women may be at increased risk for postoperative complications such as infection. Current US guidelines recommend discussion of elective cesarean section at 38 weeks gestation with women whose HIV viral load is greater than 1000 copies/mL (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission 2014). Conversely, the WHO does not recommend cesarean section in resource-limited settings specifically for HIV infection; rather it is recommended for obstetric and other medical indications (WHO guidelines 2013).

Care of Pregnant HIV-Infected Women

Antenatal care of the HIV-infected pregnant woman requires coordination between multiple providers including her primary care provider,

obstetrician, and HIV specialty care providers. An initial evaluation should include thorough examination of her HIV history, including past and current CD4 counts and HIV viral loads, and determination of appropriate ART treatment, whether she is ART-naïve or whether her current regimen needs to be altered. The history and physical should also assess risk factors for increased perinatal transmission, including the use of tobacco, alcohol, or drugs, a history of sexually transmitted diseases, and whether she engages in unprotected sexual intercourse. The CD4 count should be assessed at least every trimester in most pregnant women. Consideration can be given to check the CD4 count every 6 months in women who have been virally suppressed for two or three years and are clinically stable. Because of hemodilution, the CD4 percentage may be a more stable parameter to follow during pregnancy compared to the absolute CD4 count. Viral loads should be monitored closely (at the initial visit, 2–6 weeks after starting/changing ART, monthly until undetectable, and then every 3 months) because of the importance of decreasing the pregnant woman's viral load as soon as possible to decrease the risk of perinatal transmission. Viral load should also be measured at 34–36 weeks gestation to inform decisions about the mode of delivery. Gestational age should also be assessed via ultrasound in the first trimester or as soon as the woman presents for care because if a cesarean section is deemed appropriate, this is usually scheduled at 38 weeks gestation. Pregnant women receiving NRTI therapy should also have their hepatic enzymes and electrolytes monitored because of an increased risk of lactic acidosis with these therapies. HIV-infected women on ART should receive a standard glucose tolerance test at 24–28 weeks although some experts would recommend earlier screening in women taking protease inhibitors prior to becoming pregnant as they may be at increased risk of glucose intolerance. The risk of transmission during amniocentesis or during other invasive procedures such as chorionic villus sampling in women on effective ART resulting in viral suppression does not appear to be increased.

The ultimate decision for initiation of ART is the responsibility of the woman. A detailed discussion of the risks and benefits of ART during pregnancy should be undertaken with a strong emphasis placed on the health benefits of HIV treatment for both the mother and the infant. Adherence to ART should also be strongly emphasized and social support resources should be employed if possible to increase chances of successful ART in promoting her health and reducing perinatal transmission.

Use of Antiretroviral Therapy in Pregnancy

The goal of ART use in pregnancy is to improve maternal health, reduce transmission of HIV to the newborn, prevent horizontal HIV transmission to sexual partners, and avoid potential maternal or fetal toxicity associated with ART. The first major breakthrough in PMTCT was the Pediatric AIDS Clinical Trial Group Protocol 076 in which pregnant women were randomized to receive pre- and postpartum zidovudine (ZDV) monotherapy, including an intravenous bolus during labor vs. placebo during pregnancy and intrapartum. Newborns were given ZDV for the first 6 weeks of life. The trial was completed in 1994, and the rate of perinatal transmission was 8.3% in the ZDV group compared to 25.5% in the placebo group, a reduction in risk of perinatal transmission of almost 70% (Connor et al. 1994). The three-part regimen proved logistically difficult to carry out in resource-limited settings, and later trials evaluated shorter regimens, including single-dose nevirapine given to the mother at the onset of labor and to the newborn within 72 h of birth. Single-dose nevirapine reduced perinatal transmission by 50–60% (Guay et al. 1999). Subsequent clinical trials and observational studies have demonstrated that combination ART given to the mother both pre- and postpartum was associated with further declines in perinatal transmission to less than 2%. Antenatal combination drug regimens are now considered the standard of care for preventing perinatal transmission, and the goal of global

health agencies is to supply suppressive ART for all pregnant and breastfeeding women.

PMTCT has evolved significantly since the initial use of zidovudine monotherapy in the mother and infant. The 2010 WHO PMTCT ART guidelines stratified the need for lifelong HIV treatment versus the need for treatment only during pregnancy and the breastfeeding period based on the mother's CD4 count (WHO 2010). The two available options, Option A and B, also differed in the recommended ART regimen for healthier women – monotherapy with zidovudine versus triple drug ART, respectively. Compliance with Option A was difficult for many programs, because of logistical difficulties in providing different ART during different periods of pregnancy and the need for a timely CD4 count result in order to stratify women to the correct treatment arm. The updated WHO guidelines published in 2013 represented a significant paradigm shift and reflected the emphasis on the global community's commitment to the elimination of new HIV infections in children by 2015 (UNAIDS 2011). Option A was no longer recommended, and all pregnant women were to start triple ART during pregnancy. Further, it was recommended that all pregnant and breastfeeding women with HIV continue lifelong ART (Option B+). Countries could choose to adopt a policy wherein consideration may be given to stopping ART after the breastfeeding period if the mothers are not eligible for ART for their own health (Option B). The selection of Option B or Option B+ is conditional, based on the epidemic setting and the country program. It is estimated that with the new treatment eligibility threshold of CD4+ cell count ≤ 500 cells/mm³, approximately 60% of HIV-infected pregnant women will meet treatment eligibility criteria for their own health. Options B and B+ are also more efficient because the same ART regimen can be used for the duration of pregnancy and into the postpartum period. Option B+ has several additional advantages including (1) no need for CD4 count testing prior to initiation of treatment; (2) extended protection for future pregnancies, starting at conception; (3) potential for prevention of transmission to an HIV-negative partner; (4) benefit to the woman's health and avoidance

Pregnant Women: Care and Treatment, Table 1 Summary of first-line antiretroviral regimens recommended by the World Health Organization for adults, including pregnant and breastfeeding women

Preferred first-line regimen	Alternative first-line regimens
Tenofovir (TDF) + lamivudine (3TC) or emtricitabine (FTC) + efavirenz (EFV)	1. Zidovudine (ZDV) + 3TC + EFV 2. ZDV + 3TC + nevirapine (NVP) 3. TDF + 3TC or FTC + NVP

of risk of stopping/starting ART; and (5) extending the public health message in communities that once ART is started, it is taken for life. While the cost of lifelong ART continues to be an issue in low-resource settings, the average cost of ART is continuing to decrease, and a study from the WHO in 2014 found that from a cost perspective, switching from Option B to Option B+ was feasible (O’Brien et al. 2014). Similarly, a cost-effectiveness study performed in Malawi, one of the first countries to adopt Option B+, found that although Option B+ would cost more initially, it would save societal resources in the long term (Fasawe et al. 2013).

Transplacental drug passage is an important mechanism for infant preexposure prophylaxis and as such NRTIs with high placental transfer should be included (i.e., zidovudine, lamivudine, emtricitabine, tenofovir, or abacavir). The preferred first-line regimen recommended by the WHO for HIV-positive pregnant or breastfeeding women is tenofovir (TDF) plus lamivudine (3TC) or TDF plus emtricitabine (FTC) in combination with efavirenz (EFV) (Table 1). Alternative regimens are also recommended (Table 1). The advantage of TDF/FTC/EFV as a first-line regimen is that it is available as a fixed-dose combination that allows once-daily dosing, has a more favorable toxicity profile, and has an enhanced activity against hepatitis B.

Guidelines for the use of ART in HIV-infected pregnant women differ in resource-rich settings, but there is significant overlap with the WHO guidelines. Guidance on care of HIV-infected pregnant women in the United States is provided by the Department of Health and Human Services

Pregnant Women: Care and Treatment, Table 2 Initial combination antiretroviral therapy regimens recommended by the Department of Health and Human Services (USA) for antiretroviral-naïve pregnant women

Preferred two-NRTI backbone	ABC/3TC, TDF/FTC or 3TC, ZDV/3TC

Alternative NNRTI regimen	NVP + two-NRTI backbone
Integrase inhibitor regimen	RAL + two-NRTI backbone

NRTI nucleoside reverse transcriptase inhibitor, *NNRTI* non-nucleoside reverse transcriptase inhibitor, *ABC* abacavir, *3TC* lamivudine, *TDF* tenofovir, *FTC* emtricitabine, *ZDV* zidovudine, *ATV/r* ritonavir-boosted atazanavir, *LPV/r* ritonavir-boosted lopinavir, *EFV* efavirenz, *DRV/r* ritonavir-boosted darunavir, *SQV/r* ritonavir-boosted saquinavir, *NVP* nevirapine, *RAL* raltegravir

^aAll ritonavir-boosted PI regimens are low dose

(DHHS Guidelines 2014). As in the WHO guidelines, a combined approach of antepartum and intrapartum ART administered to the mother and postpartum infant prophylaxis is recommended to reduce perinatal transmission of HIV. Similarly, a regimen that is the same in HIV-infected pregnant women and nonpregnant individuals is ideal. In resource-rich settings, ARV treatment resistance testing should be undertaken in all women prior to initiating an ART regimen. Preferred NRTI regimens in ART-naïve pregnant women include TDF plus either 3TC or FTC, abacavir (ABC) plus 3TC, or ZDV plus 3TC (Table 2). ZDV may be contraindicated if a woman has significant anemia. In addition to the dual NRTI backbone, either a low-dose ritonavir-boosted protease inhibitor (PI) (lopinavir or atazanavir) or an NNRTI (i.e., EFV) is recommended. Data are limited on newer-generation PIs such as darunavir or tipranavir or entry inhibitors enfuvirtide or maraviroc. Experience with the integrase inhibitor, raltegravir, is increasing, especially as an

addition to an existing regimen to rapidly decrease viral load in late pregnancy.

Physiologic changes during pregnancy such as changes in body water and fat and changes in renal and liver blood flow can affect pharmacokinetics of antiretroviral medications. In general, the pharmacokinetics of NRTIs and NNRTIs are largely unaffected during pregnancy. Protease inhibitor pharmacokinetics is more variable during pregnancy, and levels of several PIs such as lopinavir and ritonavir are reduced in the second and third trimesters.

While concern for genotypic resistance exists when ARVs are used only during pregnancy and then discontinued, treatment failure is rare in high-income settings and also is not common in Africa when reinitiating combination ART after prophylactic use of ARVs during pregnancy. While the DHHS guidelines recommend genotyping for drug resistance prior to the initiation of ART, genotyping is often not accurate after 4 weeks have passed between testing and discontinuation of the prior regimen because the virus will often revert to wild type. Therefore, when selecting a new regimen, all information about a woman's previous HIV history, including previous regimens and adherence and tolerability, should be obtained. If a woman presents late in pregnancy, ART should be initiated without waiting for genotype results. Genotyping is also recommended in pregnant women that do not achieve optimal viral suppression. Adherence to an ART regimen is the best way to prevent development of HIV drug resistance. Another strategy is to continue the NRTI components of an NNRTI-based regimen for 7–30 days after discontinuation of the NNRTI to minimize the risk of resistance given the prolonged half-life of NNRTI medications.

Any antiretroviral drug use during pregnancy is not without risk to the fetus, but the benefit of preventing HIV transmission and the benefit of ART to the mother's health are generally felt to outweigh the risk. Early data about neural tube defects among primates exposed to EFV led to concern about using EFV in the first trimester of pregnancy or in women with childbearing potential. More recent data are reassuring; an updated

systematic review and meta-analysis reported no increase in overall birth defects in infants born to mothers receiving EFV in the first trimester (Ford et al. 2011). While EFV remains FDA pregnancy category D, both the WHO and DHHS guideline panels felt comfortable recommending EFV as part of first-line therapy in HIV-infected pregnant women given the available data.

Efavirenz is preferred over nevirapine (NVP) because of the potential for hepatotoxicity in women with CD4 counts >250 cells/mm³. While there are continued concerns about an even higher risk of severe hepatic and skin reactions in pregnant women using NVP at higher CD4 counts, a systematic review suggested that the frequency of adverse events is elevated but no higher than that observed in the general HIV-infected adult population (Ford et al. 2013).

A previous systematic review did not report an increased prevalence of overall birth defects, and a number of studies have showed no difference in fetal growth between infants exposed to TDF and those not exposed. TDF also has limited penetration into breast milk which limits potential toxicity to breastfeeding infants.

Some studies have suggested that women taking combination ART, with or without protease inhibitors, have an increased risk of adverse pregnancy outcomes such as preterm delivery, stillbirth, or low birth weight compared to pregnant women with HIV infection on no medications or on mono- or dual-NRTI prophylaxis. However, data are conflicting as several variables can confound these observational studies, such as overall maternal health and severity of HIV disease. While clinicians should be aware of the possibility of an association between combination ART and preterm delivery, the benefits of combined ART to maternal health and to decreasing perinatal transmission are clear, and these medications should not be withheld out of concern for preterm birth.

If a woman is already on ART at the time that she becomes pregnant, treatment should be continued for the duration of the pregnancy. Current evidence does not suggest that teratogenic effects are caused by most antiretroviral medications. Certain drugs are of greater concern than others, specifically EFV, which should be avoided in the

first trimester due to nonhuman animal data of concern. However, an HIV-infected woman should continue EFV if it is already part of her existing regimen. This is because the greatest risk of neural tube defects is in the first 5–6 weeks gestation and pregnancy is rarely recognized before 4–6 weeks. Stopping a regimen abruptly is associated with HIV viral rebound which can have serious consequences on HIV transmission and progression of disease.

Intrapartum Management of HIV-Infected Pregnant Women

Intravenous ZDV should be administered intrapartum for pregnant women with HIV RNA greater than or equal to 400 copies/mL (WHO) or 1000 copies/mL (DHHS), poor adherence, or unknown HIV RNA levels near delivery, regardless of mode of delivery or antepartum ART regimen. Intrapartum prophylaxis with ZDV in women who are virally suppressed has not been associated with reduced risk of perinatal transmission. Women that are already receiving ZDV as part of their antepartum ART regimen should be administered IV ZDV while the other antiretrovirals can be administered orally.

It is recommended in resource-rich countries that women who have been on antepartum ART but have not achieved HIV viral suppression (i.e., HIV RNA >1000 copies/mL) should undergo scheduled cesarean section at 38 weeks gestation to minimize the risk of transmission of HIV to the neonate. It is not clear whether cesarean delivery after rupture of membranes or onset of labor provides benefit in preventing perinatal transmission. Management of women originally scheduled for cesarean delivery who present with ruptured membranes or in labor must be individualized at the time of presentation.

In women that experience postpartum hemorrhage due to uterine atony, oral or parenteral methylergonovine or another ergot alkaloid is often administered as a first-line agent. These medications should not be coadministered with protease inhibitors or EFV as the latter agents are CYP3A4 inhibitors. Concomitant use of these

Pregnant Women: Care and Treatment, Table 3 WHO guidelines for infant postexposure prophylaxis

Breastfeeding infants	Infant age	Nevirapine
	Birth to 6 weeks	10 mg once daily
	Birth weight 2000–2499 g	15 mg once daily
	Birth weight ≥ 2500 g	
	>6 weeks to 6 months	20 mg once daily
	>6 months to 9 months	30 mg once daily
	>9 months until breastfeeding ends	40 mg once daily
	Replacement feeding	
	Infant age: birth to 6 weeks	Zidovudine
	Birth weight 2000–2499 g	10 mg twice daily
	Birth weight ≥ 2500 g	15 mg twice daily

medications leads to increased serum levels of ergotamines and subsequent severe vasoconstriction. If there is no alternative therapy for postpartum hemorrhage, ergotamines should be used at the lowest dose and the shortest duration possible.

The goal of prophylaxis in breastfeeding infants is prevention of transmission from HIV exposure during labor and during the early breastfeeding period. The WHO recommends 6 weeks of NVP for infants born to HIV-infected mothers for breastfeeding infants and 4–6 weeks of NVP or ZDV for formula-fed infants (Table 3; see below: “Breastfeeding”). A longer duration of infant prophylaxis may be indicated in breastfeeding infants whose mothers did not receive antiretroviral agents prior to labor. The goal of prophylaxis in formula-fed infants is prevention of transmission from HIV exposure during labor. The DHHS guidelines differ from the WHO guidelines in that breastfeeding is not recommended and 6 weeks of ZDV is recommended for all HIV-exposed neonates; a 4-week regimen can be considered if the mother has received combination ART during pregnancy with consistent viral suppression; and there are no concerns about adherence (Table 4). If mothers

All HIV-exposed infants (initiated as soon as possible after delivery, preferably within 6–12 h)		
Zidovudine (ZDV)	Dosing	Duration
ZDV	≥35 weeks' gestation at birth: 4 mg/kg/dose PO twice daily. If unable to tolerate PO agents, 3 mg/kg/dose IV twice daily	Birth through 4–6 weeks ^a
ZDV	≥30 to <35 weeks' gestation at birth: 2 mg/kg/dose PO twice daily, advanced to 3 mg/kg/dose PO (or 2.3 mg/kg/dose IV) twice daily at age 15 days	Birth through 6 weeks
ZDV	<30 weeks' gestation at birth: 2 mg/kg PO or 1.5 mg/kg/dose IV twice daily, advanced to 3 mg/kg/dose PO (or 2.3 mg/kg/dose IV) twice daily after age 4 weeks	Birth through 6 weeks
Additional antiretroviral prophylaxis agents for HIV-exposed infants of women who received no antepartum antiretroviral prophylaxis (initiated as soon after delivery as possible)		
In addition to ZDV as shown above, administer nevirapine (NVP)	Birth weight 1.5–2 kg: 8 mg/dose PO Birth weight >2 kg: 12 mg/dose PO	3 doses in the first week of life 1st dose within 48 h of birth (birth to 48 h) 2nd dose 48 h after 1st 3rd dose 96 h after 2nd

^aA 6-week course of neonatal zidovudine is generally recommended. A 4-week neonatal zidovudine chemoprophylaxis regimen may be considered when the mother has received standard ART during pregnancy with consistent viral suppression and there are no concerns related to maternal adherence

have not received combination ART, exposed neonates should receive 6 weeks of ZDV combined with three doses of nevirapine in the first week of life. For infants born to mothers with unknown HIV status, prophylaxis should be initiated immediately and discontinued if confirmatory testing is negative.

Care of the HIV-Positive Woman in the Postpartum Period

The immediate postpartum period can pose unique challenges for adherence to ART. For women that were diagnosed when they presented in labor, comprehensive follow-up and counseling are required. The decision to continue or stop ART should take into account current recommendations for initiation of ART, CD4 count and HIV viral load, adherence issues, and patient preference. As noted above, the WHO has recommended Option B+, where a woman initiates combination ART during pregnancy and continues lifelong treatment.

Contraceptive counseling is also a critical aspect of postpartum care, and this time represents an opportunity to optimize a woman's health, including cervical cancer screening, mental health evaluation and substance abuse evaluation, and treatment as needed.

Breastfeeding

HIV-1 can be detected in the cellular and acellular compartments of breast milk. There have been several reports of breastfed infants becoming infected with HIV in the postnatal period. A meta-analysis of studies published before 1992 suggested an attributable risk for transmission through breast milk by women who were infected before pregnancy of 14% and by postnatally infected women of 26% (Van de Perre et al. 1991; Dunn et al. 1992). Not surprisingly, the higher the maternal serum viral load and the lower the CD4 count, the higher the breast milk viral load. The risk of transmission via breast

milk is highest early after delivery as the HIV-1 viral load has been observed to be higher in colostrum/early milk compared to milk produced later. The Centers for Disease Control and Prevention recommends that HIV-positive women living in the United States should not breastfeed because safe alternative replacement feeding is available in the developing world. However, safe and sanitary options for alternative feeding are often not available in low-income nations, and the decision to withhold breastfeeding because of concern for HIV transmission to the newborn can lead to increased rates of infant mortality from diarrhea, dehydration, and malnutrition. In fact, exclusive breastfeeding for 6 months is associated with lower rates of HIV transmission compared to mixed feeding (combination of breastfeeding with other food or liquid such as water, non-human milk, or formula). This is because the combination of breast milk with other food and liquid can disrupt the infant's fragile gut mucosa and lead to increased permeability to HIV.

The current goals as reflected in the latest WHO and UNICEF guidelines are to increase HIV-free survival of the newborn (WHO/UNICEF 2010). Several studies have demonstrated that providing ART to the infant and/or the mother is effective in preventing perinatal transmission of HIV. Based on this evidence, national programs have begun recommending breastfeeding for 12 months and exclusively for 6 months. For programmatic reasons, the WHO has focused on the use of maternal ART to prevent transmission during breastfeeding. Pregnant women should receive ART antepartum and continue for the duration of breastfeeding. Infant prophylaxis is determined by method of feeding and the mother's use of ART. All infants that are breastfed should be given 6 weeks of nevirapine prophylaxis postpartum if their mothers were initiated on ART prior to or during pregnancy. Infants whose mothers started ART during labor or immediately postpartum should receive a minimum of 6 weeks of NVP and 12 weeks is preferable. Infants who are born to mothers who interrupt ART during breastfeeding should continue NVP for 6 weeks after restarting ART or for 1 week after cessation of breastfeeding. ART should be provided to the mother and/or the

infant for at least 1 week after the cessation of breastfeeding. Because of the clear benefits of breastfeeding, mothers in developing countries should still be encouraged to breastfeed even if ART is not available unless environmental conditions are safe for alternative feeding, such as with formula. An unrestricted duration of breastfeeding is not endorsed by the WHO in the latest 2013 guidelines, even when lifelong ART is being employed for mothers, because of concerns of nonadherence to ART throughout the duration of breastfeeding, therefore increasing the risk of HIV transmission to infants. After 12 months, the benefits of breastfeeding in preventing diarrhea, malnutrition, and pneumonia decrease, at which point the risk of breastfeeding by HIV-positive mothers may outweigh the benefits of breastfeeding.

In conclusion, all pregnant women should be screened for HIV infection, and abundant, safe interventions can help reduce her disease progression and can prevent transmission to her infant. Challenges include community education, health systems strengthening, overcoming stigma, engaged men and families, and offering universal ART to women and children who need it.

Definition

Lymphoid neoplastic manifestations of HIV infection include a spectrum of diseases each with specific clinical, epidemiologic, and biological features. This chapter reviews the important lymphoid tumors occurring in HIV infection with an emphasis on the important distinctions relevant to presentation, diagnosis, and clinical management of the various entities.

Introduction and Overview

During the late 1970s and early 1980s, marked changes in the typical occurrence and clinical

behavior of aggressive B-cell lymphomas were among the initial manifestation of the new epidemic disease that ultimately became known as the acquired immunodeficiency syndrome, AIDS. The original Centers for Disease Control and Prevention case definition expanding the definition in 1982 of AIDS to include lymphoma specified that a patient with HIV and an aggressive B-cell lymphoma would carry an AIDS diagnosis. Several years later, this definition was expanded to include intermediate-grade B-cell lymphomas. The study and treatment of AIDS-related lymphoma (ARL) consequently suffered from a poorly structured case definition terminology that failed to classify distinct lymphoma types. Instead, ARL was almost thought of as a single disease. ARL was designated as AIDS indicator conditions, meaning that ARL conferred an AIDS diagnosis when it was the initial manifestation of the syndrome. As the case definition of AIDS evolved over time, the percentage of lymphoma indicator cases shifted downward somewhat as other indicator conditions were more likely to occur before ARL. For example, if another antecedent AIDS indicator condition, such as CD4 cell count falling below $200/\text{mm}^3$, had already been documented, ARL would likely go unreported. The total burden of lymphoma cases in those who already have an AIDS diagnoses is estimated to be up to 25%. About 3% of those with HIV come by their AIDS diagnosis due to ARL.

Early in the AIDS epidemic, prior to the discovery of HIV, immunologic derangement was recognized as the common pathophysiologic event leading to both infectious and neoplastic disease complications. In the ensuing thirty-plus years, the epidemiology of the common AIDS complications has evolved dynamically, owing largely to the availability of effective combination antiretroviral therapy (cART). At the same time, the approaches to lymphoid tumor biology and lymphoma classification have been revolutionized as the science has advanced. The epidemiologic patterns of ARL in the pre-cART and cART eras and the improved lymphoid tumor classification schema provide important clues to ARL presentation and pathology. This chapter will review the

highlights of HIV-related lymphoid tumor epidemiology and pathophysiology that have been described in the context of the still evolving AIDS epidemic. Although the formal AIDS case definition does not include all the lymphoma types discussed in this chapter, the broader range of lymphoid tumors occurring in those with HIV infection will be presented under the designation of AIDS-related lymphomas (ARLs).

A critical concept to appreciate is that ARL is not a clinically or biologically specific term. There are specific ARL entities, each of which requires clinical management approaches specific to the ARL type. Expert hematopathology consultation is thus required to ensure accurate diagnosis and to thus plan optimal therapy. Owing to substantially improved prospects for near-normal life span with effective management of HIV infection, curative treatment for ARL should be considered in most cases.

Mounting evidence suggests the immune status plays a substantial role in the type of ARL that develops. This evidence is comprised of studies of the epidemiology, pathobiology, and clinical studies in ARL. As immunodepletion advances, the risk of ARL increases. Moreover, the type of ARL likely to manifest is related to the degree and duration of HIV replication and immunosuppression. Highlighting this is the marked shift in the occurrence of certain lymphoid tumor types that has been observed in populations where cART is widely used. The ARL epidemiology in such populations diverges markedly from that of pre-cART historic controls and from those populations without widespread access to cART. Cataloging the specific ARL entities thus becomes important not only to individual patient management but also for understanding these tumors in AIDS. Table 1 summarizes the clinicopathological HIV-lymphoma types according to the WHO classification of lymphoid tumors and also incorporates other ARL-specific data (Little et al. 2003; Swerdlow et al. 2008).

ARLs are nearly all B-cell lymphomas. B-cell neoplasms to some extent resemble normal B cells at a particular stage of differentiation. This similarity between the neoplasm and the normal or postulated normal counterpart forms in large part

Presentation and Pathogenesis of B-Cell Lymphoid Cancers Associated with HIV Infection, Table 1 Human immunodeficiency virus (HIV)-associated lymphomas: viral, genetic, and clinical feature

Histological subtype	Percent association										CD4 cells	Prospects for chemosensitivity	Prognosis in cART era
	EBV	KSHV	BCL-2	BCL-6	TP53	MYC	CD4 cells	Prospects for chemosensitivity	Prognosis in cART era				
Burkitt	<50	0	0	100	40–60	100	Usually relatively well preserved	Excellent	Excellent	Excellent			
DLBCL-GC	<30	0	0	>75	Rare	0–50	Variable but rarely depleted	Favorable	Excellent				
DLBCL-ABC	>50	Rare	30	0	0	0–20	Usually low	Intermediate	Intermediate				
PCNSL	100	0	90	<50	0	0	<50	Good (limited data)	Intermediate/good if CD4 recovery can be achieved				
Hodgkin lymphoma	>70	0					Generally preserved	Good	Intermediate (relapse common)

Large B-cell lymphoma arising in HHV-8 multicentric Castleman disease ^a	0	100					Variable	Intermediate	Poor				

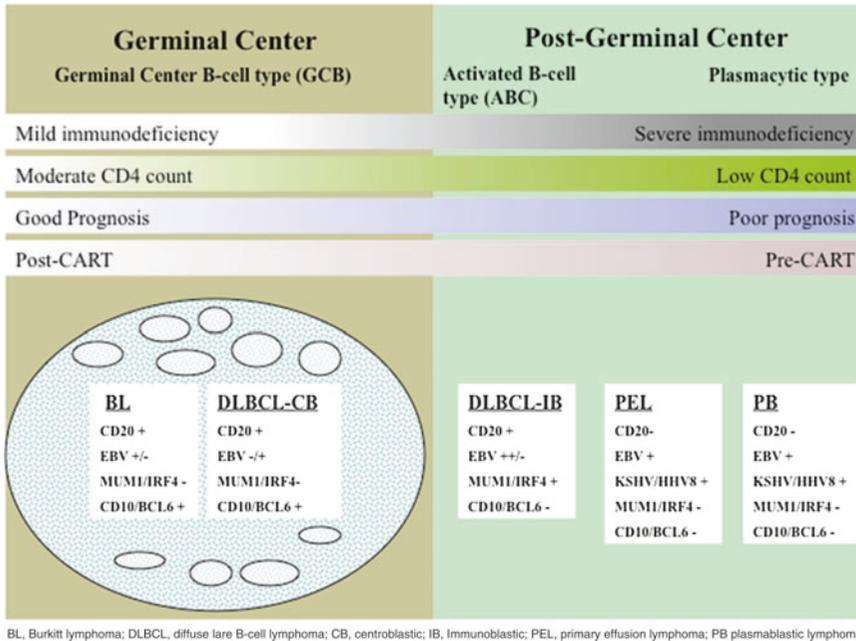

^aOccurs more specifically in HIV

the classification and nomenclature of lymphoid tumors. An advantage to this organizational system is that it aids in correlating the tumor cell morphology, its immunophenotype, and provides insights into clinical behavior by relating tumors back to the cells from which they seem to derive. It is beyond the scope of this chapter to review normal B-cell development, but there are several important aspects in relation to ARL that should be mentioned.

Normal B cells begin from common lymphoid progenitor cells in the bone marrow and develop into mature B cells expressing surface immunoglobulins. During this process, immunoglobulin heavy chain (IgH) and light chain (IgL) genes are formed through a process where the V, D, and J gene segments are recombined to create a vast immunologic repertoire. Until the B cells encounter an antigen with a specific fit for their surface immunoglobulin receptor, they are considered mature naïve B cells. When they encounter antigen, the B cell is activated to proliferate, and this begins a process wherein the cells differentiate into centroblasts or plasma cells. This is accomplished via interactions within peripheral lymphoid tissues. A process of immunoglobulin somatic hypermutation (SHM) of the immunoglobulin heavy chain variable region (IGHV) genes occurs, and class-switch recombination is the end result. In HIV disease, the lymph node's normal architecture, including a derangement in the proportion of follicular T-helper cells involved in regulating B-cell responses, is disrupted (Lindqvist et al. 2012). The degree of lymph node derangement is correlated with the HIV disease status and may influence the processes of normal B-cell differentiation. It may also influence both the risk and type of B-cell neoplastic disease that occurs. Consistent with this hypothesis is the differential risk of the specific lymphoma types that occur in association with the duration and magnitude of HIV replication and the degree of T-cell depletion in HIV disease (Little et al. 2003; Shiels and Engels 2012).

Aggressive B-cell neoplasms, such as those typically found in association with AIDS, broadly correspond to later stages of B-lymphocyte development (beyond the stem cell and lymphoblast

stages). If naïve to antigen, such a cell will undergo a blast transformation when it is exposed to antigen. These are large proliferating cells that give rise to progeny cells that have activity against the specific inciting antigen. HIV-related antigenic stimulation results in this type of activation and is thought to be an important initiator of lymphomagenesis. The effect is related to the degree and duration of immunodepletion, which can be modified by effective cART. In addition to the CD4 cell counts and HIV viral loads, several other biomarkers appear to be related to the lymphomagenic immunologic interface. For example, HIV induces cytokine dysregulation and polyclonal B-cell expansion (Breen et al. 2006). Biomarkers that correlate with B-cell expansion, such as elevated serum CD30 and CD23 and serum free light chains, appear to be associated with increased risk of ARL. The gammaherpesviruses EBV and HHV-8 are associated with ARL that occur at low CD4 cells and could reflect derangements in immune control of the viruses in association with chronic antigenic stimulation. These viruses, along with other infections, can perturb the cytokine profile in patients, potentially making them useful as diagnostic or risk biomarkers. However, dysregulation of cytokines such as IL-6, IL-7, IL-8, IL-10, and IL-15 is found to be perturbed in HIV cases without lymphoid neoplastic disease. These cytokines are not at present reliable markers for lymphoma, either diagnostically or prognostically, most likely owing to a variety of features including host immune genetics such as HLA type. Yet, these features suggest that early therapeutic intervention for HIV could have a beneficial effect on lymphoma prevention. Indeed, preservation of higher CD4 cells has reduced the incidence of ARL overall by around 50% (Besson et al. 2001). Although overall ARL risk is reduced with cART, there is not absolute risk normalization. In addition to reduced overall ARL risk, cART appears to shift the ARL type that does occur toward those having more favorable biology and prognosis (Fig. 1) (Dunleavy and Wilson 2012). The positive effects of cART on lymph node preservation, reduction in antigenic stimulation, and gammaherpesvirus control are features

Presentation and Pathogenesis of B-Cell Lymphoid Cancers Associated with HIV Infection, Fig. 1 A modal for the histogenesis of human immunodeficiency

virus (HIV)-associated lymphomas showing molecular and viral pathogenesis and diffuse large B-cell lymphoma taxonomy (From Dunleavy and Wilson 2012)

that underlie the changing ARL epidemiology in the cART era.

background population, and so the possibility of lymphoid malignancy should always be a consideration in the HIV-infected patient.

The clinical presentation of lymphomas can be understood in terms of these immunologic and cytokine effects as well. The systemic symptoms that are associated with frank lymphoma, such as fever, fatigue, and weight loss, are partly related to cytokine abnormal production. Likewise, cytopenias, and even psychiatric symptoms, may be explained in part by cytokine derangements, though these can also be due to the presence of tumor in the affected organ systems. However, some cases present with no symptoms at all, other than adenopathy. The mass effect from enlarged nodes can mechanically compress nerves and other organs with specific related pain or vague discomfort in some cases. Thus, given the elevated risk of NHL in HIV-infected persons, vigilance and recognition of such symptoms merit consideration for ARL in the differential diagnosis for patients presenting with any of these symptoms. Even with well-preserved CD4 cell counts in patients on cART, lymphoid tumors have a markedly excess incidence relative to the

Specific AIDS-Related Lymphomas

ARL can broadly be viewed as (a) those lymphoid tumors that also occur in immunocompetent hosts and (b) those that occur more specifically in persons with HIV infection (Table 1). The following section reviews the specific lymphoma types in that context. A common theme among the histologic types is that the more advanced the immune dysregulation, the greater the propensity for an oncogenic virus to be associated with the tumor and for other biological features that may confer relative treatment resistance to be present.

Burkitt Lymphoma

Burkitt lymphoma accounts for approximately 30% of lymphomas in HIV-infected persons.

Burkitt typically occurs early in the course of HIV disease before the CD4+ cells are greatly depleted, and this is true for patients treated with cART as well as those who are not. This likely accounts for the relatively little change in Burkitt incidence comparing pre-cART and cART treatment eras. It is not yet clear whether these tumors continue to occur at a constant risk over the duration of HIV infection or whether with time, the lymphoma risk largely shifts to another histologic type, even though the CD4 cell counts are preserved. After all, non-AIDS-Burkitt occurs mainly in children and younger adults, so as those with HIV infection age, the age pattern of NHL may parallel that observed in the HIV-unrelated setting. If this turns out to be the case, over time, a person's risk of Burkitt lymphoma may decline, and the risk for diffuse large B-cell lymphoma may increase, similar to the background population epidemiologic patterns. However, in the developing world, Burkitt incidence may have increased to some extent since the introduction of cART (Abayomi et al. 2011). As yet these findings are not fully understood, but may reflect differences in guidelines for cART including timing of treatment initiation and definitions for viral suppression. The role of EBV in African Burkitt may also influence the emerging epidemiologic patterns there.

There are three epidemiologic forms of BL: sporadic (sBL), seen in developed Western countries; EBV-associated endemic BL (eBL), seen in Africa; and HIV-associated BL (HIV-BL). The three forms are clinically and biologically distinct, but share major similarities. Burkitt lymphoma is an aggressive mature B-cell neoplasm that histologically appears as sheets of medium-sized cells with a growth fraction of essentially 100%, and this in part accounts for the treatment failure seen with standard CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) therapy. The proliferation rate is essentially 100%, and the cells rapidly undergo apoptosis and are phagocytosed by macrophages, leading to an appearance commonly called the "starry sky" pattern. Burkitt express CD10 and BCL6, along with mutated immunoglobulin genes suggesting a germinal center origin. CD20 and CD79a (both B-cell

markers) are essentially always present. The cells are generally negative for BCL2. Constitutive MYC protein expression is characteristic owing to the translocation of the MYC gene to one of the immunoglobulin gene loci, causing deregulated cell cycle control. The most common translocation is t(8;14) (q24;q32), which occurs in 70–80% of patients. MYC activation can also be caused by variant translocations, t(2;8) (p12;q24) and t(8;22) (q24;q11), which occur in 10–15% of patients. MYC overexpression induces apoptosis through a p53-dependent pathway in normal B cells. TP53 mutations occur in Burkitt and could override this effect. However, this may be negated by BIM (Bcl-2-interacting mediator of cell death) downregulation through a variety of mechanisms including EBV, thus in balance promoting cell survival.

Clinically, eBL, which is nearly always EBV associated, occurs mainly in children and involves the abdomen and jaw most frequently. Its geographic distribution overlaps areas where malaria and parvovirus infections are high, and these appear to be not only epidemiological features but also possibly biological cofactors. The incidence of eBL is up to 200 times greater than other BL forms. Indeed, there appear to be molecular interactions between malaria and EBV resulting in viral reactivation that may in part explain the epidemiologic findings.

The sBL form typically occurs in a wide range of ages, but the median is in the young adult years. EBV is seen in 30% or less of cases. HIV-BL is similar to sBL in terms of EBV association and is often the first AIDS complication and initial manifestation of HIV disease. However, in areas of Africa where HIV and eBL overlap, it is not as yet fully clear what the epidemiological dynamics are. This may be in part due to patterns of diagnosis and treatment. The increase in HIV-BL is only partially explained by the various cofactors for sBL and eBL. As mentioned above, immunosuppression is generally relatively mild. However, there is ongoing immune activation in the presence of HIV, even when well treated. This can result in deregulated cytokine profiles affecting B-cell proliferation and survival involving activation-induced cytidine deaminase (AID),

which can lead to c-MYC translocation. Duration of HIV viremia, independent of CD4 cell counts, appears to be associated with risk of NHL development. If HIV viremia is key, then it would seem a potent effect at low replication levels. Apparently, early cART initiation after HIV diagnosis has no effect on Burkitt incidence, but it will be important to see whether this observation holds over time.

An emerging appreciation for the biological differences in the three BL forms suggests that the eBL and sBL have distinct molecular characteristics and that the HIV-BL shares some characteristics of both (Schmitz et al. 2012). The eBL and HIV-BL have higher rates of immunoglobulin heavy chain mutations than sBL, and they show signs of antigen selection, in contrast to the sBL form. When the tumors are segregated on the basis of EBV association (regardless of which epidemiologic form), the differences segregate more pronouncedly by EBV status. Overall, the molecular findings suggest that EBV-negative BL derives from early centroblasts, whereas the EBV-positive BL might derive from late GC B cells that have already started to differentiate into memory B cells. However, it has been suggested that activated C-MYC gene can influence cellular phenotype to appear similar to GC cells making definite assignment of histogenic derivation easier said than done.

The clinical presentation for AIDS-related Burkitt lymphoma is variable. Unexplained fever and night sweats may be the initial symptoms leading to the suspicion of an infection. Bone marrow infiltration can lead to bone pain and cytopenias with consequent easy fatigability, bruising, and bleeding. Abdominal pain or distention, nausea, vomiting, or gastrointestinal bleeding is relatively common owing to a predilection for intra-abdominal involvement by BL. Head and neck presentation is also common, with involvement of the sinuses, oropharynx, and tonsils accounting for symptoms referable to those sites. Involvement of the CNS is common, and the CSF of patients with Burkitt lymphoma should be checked by cytology and flow cytometry for the presence of leptomeningeal disease. Owing to the rapid proliferation rate, Burkitt lymphoma is

highly aggressive and often presents with rapid clinical decline. Elevated lactate dehydrogenase, renal and hepatic abnormalities, urate elevations, and electrolyte abnormalities are common. Coagulation proteins may also be abnormal with frank bleeding. It is essential to recognize that these derangements are due to the lymphoma, and prompt lymphoma therapy is mandatory. Delays in lymphoma therapy can adversely affect survival prospects in this disease, and as such, the cancer therapy and supportive care for the lymphoma complications should take priority in clinical management over any concerns for HIV therapy. The hepatic and renal abnormalities may render cART infeasible to administer until improvement is achieved from lymphoma therapy. It is important to recognize that CHOP is not the appropriate therapy for Burkitt, although earlier in the AIDS epidemic it was often utilized for HIV-BL. The current standard of care is to utilize standard Burkitt lymphoma regimens, such as CODOX-M/IVAC in the treatment of AIDS-Burkitt lymphoma. In the USA, the National Cancer Institute-sponsored nationwide clinical trial of rituximab with infusional dose-adjusted EPOCH (etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin) chemotherapy is under way. The infusional regimen appears to overcome resistance related to high proliferation providing evidence for a rational and less toxic effective therapy for Burkitt lymphoma relative to other regimens.

Diffuse Large B-Cell Lymphoma (DLBCL)

The clinical presentation for DLBCL has been reviewed in the introductory comments. Where there are special considerations, these will be mentioned for each of the following DLBCL types.

DLBCL, Not Otherwise Specified (NOS)

Patients often present with advanced stage disease, including extranodal involvement. The bone marrow should always be examined. The

cerebrospinal fluid (CSF) should be sampled for cytological and flow cytometric evidence of leptomeningeal involvement in all cases with extranodal or marrow involvement. Some experts suggest sampling the CSF regardless. Constitutional symptoms include unexplained fevers, drenching night sweats, fatigue, and unexplained weight loss.

DLBCL NOS is a diagnosis of exclusion, not corresponding to other more specific diagnostic categories within the DLBCL category. It is termed “not otherwise specified” because there are no clear and accepted criteria for further subdivision, although it is clear that within this category there are biologically heterogeneous entities. DLBCL NOS is the most commonly occurring NHL among persons with HIV infection. Within this DLBCL NOS group, there are three common morphological variants, two of which account for the bulk of HIV-DLBCL: the centroblastic and the immunoblastic variants. These also occur in the immunocompetent host. In the immunocompetent setting, DLBCL NOS comprises about 30% of adult NHL, and the median age is 70 years. In the setting of HIV, they comprise over 70%, and the median age is reported to be less than 40 years.

The immunoblastic variant of DLBCL shows a preponderance of cells with pronounced basophilic cytoplasm and plasmacytoid differentiation seen in some cells. Up to 90% are EBV associated. These tend to occur with more advanced immunodepletion. In contrast, the centroblastic variant occurs at higher CD4 cell counts and histologically appears as medium to large lymphoid cells with oval to round vesicular nuclei. There is a monomorphic cellular appearance with scanty cytoplasm that stains with either basic or acidic dyes. EBV association is found in less than 30% of cases. Some cases do include immunoblasts admixed among the predominant centroblasts.

Gene expression profiling (GEP) of DLBCL of HIV-unrelated cases has identified distinct molecular subtypes that have marked differences in survival probability. Two major types identified are those with GEP similar to germinal center B cells (GCBs) and those that are similar to activated B cells (ABCs), and this established the

concept that DLBCL biology was based on the histogenic cell of origin in lymphomagenesis (Alizadeh et al. 2000; Rosenwald et al. 2002). The GCB subtype has marked survival advantage compared to the ABC type, controlled for other clinical features. A third unclassifiable GEP type has survival intermediate between the other two. Although initially conceived as markers of cellular origin, increasingly it is recognized that the molecular subtypes also have differing signaling pathways for cellular transformation and oncogenesis. This may have therapeutic implications if the pathways can be successfully exploited. For example, in the ABC type, the chronically stimulated B-cell receptor (BCR), either through subunit mutations or CARD11, leads to constitutive NF- κ B activation. Recruitment of Bruton’s tyrosine kinase (BTK) is required as part of this signaling, and thus ABC viability involves CARD11-dependent constitutive NF- κ B activation. Also involved in NF- κ B activation is MYD88. These findings suggest potential roles in the ABC subtype for drugs such as BTK inhibitors, bortezomib (to inhibit NF- κ B activation), and lenalidomide (to downregulate MYD88 and other pathways) (Yang et al. 2012). Although the GEP-defined molecular subtyping and prognostic validity have not been confirmed in HIV-DLBCL, a number of features suggest there are parallels in the biology and clinical outcomes (Dunleavy et al. 2010). Precise determination of histogenic and molecular subtypes of HIV-DLBCL will be essential if biologically based advances in HIV lymphomas are to be successfully realized.

Attempts to use immunohistochemical (IHC) algorithms to replicate GEP results and/or stratify patients according to survival have been pursued, in part because they are technologically more straightforward. However, while IHC can accurately identify the majority of cases as GCB, the various algorithms have not been universally successful in maintaining the prognostic value of GEP (Chadburn et al. 2009; Castillo et al. 2012). For ARL cases treated across a spectrum of backbone regimens, IHC designation of GCB and non-GCB-DLBCL subtypes did not segregate the subtypes by overall survival (Chadburn et al. 2009). Also, CD4 count at cancer

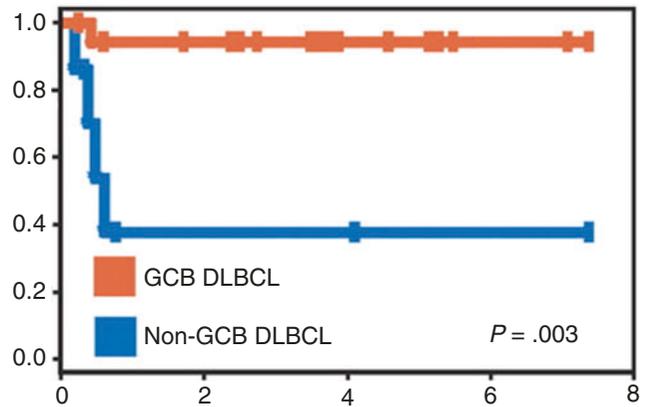

presentation did not segregate according to DLBCL subtype. A drawback to the various immunohistochemical algorithms is that while they identify the GCB type fairly well, they poorly separate the unclassifiable and the ABC type, and this blurs the outcome measures (when unclassifiable and ABC type are combined, the grouped outcome is less bad). In addition, if the treatment administered is not optimal, any potential outcome differences may be further obscured. Since ARL-DLBCL tend to be highly proliferative, they may have relative chemoresistance to standard CHOP chemotherapy, thus making outcome differences by histogenic subtype less obvious. Additionally, if there is death due to nonlymphoma causes, it is difficult to ascribe outcomes according to lymphoma subtype. There is nevertheless data supporting the parallel in HIV and non-HIV-DLBCL outcomes by histogenic subtype. A number of studies have suggested that dose-adjusted infusional EPOCH-R overcomes the resistance due to high tumor proliferation. In a phase II study using IHC to identify the DLBCL subtypes, there was marked segregation in outcome by subtype, again highlighting the critical interrelationship with tumor biology and specific treatment (Dunleavy et al. 2010). Because ARL is a rare disease, each case should be approached as a vital opportunity to better define the tumor biology. Utilization of gold standard biomarker technology should be used in order to avoid pitfalls of conflating inadequate biomarker technology with conclusions regarding biological differences and clinical behavior in ARL. RNA extraction from formalin fixed, paraffin embedded provides accurate GEP-based classification of DLBCL and has potential for use in stratified trial designs.

Epidemiological dynamics over the period of the AIDS epidemic provide important clues toward integrating the knowledge gained from HIV-unrelated cases to the AIDS lymphomas. The incidence of AIDS-defining cases of DLBCL peaked in the early 1990s and then substantially declined in areas where widespread use of effective combination antiretroviral therapy (cART) became available. The risk of DLBCL in HIV is inversely associated with CD4 cell count.

Since cART increases and/or maintains higher CD4 cell counts, the prevalence of those low-CD4 AIDS cases has decreased by over 50%, and consequently a 50% decrease in DLBCL incidence has been observed (Besson et al. 2001). This is due to cART keeping the majority of patients in a CD4 cell range where the lymphoma risk is somewhat reduced compared to the higher lymphoma risk seen when the CD4 cells are low. It is instructive to note that within any given CD4 strata, the risk on ARL is unchanged when comparing pre-cART and cART treatment eras. Also, high CD4 cell levels do not fully normalize the risk of HIV-DLBCL, which remains elevated over the background population by over 50-fold.

In addition to the CD4-related overall risk of ARL, there appears to be an association between the CD4 cell count and the specific biologic and clinical characteristics of the ARL type most likely to occur (Dunleavy et al. 2010; Dunleavy and Wilson 2012) (Fig. 1). Patients with advanced immunodepletion are more likely to develop EVB-associated immunoblastic tumors with ABC characteristics, known to have a poor outcome in the background population because of the inferior curative potential of this subtype. In contrast, those who develop DLBCL at relatively high CD4 cell counts are more likely to develop GCB-DLBCL. Thus, the observation that survival has improved for ARL in the cART era is likely to be explained in part by the improved curability of the GCB-DLBCL subtype and its rise as the predominant DLBCL type owing to less advanced immunosuppression (Little et al. 2003). Further advances in ARL outcomes will depend on accurate biologic identification of cases and will most likely involve relevant targeting of molecular pathways with rational novel therapeutic agents (Wilson et al. 2010). Moreover, it is essential to recognize the differences in prognosis on the basis of tumor biology. The GCB-DLBCL in HIV may already have excellent outcome for which further improvement will be difficult to measure. However, ABC-DLBCL clearly has a poor prognosis, and outcome improvements can be meaningfully targeted in reasonably sized clinical trial designs (Fig. 2).

Presentation and Pathogenesis of B-Cell Lymphoid Cancers Associated with HIV Infection, Fig. 2 PFS for GCB and non-GCB-DLBCL (From Dunleavy et al. 2010)

Primary Diffuse Large B-Cell Lymphoma of the Central Nervous System

AIDS-related primary central nervous system lymphoma (AR-PCNSL) is a CD20+ immunoblastic diffuse large B-cell lymphoma. It is almost always restricted to patients with severe T-cell depletion of less than 50 CD4+ cells/mm³ and is essentially always associated with EBV in the malignant cells. The risk of AR-PCNSL is several thousandfold greater than in the background population. Thus, while PCNSL also occurs in the immunocompetent population, in those with HIV infection, its singular relationship with severe immunodepletion and the fact that each cell harbors latent EBV infection suggest substantial pathobiological differences relative to PCNSL occurring in the immunocompetent host. AR-PCNSL is truly an opportunistic cancer. This is highlighted by the marked decrease in incidence of AR-PCNSL in areas where there is widespread use of cART. Occasionally PCNSL develops in an HIV-infected person with no prior AIDS complications and with CD4 cells counts in the normal range. Such cases may be EBV unrelated and likely represent a qualitatively separate process more akin to those PCNSL occurring in the background population. It is questionable whether these cases are truly AR-PCNSL, and it is more likely that they represent primary brain lymphoma coincidentally occurring in a substantially non-immunosuppressed HIV-infected person. It is worth recognizing that HIV-infected persons get cancers seen in the background population

with similar presenting features and risks. Discussed here are those PCNSL occurring at very low CD4 cell counts.

The pathogenesis of AR-PCNSL remains unclear. The finding of sentinel white matter lesions in the brain suggests that normal B-lymphocytes may undergo clonal proliferation as the basis for lymphomagenesis. The EBV latent membrane protein LMP1 likely contributes to malignant transformation through upregulation of the antiapoptotic protein BCL2. Alternative explanations involve the trafficking of peripheral lymphocytes into the brain. Toll-like receptor (TLR) activation from HIV-nef and other proteins may lead to immune activation and dysregulation of cytokines (Sasakawa et al. 2012). TLR polymorphisms (e.g., TLR9) may predispose to AR-PCNSL through effects of EBV. Preclinical models of PCNSL suggest higher expression of certain adhesion molecules (such as LFA-1 and ICAM-1) mediated by dysregulated cytokines such as IL-8 in HIV compared to non-HIV-derived specimens and that these can be interrupted with agents such as zidovudine. Interestingly, AR-PCNSL responses have been reported with the use of high-dose zidovudine (Raez et al. 1999). In patients with advanced HIV infection, poor immunosurveillance enables EBV-related lymphoma cells to escape detection and then to disseminate and lodge through interactions between chemokine receptors on lymphocytes and brain vascular endothelium owing to HIV-induced aberrant cell adhesion and chemokine receptor expression. These factors likely

create a unique microenvironment for the development and growth of opportunistic tumors. Though no studies have performed molecular profiling on AR-PCNSL, the few studies that have done so in HIV-negative PCNSL suggest that these tumors are of late or post-germinal center origin and may be susceptible to strategies that target NF-kappa B.

The clinical presentation for AR-PCNSL varies considerably. Patients can be symptomatic in a very subtle sense, showing only vague personality changes such as poor attentiveness or memory loss or mild lethargy. Neurological deficits such as cranial nerve paralysis, visual impairment, aphasia, and seizures can be seen. Headache is less common than one might suspect, but can be the only presenting feature. Rapid clinical deterioration over days or weeks is typical.

Radiological findings are nonspecific but very sensitive. There can be considerable overlap with toxoplasmosis or other CNS abscess. On brain imaging, there can be unifocal or multifocal lesions that are variably radiodense on non-contrast CT scan. MRI typically shows a hypointense or isointense T1-weighted image. Gadolinium-enhanced MRI can appear as ring enhancing or a variety of other forms and even non-enhancing at all.

The near-universal association with EBV in AR-PCNSL and the fluorodeoxyglucose (^{18}F) positron emission tomography (FDG-PET) avidity of the tumor provide the basis for an important diagnostic biomarker. In cases where CSF is collected and found to be positive for EBV by polymerase chain reaction (PCR), and where the FDG-PET is also positive, the positive predictive value for AR-PCNSL approaches 100%. If both tests are negative, the negative predictive value approaches 100%. Thus, in cases where definitive biopsy diagnosis is not feasible, definitive therapy for lymphoma can be commenced without the traditional delays in waiting for evidence that antibiotic intervention is failing. The standard approach in the era prior to cART was to first treat for presumptive infectious toxoplasmosis; if the patient did not respond, it was then thought likely that the diagnosis was lymphoma. This approach is no longer justifiable, at least for many cases. Understanding the rationale that

distinguishes past and current practice is critical. Prior to cART, patients with AR-PCNSL had a dismal prognosis based on both the brain tumor and the advanced irreversible HIV disease. In contrast, a patient in the current era may have highly reversible HIV disease, particularly if cART naïve. Thus, a patient who presents with AR-PCNSL may have a rapid immune reconstitution (including specific EBV immunosurveillance) and rapid tumor resolution if therapy is promptly initiated for both the HIV and the brain tumor. Therefore, urgent initiation and completion of definitive diagnostic work-up and treatment initiation for the identified pathology should be the standard of care in the current era. In the HIV-unrelated setting, a trial of antibiotics for undiagnosed intracranial processes would be an egregious and indefensible approach. In the cART era, if the HIV is highly treatable, the approach to those with AIDS should be just as urgent as in the HIV-unrelated setting.

Unfortunately, use of a biomarker-driven diagnostic approach and its potential lifesaving application is difficult to study well owing to the rarity of the disease. The irony is that with improved therapy and improved diagnostics available, the condition has become even more rare, and producing a high level of evidence to inform practice is increasingly elusive. Nevertheless, there is little justification for adhering to the clinical approach established in the early 1980s. Administering a trial of anti-toxoplasmosis therapy and waiting for that to fail before commencing with definitive lymphoma only increase the permanent morbidity and lethality of the tumor. Though the evidence is limited, AR-PCNSL may be particularly responsive to therapy, and the approach to care should consider the prospects for long-term control of the underlying HIV.

It is important to reiterate that more typical PCNSL may occur in those with well-treated HIV disease without advanced immunosuppression. These cases are likely to be like those in the elderly background population. The diagnostic approach should be the same as in the background population, as the association with EBV is likely to be much less than then AR-PCNSL as categorized here.

Hodgkin Lymphoma

Hodgkin lymphoma clinical presentation is similar to that for DLBCL, with the exception that the central nervous system is not involved. Patients may present with minimal symptoms or with the constellation of systemic symptoms mentioned as in the DLBCL section above.

Although not designated as an AIDS-defining condition, the risk of classical Hodgkin (CHL) lymphoma is elevated eightfold or more in HIV-infected persons relative to the background population. CHL is distinguished from nodular lymphocyte predominant Hodgkin lymphoma (NLPDHL) owing to distinct clinical, epidemiological, and biological features. NLPDHL is not elevated in HIV. There are four histological subtypes of CHL: lymphocyte-rich CHL, nodular sclerosis CHL (NSCHL), mixed cellularity CHL (MCCHL), and lymphocyte-depleted CHL (LDCHL). In HIV, MCCHL and LDCHL are the predominant forms seen. In the background population, NSCHL is the most common form.

The risk of CHL appears to have increased during the cART era, though whether this is mainly due to changes in diagnostic accuracy, the increasing prevalence of persons with HIV in the cART era, or to aging over the period of the AIDS epidemic is somewhat unsettled. Also, the risk of CHL appears greatest during the first few months after initiation of cART and then decreases or stabilizes with chronic therapy, and this may contribute to the apparent increase in CHL in the cART era. Patients with 50–99 CD4 cells/mm³ appear to be most affected by cART initiation, suggesting that CHL could be related to immune recovery. Most cases present with advanced stage, and nearly 50% have extranodal sites or marrow involvement. This may reflect in part that MCCHL has a propensity for disseminated presentation with abdominal and splenic involvement, in contrast to NSCHL, which typically spreads in an orderly fashion among contiguous lymph node groups. Also, in HIV infection, 80% of cases are EBV associated. Interestingly MCCHL is more likely to EBV associated than NSCHL regardless of HIV status. The EBV-associated cases express the latent membrane protein 1 (LMP1) and are

EBER positive. An interesting finding in CHL is that while the immunophenotype of the tumor cells is similar among the subtypes, there are marked difference in other features including the sites of involvement, clinical features, growth pattern, presence of fibrosis, and the composition of the cellular background. It has been postulated that cART enables the cellular background to thrive and promote CHL (Biggar et al. 2006).

CHL is characterized by the presence of Reed-Sternberg (HRS) cells that are multinucleated monoclonal B cells residing in a background of nonneoplastic reactive cellular infiltrate (Swerdlow et al. 2008). It is the appearance of this infiltrative process that defines the CHL subtype. HRS variants that have only one nucleus are called Hodgkin cells. The HRS or variant usually is the minority of cells comprising the affected tumor tissue, making up less than 10% of the total cellularity. They are CD30+ in nearly all cases, and this feature is being exploited in clinical trials of the conjugated monoclonal antibody brentuximab vedotin in HIV-CHL. CD15 is found in about 85% of cases. If CD20 expression is detected, it is generally variable in its intensity on the neoplastic cells, with many of them not expressing it at all. Other markers of B-cell specificity include PAX5/BSAP seen in activated B cells, though its comparatively weaker intensity in HRS cells distinguishes them from the former. There is overexpression of cytokines and chemokines and/or their receptors in CHL, and this feature is consistent with the inflammatory CHL tumor appearance. Clonal immunoglobulin gene rearrangement is found in the HRS cells in nearly all cases. Along with the finding that these show somatic hypermutation and other features, HRS cells appear to be derived from a germinal center B cell. In cases associated with HIV, this is consistent with the finding that many cases occur when the CD4 cells are relatively intact or improving during cART initiation as mentioned above. Nevertheless, HRS appears to have lost much of the typical B-cell gene expression pattern. Deregulated NKκB, JAK/STAT, and other transcription factors are found by gene expression in HIV-unrelated cases. These features require further study in HIV-related cases.

Therapeutically, classical HL in the setting of HIV should be approached in the same way as HIV-negative HL, and regimens such as ABVD should be the standard approach. Recent data shows HIV status does not influence outcome in patients with cHL treated with ABVD chemotherapy in the cART era (Montoto et al. 2012).

Primary Effusion Lymphoma

Primary effusion lymphoma (PEL) is a large B-cell lymphoma with variable morphology (Swerdlow et al. 2008). It can appear as plasmablastic, immunoblastic, or frankly anaplastic. It almost always presents as a serous effusion, hence its synonym body cavity lymphoma. Generally it is asymptomatic until the effusion has accumulated sufficiently to cause mechanical effect, such as pain or a feeling of fullness. If the effusion is in the pleural space, shortness of breath may occur. If the effusion is in the pericardial space, fatigue, dizziness, and signs of heart failure can occur as cardiac function becomes compromised. Patients presenting with PEL may have concomitant Kaposi sarcoma and/or multicentric Castleman disease (MCD) or a history of these.

Diagnosis is confirmed by examination of the cellular component of the effusion, which can sometimes be aspirated in large quantities. PEL is always positive for the human herpes virus-8 (HHV-8, also known as the Kaposi sarcoma-associated herpes virus, KSHV). In upwards of 70% of cases, the tumor cells are dually coinfecting with HHV-8 and EBV. If HHV-8 is not present, but EBV is found in a lymphomatous effusion, the likely diagnosis is pyothorax-associated DLBCL, not PEL.

B-cell immunophenotypic markers can be lost in PEL, though some are weakly CD20 positive. Nonlineage antigens including CD30 can be present, possibly suggesting a role for the use of brentuximab vedotin therapeutically. B-cell histology can be confirmed by molecular analysis and the finding that immunoglobulin genes are clonally rearranged and hypermutated. GEP shows a distinct profile with features of both

plasma cells and EBV-transformed lymphoblastoid cell lines (Fan et al. 2005).

It is reported that PEL occurs mainly with depleted CD4 cell counts, though cases clearly do occur when the CD4 cell count is near normal. The HHV-8 gene expression program includes a number of human gene analogues that can affect immunosurveillance and immune evasion. The prognosis is generally not favorable, and the response to chemotherapy is poor. Targeted therapies based on the virology and tumor pathobiology will likely be critical to improving the therapeutic outcomes.

Plasmablastic Lymphoma

Plasmablastic lymphoma (PBL) is an uncommon B-cell tumor occurring predominantly in HIV-positive middle-aged males (Swerdlow et al. 2008). It can also occur in other immunodeficiency states. Among the elderly, it can occur without evident immunodeficiency. In nearly all cases, the tumor is EBV infected. PBL frequently involves the oral cavity and originally was termed PBL of the oral cavity prior to the realization that it does involve other anatomic sites as well. Most patients have stage III–IV disease at presentation and a high-risk international prognostics index score, a clinical rating system of lymphoma prognosis.

There is a spectrum of morphologic appearances in PBL. PBL can resemble immunoblasts or have a more plasmacytic differentiation appearing similar to plasmablastic plasma cell myeloma. They often have a high proliferation fraction with a monomorphic plasmablastic cytology, particularly when presentation involves the oral, nasal, and paranasal areas in those with HIV infection. The immunophenotype shows expression of CD138, CD38, Vs38c, and IRF4/MUM1, with weak or no expression of CD45 and CD20. CD79a (a B-cell marker) is present in the majority of cases. Cytoplasmic immunoglobulins are expressed and most are IgG with restriction to either kappa or lambda light chain. Clonal immunoglobulin heavy chain rearrangement is found even when immunoglobulin expression is not detectable. CD30 is frequently expressed and

may suggest a role for brentuximab vedotin. Ki67 index is usually over 90%, so the tumor is highly proliferative. EBV EBER in situ hybridization is positive in most cases, but LMP1 is rarely expressed. HHV-8 is absent. The clinical course is very aggressive with median survival less than 1 year. Cases with limited involvement may respond well to chemotherapy followed by involved field radiotherapy.

HHV-8 Multicentric Castleman Disease

HHV-8 multicentric Castleman disease (MCD) is a syndrome of constitutional symptoms with variable organ and hematopoietic dyspoiesis. Histopathologically it is characterized by an involution and hyalinization of germinal centers of B-cell follicles in the lymph nodes and spleen. The mantle zone can be prominent and intrude into the germinal center. In the mantle zone are found larger plasmablastic cells that are positive by immunohistochemistry for HHV-8 latent nuclear antigen-1 (LANA). The syndrome is mediated in part by aberrant interleukin-6 (IL-6) production (Uldrick et al. 2011). HHV-8 encodes for a viral form of IL-6 and can also serve to promote human IL-6. Immunoglobulin M lambda is expressed without evidence of monoclonality. Consideration for HHV-8 MCD should be raised in a patient with intermittent constitutional symptoms, fevers, and cytopenias. HHV-8 serology and viral loads can be determined in support of the diagnosis. Though splenomegaly may be impressive, there may be only moderate adenopathy. FDG-PET may be useful to identify metabolically active nodes and help to identify the most likely lymph node to biopsy in order to confirm the histopathologic diagnosis. Needle aspiration yields inadequate architecturally intact material for diagnostic utility.

Conclusions

The availability of cART has significantly changed the landscape of HIV-associated lymphoma. Both BL and DLBCL, in the setting of HIV infection, are now highly curable with current strategies. For

these lymphomas, future directions should focus on identifying driver pathways and novel targets and improving strategies particularly for the treatment of non-germinal center tumors.

Preventing HIV-1 Transmission Through Vaccine-Induced Immune Responses

Jean-Louis Excler, Merlin L. Robb,
Jerome H. Kim and Nelson L. Michael
U.S. Military HIV Research Program, Bethesda,
MD, USA

Definition

According to UNAIDS, globally 35.0 million people were living with HIV at the end of 2013. Sub-Saharan Africa remains most severely

affected, accounting for 71% of the people living with HIV-1 worldwide. The number of people newly infected or who died from AIDS-related causes declined worldwide. Despite genuine, although unequal and fragile, successes in prevention programs attributed to strengthening and scaling up prevention strategies and antiretroviral treatment, the development of a preventive HIV-1 vaccine as part of a comprehensive prevention package remains among the best hopes for controlling the HIV-1 pandemic. By inducing appropriate immune responses directed against a specific pathogen, vaccines remain the most powerful public health tool to prevent infectious diseases. They may either prevent infection by the pathogen or the development of the disease due to this pathogen.

Goals of an HIV-1 Vaccine

The most promising approach to lead an HIV-1 vaccine to licensure remains to prevent HIV infection and provide sterilizing immunity. A second goal would be to reduce HIV-1 viral load (VL) by controlling viral replication to stop progression to disease, and reduce subsequent transmissibility, in vaccine recipients who became HIV infected. These two goals are complementary. However, from a regulatory and licensure perspective, the acceptance of a vaccine that would only reduce VL seems unlikely, as the validation of immune markers that counter viral replication would need to be supported by tangible long-term clinical benefits. This might not be feasible and is likely unethical to demonstrate, as HIV-infected individuals should benefit from early antiviral treatment. High community VL may be a central driver of the HIV-1 epidemic in Africa. Thus, by decreasing community VL over time as the portion of the infected community members with reduced viral load, thanks to vaccination, increases, a reduction in overall may be achieved. This rationale has been at the basis of treatment-for-prevention strategies now developed for HIV-infected people. However, demonstrating the same impact from vaccines would take a very large study over an extended

period and is likely not feasible. Thus the primary goal of an HIV vaccine is prevention.

HIV-1 Vaccine Immunological Concepts

Natural immunity to HIV-1 does not protect against infection and progression to disease. Theoretically then, an effective HIV-1 vaccine needs to generate qualitatively or quantitatively different immune responses, perhaps responses not identified in natural infection, sufficient to block or modify infection. Until recently, the nature of a vaccine-induced protective immune response remained elusive and the development of an HIV-1 vaccine included a substantial empiric approach. The understanding of which immune responses should be induced for protection (immune correlates of protection) in humans and nonhuman primates studies (NHP) was, and still is, limited.

One of the major difficulties for an HIV-1 vaccine is the induction of immune responses that overcome HIV-1 variability. The HIV-1 envelope is particularly variable among HIV-1 subtypes and circulating recombinant forms. Ideally, antibodies induced by the HIV-1 envelope immunogens should neutralize free virus and/or by linking the envelope expressed at the surface of HIV-infected cells to killer cells will eliminate infected cells through antibody-dependent cell-mediated cytotoxicity (ADCC). In contrast, core proteins (Gag, Pol, Nef, Tat, Vif) expressed at the surface of HIV-infected cells are more conserved among HIV-1 subtypes. By targeting HIV-1 proteins expressed at the surface of HIV-infected cells, HIV-specific cytotoxic T lymphocyte (CTL) will contribute to eliminate these HIV-infected cells.

It has therefore been postulated that both vaccine-induced humoral and cell-mediated immune responses would be needed to counter HIV-1 in the peripheral compartment (blood, lymph nodes) and mucosal tissues (cervicovaginal, gut), the entry point of the virus for sexual transmission. These considerations have led to vaccine and regimen designs aiming at inducing both types of responses (Walker et al.

2011). Antibodies are better induced by vaccination with HIV-1 soluble envelope subunit proteins. CTL are classically induced by vaccine components such as DNA and recombinant vectors either alone or in combination and expressing HIV-1 core proteins presented to the immune system via the HLA-I pathway. To that effect, the “prime-boost” regimen consisting of priming the immune system with a vaccine component (e.g., vector or DNA) and boosting the immune response with another vaccine component (e.g., an Env subunit protein or vector) is now common.

Vaccine Efficacy and Immunogenicity

Table 1 shows the various vaccine approaches tested in humans so far. The main findings of vaccine-induced immune responses in early clinical development (phase I and II trials) are summarized in Table 2. Table 3 shows vaccine regimens that have reached advanced development and efficacy clinical trials in humans.

Canarypox (ALVAC), fowlpox, attenuated replication-incompetent vaccinia: modified vaccinia Ankara (MVA), NYVAC
Replication-defective adenovirus vectors
Human (Ad5, Ad35, Ad26) and chimpanzee (ChAdV63) subtypes
Replicating vectors
Vaccinia Tiantan, paramyxoviruses (measles, Sendai), vesicular stomatitis virus
Other vectors
Adeno-associated virus vector type 2, alphavirus replicon Venezuelan equine encephalitis
DNA
Vaccine combinations (prime-boost)
DNA + Env subunit protein, DNA + recombinant vector, Vector + Env or non-Env fusion subunit protein, Vector + vector

Preventing HIV-1 Transmission Through Vaccine-Induced Immune Responses, Table 2

Main immunogenicity findings of phase I/II trials

Antibody responses

No broadly neutralizing antibodies to HIV-1 are induced by current vaccines

Binding antibodies, ADCC, and neutralizing antibodies against easy-to-neutralize and some against more difficult-to-neutralize HIV-1 isolates are induced by Env subunit proteins formulated with potent adjuvants

Env antibody titers increase after Env protein booster doses but wane rapidly to lower levels

An Env subunit protein boost seems necessary to induce higher levels of serum antibodies

Mucosal and systemic immunizations are able to induce both IgG and IgA in plasma and mucosal secretions

T-cell-mediated responses

Polyfunctional CD4⁺ and CD8⁺ T-cell immune responses are detected in a majority of vaccine recipients immunized by vectors alone and to some extent by DNA alone. Generally of low to moderate magnitude, these responses are generally significantly augmented by immunization with vaccine combinations

CD8-mediated inhibition of *in vitro* viral replication can be detected after vector vaccination

Cell-mediated responses to DNA administered by electroporation are significantly augmented compared to intramuscular needle injection

Specific gene activation immune signatures can be identified as predictive of the immune responses

Natural preexisting immunity to vectors may modulate vaccine-induced immune responses

Protection of HIV Acquisition by Antibodies

Three efficacy trials (RV144, Vax003, and Vax004) tested the hypothesis that antibodies directed against the HIV-1 envelope could protect against HIV acquisition.

RV144

RV144, a seminal community-based efficacy trial conducted in Thailand, tested a recombinant canarypox vector (ALVAC-HIV) prime and gp120 Env protein boost regimen and provided the first evidence that protection against HIV-1 acquisition could be achieved. These findings have generated considerable interest and opened new and unprecedented avenues to accelerate the development of a licensed HIV vaccine.

The vaccine regimen conferred an estimated vaccine efficacy of 31.2% against HIV-1 acquisition after 42 months of follow-up (Rerks-Ngarm et al. 2009). The interaction of risk status and acquisition efficacy was significant with greater benefit in low-risk individuals. Vaccine efficacy appeared to be higher (60%) at 12 months post vaccination, suggesting an early, but nondurable, vaccine effect (Robb et al. 2012). The vaccine had no effect on early postinfection HIV-1 RNA VL or CD4⁺ T-cell count, nor did it affect the clinical course of HIV disease after infection. A further analysis showed evidence of lower seminal VL in vaccine recipients who acquired HIV infection (Rerks-Ngarm et al. 2013).

HIV-specific T-lymphocyte responses detected were predominantly polyfunctional effector memory CD4⁺ T cells and recognized peptides derived from the Env V2 loop region (de Souza et al. 2012). The V2 loop region includes the $\alpha 4\beta 7$ integrin-binding site, a mucosal homing marker.

Plasma binding antibodies against Env was nearly uniformly present including antibodies to V2 synthetic peptides. ADCC activity was also detected (Bonsignori et al. 2012). In the TZM-bl system, neutralizing antibodies (NAb) to easy-to-neutralize (tier-1) viruses were detected but not against difficult-to-neutralize (tier-2) viruses (Montefiori et al. 2012).

Vax003

Vax003 was a phase III trial testing a gp120 vaccine (subtype B and CRF01_AE gp120 proteins) in injecting drug users (IDU) in Bangkok, Thailand. The vaccine did not prevent HIV acquisition or disease progression (Pitisuttithum et al. 2006). The reasons why Vax003 regimen failed to protect whereas the RV144 regimen conferred some protection despite using similar envelope immunogens are unclear. NAb to tier-1 viruses were higher in Vax003 than in RV144 and sporadic tier-2 NAb were detected. The quality of the antibody response, in particular the Env-specific IgG subclasses, may explain such difference. In previous trials, gp120 only induced high levels of Env-specific IgG4 antibodies while ALVAC prime and gp120 boost

Preventing HIV-1 Transmission Through Vaccine-Induced Immune Responses, Table 3 HIV-1 vaccine efficacy trials in humans

Study protocol	Vaccines	Population enrolled	Location	Result
HVTN 505	DNA + Ad5	Circumcised MSM and TG who are Ad5 Ab negative	USA	Stopped for futility. No efficacy; nonsignificant increase of HIV infection rate in vaccinees
RV144	ALVAC-HIV and AIDSVAX B/E gp120	Community mostly at low risk for HIV infection	Thailand	31.2% efficacy against HIV acquisition. No effect on plasma viral load
HVTN 502 Step trial	MRKAd5 HIV-1 gag/pol/nef B	MSM, high-risk heterosexual men and women	North and South America, Australia, Caribbean	No efficacy; transiently increased HIV infection risk in vaccinees
HVTN 503 Phambili trial	MRKAd5 HIV-1 gag/pol/nef B	Heterosexual men and women	South Africa	No efficacy; nonsignificant increase of HIV infection rate in vaccinees
Vax003	AIDSVAX B/E gp120	Injecting drug users	Bangkok, Thailand	No efficacy
Vax004	AIDSVAX B/B gp120	MSM, high-risk women	USA	No efficacy

ALVAC-HIV: recombinant canarypox vector (vCP1521) encoding HIV-1 Gag and protease subtype B and Env gp120 CRF01_AE linked to the transmembrane-anchoring portion of subtype B gp41 protein

Ad5 Ab: Ad5-specific neutralizing antibody

DNA plasmids expressing HIV-1 Gag, Pol, and Nef subtype B and HIV-1 Env subtypes A, B, and C

Ad5: mixture of four Ad5 vectors encoding the HIV-1 Gag-Pol polyprotein subtype B and HIV-1 Env A, B, and C matching the DNA Env components

MSM: men who have sex with men; TG: male-to-female transgender persons who have sex with men

elicited lower IgG4 relative to IgG1 and IgG3 antibodies. Antigen-specific IgG3 antibodies have been associated with control of the pathogen and clinical protection in several infectious diseases. Despite lower antibody responses in RV144, specific qualities of these responses involving IgG3 antibodies and functions were higher in RV144 than in Vax003 and may have played a role in protection. Other plausible explanations include the role of ALVAC priming and the low-risk mostly heterosexual study population in RV144 compared to Vax003 conducted in high-risk IDU with a radically different, nonsexual mode of transmission.

Vax004

Vax004 tested a similar bivalent gp120 vaccine (subtype B) in US men who have sex with men (MSM) and women at high risk for heterosexual transmission of HIV-1. The vaccine did not prevent HIV-1 acquisition or disease progression. Peak antibody levels inversely correlated with

HIV-1 incidence. The levels of antibodies either caused an increased risk among low responders or a decreased risk among high responders for HIV-1 acquisition. Most vaccine recipients mounted potent NAb against tier-1 viruses and occasional weak tier-2 NAb. Vaccination was associated with the presence of gp120-binding IgG in mucosal secretions and plasma and IgA in plasma. HIV acquisition correlated inversely with serum antibody-dependent cell-mediated virus inhibition (ADCVI) activity but poorly with neutralizing or CD4-gp120-blocking antibody activity against laboratory strains.

Immune Correlates of Risk for HIV-1 Acquisition

A correlate of risk is defined as an immunological measurement that correlates with the rate or level of a study endpoint used to measure vaccine efficacy in a define population. A correlate of protection is an immune marker statistically correlated with vaccine efficacy (equivalently, predictive of

vaccine efficacy) that may or may not be a mechanistic causal agent of protection (Plotkin and Gilbert 2012).

RV144 provided the first opportunity to study the correlations between vaccine-induced immune responses with vaccine efficacy (Haynes et al. 2012). A complex set of analyses identified two immune variables that correlated significantly with HIV-1 infection risk: plasma IgG binding antibody to scaffolded gp70 V1V2 envelope proteins correlated inversely with risk, while Env plasma IgA correlated directly with risk, raising the hypothesis that IgA responses against Env and IgG responses directed against V1V2 may be mechanistically associated with protection. Neither low levels of V1V2 antibodies nor high levels of Env-specific IgA antibodies were associated with higher rates of infection than in the placebo group, suggesting there was no evidence for enhancement of infection risk. IgG avidity, ADCC, NAb, and Env-specific CD4+ T cells were inversely correlated with risk of infection in vaccinees with low levels of Env-specific IgA antibodies. These V2-specific antibodies can mediate ADCC, neutralization, and low-level virus capture.

Most of RV144 incident HIV-1 infections were CRF01_AE, the HIV-1 strain predominantly circulating in Thailand and much of South East Asia. An analysis looking for a difference in the sequences of viruses infecting vaccine versus placebo recipients, also called “sieve” analysis, supported the hypothesis that immune responses directed against two specific amino-acid positions in the V2 loop were associated with protection (Rolland et al. 2012).

The reasons for negative association between high levels of plasma IgA and protection are unclear. IgA may block the action of IgG, in particular ADCC and phagocytosis. The gp120 C1 region contains a target epitope on the surface of virus-infected cells for antibodies that mediate ADCC. Vaccinees with IgA antibodies to the gp120 C1 region had a higher risk of infection than vaccinees without these antibodies. IgA antibodies elicited by RV144 can block C1 region-specific IgG-mediated ADCC.

Hypothetical Mechanisms of Action

There is no clear correlate of protection for several successful vaccines where antibody appears to play a major role, suggesting that protection may not be conferred exclusively by NAb. RV144 generated robust Env-binding antibodies that showed poor neutralizing activity suggesting that non-neutralizing, but functional, binding antibodies may play a role in protection from HIV-1 acquisition.

Cervical mucus and cervicovaginal mucus naturally hinder the diffusion of HIV-1 in an envelope-independent manner. One hypothesis is that binding antibodies may potentially inhibit HIV transmission at the genital mucosa by mechanisms such as formation of large complexes that cannot penetrate superficial epithelial barriers. In mucosal tissues, a subset of CD4+ T cells express the integrin $\alpha 4\beta 7$, the gut homing receptor. These T cells are highly susceptible to HIV infection. Env gp120 binding to $\alpha 4\beta 7$ is mediated by an Env region located in V1V2. It is therefore conceivable that gp120 antibodies may block the gp120- $\alpha 4\beta 7$ interaction and contribute to the protective effect against HIV sexual transmission.

Mediation of antigen-specific targeting and killing of infected cells through ADCC almost necessarily occurs after the virus had traversed the epithelial boundary. Following vaccination with rgp120 in Vax003, ADCVI activity was higher among those with a lower rate of sexually acquired HIV infection.

Nonhuman Primate Challenge Studies Supporting RV144 Findings

Following the release of the RV144 results, the outcome of various nonhuman primate (NHP) challenge studies was revisited. ALVAC-SIV prime and gp120 boost regimen recapitulating the RV144 regimen conferred protection against acquisition following a repeated low-dose mucosal challenge of SIVmac251 in 30% of the vaccinated animals, a proportion similar to that observed in RV144. Protected animals had higher avidity antibodies to gp120, recognized the V2 variable envelope region, and reduced

SIVmac251 infectivity in cells expressing high level of $\alpha 4\beta 7$, suggesting a functional role of V2 antibodies. Similarly, in macaques vaccinated with various combinations of DNA and vectors, protection against SIV acquisition correlated with Env and V2-specific binding antibodies and tier-1 NAb (Barouch et al. 2012). A sieve analysis of breakthrough infections in vaccinated animals supported the possible role of protective responses directed against the Env-V2 region.

HIV Vaccines that Primarily Induce T-Cell-Mediated Immune Responses

The failure of antibody-inducing vaccines in Vax003 and Vax004 and the lack of vaccines able to induce bNAbs led to the concept of vaccines whose principal mechanism of action was the induction of cell-mediated (largely cytotoxic) immune responses.

Step (HVTN502) and Phambili (HVTN503) Vaccine Efficacy Trials

The Step (Buchbinder et al. 2008) and Phambili vaccine trials (Table 3) were the first clinical trials assessing the efficacy of a T-cell-based vaccine. The Merck vaccine (MRKAd5 HIV-1) was a mixture of replication-defective Ad5 vectors expressing HIV-1 *gag*, *pol*, and *nef* subtype B genes; no *env* gene was present. The Step trial was unexpectedly halted. In subjects with preexisting Ad5-specific neutralizing antibody titers, a greater number of HIV infections occurred in vaccine than in placebo recipients. Post hoc analysis suggested that the greatest increased risk was in uncircumcised men with preexisting Ad5-specific NAb. The vaccine-associated risk seen at interim analysis was confirmed but waned with time from vaccination. The hypothesis that anamnestic Ad5-specific CD4+ T lymphocytes after vaccination in Ad5-seropositive subjects may have served as increased numbers of targets susceptible to HIV-1 infection was not supported by further analysis. A follow-up analysis of Phambili participants suggests a nonsignificant increased rate of

HIV infection in the vaccine recipients compared to placebo recipients.

MRKAd5 HIV-1 vaccine induced HIV-specific CD8+ and CD4+ T-cell-mediated responses in a majority of vaccinees, although of low magnitude. A sieve analysis of breakthrough infections revealed that HIV strains from vaccinees were more likely to encode epitopes that differed from those present in the vaccine. With a median frequency of four CD8 epitopes per vaccinee, highly conserved epitopes were detected at a lower frequency, similar to the frequency in natural infection, suggesting potential epitope masking of these responses. These results suggest that breadth alone may not be sufficient and that stronger T-cell responses toward conserved regions of the genome in particular are needed to rapidly eliminate and limit escape mutations and confer some protective effect.

A ► **systems biology** analysis revealed immune signatures in humans following vaccination that predicted subsequent induction and magnitude of HIV-specific T-cell responses. Responses of vaccinees with preexisting Ad5 NAb were strongly attenuated, suggesting that enhanced HIV acquisition in Ad5-seropositive subgroups in the Step Study may relate to the lack of appropriate innate activation rather than to increased systemic immune activation (Zak et al. 2012).

Ad5 vector-based vaccines did not protect macaques from infection after SHIV challenge but did reduce VL and preserve CD4+ T-cell counts after infection, findings that were not reproduced in the human trials. The outcome of the Step trial was recapitulated in a macaque study where animals vaccinated with a regimen similar to that employed in the Step trial were not protected against a SIVsmE660 challenge. In a separate study, macaques chronically infected with a host-range mutant Ad5 and then immunized with Ad5 SIVmac239 *gag/pol/nef* vaccine were not protected against challenge with escalating dose penile exposures to SIVmac251, despite SIV vaccine-induced CD8+ T-cell responses in 70% of the monkeys, a proportion similar among responders to that observed in the Step trial.

HVTN 505

A vaccine regimen with DNA-HIV vaccine prime expressing *gag*, *pol*, and *nef* subtype B genes and *env* genes from subtypes A, B, and C and replication-defective Ad5-HIV vaccine boost encoding the same genes as the DNA components was recently tested in phase I and IIA trials. The vaccine regimen induced polyfunctional CD4+ and CD8+ T cells and multi-clade anti-Env-binding antibodies, mostly tier-1 and limited tier-2 NAb.

Although the regimen failed to protect immunized macaques against SIVmac251 infection, half of vaccinated monkeys were protected against heterologous SIVsmE660 challenge. Among SIVsmE660-infected animals, a one-log reduction in peak plasma RNA VL was observed in Mamu-A*01 monkeys, suggesting that CTL were involved in the control of SIV replication. In Mamu-A*01-negative monkeys, no CD8+ T-cell response or innate immune response was associated with protection against virus acquisition. However, low levels of NAb and an Env-specific CD4+ T-cell response were associated with vaccine protection. SIV-specific CD8+ T cells showed strong virus-inhibitory activity (VIA) and displayed an effector memory (EM) phenotype. VIA correlated with high levels of CD107a and perforin expression in SIV-specific CD8+ T cells. Both the frequency and the number of Gag-specific responses were strongly correlated with VIA mediated by CD8+ T cells.

The results of the preliminary clinical studies combined with the findings of the NHP challenge studies led to the initiation of a phase IIB study of the DNA-HIV prime, Ad5-HIV boost regimen (HVTN 505) in a US population of circumcised, Ad5-seronegative men who have sex with men (MSM). HVTN 505 was stopped for futility, showing no efficacy and no significant effect on viral load. There were nominally more HIV infections in the vaccine group compared to the placebo group but the result was not significant. Studying how immune responses correlate with infection risk after the DNA primes versus after the Ad5 boost might give clues to whether certain immune responses are or aren't important for protection.

Protective Role of Cell-Mediated Immune Responses

The role of CD8+ T cells in preventing HIV infection and disease by controlling HIV replication is now well established. Several macaque studies support this hypothesis, but results differ depending on the virus challenge and immunological endpoints used and predict inconsistently the results in humans.

A relatively small number of immune effectors at the mucosal site of entry might be at the right place at the right time to be “enough and soon enough” to clear infection (Haase 2010). Consistent with this hypothesis, vaccine-induced CTL were able to delay SHIV dissemination from mucosa following rectal challenge. Similarly, prior infection of rhesus macaques with an attenuated SHIV conferred protection against vaginal challenge associated with SIV-specific CTL in cervical vaginal tissues, suggesting that a modest vaccine-induced CD8+ T-cell response in the context of immunoregulatory suppression of T-cell activation may protect against vaginal HIV transmission. Supporting this hypothesis, macaques immunized with an oral vaccine comprised of *Lactobacillus plantarum*, a commensal bacterium that favors immune tolerance, and inactivated SIVmac239-induced CD8+ regulatory T cells that conferred complete protection in most of the animals challenged intrarectally with SIVmac239 or heterologous strain SIVB670 despite the absence of SIV-specific antibodies or CTL.

Whether systemic vaccination can induce potent and durable cellular responses at the mucosal sites deserves further exploration. Different prime-boost vaccination regimens generate SIV-specific CD8+ T-cell responses as clonally diverse as those induced by SIV infection. Systemic vaccination with non-replicating vectors induced rapid and clonally diverse mucosal cellular immune responses that are sustained over time. Vaccine-induced CD8+ T cells migrate into the intestinal mucosa, differentiate into effector memory CD8+ T cells in situ, and remain resident there without recirculating.

A rhesus cytomegalovirus expressing SIV antigens elicited and maintained virus-specific effector memory CD4+ and CD8+ T cells at extra-

lymphoid sites and conferred partial protection against repeated intrarectal challenge (Hansen et al. 2009). A vaccine would need to induce and maintain a population of effectors at the portal of entry to resist the challenge, in particular for rectal transmission where infection is more quickly disseminated. Such rapid first-line intervention force would likely be achieved by functional antibodies rather than by cell-mediated responses, although both could complement each other, the first “neutralizing” the majority of the viruses and the second “mopping up” the remaining infected cells.

New Vaccine Designs

Although considerable efforts are deployed to better understand the mechanisms of neutralization and to design immunogens capable to induce broadly neutralizing antibodies, these antigens are not yet available for testing. Current efforts in multiple laboratory groups are now focusing on Env subunit protein designs aiming at improving the RV144 results, in particular to improve antibody responses directed against the V2 loop.

The induction of immune responses capable of overcoming HIV-1 variability remains one of the main hurdles for HIV-1 vaccines. The RV144 V2-specific antibodies cross-react with multiple HIV-1 subtypes. The original reagent used to identify a V2 serologic correlate of risk was a gp70V1V2 scaffold protein derived from HIV-1 subtype B. Interestingly, unpublished data show binding to scaffold proteins derived from HIV-1 subtype C and CRF01_AE is also highly correlated with reduced HIV acquisition risk. It is therefore conceivable that Env immunogens whose sequences are mismatched to those of the circulating HIV-1 strains be able to induce high cross-reactive V2 antibody titers and be effective vaccines. The potentiating effect of adjuvants in terms of magnitude, durability, and IgG subclass of the V2 antibody response compared to the classical alum adjuvant (used in RV144, Vax003, and Vax004) needs further study.

Immunization with soluble Env was reported to induce short-lived antibody responses with robust peak followed by rapid contraction of

circulating antibody and memory B cells. Increased deposition and retention of antigen drives B-cell responses locally in the tissue, enhances antigen presentation by dendritic cells, and contributes to the stimulation of the formation of germinal centers in lymph nodes with enhanced development of CD4⁺ T follicular helper cells required for the formation of memory B cells (Nutt and Tarlington 2011). Such vaccine approaches deserve to be explored for HIV-1 vaccines aiming at inducing sustained antibody responses.

None of the vaccines tested so far for efficacy in humans were able to reduce VL postinfection. Several immunogen design strategies able to increase breadth and depth of the CD8⁺ T-cell responses are being pursued such as use of HIV-1 conserved sequences (core and envelope proteins) and mosaic of HIV-1 antigens.

Conclusion

RV144 and the study of immune correlates of risk have led to improved vaccine designs and accelerating vaccine development to licensure for the most exciting time of HIV-1 vaccine development. The use of an HIV-1 envelope protein immunogen seems to be key for inducing protective immune responses against HIV acquisition by sexual transmission. The still uncertain predictive value of animal models and biomarkers of immune protection against HIV-1 necessitate however that vaccines be tested in clinical trials coordinated with animal model studies to better understand their predictive value. It remains critical to assess vaccine efficacy and correlates of risk in populations with different intensity of risk and mode of HIV-1 transmission. A long-term strategy to ultimately end the AIDS pandemic must include both scale-up of existing HIV combination prevention, treatment, and care programming and sustained investment in research and development for a preventive HIV-1 vaccine.

Preventing Mother-to-Child Transmission (PMTCT): Prevention of HIV

Carla J. Chibwasha, Lisa Rahangdale and Benjamin H. Chi
Department of Obstetrics and Gynecology,
University of North Carolina at Chapel Hill,
Chapel Hill, NC, USA

Definition

Without any intervention, 14–48% of HIV-infected women will transmit the infection to their newborn infant. The greatest risk of transmission occurs around the time of delivery, likely due to direct exposure to HIV, accounting for two-thirds of perinatal infections. Significant transmission also occurs in the antenatal period (25%) and the postpartum period (15%) if the mother breastfeeds (Simonon et al. 1994). Prevention of mother-to-child transmission (PMTCT) of HIV encompasses the range of biomedical and behavioral interventions that – used in combination and implemented fully – can reduce this rate of infant HIV infection to less than 2% (European 2005). While vertical transmission of HIV has decreased dramatically in North America and Europe, progress has lagged in many resource-constrained settings for a number of contextual reasons. Over the past decade, however, numerous scientific, policy, and program advances have dramatically changed the landscape for PMTCT and renewed hope for the virtual elimination of pediatric AIDS worldwide (UNAIDS).

Framework for PMTCT

The World Health Organization (WHO) and others have endorsed a holistic approach to reducing pediatric AIDS globally. This framework articulates four “prongs” that consider both direct and indirect contributors: (1) primary prevention of HIV among women of childbearing age, (2) prevention of unintended pregnancies among HIV-infected women, (3) prevention of mother-to-child transmission among HIV-infected women, and (4) linkage of HIV-infected women and children to long-term HIV care and treatment. Comprehensive programs for HIV prevention, care, and treatment must address each of these areas in order reach the ambitious goal of eliminating pediatric HIV globally (Mahy et al. 2010). In this section, we focus primarily on prong three: interventions that directly reduce transmission from HIV-infected mothers to their infants. Other prongs are considered elsewhere in this volume.

PMTCT in Resource-Rich Settings

Dramatic reductions in the vertical transmission of HIV have been observed in North America and Europe. In the USA, the Centers for Disease Control and Prevention reported a peak in new pediatric HIV in 1991, with sharp declines in the subsequent decade. In 2013, only 107 cases of perinatal HIV transmission were reported nationwide (Centers for Disease Control and Prevention. HIV surveillance report 2013). Similarly low rates were observed in a national surveillance study in the UK (2000–2011), where overall mother-to-child transmission declined to 0.5% following the introduction of comprehensive PMTCT guidelines (Townsend et al. 2014). These reports are also supported by other large European cohorts, including the European Collaborative Study and the French Perinatal Cohort.

Several clinical and public health interventions have played a critical role in these declines. Foremost has been the availability of effective antiretroviral drug regimens for PMTCT. In 1994, the landmark PACTG 076 trial established the

efficacy of antiretrovirals for PMTCT, showing a 67% reduction in new infant HIV infections when zidovudine was administered to mothers during pregnancy and labor and to infants during the first 6 weeks of life (Connor et al. 1994). In the decade that followed, a number of studies demonstrated that three-drug combination regimens – already recommended for HIV treatment – could drive down transmission even further, to rates consistently below 2%. The optimal combination regimen has changed over time, refined out of concerns about drug toxicity and adverse pregnancy outcomes. Nevertheless, this strategy was adopted as the standard of care in the US National Guidelines by 2007 – and continues to this date – with similar practices mirrored in other resource-rich countries.

The effectiveness of antiretroviral regimens for PMTCT is highly associated with maternal virologic suppression. As such, close virologic monitoring during pregnancy has become the standard of care in many resource-rich settings. According to the US Perinatal Guidelines, for example, viral load testing is recommended on a monthly basis until virologic suppression is achieved and then quarterly thereafter. Maternal viral load is again tested at 34–36 weeks gestation to guide counseling about mode of delivery (see below). With the growing availability of HIV genotyping, drug resistance testing is also recommended early in pregnancy and in cases of suspected treatment failure, to help to optimize antiretroviral drug regimens ([Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission](#)).

Elective cesarean delivery is associated with a 50% reduction HIV transmission rates (The International Perinatal HIV Group 1999); however, the procedure may be associated with surgical complications for the mother as well as risks of neonatal respiratory morbidity. Current evidence suggests that, for HIV-infected pregnant women with viral loads <1,000 copies/mL, infant transmission rates are similar between vaginal and elective cesarean delivery. Viral load testing in the third trimester is typically used to triage patients and to guide mode of delivery counseling. In many resource-rich settings, elective cesarean

delivery remains an important PMTCT strategy for high-risk pregnancies, including those with elevated or unknown maternal viremia. Because the PMTCT benefits of cesarean delivery appear to diminish following the onset of labor, elective cesareans are typically scheduled at (or soon after) 38 weeks gestation. To minimize the risks of an iatrogenic premature delivery, obstetrical guidelines emphasize the need for early engagement into care and reliable gestational age dating of the pregnancy ([Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission](#)).

Alternatives for infant feeding have also played an important role in limiting HIV transmission from mother to child. Unlike in many resource-constrained settings, where breastfeeding is often a necessity, the availability of replacement feeding options has eliminated continued exposure to HIV following delivery. While infant formula has traditionally been recommended, there is a growing literature as to the immunological and nutritional benefits of breastfeeding for the newborn. Harm reduction strategies for breastfeeding, including options for flash heating and banked milk, appear safe and effective ([Levison et al. 2014](#)).

PMTCT in Resource-Constrained Settings

Progress in PMTCT has lagged in comparison in the resource-constrained settings of Africa and Asia. Barriers have included some – if not all – of the following: generalized HIV epidemics with large numbers of HIV-infected women; limited infrastructure for health services, particularly in rural areas; traditions of antenatal care and delivery outside of the health system; deep-seeded misconceptions and stigma about HIV infection; and lack of safe, affordable, and socially acceptable alternatives to breastfeeding. Important advances in clinical research, international policy, and program implementation, however, have begun to address these issues in a systematic fashion, providing renewed hope for an AIDS-free generation ([UNAIDS](#)).

Antiretroviral regimens for PMTCT in resource-constrained settings have undergone considerable evolution. Early studies sought to simplify antiretroviral regimens by reducing the duration and frequency of dosing. Trials in Thailand and Cote d'Ivoire evaluated modified versions of the original PACTG 076 zidovudine regimen, including the addition of lamivudine during pregnancy. The HIVNET 012 study in Uganda demonstrated that two-dose peripartum nevirapine – one dose to the mother in labor and one dose to the newborn within 72 h of birth – could reduce the relative risk of HIV transmission at 18 months of life by 41% ([Jackson et al. 2003](#)). Although enthusiasm for this regimen eventually waned because of its moderate efficacy and its selection for drug-resistant variants, two-dose peripartum nevirapine nevertheless played a critical role in catalyzing PMTCT program expansion globally. Following the PHPT-2 results from Thailand, a combined approach of antenatal and intrapartum zidovudine coupled with peripartum nevirapine became the global standard of care for PMTCT in 2004. The antenatal and intrapartum HIV transmission rates in the intervention arms of the Thai trial were 2–3% ([Lallemant et al. 2004](#)) – i.e., comparable to that of three-drug combination regimens in the USA – for women were not yet eligible for antiretroviral therapy for HIV treatment. Despite its high efficacy, this regimen did not address continued HIV transmission risk during the postpartum period for women who breastfed their infants.

Several important studies have since demonstrated the efficacy of antiretroviral-based strategies to reduce mother-to-child HIV transmission during the breastfeeding period. Two approaches have been shown to be highly effective in preventing postpartum HIV transmission: daily nevirapine prophylaxis administered to the infant and three-drug combination regimens provided to the mother. To date, there have been no head-to-head comparisons; however, because of the low transmission rates observed in randomized studies, both strategies were included in the WHO 2010 PMTCT guidelines. While the WHO initially recommended that countries choose between one of two regimens for PMTCT ([Table 1](#)), the

Preventing Mother-to-Child Transmission (PMTCT): Prevention of HIV, Table 1 Summary of WHO guidelines for the prevention of mother-to-child HIV transmission 2004, 2006, 2010, and 2013

	<p>Triple ARVs for CD4 count ≤ 350 cell/uL</p> <p>All women with WHO stage 3 or 4, irrespective of CD4 count</p>	<p><i>Antepartum:</i> Triple ARVs from 14 weeks</p> <p><i>Intrapartum:</i> Triple ARVs</p> <p><i>Postpartum:</i> Triple ARVs continued through childbirth <i>or</i> until cessation of breastfeeding</p>	NVP or ZDV for 4–6 weeks regardless of feeding method
2013	Use lifelong ART for all pregnant and breastfeeding women (Option B+)		
	<p>Triple ARVs started as soon as diagnosed and continued for life, regardless of CD4 count</p> <p>For certain settings, guidelines support the use of lifelong ART only for pregnant and breastfeeding women eligible for treatment (Option B)</p>		<p>NVP for 6 weeks if breastfeeding</p> <p><i>or</i></p> <p>NVP or ZDV for 4–6 weeks if not breastfeeding</p>

Notes: *ART* antiretroviral therapy, *ARVs* antiretrovirals, *NVP* nevirapine, *sd-NVP* single-dose nevirapine, *WHO* World Health Organization, *ZDV* zidovudine, *3TC* lamivudine

“Option B” strategy – i.e., provision of maternal three-drug regimens during pregnancy, delivery, and breastfeeding – was later endorsed as the preferred approach for operational and programmatic reasons. As part of its 2013 consolidated guidelines for HIV, the WHO went a step further to support the universal and lifelong treatment of HIV-infected pregnant and breastfeeding women, regardless of CD4 status (also known as “Option B+”). Although scientific evidence behind this

approach at the time was sparse, this innovative policy decision sought to better align PMTCT and HIV treatment strategies, improve maternal health, reduce horizontal transmission to serodiscordant partners, and minimize mother-to-child transmission in future pregnancies. Because of the shortened duration between breastfeeding cessation and subsequent pregnancies in many target countries, the rationale for Option B+ was that this approach would limit

interruptions in antiretroviral therapy and promote long-term medication adherence and retention in care over time.

Alongside these effective clinical interventions have been successful public health strategies to increase the uptake of PMTCT services by HIV-infected pregnant women. The implementation of “opt-out” antenatal HIV screening, for example, has greatly aided the identification of HIV-infected women during pregnancy (Tudor Car et al. 2013). Provision of combination antiretroviral therapy in the same location as PMTCT services and male partner involvement in care may also improve the uptake of PMTCT services and decrease attrition from care (Wettstein et al. 2012).

The evolving practices for antiretroviral treatment and prophylaxis have influenced policies on infant feeding. There has been strong evidence supporting exclusive breastfeeding over the first 6 months of life. Given the efficacy of PMTCT regimens during the postpartum period, however, the WHO extended its recommendation for breastfeeding out to 12 months, with gradual weaning afterwards. In many settings, infant formula remains a viable option, provided it is acceptable, feasible, affordable, sustainable, and safe. While programs for replacement feeding have largely been successful, there have been cases where top-down policies have led to unintended public health consequences. In Botswana, for example, extensive flooding in 2005–2006 led to an outbreak of diarrheal disease and malnutrition among children. A key factor in the high morbidity and mortality observed was the reliance on formula feeding despite the lack of reliably safe drinking water. This episode led the Government of Botswana to review its national guidelines regarding infant feeding and to ultimately align them with international recommendations from the WHO.

When fully implemented, these strategies for PMTCT hold great promise. Despite considerable investment thus far, however, coverage of services remains low in many settings. The “PMTCT cascade” (i.e., the steps that an HIV-infected woman and her HIV-exposed infant must navigate to minimize the risk of HIV transmission) has identified

multiple points of attrition – and of potential intervention – over the course of antenatal, intrapartum, and postpartum care. Program innovations are needed to increase uptake of and maximize retention within PMTCT services, including engagement of women and their partners at the community level, integration of PMTCT into existing health services, incorporation of trained lay workers to support PMTCT programs, and use of innovative technological and structural interventions to promote uptake. New models for monitoring, evaluation, and program improvement also hold potential, with important and broad collateral benefits for health systems in general.

Future Directions

Between 2009 and 2013, a 43% reduction in the number of new HIV infections among children was reported for 21 Global Plan priority countries (UNAIDS 2014), demonstrating the recent success of PMTCT programs in low- and middle-income countries (LMICs) in Africa and Asia. Despite this success, there remains much work to be done to end the epidemic and to reverse its devastating impact on health outcomes, survival, and economic development. The post-2015 global health agenda is now focused on women’s and children’s health, with new and renewed international commitments in HIV prevention and treatment, family planning, maternal health, and child survival. Much of groundwork for the so-called UNAIDS “90-90-90” target for 2020, through which 90% of HIV-infected individuals will be diagnosed, 90% receiving antiretroviral therapy, and 90% virologically suppressed, has been achieved through commitments set out in the UNAIDS *Getting to Zero: 2011–2015 Strategy*, the Global Plan towards the elimination of new HIV infections among children by 2015 and keeping their mothers alive, and the WHO *Treatment 2.0 Framework for Action*. These initiatives – and their accompanied funding – have the potential to be truly transformative and to virtually eliminate pediatric HIV infections.

Implementation of these ambitious prevention and treatment strategies will undoubtedly present challenges for many African and Asian health systems facing a growing burden of non-communicable diseases, new and reemerging infectious epidemics, and severely limited human resources for health. Future investments in implementation science research – a field that generates evidence and best practice for “real-world” program implementation – will therefore be critical to achieving the ambitious global targets set forth for eliminating pediatric HIV.

In both resource-rich and resource-constrained settings, efforts to engage vulnerable and hard-to-reach populations such as adolescents, those with substance abuse and mental health problems, incarcerated individuals, and LGBT and other marginalized communities will need to be expanded. In resource-rich settings, assisted reproductive technologies, such as sperm washing and, more recently, preexposure chemoprophylaxis (PrEP) (Savasi et al. 2013), are increasingly being integrated into individualized treatment planning for HIV-infected individuals, the majority of whom are in their reproductive years. Similar counseling and reproductive assistance for HIV serodiscordant couples wishing to conceive in resource-constrained settings should also be considered a PMTCT priority. Finally, early and multidrug ART regimens aimed at prevention for high-risk infants (Nielsen-Saines et al. 2012) and sustained remission for infants infected at birth (Rainwater-Lovett et al. 2015) will likely continue to be the focus of future pediatric trials.

Conclusion

Over the past two decades, public health policy and clinical guidelines in both resource-rich and resource-constrained settings have evolved and converged to emphasize universal testing during pregnancy and early antiretroviral treatment to improve women’s own health and to prevent mother-to-child HIV transmission. The result has been a dramatic decline in pediatric AIDS, with

perinatal HIV transmission rates now well below 5% in most countries, ever-decreasing numbers of HIV-infected children under the age of 14, and rapid expansion of HIV treatment services for women and their families. However, numerous disparities remain. Women continue to face a disproportionate burden of new HIV infections in sub-Saharan Africa and Asia. Between a third and a quarter of women in LMIC settings still do not have access to antiretroviral drugs for PMTCT. In addition, in many resource-constrained settings, the treatment gap between adults and children continues to widen. Innovations in basic, translational, and implementation science, strong and evidence-based global guidance, and sustained local and international funding commitments for women’s and children’s health are all needed to address these ongoing disparities and to achieve virtual elimination of pediatric HIV.

Preventing Mother-to-Child Transmission of HIV-1

Grace C. John-Stewart

Departments of Global Health, Medicine, Epidemiology, and Pediatrics, University of Washington, Seattle, WA, USA

Definition

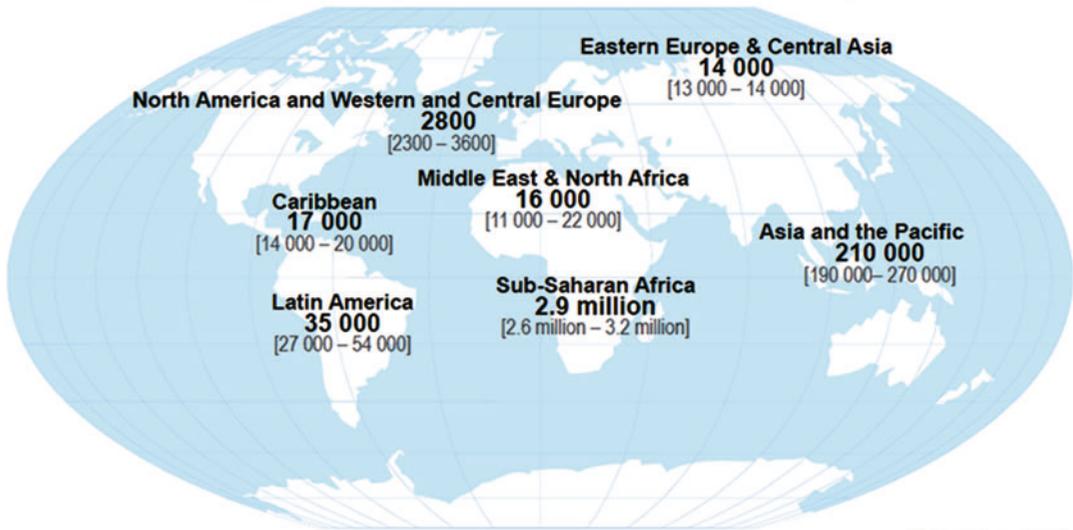

Mother-to-child transmission of HIV-1 (MTCT) occurs in utero, during delivery, and through breastfeeding. MTCT transmission risk ranges from ~30% to 45% in untreated breastfeeding HIV-1-infected mothers. With combination antiretroviral therapy (ART), transmission risk can be lowered to ~1–5%. There is a recent concerted effort toward “virtual elimination” of pediatric HIV by 2015. This will require enhanced implementation strategies both to diagnose women and promptly deliver ART.

Epidemiology and Transmission Rates

In 2013, an estimated 3.2 million children <15 were living with HIV, most of whom acquired HIV from their mother (UNAIDS 2014, Fig. 1a). An estimated 240,000 children acquired HIV in 2013, the majority (>90%) in sub-Saharan Africa (Fig. 1b). Infant HIV-1 incidence mirrors maternal HIV-1 prevalence. Thus, regions in South and East Africa, with the highest maternal HIV-1 prevalence have typically had the highest numbers of HIV-1-infected infants. However, the global number of new infant HIV-1 infections continues to decrease from its peak in the previous years (>500,000 per year), reflecting expansion of programs to prevent MTCT (PMTCT); some countries with high maternal HIV-1 prevalence have had exceptionally high PMTCT program coverage, leading to marked reductions in infant HIV-1 incidence.

MTCT includes ~5–10% risk in utero, ~10–20% risk at delivery, and ~10–20% risk

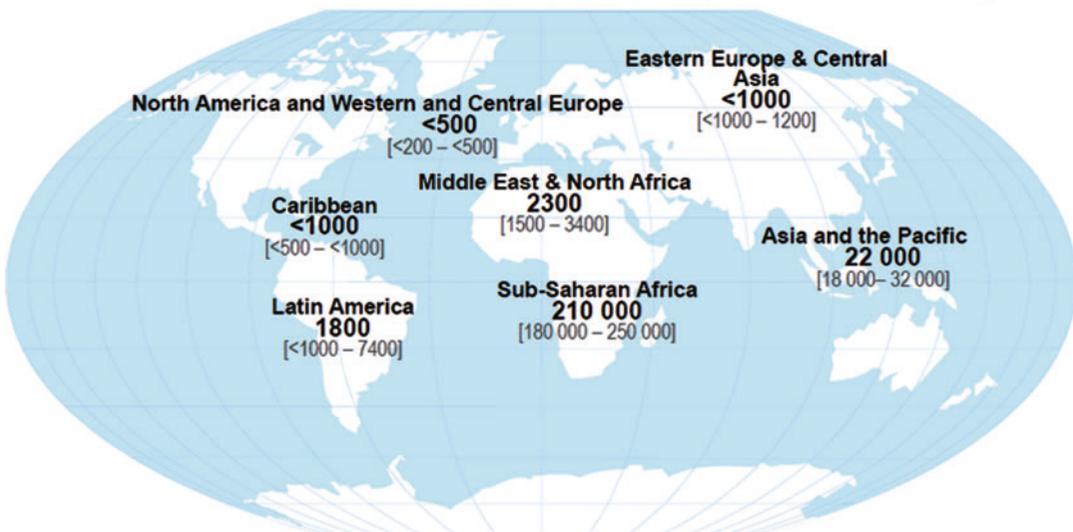

a Children (<15 years) estimated to be living with HIV | 2013

Total: 3.2 million [2.9 million – 3.5 million]

b Estimated number of children (<15 years) newly infected with HIV | 2013

Total: 240 000 [210 000 – 280 000]

Preventing Mother-to-Child Transmission of HIV-1, Fig. 1 Global Estimates of Children Living with HIV and New Infant Infections UNAIDS 2014 report (UNAIDS epidemiology slides 2012)

through breastfeeding (De Cock et al. 2000). Vertical HIV-1 transmission (or MTCT) has several features that differ from sexual HIV-1 transmission: a higher risk of transmission, three types of transmission (in utero, intrapartum,

breastfeeding), and an easily recognized time-limited period of HIV-1 exposure. In utero HIV-1 transmission predominantly occurs during the last trimester of gestation and intrapartum transmission usually occurs within a <24-h

period. Breast milk HIV-1 transmission occurs throughout breastfeeding with cumulative exposure to hundreds of liters of HIV-1-infected breast milk. Breast-milk HIV-1 infectivity has been modeled with estimated transmission risk of 0.00064 per liter or 0.00028 per day. The risk per liter of breast milk or per day of breastfeeding is similar to the risk per coital event in sexual transmission (Richardson et al. 2003). Cumulative exposure and duration of breastfeeding contribute incremental transmission risk. There is some evidence to suggest that the early postpartum period has a higher breast-milk HIV-1 transmission probability than the later postpartum period (De Cock et al. 2000).

Mechanisms and Cofactors of MTCT

As in most infectious diseases, the *transmitter pathogen burden* strongly influences transmission efficiency in MTCT (Table 1). *Host susceptibility* also influences transmission risk. Finally, the *interface between mother and child* may vary, contributing to a likelihood of transmission.

Transmitter pathogen burden: Maternal HIV-1 viral load is the most important predictor of MTCT (John and Kreiss 1996). Maternal systemic plasma HIV-1 RNA is highly associated with MTCT. Infants encounter HIV-1 transplacentally while in utero, during passage through the infected birth canal, and via breastfeeding. HIV-1 is detectable in cervical and vaginal secretions and in breast milk. While the levels of HIV-1 in these compartments are correlated with systemic HIV-1

levels, there can be compartmental differences in HIV-1 levels. HIV-1 levels in genital secretions and breast milk have each been associated with MTCT, *independent* of systemic HIV-1 burden, demonstrating the importance of HIV-1 load at the mucosal site to which the infant is exposed (John et al. 2001).

Both cell-free and cell-associated HIV-1 levels have been associated with MTCT (Rousseau et al. 2004). Comparing transmission risk due to cell-free versus cell-associated virus is difficult because these parameters are highly correlated with each other. Recent studies have suggested local mammary HIV-1 replication occurs with evidence that maternal-child cell-cell transfer of HIV-1 is the key route of breast milk MTCT (Van de Perre et al. 2012). This is consistent with the high early postnatal HIV-1 transmission at the time when breast-milk cellularity is highest (Rousseau et al. 2004). However, HAART, which markedly diminishes breast-milk HIV-1 RNA but has minimal effect on cell-associated HIV-1 DNA, significantly decreases MTCT, suggesting that HIV-1 RNA is the more relevant correlate of MTCT (Lehman et al. 2008). It is likely that both cell-free and cell-associated viruses contribute to MTCT.

Host susceptibility: Evidence for the role of host susceptibility includes increased risk among preterm infants who have immature immune development (although reverse causality may explain this association) (John and Kreiss 1996). HIV-1-uninfected, exposed infants have detectable HIV-1-specific immune responses and are born with passively transferred maternal HIV-1

Preventing Mother-to-Child Transmission of HIV-1, Table 1 MTCT cofactors

Mother-transmitter	Interface between mother-infant variations in HIV-1 exposure	Infant-host
Systemic HIV-1 RNA (plasma)	Maternal coinfections (STIs/mastitis) increased HIV-1 replication at surface to which infant is exposed	Prematurity, low birth weight
Genital HIV-1 RNA, DNA	Vaginal delivery, first-born twin	Genetic and innate factors (HLA, SLPI, TLR polymorphisms)
Breast-milk HIV-1 RNA, cell-associated virus	Placental breaches (syphilis, malaria)	Humoral immune responses (HIV-1-specific neutralizing antibody passively transferred)
CD4 count	Breastfeeding	HIV-1-specific cellular immune responses

neutralizing antibodies (Lehman and Farquhar 2007). There is evidence that cellular and humoral HIV-1-specific immune responses contribute some protection from MTCT. Genetic factors may modify MTCT risk. Selected infant and maternal HLA types influence MTCT. Mother-infant pairs who share HLA types are more likely to have MTCT compared to pairs with more HLA discordance, suggesting the importance of diversified immune protection conferred from paternally HLA-derived cellular responses (Mackelprang et al. 2008). Innate factors such as SLPI or defensins in infant saliva may influence MTCT. Some studies have noted an increased susceptibility of female infants to HIV-1 infection.

Interface between mother and infant may influence a likelihood of exposure: The type of encounter between transmitter and host may modify transmission risk by providing more or less exposure to HIV-1 virus. Thus, vaginal delivery has been associated with a higher transmission risk, as has first- vs. second-born twin delivery (John and Kreiss 1996). Both of these findings suggest that passage through the HIV-1-infected birth canal or ascending genital HIV-1 infection following ruptured membranes contributes substantial HIV-1 exposure to infants at delivery, which in turn leads to infection. Alternatively, increased transplacental microtransfusions during labor may explain this association. Genital or breast-milk coinfections (with sexually transmitted infections or mastitis) may increase MTCT by increasing local HIV-1 replication as a result of inflammation, immune activation, and recruitment of HIV-1-infected lymphocytes.

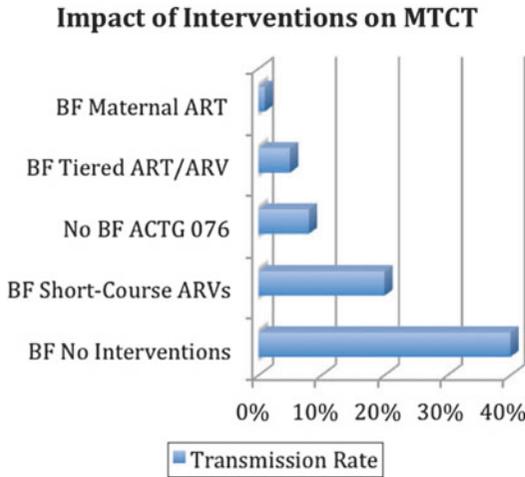

The place at which transmission occurs in the infant is undefined. Speculation from animal models note possibilities including tonsillar or gut infection (Abel et al. 2006). A series of studies noted increased breast-milk HIV-1 transmission when breastfeeding mothers introduced mixed feeding during the first few months postpartum (Young et al. 2011). It was speculated that gut permeability may be compromised by mixed feeding, leading to MTCT; however, there has not been data to support this. A recent study noted increased breast-milk HIV-1 RNA levels following the cessation of breastfeeding or during

mixed feeding when compared to exclusive breastfeeding (Kuhn et al. 2013). This study provides another potential explanation for increased MTCT during mixed feeding - that breast-milk HIV-1 levels increase. Ongoing studies are exploring the impact of exclusive versus mixed breastfeeding or replacement feeding on gut microbiota and immune development, both of which may influence susceptibility to HIV-1.

The breast milk of HIV-1-infected women contains a rich milieu of protective substances, including antimicrobial substances, cytokines, antibodies, and immune cells; breast milk has been noted to contain almost 3,000 substances in proteomic studies (Van de Perre et al. 2012). In murine studies, breast milk protected from HIV-1 infection, illustrating the dual role of breast milk in HIV-1 MTCT in increasing transmission risk because it contains the pathogen but protecting from transmission because of its many immune components (Wahl 2012). Antiretrovirals optimize the benefit/risk ratio of breastfeeding and enable long-term breastfeeding by HIV-1-infected mothers with minimal risk of transmission.

Prevention of MTCT (PMTCT) Research Landmarks and Guidelines

PMTCT has been a dynamic area of progress, following the landmark study ACTG 076, which was the first study in HIV-1 in general to demonstrate that antiretrovirals could decrease transmission (Paintsil and Andiman 2009) (Fig. 2). Infants receiving zidovudine monotherapy in ACTG 076 had a highly significant substantial reduction in MTCT from 24% to 7% (67% reduction), leading to guidelines to provide the zidovudine regimen to HIV-1-infected pregnant women and infants in resource-rich settings. However, the 076 regimen was not implemented in low- and middle-income countries (LMICs) because efficacy during breastfeeding was undefined, intravenous administration posed implementation challenges, and the regimen was cost prohibitive. To address these issues, trials were conducted to evaluate shorter “short-course” antiretroviral regimens without intravenous dosing, in

Preventing Mother-to-Child Transmission of HIV-1, Fig. 2 Mother to Child HIV Transmission Risk with Different PMTCT Regimens. Abbreviations. BF: breastfeeding. Short-course ARV: either short-course zidovudine or nevirapine. Tiered ARV/ART: ART-eligible receive ART, others ARVs also known as Option A

breastfeeding populations. These trials demonstrated that efficacy persisted with “short-course” regimens with some attenuation of efficacy due to regimen differences and further attenuation due to breastfeeding (~50% efficacy without breastfeeding and ~33% efficacy with breastfeeding). Remarkably, the HIVNET 012 trial, in which only a *single* dose of nevirapine (SD NVP) was administered both to mother and infant peripartum, demonstrated 50% efficacy in decreasing MTCT risk over 18 months of breastfeeding. This regimen revolutionized efforts to scale up PMTCT, because of its simplicity and low cost. Over time, combined regimens were used with higher efficacy. A final pivotal insight in PMTCT research came from several clinical trials among breastfeeding infants whose HIV-1-infected mothers did not receive ART in whom infant antiretroviral exposure prophylaxis significantly decreased MTCT (Kumwenda et al. 2008). These were the first studies to demonstrate the proof of concept that exposure prophylaxis could decrease HIV-1 transmission.

A variety of non-ART interventions were examined for effects in preventing MTCT. Elective cesarean section significantly decreased

MTCT versus vaginal delivery in a randomized trial conducted in Europe. Micronutrients, vitamin A, and chlorhexidine washes did not decrease MTCT in RCTs in Africa. In the absence of antiretrovirals, formula feeding was associated with decreased MTCT and HIV-free survival in an LMIC setting. However, cesarean section and replacement feeding became less relevant for PMTCT once antiretroviral approaches were implemented.

Breastfeeding HIV-1 transmission has been a key area of research, because MTCT through this route is substantial (16% among chronically infected and 29% in acutely infected women). Although avoiding breastfeeding spares infants’ exposure to HIV-1-infected breast milk, replacement feeding is risky in LMIC settings, leading to increased mortality and severe morbidity. Addressing breast-milk HIV-1 transmission has been challenging for policy-makers trying to optimize child health outcomes by preventing both HIV-1 and infectious morbidity and mortality. Mixed breastfeeding, replacement feeding, and early cessation of breastfeeding are associated with increased morbidity and mortality. Thus, the finding that maternal ART or infant prophylaxis could make breastfeeding safe has enabled policies to lengthen breastfeeding and avoid pitfalls of no or shortened breastfeeding. Over the past two decades, recommendations by WHO/UNAIDS underwent several changes as research matured – initially women in LMICs were recommended to breastfeed (1992), then to replacement feed if affordable, feasible, acceptable, sustainable, and safe (AFASS), but otherwise to exclusively breastfeed for 6 months then stop (2001), and then to use maternal ART or infant ARV prophylaxis through extended breastfeeding for at least a year (2010). The changes in breastfeeding recommendations have caused confusion for programs, mothers, and health-care providers (Young et al. 2011).

In 2004, funding from the Presidential Emergency Fund for AIDS Relief (PEPFAR) and Global AIDS Program (GAP) resulted in a widely expanded access to combination ART. This enabled women in LMICs who met ART eligibility (initially CD4 <200) to receive ART. Because

Preventing Mother-to-Child Transmission of HIV-1, Table 2 WHO Option A and Option B/B+ (From WHO 2012, April 12 programmatic update)

	Woman receives		Infant receives
	Treatment (for CD4 count ≤ 350 cells/mm ³)	Prophylaxis (for CD4 count > 350 cells/mm ³)	
Option A ^a	Triple ARVs starting as soon as diagnosed, continued for life	Antepartum: AZT starting as early as 14 weeks gestation	Daily NVP from birth through 1 week beyond complete cessation of breastfeeding, or, if not breastfeeding or if mother is on treatment, through age 4–6 weeks
		Intrapartum: at onset of labor, sdNVP, and first dose of AZT/3TC	
		Postpartum: daily AZT/3TC through 7 days postpartum	
Option B ^a	Same initial ARVs for both ^b		Daily NVP or AZT from birth through age 4–6 weeks regardless of infant feeding method
	Triple ARVs starting as soon as diagnosed, continued for life	Triple ARVs starting as early as 14 weeks gestation and continued intrapartum and through childbirth if not breastfeeding or until 1 week after cessation of all breastfeeding	
Option B ⁺	Same for treatment and prophylaxis ^b		Daily NVP or AZT from birth through age 4 to 6 weeks regardless of infant feeding method
	Regardless of CD4 count, triple ARVs starting as soon as diagnosed, ^c continued for life		

Note: “triple ARVs” refers to the use of one of the recommended 3-drug fully suppressive treatment options

^aRecommended in WHO 2010 PMTCT guidelines

^bTrue only for EFV-based first-line ART; NVP-based ART not recommended for prophylaxis (CD4 > 350)

^cFormal recommendations for Option B+ have not been made, but presumably ART would start at diagnosis

MTCT is highest in women with immunosuppression and high viral load, provision of ART to ART-eligible women substantially decreased MTCT. In these “tiered” programs, in which ART-eligible women received ART and ART-ineligible women received zidovudine/nevirapine prophylaxis, MTCT rates decreased to ~5%. Rates below 5% have been noted with either ART to all women or tiered ART/ARV approaches with provision of infant antiretroviral prophylaxis throughout breastfeeding (Jamieson et al. 2012). Remarkably, in a Botswana study of maternal ART administered through pregnancy and 6 months of breastfeeding, overall MTCT was only 1% (Shapiro et al. 2010).

Since 2009, WHO has recommended two options – Option A and Option B/B+ (Table 2). Both provide ART to ART-eligible women; Option A provides combined prophylaxis regimens to ART-ineligible women/infants, while Option B provides ART to all women, even ART-ineligible women. Both Option A and B end after lactation ends, while Option B+

continues with lifelong ART for women. While there has been healthy debate about the relative merits of the two options, there is a momentum to move to Option B/B+ as UNAIDS targets “virtual elimination” of pediatric HIV by 2015. Cost considerations are approximately equivalent; Option B/B+ may contribute decreased sexual transmission to partners, less delay in initiating interventions in pregnancy because there is no need to stage women to determine eligibility, and alignment with treatment program regimens. Recently, the PROMISE study, an RCT comparing Option A to B demonstrated lower MTCT in mother-infant pairs randomized to Option B (presented at CROI 2015).

Mechanisms of PMTCT ART Efficacy

Antiretrovirals result in decreased systemic, genital, and breast-milk HIV-1 RNA levels. In addition, breastfeeding infants ingest maternal antiretrovirals via breast milk, often resulting in

appreciable drug levels. Thus, both transplacental and breast-milk ART provide dual protection through decreased maternal virus and transferred antiretrovirals to the infant which provide prophylaxis. Nevirapine efficacy to decrease transmission resulted from both sustained and decreased maternal HIV-1 and infant prophylaxis – its long half-life resulted in decreased breast-milk viral load for ~2 weeks following a single maternal dose (Chung 2007). In infants whose mothers have not received any antiretrovirals, infant NVP prophylaxis was shown to significantly decrease transmission in randomized trials (Kumwenda et al. 2008). Maternal ART and infant prophylaxis may provide similar protective efficacy for breast-milk HIV-1 transmission among ART-ineligible mothers (Jamieson et al. 2012). Both approaches require adherence and maternal ART needs to have resulted in maternal viral suppression to exert its optimal prevention effect. Thus, for mothers starting ART postpartum, a period of infant prophylaxis for 4–6 weeks is necessary to protect infants until maternal viral suppression occurs.

Nevirapine (NVP) monotherapy, while effective for PMTCT, compromises future ART effectiveness among women. Following nevirapine monotherapy, the majority of women had evidence of NVP resistance mutations. Combining NVP monotherapy with a “tail” of other antiretrovirals decreased the likelihood of resistance and became the recommended approach. Alternatively, the earlier use of other prophylaxis (zidovudine) or ART in Option A or B also decreases the development of NVP resistance.

Implementation of PMTCT

Following the identification of efficacious PMTCT regimens, the broad implementation of PMTCT posed the next challenge. The PMTCT delivery cascade involves diagnosing women with HIV in pregnancy, providing ARV regimens and following women and children to ensure adherence to PMTCT regimens and early infant diagnostic testing. Decentralized point-of-care rapid assays to accelerate the diagnosis of

HIV-1 among pregnant women were critical for programmatic expansion. Similarly, “opt-out” counseling programs with group pretest counseling, which normalized HIV testing only excluding women who asked not to be tested, contributed wider HIV testing coverage. CD4 staging posed a persistent bottleneck, leading to noninitiation or delayed initiation of PMTCT while waiting for CD4 results and prompting enthusiasm for Option B strategies, which did not require CD4 counts. In 2011, Malawi opted for a national program that provided Option B+, with early program data noting ~77% retention at 1 year with increased coverage of HIV-1-infected women compared to the previously used Option A approach (Chimbwandra et al. 2013). In the next decade, many countries are planning to transition to Option B/B+, and WHO/UNAIDS has provided toolkits to facilitate national programs in this transition. While there has been a persistent concern that stigma and partner influence may be barriers to PMTCT implementation, health systems may pose the more critical determinant of uptake. When antenatal clinics reliably offer rapid opt-out HIV testing, maternal HIV test uptake of >90% has been observed.

There is a marked heterogeneity in PMTCT coverage – for example, there is a high coverage in Botswana and South Africa and low coverage in Nigeria and Congo (Fig. 3). Systematic PMTCT evaluation methods enable objective comparisons of PMTCT programmatic performance by measuring infant HIV transmission rates. National surveys of 6-week olds attending routine child health immunization visits (attended by >90% of children) have been designed to incorporate HIV testing; this enables sampling of infants whose mothers attended or did not attend PMTCT, yielding a population infant HIV-1 transmission estimate. Recently, one such country-level PMTCT evaluation in South Africa (which was using Option A at the time) demonstrated low 6-week MTCT rates at a population level of 2.7%, reflecting a high population PMTCT coverage, good adherence to regimens, and effective regimens (Barron et al. 2013). Future evaluation methods will need to assess older infants to

Preventing Mother-to-Child Transmission of HIV-1, Fig. 3 PMTCT Intervention Coverage and Effectiveness in Different Countries. Source: UNAIDS World AIDS Day Report 2012

capture later breast-milk HIV-1 transmissions and estimate HIV-1-free survival.

As PMTCT expands, an increasing number of HIV-exposed uninfected (HEU) infants will emerge. HEU infants have been observed to have increased susceptibility to infections, morbidity, and mortality (Heidari 2011). The reasons for this increased susceptibility are undefined -- HIV-1 exposure has been associated with changes in immune development and vaccine responses. However, HIV-1 exposure often includes ART

exposure, maternal coinfections, and social factors, each of which may influence infant outcomes.

New Directions

HIV-1 MTCT research has been an area of rapid translational impact and has yielded critical insights for HIV-1 prevention in general. The unfortunately high time-limited risk of MTCT in

the absence of interventions enabled relatively small cohorts to quickly identify cofactors for transmission and effective preventive interventions. Thus, MTCT was the first HIV-1 transmission model in which treatment for prevention and exposure prophylaxis for prevention were shown to be effective in clinical trials, foreshadowing trials and results in adult sexual transmission.

Following clinical trials, PMTCT implementation research and advocacy led to programmatic innovations and expansion, which promise to continue to rapidly decrease infant HIV-1 infections worldwide. However, despite the impressive expansion of PMTCT programs, novel strategies for preventing infant HIV-1 are necessary to compensate for residual challenges in coverage, retention, and adherence. Vaccine approaches that combine passive antibody and induction of adaptive responses, analogous to hepatitis B vaccines, remain attractive because of their potential feasibility and scalability. High priorities for future MTCT research include optimization of PMTCT (regimens, outcomes, and programs) and development of infant HIV-1 vaccine strategies.

Introduction

Despite a growing trend in global declines in new HIV infections and AIDS-related deaths since 2005, HIV remains a global health challenge.

The Joint United Nations Programme on HIV/AIDS (UNAIDS) estimates that 36.7 million people were living with HIV in 2015 and a further 2.1 million people acquired HIV during 2015. About 80% of new HIV infections are sexually acquired and this remains the dominant mode of transmission. About two out of three new HIV infections occur in sub-Saharan Africa and one out of three new infections are in young people aged 15–24 years; notably in young and adolescent women. Reducing sexual transmission of HIV is critical to altering the current epidemic trajectory in many parts of the world but remains an ongoing challenge. Prevention of sexual transmission can be achieved through reduction in the number of discordant sexual acts and/or reduction of the probability of HIV transmission in discordant sexual acts but, in real life, this is a more complex interplay of amongst other issues, lack of knowledge of HIV status, biology, gender-power dynamics, and limited options for women unable to negotiate safer sex practices. A substantial body of literature exists that capture extensive efforts to advance HIV prevention efforts. We focus this chapter only on evidence from randomized controlled trials as highest level evidence to inform programmatic scale-up. Compared to the first 29 years of the HIV epidemic, the last 7 years has witnessed a dramatic transformation regarding HIV prevention, primarily around the prophylactic and systemic use of antiretroviral agents. This chapter reviews the HIV prevention clinical trials that have been conducted up until 2015 for the prevention of sexual transmission of HIV and highlights some of the future directions in HIV prevention science.

Treatment of Sexually Transmitted Infections

There is a bidirectional relationship between HIV and other sexually transmitted infections. HIV transmission and acquisition is enhanced in the presence of other bacterial and viral sexually transmitted infections (STI), particularly ulcerative infections such as syphilis, chancroid, and *Herpes simplex* type-2 virus infection. Genital

Study

HPTN 052 – antiretroviral treatment as prevention (Discordant couples – Africa, Asia, Americas)

IPERGAY – on demand oral Truvada (MSM – France)

PROUD – daily oral Truvada (MSM – United Kingdom)

Partners PrEP – daily oral Truvada (Discordant couples – Kenya, Uganda)

Partners PrEP – daily oral Tenofovir (Discordant couples – Kenya, Uganda)

TDF2 – daily oral Truvada (Heterosexuals men and women- Botswana)

Orange Farm, Rakai, Kisumu – medical male circumcision (Men – South Africa, Uganda, Kenya)

iPrEx – daily oral Truvada (MSM- America's, Thailand, South Africa)

Mwanza trial – sexually transmitted infection treatment (Men and women - Tanzania)

CAPRISA 004 – coital Tenofovir gel (Women – South Africa)

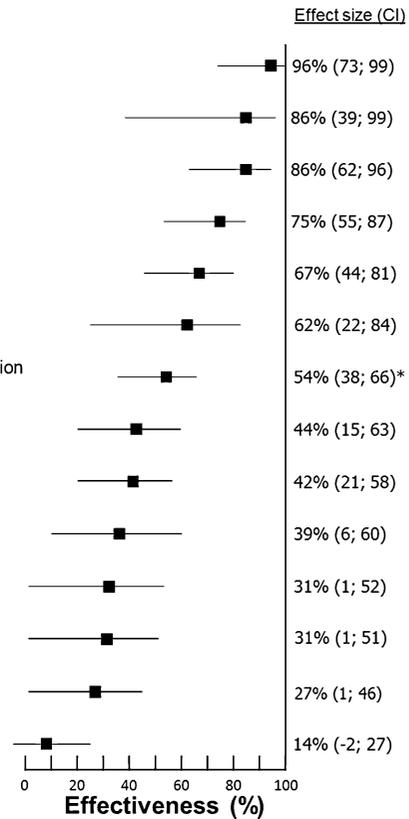

RV144 – HIV vaccine (Men and Women – Thailand)

Ring Study – monthly dapivirine vaginal ring (Women – South Africa, Uganda)

ASPIRE – monthly dapivirine vaginal ring (Women – Malawi, South Africa, Uganda, Zimbabwe)

Project accept – HIV counseling and testing (Men and Women – Africa, Thailand)

*meta analysis of 3 trials

Prevention Clinical Trials: Highlights of Evidence and Research, Fig. 1 Randomized controlled trials demonstrating a reduction in sexual transmission of HIV infection. *Meta-analysis of three studies. Note the Bangkok

tenofovir study among people who inject drugs has not been included as it is not possible to distinguish between HIV transmission that occurs through sex and that which occurs parenterally

ulceration or inflammation caused by STIs increase the infectiousness of HIV positive individuals and the susceptibility of HIV negative individuals.

Nine clinical trials have assessed the impact of STI treatment on the incidence of HIV infection, with some variation in approach, but, to date, only one trial has demonstrated a significant impact on preventing HIV infection (Ng et al. 2011). The Mwanza community randomized controlled trial, conducted in rural Tanzania among 12,537 individuals, showed that improved STI case management at primary health care level reduced incident HIV infections by 42% (Grosskurth et al. 1995) (Fig. 1). This was the first randomized trial to demonstrate an impact of a preventive intervention on HIV acquisition in the general population.

Although none of the eight subsequent STI treatment trials have replicated this finding, the treatment of STIs remains an important public health priority and is included in HIV prevention efforts programmatically as STIs are a major contributor to the global burden of disease, causing substantial illness, severe medical complications, and infertility.

Medical Male Circumcision

Since the 1980s, over 30 observational studies have suggested a protective effect of male circumcision on HIV acquisition in heterosexual men. These studies have been confounded by a number of factors including religion, behavior, and timing

and age of circumcision. In 2002, three independent randomized control trials were initiated in sub-Saharan Africa. Uncircumcised, HIV uninfected males from the general population in South Africa (N = 3,274), Uganda (N = 4,996), and Kenya (N = 2,784) participated in these trials. All three trials demonstrated a consistent HIV prevention benefit of 50–60% of forceps guided medical male circumcision in reducing female-to-male transmission of HIV (Auvert et al. 2005; Bailey et al. 2007; Gray et al. 2007) (Fig. 1).

Although male circumcision has limited immediate benefit to women, it could potentially impact on HIV incidence rates in women in the long-term through diminished exposure to HIV because of lower HIV levels among circumcised men. Evidence for the impact of circumcision on the epidemic trajectory at community level is starting to accumulate. Scale-up of voluntary medical male circumcision (VMMC) from 12% in 2007 to 53% in 2010 in one South African community has led to a 19% reduction in HIV prevalence and up to 61% reduction in incident HIV infection (Auvert et al. 2013).

Notable progress is being made in scaling up voluntary medical male circumcision (VMMC) programs as an HIV prevention strategy in 14 priority countries with HIV burden and low male circumcision rates. Approximately 11.6 million adult African men were circumcised for HIV prevention by the end of 2015, but more needs to be done to realize its public health benefit at a country level. Targeting of VMMC to young men, demand creation for, and uptake of VMMC by early adopters are some of the innovative approaches being utilized in sub-Saharan Africa to increase uptake and thereby impact HIV infection rates in these settings. The recent introduction of nonsurgical technologies such as the ShangRing and PrePex devices may facilitate task-shifting of circumcisions from doctors to mid-level health professionals, including nurses. These innovations and strategies are helping countries accelerate access to VMMC services. Data on the preventive benefits of VMMC in MSM populations are conflicting, but a Chinese observational study suggests that a clinical trial is needed (Qian et al. 2016).

Antiretroviral Treatment as Prevention (TasP)

Remarkable progress has been made in scaling-up antiretroviral therapy (ART) for the treatment of AIDS, with an estimated 18.2 million people receiving ART by June 2016. In addition to averting an estimated 7.6 million deaths globally since 1995, ART has the added benefit of preventing new HIV infections through the suppression of viral replication in the infected individual. Seminal papers published by Quinn et al. (2000) and Fideli et al. (2001) highlighted the positive correlation of plasma viral load and the risk of female and female-to-male transmission of HIV. A systematic review and meta-analysis of studies of HIV transmission among heterosexual couples, where the HIV-positive partner had been on ART for at least 6 months, estimates the transmission rate to be <13/100,000 unprotected sex acts. Observational data from the PARTNERS study, which included both heterosexual and men who have sex with men (MSM) couples, show zero-linked transmission events in discordant couples when the HIV-positive partner has a viral load <200 copies/mL.

The HPTN 052 randomized controlled trial among 1,763 HIV-discordant couples from nine countries, comparing early therapy (immediate ART initiation) to delayed therapy (ART initiation after a decline in the CD4 count or the onset of AIDS-related symptoms), showed that early initiation of ART in HIV-positive patients with CD4 counts between 350 and 550 cells/mm³ reduced HIV transmission by 96% (95% CI: 73–99.5) (Cohen et al. 2011) (Fig. 1). The reduction in HIV transmission based on this strategy is durable and ongoing follow-up for 5 years of this cohort revealed a 93% (95% CI, 78–99.9) lower risk of linked partner infection than was delayed ART (Cohen et al. 2016), thus providing compelling evidence of the prevention benefits of antiretroviral treatment also referred to as Treatment as Prevention (TasP).

Although there was some preliminary evidence from rural KwaZulu-Natal showing that a modest 30–40% ARV treatment coverage and initiation at CD4 counts <200 copies/mL,

resulted in a 34% reduction in new HIV infections, a large cluster-randomized trial assessing the universal test and treat (UTT) approach was unable to demonstrate a population level impact. The ANRS 12249 TasP trial, which was implemented in 22 rural communities in KwaZulu-Natal, South Africa, showed that although there was a high acceptance of home-based HIV testing and high levels of viral suppression among individuals on ART, overall linkage to care was suboptimal and there was no overall reduction in HIV incidence (Iwuji et al. 2016). Further, although countries like Botswana have reached the UNAIDS HIV treatment targets of 90-90-90, they continue to experience high community HIV incidence rates (Abdool Karim 2016). These results highlight the need for a more nuanced understanding of transmission dynamics, treatment coverage rates needed and timing thereof for epidemic control. Importantly, it is unlikely that TasP on its own is likely to achieve epidemic control but will need to be combined with a local understanding of the epidemic, an understanding of what the drivers of transmission are and targeting an appropriate combination of interventions most suited for the evolving epidemic at a local level.

Oral Pre-exposure Prophylaxis (PrEP)

The use of antiretroviral (ARV) agents as pre-exposure prophylaxis (PrEP) to reduce HIV transmission from infected mothers to their unborn infants has made a substantial impact on reducing HIV infection in infants. It was not until the early 2000s that this approach started to be explored to prevent sexual transmission of HIV.

Since 2010, the evidence for the protective benefits of PrEP has been consistently growing (Fig. 1). Results from seven randomized trials assessing prevention benefits of prophylactic use of oral tenofovir-based ARV agents provide compelling evidence that ARVs can prevent sexual transmission of HIV in men who have sex with men and heterosexual men and women in daily and intermittent dosing strategies ranging from 44% to 86%. Daily oral PrEP has also been

shown in one study to be effective in a population of people who inject drugs (Choopanya et al. 2013).

The first oral PrEP study to demonstrate an impact on HIV prevention was the iPREX trial, which showed that the daily oral tenofovir disoproxil fumarate (TDF) and emtricitabine (FTC) combination (Truvada[®]) reduced HIV incidence by 44% (95% CI: 15–63) among 2,499 men or transgender women who have sex with men (Grant et al. 2010). Evidence for the effectiveness of daily oral PrEP in heterosexual men and women comes from results of the PartnersPrEP trial (Baeten et al. 2012) and the Botswana TDF2 trial (Thigpen et al. 2012). The PartnersPrEP trial, which included 4,758 HIV discordant couples from Kenya and Uganda, showed that daily oral TDF and TDF-FTC reduced HIV incidence by 67% (95% CI: 44–81) and 75% (95% CI: 55–87) respectively, while the Botswana TDF2 trial, conducted among 1,200 heterosexual men and women from the general population, found that daily oral TDF-FTC reduced HIV incidence by 62% (95% CI: 22–83) (Fig. 1).

Two additional trials – FEMPrEP and the VOICE – conducted exclusively among women were not able to demonstrate a protective effect against HIV due to suboptimal adherence (Marrazzo et al. 2015; Van Damme et al. 2012). The HIV incidence in the FEM-PrEP study, which was conducted in 1,951 women aged 18–35 years from South Africa, Kenya, and Tanzania, was 4.7 per 100 person-years in the TDF-FTC group and 5.0 per 100 person years in the placebo group. Drug level testing revealed that <40% of women had evidence of recent pill taking. The Vaginal and Oral Interventions to Control the Epidemic (VOICE) trial assessed daily oral TDF, daily oral TDF-FTC, or daily 1% tenofovir vaginal gel (discussed below in the microbicide section) as PrEP against HIV infection in 5,029 women at 15 trial sites in South Africa, Uganda, and Zimbabwe. The effectiveness in the VOICE trial was –49.0% with TDF and –4.4% with TDF-FTC. Tenofovir drug levels were only detectable in 30% and 29% of available plasma samples from participants randomly assigned to receive TDF and TDF-FTC, respectively.

Given the anti-HIV specificity of PrEP, adherence is essential for its success. There is a strong correlation between high rates of adherence and effectiveness. Given that adherence can be challenging, even in a clinical trial setting, high levels of adherence may be difficult to achieve in “real world” settings where PrEP may be implemented in underdeveloped public health care facilities without adequate attention to adherence support. Not only will poor adherence contribute to sub-optimal protection, but it may also impact on the emergence of drug resistant strains of HIV akin to experience with tuberculosis.

The IPERGAY trial assessed an “on demand” PrEP dosing strategy in a cohort of HIV uninfected MSM wherein participants took two pills 2–24 h before each act of sexual intercourse, another pill 24 h after sex, and a fourth pill 48 h after sex. An 86% reduction in the incidence of HIV with on demand PrEP (95%CI: 39.4–98.5%, $P = 0.002$) (Molina et al. 2015) was achieved compared to placebo. These results have provided the first evidence that intermittent oral PrEP is highly effective in preventing HIV infection in men who have sex with men.

One of the concerns about widespread scale up of PrEP is the potential for risk compensation (also referred to as behavioral disinhibition), where PrEP users may reduce their use of higher efficacy HIV prevention strategies (like condoms) or may engage in riskier sexual practices. Risk compensation is a potential concern when implementing any new suboptimal HIV prevention strategy and is not specific to PrEP. However, risk compensation could potentially undermine and even reverse the beneficial effects of PrEP, as shown by mathematical models on HIV epidemics in Botswana, Kenya, and southern India (Vissers et al. 2008). The Pragmatic Open-Label Randomized Trial of Pre-exposure Prophylaxis (PROUD) study in MSM utilizing 13 sexual health clinics in England showed that there was no evidence of increased risky sexual behavior among MSM taking daily oral PrEP and led to an 86% reduction in HIV incidence (Fig. 1).

This series of scientific breakthroughs in HIV prevention, combined with the approval in 2012 of the first antiretroviral drug (TDF-FTC) as PrEP

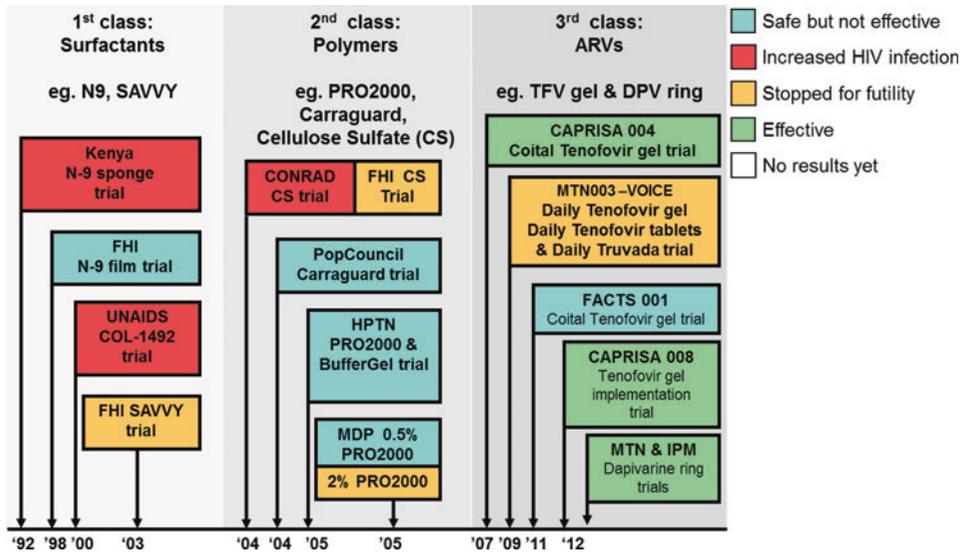

for reducing the risk of sexually acquired HIV infection by the U.S. Food and Drug Administration, has made the use of ARV drugs, as part of a comprehensive HIV prevention package, a reality, and has created newfound hope that the epidemic can be controlled, particularly among MSM. The use of PrEP in women appears to be a bit more complex and needs to be urgently unravelled.

Microbicides Including for the Prevention of HIV

Microbicides are topical agents applied in the genital tract to prevent HIV infection and were initially focused on vaginal products for HIV prevention in women in recognition of the urgent and growing need for women initiated technologies given this gap in current safer sex approaches that include abstinence, behavior change, use of male and female condoms, and counselling and testing which are all dependent on male partner initiation and or cooperation. Since then microbicide development has expanded to include topical agents that could be used rectally by men and women. Over the past 25 years of microbicide development, 15 advanced clinical trials of 8 candidate products (some tested as multiple doses and formulations) have been completed. To date only the CAPRISA 004 tenofovir gel trial and the two dapivirine ring trials have demonstrated a significant reduction in HIV acquisition in women (Fig. 2).

Early microbicide development focused on surfactants, e.g., nonoxynol-9 (Advantage 24; Columbia Research Laboratories, Rockville Center, NY) and SAVVY[®] (C31G, Cellegy Pharmaceuticals Inc., Huntingdon Valley, PA, USA), which act by disrupting cell membranes. Several formulations of nonoxynol-9 were evaluated but none were shown to provide protection against HIV and the phase III trial showed that the gel formulation of nonoxynol-9 may have increased the risk of HIV infection among women who used the product most frequently.

The next generation of microbicide candidates evaluated was vaginal defense enhancers, e.g. BufferGel, and attachment and fusion

Prevention Clinical Trials: Highlights of Evidence and Research, Fig. 2 Randomized controlled trials assessing microbicide candidates

inhibitors, e.g. Carraguard, PRO2000, and Cellulose Sulphate. Although the HPTN 035 trial, which assessed 0.5% PRO2000 compared with placebo, showed a signal for protection, the much larger MDP 301 trial, also testing PRO2000, showed no protective effect against HIV. Trials of Cellulose Sulphate were stopped in 2007 due to safety concerns.

The current category of microbicides that are being assessed in clinical trials includes antiretroviral agents that inhibit specific steps in the HIV life cycle.

Tenofovir gel was the first antiretroviral drug that was shown to significantly reduce the risk of both HIV and HSV-2 acquisition in women. In 2010, the CAPRISA 004 tenofovir gel trial showed that HIV acquisition was reduced by 39% and HSV-2 by 51% when tenofovir gel was used before and after sex (Abdool Karim et al. 2010). Despite these very encouraging results, even with high levels of adherence, tenofovir gel was shown to provide a moderate 54% protection and in women with detectable drug levels of >1,000 ng/ml tenofovir gel's effectiveness reached 74% (S. S. Abdool Karim et al. 2011). Two other trials – the VOICE and FACTS 001 trials – which also assessed tenofovir gel, showed no protective effect

against HIV. The VOICE trial, which evaluated a daily dosing regimen, showed that the effectiveness of tenofovir gel was 14.7% (95% CI: -21;40) (Marrazzo et al. 2015). The lack of protection observed in this study was primarily due to the low levels of adherence; estimated, based on detectable drug levels, to be 25% (Marrazzo et al. 2015). The Follow-on African Consortium for Tenofovir Studies (FACTS) 001 trial (CONRAD 2011), which included 2,059 South African women and assessed the same dosing strategy as the CAPRISA 004 trial, showed no overall HIV prevention benefit of the gel. However, a cohort analysis of 214 participants in the TFV-treated group showed a 52% reduction in HIV infection when tenofovir was detected in genital fluid.

Research on tenofovir gel is continuing. Tenofovir gel is currently being studied by the Microbicide Trials Network as a rectal application in MSM in several countries, including South Africa. CAPRISA is in the process of completing the CAPRISA 008 trial, which assesses gel adherence in women receiving tenofovir gel in conjunction with family planning. This real world implementation study may shed additional light on adherence when using a product that users know works. Further, a vaginal ring with both

tenofovir and a contraceptive is being developed with the aim of improving tenofovir adherence in women who are also strongly motivated to prevent pregnancy.

Focus in the microbicide field has also shifted toward developing products that are less dependent on user compliance and products that can meet multiple sexual reproductive health needs, for example STI and pregnancy prevention. Data from two long-acting antiretroviral intravaginal ring trials, which release drugs slowly over a 28 day period, were released in 2016 and showed that the dapivirine vaginal ring reduced HIV incidence overall by 27% (95% CI: 1–46%) in the Microbicide Trials Network-funded ASPIRE trial and by 31% (95% CI: 1–51%) in the International Partnership for Microbicides Ring trial (Baeten et al. 2016; Nel et al. 2016) (Fig. 2). However, the results show that protection differed by age; with no protection observed in young women below the age of 21, possibly due to lower rates of adherence in this age group (Baeten et al. 2016). More research is needed to fully understand and overcome the remaining challenges for sustained adherence in this high-risk population. An open label post-trial access study is ongoing and will hopefully contribute to our understanding of the contextual factors that impact on adherence in young women.

Long-Acting Biologicals

There are two categories of promising long-acting products for HIV prevention in early stages of clinical development. The first category includes prophylactic use of ARV based injectable agents and the second category is the use of broadly neutralizing antibodies as immunotherapy.

Long-acting antiretroviral injectable agents such as rilpivirine (TMC278) and cabotegravir (GSK1265744), which can be administered every 2–3 months, are in early stages of clinical testing as potential microbicide / PrEP agents and offer the advantage of being less user dependent.

The potential of immunotherapy using broadly neutralising antibodies is discussed in the “[Vaccines](#)” section below.

Vaccines

There continues to be a compelling need for a safe and efficacious vaccine to prevent HIV infection. Developing such a candidate, however, has proved challenging. Initial HIV vaccine efforts were focused on generating neutralizing antibodies using recombinant monomeric envelope gp120 (AIDSVAX) as immunogen. This vaccine did not induce neutralizing antibodies and the phase III trials failed to show protection against HIV acquisition. Vaccines that focused on eliciting cellular immune responses, e.g., the adenovirus vector-based T cell vaccine, also failed to show a protective effect and may have increased risk of HIV infection in some individuals. In 2009, results from the RV144 trial in Thailand, which showed a protective effect of 31.2% (95% CI, 1.1 to 52.1; $P = 0.04$) has provided renewed hope that an HIV vaccine is possible (Rerks-Ngarm et al. 2009).

Since the RV144 trial, important progress is being made in the vaccine field. Specifically, new sites for neutralization, including a site at the gp120–gp41 interface, and isolation of even more potent neutralizing monoclonal antibodies to the V2 apex and the high mannose patch on gp120 have been identified. These neutralization sites will be important targets for a HIV vaccine (Corey et al. 2015). Preclinical studies have also shown that broadly neutralizing antibodies, while effective in preventing a SHIV challenge in monkeys, may also have therapeutic benefits.

Progress is also being made in moving vaccine candidates into early clinical testing. The most advanced candidate includes the mosaic Ad26 vectors that are likely to be used in conjunction with a trimeric envelope protein or mosaic MVA boost, as well as clade C ALVAC and NYVAC vectors that will be used in conjunction with an adjuvanted bivalent clade C gp120 protein immunogen. Clinical trials of an adeno-associated virus expressing a broadly neutralizing antibody directed at the V2 apex and passive transfer studies of potent neutralizing monoclonal antibodies have also been initiated. A recombinant CMV-HIV vector is also in development, which has shown over 50% efficacy in preclinical studies.

Structural and Behavioral Interventions

Behavior Change Intervention

A number of studies have assessed the impact of behavioral change interventions to prevent HIV. A systematic review in 2010 of 11 behavior change studies, assessing eight unique interventions, showed that only one study resulted in a reduction of HIV incidence. This study was conducted among 541 female sex workers in India and included group educational and motivational sessions over 6 months, and was shown to reduce HIV incidence after 1 year of follow up (IRR = 0.33, 95% CI: 0.15–0.72) (Bhave et al. 1995). More recently, the SHARE (the **S**afe **H**omes and **R**espect for **E**veryone) trial, a community-level mobilisation intervention in Uganda to change attitudes, social norms, and behaviors related to intimate partner violence (IPV) was shown to be associated with a 33% reduction in HIV incidence (aIRR 0.67, 95% CI: 0.46–0.97, $p = 0.036$) (Wagman et al. 2015).

Cash Incentives for HIV Prevention

A novel strategy being investigated is the use of cash incentives to reduce HIV risk. A systematic review of cash transfer studies in 2012 identified 16 studies, 10 of which have been completed. Most of the studies have been conducted in adolescents and most report reductions in risky sexual behavior such as delaying sexual debut, staying in school, and using condom. One cluster trial in Malawi of cash incentives for school attendance showed that weighted prevalence of HIV at 18 months was lower in the intervention communities (Baird et al. 2009) but none of the studies have demonstrated a reduction in HIV incidence. Data from two randomised trials assessing the impact of cash incentives on HIV incidence have recently become available. However, neither of the trials were able to demonstrate an impact of cash transfers on HIV incidence. The HPTN 068 Swa Koteka study ($n = 2,448$), which provided a cash incentives for school attendance, found no difference in HIV acquisition between the young women who received the cash transfer and those that did not (Pettifor et al. 2012). The CAPRISA 007 cluster randomised controlled

trial, which was undertaken in 3,217 consenting male ($n = 1,517$) and female ($n = 1,700$) students in grades 9/10 in 14 schools in rural KwaZulu-Natal, showed that conditional cash incentives for meeting any combination of four conditionalities (annual HIV testing, school performance, participation in a HIV prevention programme and participation in a community project) was associated with a 30% reduction in herpes simplex virus type 2 (HSV-2) incidence but did not have sufficient statistical power to demonstrate an impact on HIV incidence (Abdool Karim et al. 2015). The implementation of cash incentive programmes for HIV prevention in young women would need to be evaluated in the specific context and would most likely need to be complemented by other effective HIV prevention strategies. Results from the ongoing Iringa combination prevention community cluster randomized trial (Pettifor et al. 2012) in Tanzania among 1,800 15–24 year old girls, which is assessing the impact of unconditional cash transfer for parent/guardian and child on HIV incidence, is eagerly awaited.

HIV Counselling and Testing

Knowledge of HIV status is a vital gateway to treatment and prevention services but remains a challenge. HIV counselling and testing has been shown in a large multicenter study ($n = 4,293$), conducted in Kenya and Tanzania, to reduce risky sexual behaviors (The VCT efficacy study group 2000). Men and women randomized to receive HCT had significantly lower rates of unprotected intercourse with their primary partners than those receiving only health information (The VCT efficacy study group, 2000). A large cluster-randomized controlled trial, Project Accept, conducted in 34 communities in four sites in Africa and 14 communities in Thailand, showed modest reductions in HIV incidence combined with increases in HIV testing. HIV incidence in the intervention group was 1.52% compared to 1.81% in the control group, with an estimated reduction in HIV incidence of 13.9% (relative risk [RR] 0.86, 95% CI: 0.73–1.02; $p = 0.082$). HIV incidence was significantly reduced in women older than 24 years (RR = 0.70, 0.54–0.90; $p = 0.0085$), but not in other age or

sex subgroups. Community-based voluntary counselling and testing increased testing rates by 25% overall (12–39; $p = 0.0003$), by 45% (25–69; $p < 0.0001$) in men and 15% (3–28; $p = 0.013$) in women (Coates et al. 2014).

Conclusion

Over the past 20 years, over 40 randomized controlled trials to prevent HIV infection have been undertaken but, to date, only 16 have demonstrated significant reductions in HIV. The proof of concept evidence is only the first step. Programmatic scale-up of what works is key to translate science to action and public benefit. Medical male circumcision is already being implemented and scaled up as a prevention option for men in high HIV burden countries. The use of oral antiretroviral drugs, as treatment or as PrEP, has created newfound optimism in HIV prevention. ARVs increase options for HIV prevention, especially for specific high-risk populations such as MSM and HIV serodiscordant couples. There are no magic bullets but these scientific advances in combination could advance efforts to achieve epidemic control. The quest for women initiated HIV prevention technologies remain urgent and long-active products that are less dependent on user compliance are promising. The development of a safe and effective HIV vaccine will substantially advance the progress toward eliminating HIV infection.

Prevention Counseling and Other Strategies in the HIV Care Setting

Safiya George Dalmida,

Drenna Waldrop-Valverde and Rashunda Lewis
Capstone College of Nursing, The University of
Alabama, Tuscaloosa, AL, USA

Definitions

Prevention counseling is a form of psychological, educational, and practical support intended to prevent a particular issue, event, or condition. This type of counseling incorporates education and psychotherapy and can be provided for an individual, pairs, or a group. This type of counseling may focus on primary or secondary prevention and may be conducted by psychologists, psychiatrists, mental health counselors, nurses, physicians, social workers, prevention case managers, and other professionals. Prevention counseling is an important component of HIV counseling (CDC 2010), which also includes the provision of information.

HIV prevention counseling is “an interactive process of assessing risk, recognizing specific behaviors that increase risk of acquiring or transmitting HIV, and developing a plan to take specific steps to reduce risks” (CDC 2006). HIV prevention counseling focuses on counseling

strategies that either support and encourage (1) people living with HIV/AIDS (PLWHA) to make decisions and engage in behaviors that reduce their risk of transmitting HIV to others (secondary prevention) or (2) people who are at risk for HIV to make decisions and engage in behaviors that reduce their risk of contracting HIV (primary prevention). It may also be focused on tertiary HIV prevention which promotes health and prevention of HIV disease progression. Overall, HIV prevention counseling relies on interventions aimed at changing behaviors, including counseling and testing in various settings and formats (Mizwa and Gwebu-Storer 2010).

Primary HIV Prevention Counseling

The Centers for Disease Control and Prevention (CDC) and the World Health Organization (WHO) support prevention counseling across all settings for persons at high risk for HIV. CDC recommends that patients receive information about HIV testing, infection, and the meaning of test results – separate from or in conjunction with counseling (Mizwa and Gwebu-Storer 2010).

HIV Prevention Counseling Regarding HIV Testing

Information regarding the HIV test, estimated time to receive results, and the associated benefits and consequences can be provided in a face-to-face meeting with a counselor, in a brochure, pamphlet, or video (CDC 2006), or via telephone. Regardless of the type of HIV test, clients should be given information about the routes of HIV transmission, strategies to prevent transmission, the lay meaning of test results, and need for confirmatory testing if the screening test is reactive and where to obtain additional information and services, including treatment.

Fundamentals of HIV Prevention Counseling

HIV prevention counseling fundamentals include performing a personalized risk assessment, acknowledging and encouraging ongoing prevention efforts, clarifying myths and misconceptions about HIV risk and transmission, and maintaining a focus on risk reduction (CDC 2006). It is crucial

to tailor counseling strategies to the needs and situation of the client and to help each client establish realistic and achievable behavior change goals and a strategic plan that includes concrete strategies to reduce HIV risk (CDC 2006). Also critical to prevention counseling is the need to address and reduce the internalization of stigma by providing education about HIV in a nonjudgmental manner and by treating PLWHA with respect and compassion.

Disclosure

Disclosure refers to the revelation of information to another person or party. For PLWHA, disclosure of HIV status is often a stressful topic as they consider when and to whom to disclose. In some cases, disclosure is inherent to the nature of a client–professional relationship. In other cases, automatic disclosure may occur due to state reporting laws that mandate notification of positive sexually transmitted infections (STIs), including HIV, to local state health departments. Similarly, in many states, people who test positive for STIs or HIV are legally responsible for notifying their sexual partner(s) of their positive status and the partner’s potential exposure. PLWHA also face the choice of whether or not to disclose their HIV status to relatives, friends, or other members of their social networks. They may therefore need counseling to help them make these decisions, including understanding state regulations on and other potential consequences of HIV disclosure. Counseling about HIV disclosure can also highlight its role in promoting secondary prevention as it emphasizes the responsibility of an HIV-positive person to inform sexual partners of his/her status and create the opportunity for engagement in risk reduction behaviors.

Secondary and Tertiary HIV Prevention Counseling (Prevention for Positives)

CDC recommends that HIV care clinics incorporate prevention into clinical practice. Prevention counseling in the HIV care setting occurs across the continuum of HIV care, beginning at the point of entry and continuing throughout care with a focus on preventive maintenance.

Entry into HIV Care: Early HIV Prevention Counseling

Prevention counseling for newly diagnosed patients should commence immediately following diagnosis. Patients should be screened for transmission behaviors initially and at subsequent visits, in a straightforward, nonjudgmental manner. Counseling at the early stages of diagnosis and care may include assessment of transmission risk factors, provision of education about transmission, determination of coping resources, counseling regarding HIV disclosure, and adherence to antiretroviral treatment as a strategy to reduce transmission. In the early stages of HIV care, counseling is best offered through a supportive, collaborative environment that helps patients come to terms with their diagnosis while emphasizing the importance of safe behaviors to protect their health and the health of their partners.

Preventive Maintenance and AIDS Prevention Counseling

As PLWHA live longer, fuller lives due to advances in technology and medication, consideration should be paid to health maintenance across the life span. Preventive maintenance refers to the ongoing strategies utilized to maintain health among PLWHA and prevent progression from HIV to AIDS. Cognitive-behavioral interventions (CBIs) are a useful strategy, as they have been found to be effective in improving mental health and to relate to immune functioning and CD4 counts (Crepaz et al. 2008). CBI helps to buffer the impact of stress and depressive symptoms on immune function and can slow HIV disease progression. By focusing on the interaction between thoughts, feelings, and behaviors, CBI teaches participants stress management and coping skills that may be utilized in many aspects of life.

Similarly, AIDS prevention counseling focuses on the importance of adherence to treatment to maintain or enhance immune function and prevent the development of resistant strains of HIV, as well as on behavioral modification and risk reduction. PLWHA are counseled about symptoms that are suggestive of an immunocompromised status and warrant a visit to a healthcare provider.

PLWHA are also counseled on the importance of maintaining regular healthcare visits to assess their health and risk status and to monitor HIV viral load levels, CD4 cell counts, and other laboratory markers – regardless of how well they might feel. Depending on each PLWHA's CD4 cell count level, he/she will be counseled on the importance of beginning and maintaining AIDS prophylaxis treatments. PLWHA with a CD4 cell count less than 200 cells/ μ L will be prescribed prophylaxis for *Pneumocystis jiroveci* pneumonia (known as "PJP"), and those with CD4 cell counts less than 50–100 cells/ μ L will be prescribed prophylaxis for *Mycobacterium avium* complex (MAC) and toxoplasmosis. PLWHA are also counseled regarding exposures they should avoid if they do become immunocompromised. Along with counseling, many HIV care professionals regard HIV treatment as a critical form of prevention.

HIV Prevention and Counseling Strategies and Methods

A number of HIV prevention and counseling strategies are available, including treatment as prevention (TasP), preexposure prophylaxis (PrEP), postexposure prophylaxis (PEP), behavioral interventions, prevention case management (PCM), peer counseling, motivational interviewing, group counseling, and couples/partner counseling.

Treatment as Prevention (TasP)

Treatment as prevention (TasP) operates under the assumption that transmissibility of the HIV virus is reduced when there is less viremia in the body. Effective treatment with antiretroviral therapy (ART) results in lower concentrations of the virus in seminal and vaginal fluids and is considered to be an avenue for averting sexual HIV transmission. Evidence for the potential utility of TasP was first demonstrated through prevention of vertical transmission of HIV from pregnant mothers to their fetuses/neonates; treatment with ART during pregnancy and 6 weeks after birth reduces vertical transmission by up to 66%. Further evidence for the effectiveness of TasP was seen in observational studies of serodiscordant

heterosexual couples, in which one partner is HIV-positive and the other partner is HIV-negative, and indicated that treatment with combination ART (3 or more antiretrovirals in combination) could limit transmission of the virus to HIV-negative partners as much as 80–98%. Population-level studies outside the USA also indicate combination ART may lower community HIV viral load. The most compelling evidence to date for the potential of TasP was provided by the HIV Prevention Trials Network (HPTN) 052 clinical trial. HPTN 052 found that giving combination ART immediately to an HIV-positive partner resulted in a 96% reduction in phylogenetically linked transmissions compared to the standard of care group. HPTN 052 was conducted with heterosexual partners, and given that the transmissibility for penile–vaginal sex is lower than that of penile–rectal sex, these results, although promising, are not generalizable to epidemics driven by penile–rectal sex. In order to capitalize on findings from HPTN 052, attention must be given to HIV testing and linkage and engagement in care over the disease course. Nearly 80% of persons in HIV care are estimated to have suppressed HIV viral load; however, 25% of HIV-positive persons are not in HIV care. Efforts by HIV care settings to identify, link, and retain HIV-positive individuals in clinical care are essential to TasP (Forsyth and Valdiserri 2012).

Preexposure Prophylaxis (PrEP)

PrEP refers to an HIV prevention method in which HIV-negative persons take daily medication to reduce their risk of contracting HIV. This method of prevention is used among persons who are considered high risk and has been found to be effective among populations of men who have sex with men (MSM) and heterosexual men and women. In July 2012, the US Food and Drug Administration (FDA) approved the HIV antiretroviral medication tenofovir for use as PrEP. Tenofovir belongs to the antiretroviral class of nucleotide analogue reverse transcriptase inhibitors (NRTIs), which block reverse transcriptase (an enzyme crucial to HIV viral production).

Postexposure Prophylaxis (Emphasis on Healthcare Workers)

Postexposure prophylaxis (PEP) refers to treatment started immediately after exposure to a pathogen in order to prevent infection and disease progression. In the case of HIV infection, PEP is a course of antiretroviral drugs taken after possible or suspected exposure to HIV. Exposures can be occupational or behavioral, but PEP is most often provided to healthcare workers who are occupationally exposed. PEP should be administered as soon as possible and is most effective within 72 h of exposure. Generally, a person on a PEP regimen will take 2–3 types of antiretroviral drugs for a 28-day period (www.AIDS.gov).

Behavioral Interventions

Strategies to change the knowledge, attitudes, behaviors, or practices of individuals in order to limit health risks are known as behavioral interventions. Changes in behavior can be enabled through environmental approaches in clinical settings, messages from healthcare providers, or through referral to other groups providing prevention services. Environmental approaches include flyers with prevention risk and transmission information and posters containing prevention messages displayed in waiting or exam rooms. Straightforward, brief prevention messages delivered by providers can be of benefit to all HIV-positive patients, particularly since many lack specific knowledge on risks and methods for preventing transmission. These messages may include abstinence from sex and injection drug use and safe sexual practices such as consistent condom use. Prevention messages may be tailored to meet the needs of patients with specific identified risk behaviors or positive STD tests. Reinforcement of prevention messages may need to be subsequently carried out more intensely or for a longer duration by nurses, social workers, or health educators. Underlying issues that may impede successful implementation of safer behaviors are often outside of the expertise and resources of HIV clinicians. In these situations, behavioral interventions involve referral for services such as intensive HIV prevention interventions, medical services for family planning,

contraceptive counseling, substance abuse treatment, mental health services, and social services. Referrals for patients' self-identified priorities are more likely to be successful.

HIV prevention interventions that have been found to significantly reduce unprotected sex, especially among PLWHA, include those that (1) are guided by behavioral theory; (2) have more than 2/3 of sessions focused on HIV transmission behaviors; (3) provide skills-building; (4) include intensive session delivery (>10 sessions, >20 h); (5) address issues related to coping with HIV status, adherence, and risk behaviors; and are delivered (6) in one-on-one session(s), (7) by healthcare providers or professional counselors, or (8) in HIV care setting or setting where PLWHA receive services or (9) for greater than 3-month duration (Crepaz et al. 2006; Lyles et al. 2007; Temoshok and Wald 2008). Also important is the integration of HIV prevention intervention and counseling services into multidisciplinary services, including social services (Crepaz et al. 2006; Lyles et al. 2007; Temoshok and Wald 2008; Fisher and Smith 2009).

Prevention Case Management

HIV prevention case management (PCM) approaches combine aspects of traditional case management with HIV prevention counseling strategies. PCM has been described by CDC and others as an intensive, client-focused, multi-session intervention designed to increase clients' personal risk management abilities. PCM promotes behavioral changes that reduce the chance of HIV transmission. Case management settings offer direct opportunities for professional staff to use PCM techniques while simultaneously assisting clients with housing, counseling, and other material needs. Generally, HIV case managers are professionally trained social workers or counselors who have received additional training or have expertise in HIV prevention. Although few studies have assessed the impact of prevention case management approaches, some have demonstrated efficacy in reducing risk transmission behaviors including unprotected vaginal intercourse, insertive anal intercourse, and needle sharing among HIV-positive persons and their

negative or serostatus unknown partners (Gasiorowicz et al. 2005). Further, PCM approaches are well received among specific subgroups of PLWHA. HIV-positive MSM who participated in an intervention assessing the feasibility of a PCM program indicated that they experienced a comfortable environment and a nonjudgmental stance from counselors and appreciated the resources their case managers were able to provide.

Peer Counselors/Positive Care

Peer counselors are often semiprofessional or trained laypersons who share one or more characteristics with the individual or group intended to receive the intervention. Peer-delivered counseling or interventions are intended to create an opportunity for the client(s) to connect to both the content being delivered and the shared experience(s) of the peer counselor. An HIV-positive peer sometimes delivers secondary HIV prevention interventions to PLWHA. Similarly, HIV prevention interventions designed for high-risk populations such as MSM may also be delivered by HIV-positive MSM. Overall, positive peer counseling is well received by PLWHA (Driskell et al. 2010; Safren et al. 2011) and has been shown to reduce HIV transmission-associated risk behavior (Safren et al. 2011; Simoni et al. 2011).

Motivational Interviewing

Motivational interviewing (MI) is a person-centered counseling method used to address ambivalence about change and to elicit and strengthen a person's own motivation for and commitment to change (Miller and Rollnick 2010). The MI approach emphasizes three key elements including (1) a collaborative partnership between counselor and client, (2) exploration of the client's thoughts about changing his behavior, and (3) recognition and support of clients' autonomy as a change agent. The major principles that guide MI include expressing empathy (acknowledging the challenge of change), supporting self-efficacy (focusing on previous successes and highlighting the client's innate abilities and strengths), "rolling with resistance" (avoiding struggling/arguing with a client if he

presents resistance to change), and developing discrepancy (enabling clients to recognize the mismatch between values/goals and current behavior). Counselors employ several core behaviors during motivational interviewing in order to facilitate the process: primarily the use of open-ended questions, affirmations of clients' strengths, reflective listening, and summaries of all or parts of the counseling session. MI has been successfully used to address behavior change regarding a variety of topics (substance use, sexual risk reduction, medication adherence), in varied settings (inpatient care, outpatient clinics care centers), and with a number of different populations (children, adults). Among PLWHA, use of MI has been shown to reduce sexual risk behavior and also substance use, but to a lesser extent (Naar-King et al. 2012).

Group Counseling

Group counseling is delivered by a trained facilitator or counselor in a group format often with participants with similar issues or characteristics, such as MSM or HIV-positive women. As a method of HIV prevention counseling, it is typically conducted with small groups of 10–12 and relies on the sharing and exchange of experiences among participants.

Couples/Partner Counseling

Couples/partner counseling is conducted with couples or sexual or needle-sharing partners. This type of counseling has the benefit of simultaneously counseling the complete sexual relationship or needle-sharing dyad. Counselors are able to identify attitudes and behaviors of each partner that might increase the risk of both. They can also emphasize the importance of risk reduction behaviors and help couples to learn skills or engage in activities such as role-playing to facilitate safe behavior negotiation. HIV testing is another important component in couples HIV prevention counseling. Partners who test positive may need counseling to support their response to an HIV-positive status and/or ongoing support to address denial, blame, or anger (Curran et al. 2012). If both partners are HIV-positive, it is important for counselors to educate the couple

about their ability to transmit other STIs or different strains of the virus to each other. Couples counseling emphasizes the importance of each individual knowing the HIV viral load and CD4 cell count of their partner in order to better understand their risk for HIV disease progression.

Prevention Counseling Special Considerations

Serodiscordant Couples

Behavior change strategies available to serodiscordant couples include discussions regarding reduction of outside partners, abstinence, and correct and consistent condom use (Curran et al. 2012). Counselors emphasize the importance of HIV medication adherence and viral suppression to reduce the risk of HIV transmission to the HIV-negative partner. The option of PrEP, including the associated benefits and risks, for the HIV-negative partner may also be discussed.

Family Planning/Pregnant Women

Cases of perinatally acquired HIV have been declining for a number of years, largely due to increases in routine HIV testing of women during pregnancy, availability of antiretroviral therapy for maternal treatment and perinatal prophylaxis, and delivery options that reduce chances of transmission. Accordingly, the rate of perinatal transmission of HIV has dramatically diminished to less than 2% in the USA and Europe (Birkhead et al. 2010; Panel on ARV 2012). Perinatal HIV transmission reduction strategies operate at a system-wide level and include increasing availability of early HIV testing, increasing availability of rapid HIV testing during labor and delivery, and advocating for clinical standard of care changes that incorporate HIV testing into prenatal care (Fowler et al. 2010).

In the HIV care setting, both men and women living with HIV should be provided with family planning education and counseling, including information about their contraceptive choices, options to reduce the HIV-related risks associated with conception (particularly for serodiscordant couples), and the prevalence of perinatal,

antepartum, and maternal–infant HIV transmission. For PLWHA who express an interest in conceiving a child, healthcare providers can discuss options based on existing family planning standards for the planning phase, pregnancy, and during/after delivery. In the planning phase, family planning counseling for PLWHA and their partner may include an emphasis on medication adherence for the seropositive partner and the use of PrEP for seronegative partners in order to reduce HIV viral load and the risk of HIV transmission during unprotected intercourse. For seroconcordant HIV-positive partners, medication adherence counseling emphasizes HIV viral suppression and prevention of HIV-resistant strains. Counseling should include a discussion of the benefits of ARV drugs for pregnant women and the risks of adverse events to the woman and infant. Providers may also discuss options such as artificial insemination, in vitro fertilization (IVF), or surrogate mothers. Above all, a pregnant woman's informed decision on prevention of mother-to-child transmission of HIV should be respected.

Adolescents/Young Adults

Adolescents and young adults (AYA) face unique developmental challenges that lend themselves to a variety of prevention counseling approaches. Many comprehensive sexuality education programs including information around STI/HIV prevention have been implemented in a variety of settings. Generally, approaches taken with youth fall into one of several categories: curriculum-based programs, STI/HIV education programs focusing on parents and families, video- or computer-based interventions, clinic-based reproductive health programs, school-based health centers, or community-wide STI/HIV or pregnancy prevention programs. Across intervention types, curriculum-based education programs appear to show the greatest strength of evidence for positive effects on sexual behavior. A comprehensive review of 48 STD/HIV education programs found that nearly half of interventions reviewed showed efficacy in delaying initiation of sex, reducing number of sexual partners, and increasing condom use; 29% reduced frequency of sex;

and 69% impacted one or more sexual risk behaviors. Educational programs impact behavior through affecting psychosocial mediators such as HIV/STD knowledge, perceived risk of HIV/STDs, values and attitudes toward sexual health, and self-efficacy to avoid risky sexual behaviors and engage in safer ones (Kirby et al. 2009)

Older Adults (50+)

Although most HIV infections occur among the young, nearly one-fourth of all HIV/AIDS cases in the USA are among persons over the age of 50. Stigma associated with ageism leads to less discussion and knowledge about HIV risks among older adults. Compared to their younger counterparts, older adults living with HIV have a more severe HIV disease course and shorter survival rates, poorer health indicators at diagnosis, shorter AIDS-free intervals, a higher number of opportunistic infections, and earlier development of tumors and lesions. Risk in this group may be increased due to stigma around sexual behavior, an already compromised immune system, or age-related health problems (Linsk 2000). HIV rates among older women have surpassed that of men, and due to lack of fear of pregnancy, older women may not demand that partners use a condom (Maes and Louis 2003). Symptoms of HIV/AIDS may be misdiagnosed as signs of aging or attributed to another disease or condition. Moreover, older adults are less likely to have received prevention messages from healthcare providers and are less likely to be screened for HIV and receive early intervention. Since older adults are often assumed not to be sexually active and not to be at risk for HIV, routine testing for HIV is relatively uncommon. This results in delayed diagnosis and treatment at an early stage when HIV can be most readily treated and decrease risk of transmission to others. It is important to remember that recommendations for HIV prevention among older adults are the same as those for younger individuals.

Mental Illness/Substance Use

Mental illness and substance use concerns are important factors to consider when implementing

HIV prevention strategies with PLWHA. Specific mental health concerns may include stress relating to PLWHA's HIV diagnosis or physical health, relationships with partners and family, and stigma associated with being HIV-positive. Consequently, the prevalence of mood and anxiety disorders is elevated among populations of HIV-positive persons and should be addressed within the context of HIV prevention activities. Studies have shown a negative association between depressive symptoms and medication adherence, and within some subgroups, depressive symptoms also predict risky sexual behavior. Combined mental health and HIV prevention programs, particularly those utilizing cognitive behavioral techniques, have been demonstrated to have some success in reducing both sexual risk taking and in improving medication adherence.

Similarly, HIV prevention strategies for drug users should take into account the related social and psychological factors that influence the behaviors of PLWHA. Poverty, policies criminalizing drug use, and access to drug treatment are some of the factors contributing to the spread of HIV among drug users. Drug users, particularly of injection drugs, are at increased risk of HIV transmission as a result of sharing practices and the associated increase in risky sexual behaviors common among persons under the influence of alcohol or drugs. Behavioral interventions aimed at HIV prevention with both seronegative and seropositive drug users include drug abuse treatment programs, harm reduction approaches, and community outreach programs.

Prisoners/Criminal Justice System

HIV prevalence is over 5 times greater in the incarcerated population than in the general population. Although diagnosis and treatment of HIV in correctional institutions pose unique challenges, incarcerated individuals are likely to benefit significantly from such efforts. Since non-Whites are overrepresented in the prison population, HIV prevention efforts among the incarcerated could also impact HIV/AIDS disparities. Most prisons do not

test for HIV routinely, despite CDC's recommendation for routine opt-out HIV testing in correctional settings. Far more prisons use a risk-based HIV testing approach that is highly underutilized due to stigma and lack of confidentiality. In the few settings that have implemented opt-out testing, large proportions of inmates were tested, many of whom had never been tested previously. Rapid testing, which offers the benefit of results in about 20 min, assists with providing test results in prisons with high rates of turnover.

Benefits of HIV treatment in the general population have been replicated in correctional setting with suppression of HIV viral loads prior to release. However, provision of care is expensive, and adherence to medications, particularly in institutions requiring inmates to retrieve their medications in "pill lines" that seriously undermine confidentiality, remains a barrier to effect treatment. Linkage to care post-release is difficult and often undersupplied.

Reentry into the community is a time of high stress often leading to risky behavior. Successful case management approaches have focused on HIV risk reduction, substance use counseling, and linkage services as primary prevention post-release. Couples-based prevention efforts may be an additional avenue for prevention with incarcerated individuals and their partners (Beckwith et al. 2010).

Conclusion

Prevention counseling in the HIV care setting may be offered across the spectrum and continuum of HIV care – from HIV testing and primary HIV prevention to entry into HIV care and treatment and secondary and tertiary HIV prevention. There are various HIV prevention counseling strategies, methods, foci, and formats, which can be delivered in a variety of HIV care settings and have been shown to be effective with several at-risk or vulnerable populations. Overall, HIV prevention counseling is used to promote HIV risk reduction and to promote HIV medication adherence and health outcomes.

Prevention for People Living with HIV

Nicole Crepaz and Cynthia M. Lyles
Division of HIV/AIDS Prevention, The
U.S. Centers for Disease Control and Prevention,
Atlanta, GA, USA

Definition

Prevention for people living with HIV integrates prevention, treatment, medical care, and support to improve and maintain physical, mental, sexual, and reproductive health as well as the well-being of people with HIV; to prolong survival; and to reduce the risk of transmitting HIV and acquiring other sexually transmitted infections (STIs).

History

In the early 1980s, behavioral risk-reduction methods that decreased the risk of HIV exposure during sexual contact, drug use, and pregnancy were the main strategies for reducing HIV transmission and acquisition of new infection. Throughout the first 15 years of the HIV epidemic, prevention efforts primarily focused on changing risk behaviors of persons who were at heightened risk for HIV infection. During this time, there was less emphasis on prevention for persons with HIV as no effective treatment was available. Additionally, there was concern that focusing on transmission prevention for persons with HIV would further stigmatize a population that was already facing discrimination and life-threatening illness.

The availability of highly active antiretroviral therapy (HAART) in the mid-1990s led to a new era of HIV prevention. Many HIV-positive persons had successfully lowered their viral load and achieved much-improved survival through strict adherence to their HIV regimens. Consequently, there was a dramatic decline in the incidence of AIDS and AIDS-related deaths in places where HAART was widely available. HIV was no longer considered a fatal disease but instead thought of as a treatable chronic infectious disease. The use of antiretroviral therapy (ART) to prevent HIV transmission from pregnant women to their newborns was also a major breakthrough and resulted in steady declines in the number of perinatally infected infants in many countries.

Treatment advancement also fostered a growing effort in the 2000s and early 2010 to identify people with HIV earlier; link them into HIV care; provide treatment, care, and support to improve the health of persons with HIV; and prevent further transmission of HIV. In 2001, the US Centers for Disease Control and Prevention (CDC) introduced the Serostatus Approach to Fighting the HIV Epidemic (SAFE) program, an effort to scale up HIV testing and identify HIV-positive persons who do not know their status (Janssen et al. 2001). The CDC’s “Advancing HIV Prevention” (AHP) effort in 2003 further addressed other health-care needs of person with HIV to include STI screening, substance abuse treatment, and prevention of opportunistic infections with a clear goal to reduce the number of new HIV infections by changing the behavior of persons with HIV (CDC 2003). CDC, Health Resources and Services Administration, National Institutes of Health, and HIV Medicine Association of the Infectious Diseases Society of America published guidelines for clinical providers to incorporate HIV prevention into the medical care of persons living with HIV (CDC et al. 2003). In the same year, the US President’s Emergency Plan for AIDS Relief (PEPFAR) was announced (U.S. State Department 2014) to fund prevention programs to expand access to ART within resource-limited countries with high HIV/AIDS

prevalence rates. In 2004, the Global HIV Prevention Working Group published *HIV Prevention in the Era of Expanded Treatment Access* (Global HIV Prevention Working Group 2004). This publication called for increased attention to prevention for persons with HIV as one key part of a broader HIV prevention agenda with expansion of treatment access. It also recommended to provide greater support to networks of persons with HIV and stressed the critical importance of overcoming stigma. All these earlier efforts were, however, criticized by their definitions of “prevention” – which focused almost exclusively on the prevention of transmitting HIV to other persons. The recent guidelines by the World Health Organization (World Health Organization 2008) were more centered on empowering persons with HIV by providing them with needed prevention, treatment, care, and support to stay healthy, avoid acquiring new sexually transmitted infections, delay HIV disease progression, and avoid transmitting HIV to others. The US National HIV/AIDS Strategy (NHAS) released in 2010 has emphasized increasing access to care and improving health outcomes of persons with HIV as one of the main goals, in addition to the goals of reducing HIV incidence and HIV-related health disparities (Office of National AIDS Policy 2010). Both WHO guideline and NHAS also emphasize the use of evidence-based strategies in delivering the comprehensive prevention for persons with HIV.

A Comprehensive Approach to Prevention with People Living with HIV

To date, many behavioral and biomedical interventions are shown to improve the health of persons with HIV and, at the same time, reduce HIV transmission to others. The most effective way of having the highest impact on the individual’s and community’s health is a comprehensive approach that combines prevention, treatment, care, and support together by tailoring to the needs of persons with HIV. This approach involves not only persons with HIV and HIV medical care providers but also community-based HIV service providers,

health departments, private and public sector entities, and the general public. A comprehensive approach includes efforts to enable individuals with HIV to become aware of their serostatus through HIV testing, be linked to and retained in HIV care, initiate and adhere to HIV treatment, receive risk screening and risk-reduction interventions, and be offered partner services, STD services, reproductive health care and perinatal transmission prevention, and other medical and social services that influence HIV transmission (such as substance abuse treatment and mental health services). Elements of a comprehensive prevention approach are outlined below.

Addressing Contextual Factors and Social Vulnerabilities

Factors such as poverty, homelessness, violence and abuse, and discrimination as a result of one’s age, gender, race, ethnicity, socioeconomic status, location of residence, literacy level, and sexual orientation shape the lives and health of persons with HIV and their access to prevention, treatment, care, and support. These factors often make people vulnerable to HIV in the first place and continue to impede their ability to adopt strategies to protect their health and partner’s health. HIV infection may also worsen some of these factors, making persons with HIV even more vulnerable to disparities. Understanding how these important contextual issues influence the use of prevention services and potential HIV transmission risk behavior of people living with HIV is critical. Providers and organizations working in clinical and nonclinical settings, policy makers, and affected communities need to be aware of these contextual issues and work together with persons with HIV to address them.

Knowing One’s Seropositive Status

Many HIV-positive persons substantially reduce risk behaviors after learning that they are HIV-positive (Marks et al. 2005), as many believe that they have a responsibility to protect their sex partners from HIV. However, 18% of the people with HIV in the United States are not aware of

their seropositive status (Hall et al. 2013). As a result, they miss important opportunities to initiate HIV treatment before the virus does significant damage to the immune system and potentially unknowingly pass the HIV virus to others. Several strategies are recommended to improve early detection of HIV infection and increase the proportion of tested persons who learn their test results, including reducing stigma about HIV testing, detecting HIV early on with tests for acute infection, making HIV testing more available and accessible (e.g., mobile testing, home testing), implementing HIV testing as part of routine health care, using more rapid testing technologies, and offering HIV testing and services to partners of those who are tested HIV seropositive (World Health Organization 2008).

Improving Early Entry to HIV Care and Retention in Care

After HIV diagnosis, timely entry into HIV medical care and retention in care are essential to the provision of effective ART (Thompson et al. 2012). Earlier entry into care and better retention in care have been shown to reduce the risk of developing HIV opportunistic infections, increase survival rates, improve access to psychosocial and preventive services which promotes continuity of medical care, and improve overall quality of life. However, of persons with HIV living in the United States, only 66% were linked to HIV care and only 37% were retained in care (Hall et al. 2013). Those figures are comparable with global data (Thompson et al. 2012). Several strategies may improve early entry into care and retention in care, including using HIV testing and surveillance data to identify persons who have never initiated care; offering services that promote linkage to and retention in care through collaborations among HIV testing providers, community-based HIV prevention providers, HIV care providers, case managers, and health departments; providing a brief, strengths-based case management that encourages persons with HIV to recognize and use their own abilities and strengths to access resources and solve problems; delivering intensive outreach for individuals not engaged in

medical care within 6 months; using peer or paraprofessional patient navigators; offering ancillary services (e.g., transportation, child care, mental health and substance abuse treatment) to address barriers to entry to care and retention in HIV care; and having monitoring system in place to track HIV care visits and sending reminders for any missed appointments (Higa et al. 2012; Thompson et al. 2012).

Increasing HIV Treatment Initiation and Adherence

HIV treatment guidelines recommend ART for all persons with HIV. Receiving ART earlier in the course of the disease and maintaining long-term adherence to ART provide added benefit to the individual's health and reduce the risk of transmitting HIV to partners. Inconsistent adherence may lead to treatment failure, compromise immune function, or result in mortality. Suboptimal adherence can also promote viral resistance that limits future treatment options for the patient and newly infected partners. Several effective strategies are recommended to improve HIV medication adherence, including involving patient in decisions about treatment regimens; creating a multidisciplinary team to support long-term adherence (e.g., nurse, case manager, social worker, pharmacist, counselor); offering ART regimens that are highly effective but reduce pill burden, dosing frequency, and dietary restrictions as much as possible; providing education and reminder tools to support good adherence; and providing referrals for services that address factors that may impede adherence, such as lack of health insurance or other resources to cover ART costs, drug and alcohol use, and mental illness (Thompson et al. 2012; CDC 2014).

Implementing Risk Screening and Interventions to Reduce Risk Behavior

Adopting and maintaining safer behaviors over a lifetime can be challenging for persons with HIV, especially when they feel healthy. Approximately 30–55% among various subgroups of HIV-positive persons (e.g., heterosexual men, women, men who have sex with men) reported unprotected sex after

their HIV diagnoses that put them at risk for potential STIs or put their partners at risk for HIV (Blair et al. 2011). Several behavioral risk-reduction interventions aim to reduce risk behaviors of persons with HIV by promoting behaviors such as condom use, not sharing drug injection equipment, and avoiding unprotected sexual practices. Some intervention characteristics are strongly associated with reducing the frequency of unprotected sex, including the use of motivational enhancement; providing skills building (e.g., correct use of male and female condom, role play for negotiating condom use); delivering to individuals by health-care providers or professional counselors in settings where persons with HIV receive medical care or prevention, or social services; and specifically addressing multiple facets of coping with being infected, including mental health, medication adherence, and care issues (Crepaz et al. 2006). Additionally, brief individually tailored prevention messages derived from risk screening during routine HIV care visits are also effective in reducing risk behaviors among persons with HIV. Sexually active persons with HIV should be offered regular STI screening and promptly treated if diagnosed with STI (CDC 2014). Offering HIV-positive persons of reproductive age with services for family planning and pregnancy care can improve the reproductive health of persons with HIV and also reduce potential sexual transmission and perinatal transmission (CDC 2014).

Providing Other Medical and Social Services to Enhance the Well-Being of Persons with HIV

As treatment has evolved to transform HIV into a more manageable chronic infectious disease, an increasing number of persons with HIV face emotional and physical challenges as they cope with managing HIV/AIDS over their lifetime. One of the foremost concerns for persons with HIV is telling other people about one's seropositive status. Some people may respond to the serostatus disclosure with love and support while others may not be as accepting. In most cases, sharing one's HIV status is a personal choice. However, in the case of sexual relationships, it can be a legal requirement in some states or countries. It is

important to offer support and information to persons with HIV to promote successful serostatus disclosure to sex partners to minimize risk of discrimination, prosecution, and other negative consequences. Other issues affecting the well-being of persons with HIV include relationship dynamics, sexuality, reproductive health, pregnancy prevention, mental health, employment, and basic needs (e.g., housing, food). Providing needed health and social services to address these issues increases the capacity of HIV-positive persons to take care of themselves and improve the overall quality of life.

Resources of Evidence-Based Prevention Strategies

Several guidelines emphasize the use of evidence-based prevention strategies and provide information on the strategies to support status awareness, early entry into care, retention in care, treatment initiation, long-term adherence to ART, safe behavior, and good quality of life among people living with HIV (World Health Organization 2008; Office of National AIDS Policy 2010; CDC 2014). In addition to these guidelines, the CDC's Prevention Research Synthesis Project conducts ongoing systematic reviews to identify evidence-based interventions and best practices, including those for persons with HIV (CDC and Prevention Research Synthesis (PRS) Project 2014). The CDC's dissemination effort of High-Impact Prevention Interventions and Strategies (formerly known as Diffusion of Effective Behavioral Interventions) provides a list of evidence-based interventions and public health strategies that have intervention packages and training available and also technical support to agencies that implement evidence-based interventions.

Conclusion

As the number of persons who are living with HIV grows, it is essential that HIV prevention, treatment, care, and services also expand to meet their needs. HIV medical care and prevention activities with people living with HIV play a critical role in HIV prevention. Providing good medical care to

HIV-positive persons and helping them to retain in routine HIV care and adhere to ART medication, keep viral load suppressed, and reduce risky behaviors can impact not only individual's health outcomes but also public health. Persons with HIV share some common experience, but they are not a homogeneous population. Various contextual factors affect subgroups of persons with HIV in different ways. Special consideration for the individual needs should be taken into account when providing prevention, treatment, care, and support. Maximizing the connections between prevention, treatment, care, and support will enhance the health and quality of life of persons with HIV. Everyone has a role to play and the responsibility is shared for making treatment and prevention available, reducing stigma and discrimination, and reducing HIV transmission.

Prevention of Alcohol-Related HIV Risk Behavior

Definition

HIV continues to be a major global public health concern. In order to stem the epidemic, prevention efforts must increase; programs targeting high-risk populations and behaviors are essential. Alcohol use is practiced and accepted worldwide. Alcohol is known to reduce inhibition and has been associated with increased risk-taking behaviors. Identifying strategies to prevent alcohol-related HIV risk-taking behaviors is one way to potentially decrease the spread of HIV.

Alcohol consumption is a common practice among all races, ethnicities, and cultures worldwide. Alcohol is responsible for approximately 4% of all deaths and 5% of the global burden of disease; low-income countries and poor populations are disproportionately affected (Beaglehole and Bonita 2010). Drinking patterns vary and include daily use, heavy drinking (more than 1–2 drinks per day), and binge drinking (more than 4–5 drinks on one occasion) (CDC 2014). Excessive drinking encompasses heavy and/or binge drinking and is associated with short- and long-term health risks (CDC 2014). Fifty-one percent of US adults aged 18 and over describe themselves as “regular drinkers” (Schiller et al. 2012). There is a growing population of underage drinkers in the USA, in both urban and rural settings (Yan et al. 2007).

In virtually all settings, alcohol use has been associated with an increase in risk-taking behaviors. Globally, alcohol use has been linked to concentrated HIV epidemics and to overall morbidity and mortality associated with HIV (Braithwaite et al. 2014; Fritz et al. 2010). Alcohol

is known to impair judgment and reduce inhibition, increasing the potential for other risk-taking behaviors, such as unprotected sex or injection drug use (Rehm et al. 2011; Bryant et al. 2010; Cook and Clark 2005). Under the influence of alcohol, persons often have a reduction in risk perception, making them more vulnerable to violence, coercion, and sexual risk. Additionally, the ability to negotiate safe-sex practices (condom use) is often impeded when under the influence of alcohol (CDC 2014). Changes in libido and sexual functioning associated with alcohol use may lead to a greater likelihood of receptive anal intercourse or condom failure (Bryant et al. 2010; Meade and Weiss 2007).

The exact nature of the relationship between alcohol consumption, risk-taking behavior, and specifically HIV risk is not well defined or understood. The research has not reached consensus on the causality of the interactions between the different variables contributing to individual risk taking (Rehm et al. 2011; Woolf and Maisto 2009; Cook and Clark 2005). Regardless, alcohol consumption has been associated with increased risk-taking behaviors, particularly increased sexual risk behaviors.

Populations at Risk

Individual personality traits and behavioral factors, such as risk taking and sensation seeking, influence a person’s use of and responses to alcohol (Bryant et al. 2010; Meade and Weiss 2007). Specific populations are known to have an increased likelihood of alcohol misuse and other risk-taking behaviors. Societal norms, cultural influences, establishments, and other contextual factors may impact the consumption of alcohol and subsequent associated behaviors (Li et al. 2010).

Severe Mental Illness

Persons suffering from severe mental illness (SMI), including depression, are particularly vulnerable to alcohol use and abuse. The effects of

alcohol may exacerbate mental illness; others may seek alcohol to mitigate symptoms. Persons with SMI may engage in more risky activities, including unprotected intercourse, multiple partners, trading sex for money or goods, and, more infrequently, injection drug use (Meade and Weiss 2007).

Adolescents and Young Adults

Adolescents and young adults represent a significant at-risk population for alcohol use/abuse and sexual risk taking. This age group also represents the greatest percentage of sexually transmitted infections, a potential contributor to increased HIV transmission (Wen et al. 2012). Adolescents and young adults are known to have multiple sexual partnerships (current and lifetime) as well as inconsistent and infrequent condom use. Risky encounters are more often reported while under the influence of alcohol, particularly binge or heavy drinking (Wen et al. 2012).

Men Who Have Sex with Men

Across the globe, MSM report high levels of current and episodic heavy drinking (Finlayson et al. 2011). As many as 85% of uninfected US MSM in a large, longitudinal study reported current drinking; of those 59% reported binge drinking. Heavier, episodic drinking in uninfected MSM was associated with socioeconomic status, a history of substance abuse, depression, and/or childhood sexual abuse. Men who have sex with men (MSM) represent a significant percentage of both new and current HIV cases in the USA (CDC 2012; Woolf and Maisto 2009). Heavy alcohol consumption has been identified as a significant risk factor for risk-taking behaviors, specifically unprotected receptive anal intercourse, sex with casual partners, multiple partners, and exchange of sex for money or goods (Woolf and Maisto 2009). How alcohol consumption contributes to risk taking and HIV acquisition in this population warrants further exploration.

Female Sex Workers

Given the stressors of sex work, female sex workers (FSW) may use alcohol as a means to self-medicate, increasing the likelihood of risky sexual transactions. Both parties (worker and client) may use alcohol to increase confidence and decrease inhibitions associated with transactional sex (Li et al. 2010). FSW may seek clients in alcohol-serving venues and may be expected to consume alcohol as part of the transaction. FSW are also at risk for coercion and violence and may have difficulty with condom negotiation; these risks are increased under the influence of alcohol (Li et al. 2010).

People Who Inject Drugs (PWID)

People who inject drugs (PWID) are at higher risk for HIV than the rest of the general, or even at-risk, population. Progress has been made at reducing the rate of transmission, primarily through needle-exchange programs. Alcohol has not been adequately addressed as a contributing factor to increased risk behavior in this group (Arasteh et al. 2008). PWID often report multiple sexual partners and unprotected and transactional sex. The increased risks associated with alcohol use among PWID have been documented globally (Arasteh and Des Jarlais 2010). Non-injecting partners of PWID are also at substantial, yet often unknown, risk for HIV.

Venues

While alcohol is a legal substance served in socially and culturally acceptable settings, alcohol-serving establishments may contribute to the HIV epidemic in a variety of ways. Venues may serve as “sexual networking sites” in both formal and informal ways; drinking establishments are a source of recreation and social networking among friends, and venues may provide opportunities to meet potential new sex partners and/or participate in commercial sex (Bryant

et al. 2010; Kalichman 2010; Woolf and Maisto 2009).

Interventions

Despite the association between alcohol consumption, increased risk taking, and a potential for increasing the spread of HIV, interventions specifically addressing alcohol use and its relationship to HIV acquisition are lacking (Fritz 2009; Fritz et al. 2010). The majority of interventions aimed at reducing HIV acquisition are designed to address specific, individual-level, HIV risk behaviors (e.g., sexual risk); alcohol use is not identified as a distinct variable that has been shown to significantly increase the risk of new infection. The combined impact of personal, behavioral factors, the environment, and societal and policy norms are not well integrated into the current intervention approaches and literature. The majority of interventions targeting alcohol-related HIV risk reduction fall into three categories: (1) youth-focused curriculum-based approaches, (2) individual counseling, and (3) venue-based interventions (Fritz 2009). The most successful HIV risk-reduction interventions, not specific to alcohol use, are those that have expanded beyond the individual level and incorporate social and structural factors underlying HIV risk (Finlayson et al. 2011; Harrison et al. 2010; Noar 2008). Few interventions target alcohol use specifically in PWID or persons with SMI; persons with substance use dependence or mental health issues may require concurrent substance abuse treatment in order to effectively mitigate HIV risk.

Adolescents and Young Adults

School-based curricular programs addressing HIV prevention, targeting adolescents and young adults, have been implemented in South Africa, modeled after US programs, with varying levels of success (Harrison et al. 2010; Fritz 2009). Incorporating the “causal pathways” of HIV risk,

such as alcohol use, sexual coercion or violence, and cultural or population norms and views, has had the greatest impact on success of programs, particularly in South Africa. The most successful interventions in South Africa, modeled after successful US programs, have incorporated the following key components: adopting structural approaches to change the context of individual risk (e.g., life-skills training) and changing social norms through group interventions and collaboration (Harrison et al. 2010; Noar 2008; Kalichman et al. 2007). Implementation in the school setting is also more effective when outside, trained personnel are utilized to deliver the interventions; older mentors were shown to be more effective than same-age peer mentors (Harrison et al. 2010).

This combined curricular-behavioral approach was not effective with US college students in reducing the frequency of unprotected sex or number of partners (Dermen and Thomas 2011). This population is known to engage in high-risk behavior including excess alcohol consumption; efforts to understand and address this issue in the USA are worthwhile.

Men Who Have Sex with Men

In the 1990s, an approach using “popular opinion leaders” was used to change behaviors in high-risk groups, to reduce the risk of HIV transmission. Specifically, trusted, well-liked individuals within a social network were recruited and trained to deliver a targeted intervention to reduce HIV risk; for example, safe-sex behaviors (condom use) was identified and promoted as the “new norm” within a group (Fritz 2009; Kelly et al. 1991). This approach was initially used with men frequenting gay bars; however, it has been adapted and implemented with other populations (Fritz 2009; Kalichman 2010). Characteristics of interventions resulting in behavioral change (safer sex practices, reduced alcohol intake) include a theory-based approach, interpersonal and life-skills training, support of key community members, multiple intervention sessions

using more than one method (e.g., counseling and group discussion), and consistent follow-up. This combination approach reduced the incidence of unprotected anal intercourse and number of sexual partners and increased condom use in US MSM (Herbst et al. 2005; Johnson et al. 2008). Alcohol consumption, as an independent or compounding variable, was not a specifically targeted variable in these interventions. Recent research further supports an integrated approach, incorporating HIV prevention content with behavioral risks and risk-reduction strategies in order to effect behavioral change and risk reduction (Finlayson et al. 2011; Johnson 2008).

STI Clinic Populations

Patients receiving care in US STI clinics have higher rates of alcohol misuse and are at higher risk for HIV (Carey et al. 2010). A combined brief and intensive behavioral intervention showed sustained success measured by lower STI rates, increased condom use, fewer episodes of unprotected sex, and improved knowledge and attitudes at 12 months. This two-step approach incorporated individualized counseling and risk-reduction strategies using appropriate screening tools (AUDIT), motivational interviewing, and a skills component. Personal triggers and strategies to minimize sexual risk behaviors were incorporated; alcohol use was not included as a specific variable in this study (Carey et al. 2010).

Female Sex Workers

The literature is mixed on the effectiveness of behavioral interventions to reduce HIV risk among female sex workers, particularly in Southeast Asia. The focus of behavioral interventions is on promoting condom use and increasing testing efforts, with the goal of reducing the spread of HIV; however, with the exception of the 100% Condom Use Project, implemented in Asian countries beginning in the 1990s to promote condom use with sex workers, these programs have shown little change in condom use or STI/HIV

testing (Ota et al. 2011; Tan et al. 2011). Successful programs addressed individual life skills, peer-to-peer partnerships, and those targeting sex-work establishments (Tan et al. 2011). Alcohol use or reduction efforts were not specifically addressed in any of the intervention studies with sex workers.

People Who Inject Drugs

There are limited studies addressing interventions to reduce alcohol-related risk among injection drug users. An intervention using motivational interviewing was particularly effective with PWID who participated in a needle-exchange program (Stein et al. 2002). The goals of motivational interviewing were to identify hazardous drinking behaviors, identify the relationships between alcohol and increased risk taking, and set goals for behavior change. Follow-up sessions focused on goal attainment and overcoming barriers to success.

Venue and Policy-Based Interventions

The legality of alcohol and the socially acceptable nature of alcohol consumption likely inhibit the development and implementation of effective interventions to reduce use. Policy measures have been proposed in the USA, such as increasing the tax on alcoholic beverages (Shuper et al. 2010), banning alcohol from college campuses (Cook and Clark 2005), or changing the minimum drinking age in the USA. However, these measures have not received significant support or been evaluated for their effectiveness in HIV prevention.

Given the overlap between alcohol use and risky sexual behavior, engaging alcohol-serving venues in HIV risk-reduction intervention efforts is appropriate (Kalichman 2010). Strategies can be employed in venues that will not have a direct negative impact on alcohol sales, such as making condoms available in restrooms and displaying positive messages regarding safe-sex practices. Training employees on alcohol-related HIV risk and engaging respected members of the

community, who frequent specific venues, to act as mentors for patrons to change the social norms, by promoting risk-reduction behaviors, such as safe-sex practices and reduced alcohol consumption, may also positively influence sex risk behaviors (Kalichman 2010). Venues can also increase awareness and demonstrate support by hosting events related to alcohol and HIV risk and prevention strategies. Addressing alcohol use in alcohol-serving venues, as a specific risk factor for HIV transmission and acquisition, is warranted.

Conclusions

The relationship between alcohol use and increased sexual risk behavior is well documented; the clinical significance between alcohol and HIV risk cannot be underestimated. Despite this association, interventions to reduce HIV risk do not target alcohol use/abuse; it remains a secondary, or hidden, factor.

Alcohol use/abuse is a modifiable risk factor for the acquisition and progression of HIV. Reducing problem drinking in all populations is necessary to combat the global HIV epidemic. Screening for alcohol misuse, using approved tools (e.g., alcohol use disorders identification test (AUDIT) or screening, brief intervention, referral for treatment (SBIRT)), should be incorporated into primary care visits or other healthcare settings (e.g., community programs); prompt identification of persons at risk can lead to recommendation for participation in risk-reduction programs. Integration and collaboration between disciplines as well as policymakers is an important aspect of intervention development and implementation. Alcohol, as a significant factor in the global HIV epidemic, must be more effectively addressed.

Definition

The role of antiretroviral treatment (ART) in pregnant and breastfeeding women for prevention of mother-to-child transmission (pMTCT) of HIV has become simple: control of maternal HIV viremia with highly active combination ART effectively blocks MTCT. Details, however, are complex. Lifetime optimal health for mother and child must be balanced with potential toxicities associated with such treatment. The pharmacokinetics of ART in pregnancy and transfer of ART through the placenta and in breast milk are also important considerations in optimizing the health of mother and infant. Management of opportunistic infections in the setting of pregnancy, and limitations in access to, and lack of safety data for newer combination therapies also impact the complexity of managing HIV in pregnancy. ART as preexposure prophylaxis (PreP) for serodiscordant couples planning pregnancies and the use of PreP in serodiscordant couples during pregnancy and breastfeeding have emerged as strategies in which HIV treatment is the primary prevention.

Introduction

The very first clinical trial studying the use of antiretroviral agents for prevention of HIV transmission occurred in the context of the prevention of mother-to-child transmission (pMTCT) in the

National Institutes of Health (NIH) Pediatric AIDS Clinical Trials Group protocol 076. It was a resounding success despite the limited armamentarium of azidothymidine (AZT) alone, decreasing transmission by 67% using a three-part dosing schedule beginning in the third trimester, continuing intrapartum, and incorporating treatment in the delivered infant (Connor et al. 1994). By the late 1990s, investigators knew that vertical transmission was strongly linked with maternal viral load at the end of pregnancy. Subsequent modifications of the 076 approach to using antiretroviral therapy (ART) during pregnancy for pMTCT have included everything from single-dose treatment at labor (with attendant dangers of selection for ART resistance in women and infected babies) to the advent of currently recommended highly active combination ART for all women with HIV. Almost every clinical trial of pMTCT has raised significant questions about how to simultaneously optimize maternal health and survival, prevent vertical transmission, and establish the maternal and fetal safety of new classes of drugs used during pregnancy. Ultimately, scientists, caregivers, and women living with HIV have come to realize that controlling maternal HIV viral load is the key to transmission prevention.

HIV transmission from mother to child can occur during pregnancy, around the time of delivery, and during breastfeeding. Population estimates of mother-to-child HIV transmission rates in the absence of ART are 25–30% during pregnancy and delivery and an additional 14–15% during breastfeeding. HIV exposure is thought to occur around the time of birth, with rupture of membranes; immune activation associated with delivery, especially when complicated by chorioamnionitis; and increased fetal exposure to maternal blood, both via the placenta and during passage through the birth canal. Optimized maternal ART provides effective preexposure prophylaxis by minimizing fetal exposure to maternal virus and by blocking infection of HIV-naïve fetal cells. Recent evidence from resource-limited regions suggests that continuing effective maternal ART also reduces breast milk transmission. Postexposure prophylaxis for infants requires

that ART reaches fetal and infant tissues at sufficient levels to prevent viral replication in the fetus. For the fetus, this requires transplacental passage of drugs (McCormack and Best 2014); for infants, ART can be administered directly.

Antiretroviral Therapy: What to Start and When to Start

The approach to any HIV treatment has generally been modeled to answer two questions: when to start and what to start? For women around the world, the diagnosis of HIV infection often occurs in the antenatal clinic. Depending on the gestational age at which maternal HIV is discovered, there may be some urgency to the question of when to start. The current approach of “test and treat” may be nowhere more urgent than in the pregnant woman newly diagnosed with HIV infection. The time on therapy required to achieve complete virologic suppression for effective prevention of transmission depends on maternal stage of disease, maternal viral load at presentation, an individual’s capacity to rapidly adjust to living with HIV, adherence, pill burden, and other maternal factors as well as on the choice of regimen. For women already on effective therapy at the time of conception, maintaining virologic suppression for maternal health and to prevent transmission is essential. When nausea and vomiting of early pregnancy interfere with ART adherence, anti-nausea medication prior to ART dosing is appropriate. For women starting or restarting therapy, postponing initiation of ART until later in the second or early third trimester both increases the likelihood of a successful start and decreases the chance of selecting for ART resistance to missed or vomited doses.

Treatment guidelines for pMTCT have evolved along with HIV treatment on the basis of many large-scale strategy studies. In 2013, the World Health Organization (WHO 2013) issued updated international guidelines for pMTCT which were consolidated into a single document of treatment and prevention recommendations, driven by CD4, disease stage, disease complications, pregnancy, and breastfeeding, with the goal

of harmonizing provision of ART for both treatment and prevention regionally. The options outlined in these guidelines are still being used in most countries with access to ART (WHO 2013). Very recently (September 30, 2015), the WHO again issued updated guidelines based partly on trial data indicating that initiating treatment while CD4 counts are still high reduces death, AIDS, and severity of non-AIDS disease. The new WHO guidelines call for immediate universal treatment for all people with HIV regardless of CD4 or disease stage and preexposure prophylaxis (PreP) for those at substantial risk. This would increase treatment goals to include all 37 million people currently living with HIV worldwide and harmonize with the current test-and-treat approach to HIV treatment in high-income (Panel on Antiretroviral Guidelines for Adults and Adolescents 2015) and some middle-income countries.

The answer to the question of what ART to start is constantly evolving as new drugs and combination therapies become available. The primary goal of ART in women with HIV infection, as in anyone with HIV infection, is constant and complete HIV suppression, which optimizes both maternal health and pMTCT. In pregnant women and women of childbearing potential, fetal safety also influences the choices of what to start, as discussed below. The choice of ART depends on regimen availability and supply chain requirements to maintain availability throughout the period of pregnancy and breastfeeding. In addition, women may have different levels of tolerance than men for components of any recommended regimen, and there are known genetic polymorphisms in different racial groups that may influence tolerance. Availability of alternatives and adherence support and assurance of compatibility with other required medications (i.e., antituberculous therapies, opportunistic infection prophylaxis, and, for the nonpregnant woman, hormonal contraceptives) are also considerations in regimen choice. Unfortunately, experience over many years has shown us that despite high adherence to HIV treatment throughout pregnancy, many women are at risk for inadequate treatment adherence after delivery when

newborn care and ART prophylaxis often take precedence in family life. There are substantial data indicating that despite successful pMTCT with treatment during pregnancy, if maternal health fails after delivery, even uninfected infants and children are at increased risk of morbidity, mortality, and, if they survive, growing up as orphans.

Both the WHO and the United States Public Health Service (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission 2015) specify that treatment for pregnant women and women of childbearing potential is combination antiretroviral therapy, typically with two nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs) and a non-nucleoside reverse transcriptase inhibitor (NNRTI). WHO guidelines further specify that the protease inhibitor combination of ritonavir-boosted lopinavir is an alternate regimen to the currently recommended first-line regimen of fixed-dose efavirenz (EFV) + tenofovir (TDF) + lamivudine (3TC) or emtricitabine (FTC). The prevalence of transmitted drug resistance varies widely around the world, and so it is recommended to test for HIV drug resistance prior to initiating therapy whenever possible. However, in women diagnosed late in pregnancy, the timing of ART initiation may not allow for such results to be returned, so the choice of agents may depend on some assessment of local resistance transmission patterns if that information is available. The risks of selection for drug resistance mutations using single-dose nevirapine for pMTCT have been well documented with a median overall maternal risk of approximately 38% (Arrivé et al. 2007) and 75% for infants infected despite prophylaxis. Using sensitive assay techniques to detect lower-frequency populations of resistant virus, these numbers are even higher. Consequently, the strategy of treatment only at onset of labor is no longer endorsed. Unfortunately many women in the developing world received some variation of partial treatment regimens in the context of pMTCT, placing them at risk for selection of drug-resistant virus. The assessment of archived resistance mutations in subpopulations of virus is not widely available at present.

Avoiding selection of drug resistance by optimizing continuity of complete therapeutic regimens for pMTCT preserves future maternal treatment options, including pMTCT for subsequent pregnancies.

Pharmacokinetics of Antiretroviral Therapy in Pregnancy

Part of preserving future treatment options for mothers includes optimizing pharmacokinetics during pregnancy so that drug levels do not drop sufficiently to allow loss of virologic control and/or emergence of resistance on treatment. Physiologic alterations in pregnancy affect absorption, distribution, metabolism, and elimination of many drugs, including ART (Buckoreellal et al. 2012; Gilbert et al. 2015), and changes occur even from first to third trimester. Pregnancy slows gastric emptying and intestinal motility, resulting in nausea, vomiting, and slower absorption. Changes in gastric pH may affect some drugs such as atazanavir, which requires acid for adequate absorption. Intravascular volume increases by 50%, total body water by 8 L, and total body fat by 4 kg, all affecting the apparent volume of distribution for hydrophilic and lipophilic drugs, respectively. Hepatic and placental metabolic pathways are influenced by both progesterone and estrogen in pregnancy including the cytochrome P450 isozymes and the UGT1A1/3 (uridine-5'-diphospho-glucuronosyl) transferases, both of which are important pathways in ART metabolism. Similarly, renal clearance is increased in pregnancy, which may lead to lower concentrations of renally excreted drugs or active metabolites.

Studies of ART pharmacokinetics in pregnancy have accelerated with the participation of two large study groups: the International Maternal Pediatric Adolescent AIDS Clinical Trial Network (IMPAACT) and Pharmacokinetics of Newly Developed Antiretroviral Agents in HIV-Infected Pregnant Women (PANNA). In the NRTI class overall, pharmacokinetic studies demonstrate adequate serum levels at standard dosing. Although most of these drugs are active

intracellularly, there is little data in pregnant women on intracellular drug levels. Tenofovir disoproxil fumarate, a nucleotide, is one NRTI which has demonstrated significantly increased clearance and therefore a fall in serum levels during pregnancy, though, in most patients studied, it exceeds the therapeutic target concentration in serum at standard doses throughout pregnancy. It also acts primarily intracellularly. A modified tenofovir molecule, tenofovir alafenamide, which reaches high intracellular concentrations with lower serum concentrations, is soon to be released. All of the drugs in this class show adequate placental transfer to the fetus. In the NNRTI class, which includes nevirapine, efavirenz, rilpivirine, and etravirine, most data indicate that though there is an increased clearance most likely associated with hepatic enzyme changes, trough concentrations remain above the therapeutic target and no dosage adjustments have been recommended to date. Placental transfer is comparable to NRTIs. Protease inhibitors, including the DHHS-preferred atazanavir and darunavir and the alternative, lopinavir, have been studied in pregnancy and most often show reduced plasma exposures, especially in the third trimester of pregnancy, likely due to a combination of enhanced hepatic metabolism and increases in the volume of distribution. Therefore, a boosting agent such as ritonavir is recommended with the use of any protease inhibitor in pregnancy. (Cobicistat has not been studied to date in pregnancy and is therefore currently not recommended; however, some practitioners may consider its use in fixed-dose combination pills to lower pill burden.) Protease inhibitors, including ritonavir, are subject to many drug interactions. An example of this is the interaction of tenofovir and atazanavir in which atazanavir levels are substantially decreased in the third trimester, even with ritonavir boosting, leading some experts to recommend dose increases in the second and third trimester, with similar recommendations for lopinavir/ritonavir dose increases in second and third trimester for treatment-experienced patients (Panel on Antiretroviral Guidelines for Adults and Adolescents 2015). As a class, protease inhibitors exhibit low placental transfer. Entry inhibitors

such as enfuvirtide and maraviroc have not been extensively studied in pregnancy, and they cross the placental barrier poorly, if at all, but may have utility in women with preexisting drug resistance or intolerance to other agents. Integrase strand transfer inhibitors (INSTIs) are the most recently developed category of ART, and raltegravir has recently been added to the list of preferred agents for initial therapy in HIV-infected pregnant women following sufficient evaluation of pharmacokinetics, safety, and efficacy (Panel on Antiretroviral Guidelines for Adults and Adolescents 2015). The rapid fall in HIV viral load seen with INSTI-based combination therapy has also led to its use in women diagnosed with HIV late in pregnancy. Importantly, caregivers and women should recognize that despite reassuring FDA pregnancy category ratings, limited prospective birth outcome data, especially birth defect data, on INSTI-based regimens are currently available, as detailed below.

Teratogenicity and Antiretroviral Agents

Risk of birth defects among infants exposed to ART during pregnancy has been an ongoing concern since AZT first became available. The Antiretroviral Pregnancy Registry (APR 2015) is a voluntary, prospective drug registry in which health-care providers register pregnant women taking ART before the outcome of the pregnancy is known. With almost 20,000 women enrolled and outcomes of 17,332 live births reported, it is the largest registry in history. No apparent increase in birth defects has been found, and an independent advisory committee summarizes, "APR finds no apparent increases in frequency of specific defects with first trimester (or other) exposures and no pattern to suggest a common cause; however, potential limitations of registries should be recognized" (Advisory Committee Consensus 2015). The French Perinatal Cohort study of 13,124 exposed children has also been reassuring despite their finding of a small increase in heart defects associated with AZT (no longer a component of WHO first-line therapy) and a

questionable association of early efavirenz exposure with a small increase in neurologic defects (Sibiude et al. 2014).

Efavirenz has been the subject of intense scrutiny ever since an unpublished, preclinical cynomolgus monkey study of 20 pregnancies showed a high prevalence of central nervous system and clefting abnormalities. Six retrospective case reports of central nervous system birth defects in humans have appeared. Such retrospective birth defect data must be interpreted with caution as they are subject to overwhelming selection bias. Neither APR nor a large meta-analysis of prospectively collected data in large populations of women and their infants has revealed any evidence of an increased risk of birth defects following first trimester exposures (Ford et al. 2014). Nonetheless, pending additional data, the USPHS continues to recommend avoiding initiation of EFV-based regimens in the first 8 weeks of pregnancy or in women who are contemplating pregnancy. Within the APR, a small but statistically significant increase was seen in overall birth defects for didanosine and nelfinavir, both rarely used currently in pregnancy, though there is no pattern to the defects observed, so the clinical significance is limited. Longer term follow-up of ART-exposed infants continues, and to date, no pattern of late-onset complications has been seen, though such studies are limited.

Despite such reassuring findings overall, birth defect and other pregnancy outcome data for ART that have entered the market since 2006 are very limited. In the APR January 2015 interim report, outcomes following first trimester exposure to raltegravir (180), rilpivirine (110), elvitegravir (18), cobicistat (18), and dolutegravir (3) are insufficient to detect even a potential twofold increase in all birth defects. Newer drugs and fixed-dose combinations offer low pill burden, low toxicity, enhanced tolerability, effectiveness against resistant virus, and markedly superior adherence compared to older ART which dominate the published pregnancy literature. Newer drugs and combinations are widely used outside of pregnancy and today are probably included in a

majority of pregnancy treatment plans. The need for prospective enrollment of pregnant women in clinical trials and/or APR is urgent: retrospective reports can create false alarms and dangerous treatment interruptions, while lack of prospective data could result in missing an early teratogenic signal, should any occur. Guidelines urge providers to submit cases to the APR (APRegistry.com).

Birth outcomes including low birth weight and preterm delivery in the context of maternal HIV infection and treatment are an area of controversy. Both are associated with increased morbidity and mortality particularly in the developing world. After a number of conflicting reports on the association of protease inhibitors with preterm births, more recent studies have raised additional concerns about any combination ART and preterm delivery, especially when ART was initiated pre-conception (Mofenson 2015); however, most studies are biased by enrollment after delivery and comparison of treated and untreated women in the very recent era of limiting HIV treatment to individuals with advanced disease. Careful monitoring of birth outcomes in light of newer guidelines calling for universal treatment is urgently needed and will be critical to the clarification of the risks as well as benefits associated with pregnancy in a test-and-treat environment.

Comorbidities and HIV Treatment in Pregnancy

Comorbid conditions are common in the setting of HIV infection, and strategies for pMCTC in women with concomitant tuberculosis, hepatitis B and/or C infection, malaria, or opportunistic infections present challenges in sequencing initiation of therapy to avoid immune reconstitution inflammatory syndrome, though this has been studied very little in pregnancy. The choice of NRTI therapy in pregnancy may also depend on coinfection with HBV, and avoidance of HBV flares if NRTIs are subsequently changed in pregnancy. Drug-drug interactions of antituberculous drugs with ART may be unpredictable especially in the

setting of pregnancy-induced changes in metabolism. Newer drugs are emerging, particularly in treatment of tuberculosis, and the study of these agents in women of reproductive age living with HIV, especially in pregnancy, and birth outcomes of ART-exposed infants and children will be essential to preserving maternal-child health and the effectiveness of pMTCT (McIlleron et al. 2015).

Treatment During Delivery, the Neonatal Period, and Breastfeeding

The virologic goal of maternal treatment is complete and durable virologic suppression; however, this may not be achievable in an individual pregnancy. At the onset of labor, the antepartum ART regimen is continued intrapartum for most women, and in settings where it is available and safe, intrapartum IV AZT, as well as elective cesarean delivery, before the onset of labor may be recommended to augment pMTCT if viral load at delivery is likely to be >1000 copies/ml. At the same time, data are clear that even with viral load above 1000, women taking combination ART are unlikely to transmit (Katz et al. 2010).

Regardless of the type of maternal ART, the third component of pMTCT includes 6 weeks of prophylaxis for HIV-exposed infants, although recently experts in the USA and Europe have shortened the duration of infant AZT prophylaxis to 4 weeks if the mother is fully treated at the time of delivery. In cases of less than optimal maternal virologic suppression or known or suspected ART resistance, the addition of a short course of nevirapine to AZT prophylaxis has been shown to be safe.

Breastfeeding presents another opportunity to use treatment to prevent mother-to-child transmission of HIV infection. Current recommendations in the developed world are for complete avoidance of breastfeeding (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission 2015), while in the developing world, in the absence of safe, reliable alternatives to breastfeeding, extensive data supports exclusive breastfeeding for 6–12 months with

simultaneous maternal ART for the entire duration of breastfeeding, though again, with newer recommendations for universal treatment, lifelong ART would include treatment for the duration of breastfeeding. Infant prophylaxis with AZT and up to 6 months of NVP has also been studied to prevent breast milk transmission in the setting of maternal treatment interruption postpartum. Use of breast milk substitutes in resource-limited regions, as well as early weaning and mixed formula, and breastfeeding have all been linked with increased morbidity and mortality among both uninfected and infected newborns and are not recommended outside of industrialized countries (Jamieson et al. 2012).

Preexposure Prophylaxis for Seronegative Women

Acute HIV infection occurring during pregnancy or breastfeeding is associated with a very high risk of mother-to-child transmission, presumably secondary to the extremely high levels of maternal viremia. Although treatment can be initiated rapidly in this setting, prevention is always better. Preexposure prophylaxis (PreP) with tenofovir or a fixed-dose combination of tenofovir and emtricitabine in HIV-seronegative women at risk, in addition to counseling and support for safer sex practices and effective treatment of HIV-infected sexual partners, could avoid acute infection. Pregnancy and breastfeeding are not themselves contraindications to initiation or continuation of PreP. Indeed, heterosexual transmission risk, male to female and female to male, is significantly increased during pregnancy. Monitoring for risk, continuing to offer retesting, and PreP during pregnancy for women at risk after an initial seronegative result in early pregnancy are strategies that may be used for pMTCT in uninfected women.

Achieving Pregnancy

Discordant couples desiring children face many challenges. First, partners should each know

their HIV status. Assisted reproductive technologies for prevention of transmission such as in vitro fertilization, so-called sperm washing, and artificial insemination are available to some discordant couples in resource-rich regions but not to most. Low-technology interventions to minimize sexual transmission during conception exposures include optimized control of the infected partners HIV disease with ART, semen analysis to detect azospermia and subclinical epididymitis, limiting unprotected intercourse to conception attempts only, and at-home artificial insemination for infected women with uninfected partners. Regardless of whether conception was achieved in a high- or low-technology setting, strict safer sex practices during pregnancy are universally indicated, and ongoing pre- and postexposure prophylaxis, especially for uninfected pregnant women, should be discussed and offered.

Summary and Conclusions

Prevention of mother-to-child transmission is possible in virtually 100% of women with the present regimen of antiretroviral therapies, obstetrical practices, and support and correlates with suppression of maternal HIV. Understanding the pharmacokinetics of antiretrovirals and drug-drug interactions during pregnancy and breastfeeding in both mother and infant is vital for effective pMTCT, which includes postpartum health of both mother and child. As new drugs emerge in the treatment of HIV, evaluation of efficacy and risks in the setting of pMTCT is also vital both to offer new and potentially better therapies to all persons with HIV but also to keep treatment options open for women with resistant virus. Finally, for seronegative women at risk during pregnancy and breastfeeding, the use of preexposure prophylaxis throughout may be the most effective way to pMTCT of HIV infection. Continuing to study the use of antiretrovirals in women of childbearing age will increase the ability to use these drugs effectively and safely for the health of women and children.

Primary Effusion Lymphoma

Giovanna Tosato

Laboratory of Cellular Oncology, Center for Cancer Research, National Cancer Institute, Bethesda, MD, USA

Definition

Primary effusion lymphoma (PEL) is a rare non-Hodgkin's lymphoma that characteristically presents as a malignant effusion in the body cavities

of patients with AIDS and occasionally in other patients with an underlying immunodeficiency. The malignant PEL cells are infected with Kaposi's sarcoma-associated herpesvirus (KSHV, also known as human herpesvirus-8, HHV8) and are often coinfecting with Epstein-Barr virus (EBV). PEL cells display morphologic features of large-cell lymphomas and are of B-cell lineage. The diagnosis of PEL is characteristically made in AIDS patients presenting with a malignant effusion in the pleural, pericardial, or peritoneal cavity characterized by the presence of KSHV-infected cells with characteristic morphology and phenotype. The clinical course of PEL is generally aggressive, with a mean survival of less than 1 year, despite chemotherapy.

Introduction

PEL was recognized as a distinct clinical entity when it was discovered that certain non-Hodgkin's lymphomas arising in the pleural, pericardial, or peritoneal cavity of HIV-infected patients were infected with KSHV, often in conjunction with the related herpes virus Epstein Barr Virus (EBV) (Cesarman et al. 1995). By definition, PEL cells are infected with KSHV. In 70–90% of cases, PEL cells are coinfecting with EBV. KSHV viral sequences were first identified in Kaposi's sarcoma-associated Herpesvirus (KSHV) or Human Herpesvirus 8 (HHV-8) tissues and were subsequently detected in a proportion of lymphoid tissues affected by multicentric Castleman's disease (MCD) and in PEL cells (Chang et al. 1994). KS, MCD, and PEL are the three principal malignancies caused by KSHV that arise in AIDS patients. Clinical descriptions of PEL in patients with AIDS preceded by about 5 years the discovery of KSHV, and since then it was suspected that these lymphomas might constitute a distinct entity because of their unusual presentation in body cavities, histology, and phenotypic characteristics. PEL may give rise to solid tumor masses inside the body cavities by adhesion to the mesothelial layer and may infiltrate surrounding tissues; these forms are referred to as "solid PEL" (Menon et al. 2012). More

infrequently, KSHV-infected large-cell lymphomas resembling PEL have been observed in HIV-infected individuals without malignant effusions. Because these KSHV-infected lymphomas resemble PEL in morphology, have phenotypic and genetic characteristics, and are often coinfecting with EBV, the 2008 World Health Organization classification described them under the category of PEL as they may represent part of a spectrum of PEL types (Menon et al. 2012).

Epidemiology and Pathogenesis

PEL comprises only about 4% of all HIV-associated non-Hodgkin lymphomas (AIDS-related Primary Central Nervous System Lymphoma; and Burkitt-like Lymphoma; Diffuse Large B-Cell Lymphoma; Plasmablastic Lymphoma), which are estimated to develop in 5–20% of HIV-positive patients, with a relative risk 60–200-fold higher than that of the general population (Yarchoan et al. 2005). The development of high-grade B-cell non-Hodgkin's lymphoma in an HIV-positive individual is considered an AIDS-defining illness; this occurs in 3–4% of HIV-infected individuals. The introduction of highly active antiretroviral therapy (HAART) (Antiretroviral Medications, Adult Care and Treatment) has decreased the incidence of HIV-associated non-Hodgkin's lymphomas, particularly the incidence of primary central nervous system lymphomas (AIDS-related Primary Central Nervous System Lymphoma) (Yarchoan et al. 2005).

Studies of PEL pathogenesis have focused on KSHV, since infection with this herpesvirus defines the illness, but the mechanisms by which KSHV promotes tumorigenesis are currently incompletely understood and are likely complex. KSHV is a gammaherpesvirus, which is endemic in sub-Saharan Africa (where the seroprevalence ranges between 50% and 70% of the population) and in the Mediterranean basin (where the seroprevalence ranges between 20% and 30% of the population); in North America KSHV infection among blood donors is believed to range between 1% and 3% but is higher in certain risk groups

(e.g., men who have sex with men). Some aspects of the natural history of KSHV are incompletely understood, including how the virus is transmitted to humans, in which cells it replicates, where it establishes latency, and how the immune system controls primary and latent infection. The strong association of KSHV malignancies with HIV infection has prompted investigation into the role of HIV infection. HIV does not infect PEL cells, but T-cell immunodeficiency associated with AIDS is believed to contribute to KSHV tumorigenesis by reducing immunity to the virus and to virus-infected cells, and by promoting expression of growth-promoting cytokines and growth factors. In addition, one of the HIV-1 proteins, the TAT protein (Tat Expression and Function), may facilitate KSHV infection of target cells (Yarchoan et al. 2005). The observation that the majority of PEL are coinfecting with EBV has suggested a contribution by EBV, a herpesvirus that infects most adult individuals worldwide. Unlike KSHV, which has not been shown to immortalize any cell type in culture, EBV is a potent B-cell-immortalizing herpesvirus. However, EBV is not always present in PEL cells, suggesting that it is not necessary. Nonetheless, EBV may contribute to PEL tumorigenesis. Comparative biochemical profiling of PEL cells infected with KSHV alone or coinfecting with KSHV and EBV has failed to identify major differences, except for increased activation of the MAPK (mitogen-activated protein kinase) pathway in cells infected with KSHV alone. In spite of its inability to immortalize normal cells of B-cell lineage in culture, KSHV is required for the survival and growth in culture of established PEL cell lines (Guasparri et al. 2004).

KSHV exists in PEL cells as an oligoclonal or monoclonal episome and in PEL usually does not undergo complete lytic replication resulting in the production of infectious viral particles. Rather, PEL cells are generally latently infected with KSHV, expressing only a few viral gene products. Thus, attention has focused on these KSHV latency genes (Speck and Ganem 2010). LANA (latency-associated nuclear antigen-1) is one such gene product, which tethers the viral DNA to the host-cell DNA, and this ensures viral DNA

persistence during PEL cell replication. Viral cyclin (vCYC), which is closely related to cellular cyclin D2, can inhibit the cell cycle inhibitor p27 KIP1 promoting cell cycle progression. Viral FLICE inhibitory protein (vFLIP) is required for the continuous growth and survival of PEL cells in vitro; vFLIP activates the NF κ B pathway, thereby promoting the expression of many cellular genes that can contribute to PEL survival and growth (Speck and Ganem 2010). Viral IL-6 (vIL-6), which shares similarity with cellular IL-6, is an autocrine growth factor for PEL cells in culture (Jones et al. 1999). The viral G-protein-coupled receptor (vGPCR) stimulates cell proliferation and promotes the expression of Vascular Endothelial Growth Factor (VEGF), the pro-angiogenic and vascular permeability factor VEGF (Speck and Ganem 2010). The viral Bcl2 homologue, vBcl-2, blocks cell apoptosis (Speck and Ganem 2010). All these KSHV latency genes have the potential to contribute to PEL malignant phenotype as they promote cell progression through the cell cycle resulting in uncontrolled cell growth and prevent cell death. In spite of this pattern of viral gene expression and gene function, and in contrast to their sustained and progressive growth in the body cavities, PEL is not easily propagated in culture once removed from the patients' body cavities, whether or not PEL cells are infected with KSHV alone or are coinfecting with EBV. This situation differs drastically from the ease with which B cells naturally infected with EBV can be propagated in vitro as immortalized cell lines, suggesting an important contribution of the tumor microenvironment in supporting PEL cell growth. As a consequence, only few PEL cell lines are currently available, which provide the only cells naturally infected with KSHV that can be propagated in vitro.

PEL cells resemble post-germinal center B cells because they display immunoglobulin gene rearrangement and somatic hypermutation; gene expression profile analysis suggests that PEL cells are plasmablastic (Menon et al. 2012). Consistent with this, PEL cells express the plasma cell-associated CD138/syndecan-1 marker and CD45 but lack expression of common B-cell-associated antigens (including surface

immunoglobulin, CD19, and CD20). They also generally lack the T-cell markers CD4 and CD8, although they may express cytoplasmic CD3. A number of activation markers, including CD30, CD38, CD71 and HLA-DR, are usually detected in PEL. Cytogenetic analysis has revealed no common chromosomal aberration in PEL, but Myc is often amplified (Bubman et al. 2007). Morphologically, PEL cells appear plasmablastic, immunoblastic, or anaplastic lymphoid cells.

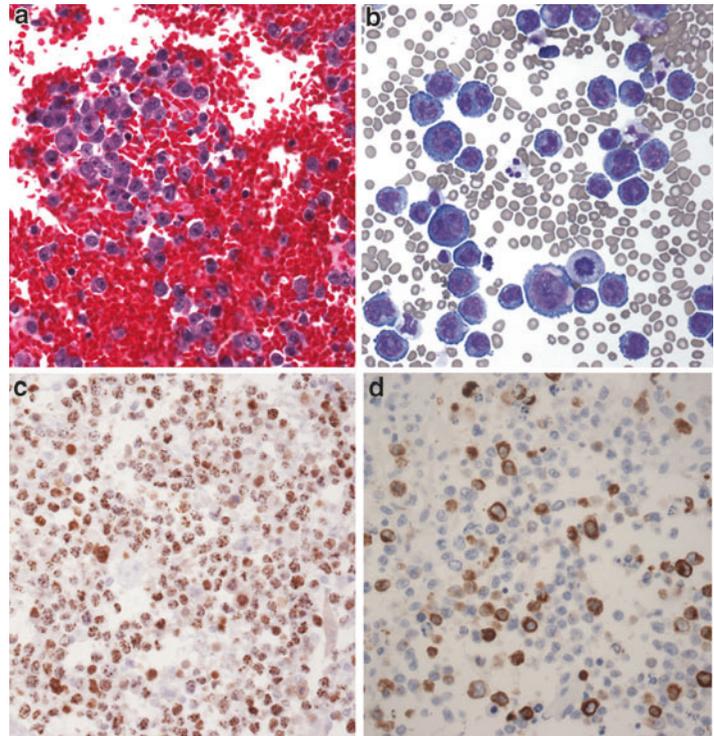

Clinical Presentation, Diagnosis, and Treatment

Patients with PEL are usually HIV-positive men, often with AIDS, presenting with symptoms resulting from accumulation of the malignant effusion in the pleural, pericardial, or peritoneal cavity, including dyspnea (pleural and pericardial PEL) and abdominal distension (peritoneal PEL). In cases of extracavitary PEL localized to the

gastrointestinal tract, soft tissue, or other extranodal sites, patients may present with symptoms reflecting PEL tissue location. A proportion of patients with PEL have preexisting or concomitant KS and/or MCD, the principal other malignancies associated with KSHV infection. Occasionally, PEL arises in pharmacologically immunosuppressed HIV-negative patients who have received a solid organ transplant. The diagnosis of PEL is based on histological, virological, immunophenotypic and molecular characteristics of the cells or tissue. Typically, PEL cells are derived from the effusions as cell suspensions and are processed as cytospin preparations or embedded as a cell block. In cases of solid PEL, the diagnostic sample is a tissue fragment. Histologically, PEL cells are large, resembling plasmablastic (eccentric nuclei and abundant cytoplasm), immunoblastic (round central nuclei with prominent nucleoli), or anaplastic (very large cells with pleomorphic nuclei) lymphoid cells (Fig. 1). All these features can be simultaneously present, resulting in PEL having pleomorphic

Primary Effusion Lymphoma,

Fig. 1 Morphology, KSHV infection, and vIL-6 expression in PEL cells. Characteristic pleomorphic morphology of PEL cells from two AIDS-associated pleural effusions (**a**, **b**). KSHV-LANA (**c**) and vIL-6 (**d**) detection in PEL cells from a case of AIDS-associated extracavitary PEL (The images from the files of the laboratory of Pathology, CCR, NCI are a gift of Dr. S. Pittaluga)

morphology. Demonstration of KSHV infection is required for diagnosis of PEL, which is usually accomplished by immunohistochemical detection of KSHV-LANA. Evidence of EBV infection is usually obtained by *in situ* hybridization of EBV-EBER (EBV-encoded RNAs). The EBV latent membrane protein-1 (LMP1) is usually not detected in PEL. Immunophenotyping reveals the expression of CD138, CD45, and cytoplasmic CD3, in the absence of mature B-cell markers. The differential diagnosis in cases of PEL includes other types of non-Hodgkin's lymphomas associated with lymphomatous effusions; many histologic subtypes of non-Hodgkin's lymphomas can present as a neoplastic effusion. Pyothorax-associated diffuse large-cell B-cell lymphoma, which develops in the pleural cavity in the setting of pyothorax in elderly HIV-negative patients, is EBV positive but KSHV negative. The correct diagnosis of PEL requires integration of clinical presentation and correct interpretation of histological, virological and immunophenotypic characteristics of the tumor cells. The initial patient evaluation includes a complete blood count and comprehensive chemistry panel together with appropriate staging to estimate disease burden and provide a baseline to assess response to treatment.

First-line therapy of AIDS-associated PEL often consists of combination chemotherapy with CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisolone)-like regimens, generally added to HAART antiviral treatment (Antiretroviral Medications, Adult Care and Treatment) (Yarchoan et al. 2005). Complete remissions have been observed in a proportion of patients (43–57% remissions). However, the 1-year overall survival rate is reported at 39.3% and the mean survival of patients with PEL is less than 1 year, despite treatment. There is evidence that the anti-CD20 monoclonal antibody, rituximab, can have activity in PEL, even though PEL cells generally express no or very low levels of CD20. The most frequent causes of death are PEL progression as a consequence of drug resistance, and complications related to HIV infection, including opportunistic infections.

Treatment of PEL arising after solid organ transplantation presents unique challenges: T-cell immunosuppression is required to prevent graft rejection but immunosuppression can be harmful to control KSHV infection. Thus far, 12 cases of posttransplant PEL have been reported: 7 post-kidney, 3 post-heart, and 2 post-liver transplantations (Riva et al. 2012). It is important to note that at least in some of these cases, the transplant recipients likely became infected with KSHV after transplantation, having acquired the virus from the KSHV-infected cell graft. In these cases, primary KSHV infection in severely immunosuppressed individuals may have played a critical role in PEL development. Treatment recommendations for posttransplant PEL include a combination of reduced immunosuppression, antiviral therapy and CHOP chemotherapy. The mTOR inhibitor rapamycin, which is often used as immunosuppressant after transplantation, has shown some efficacy in the treatment of experimental PEL, probably attributable to inhibition of VEGF translation. However, two cases of post-transplant PEL have been reported in patients on rapamycin raising concerns.

Chemotherapy at either standard or high dose has rarely cured PEL and has generally not provided long-term survival. Thus, much effort is being placed on novel approaches based on improved molecular understanding of PEL. One of the difficulties lies in the ability to recruit sufficient numbers of PEL patients for enrollment into clinical trials, which are often necessary to appreciate therapeutic advances. However, novel approaches to PEL treatment have been tested in some patients, others have been suggested from preclinical studies, and some are currently being tested or are planned. Antiviral therapy with intracavitary cidofovir was reported to prolong survival in 4 PEL patients (Luppi et al. 2005), suggesting that KSHV replication may contribute to PEL disease progression. Whether the drug targets the limited or periodic KSHV replication occurring in PEL cells or other KSHV-infected host cells is currently not clear. In part based on this experience with cidofovir, attempts have been made to purposely promote viral replication in

PEL cells and combine this approach with anti-viral agents: the antiseizure medication valproate, which promotes KSHV replication, was combined with cidofovir or foscarnet, resulting in increased PEL cell death *in vitro*. However, induction of viral replication in PEL cells by use of phorbol esters compromised the PEL proapoptotic effects of the chemotherapeutic agents doxorubicin and etoposide (Sarek et al. 2012). A different approach was based on the observation that the KSHV latency gene vFLIP, a potent activator of the NF κ B pathway, is necessary for PEL survival and growth *in vitro*. The proteasomal inhibitor bortezomib, which inhibits NF κ B signaling, promoted apoptosis of PEL cells *in vitro* (An et al. 2004). In addition, Nutlin-3, an activator of p53, induced massive cell death in PEL cells injected subcutaneously in mice (Sarek et al. 2012).

Another approach has been directed at modifying the PEL tumor microenvironment by targeting VEGF, which promotes vascular permeability and contributes to the accumulation of body cavity effusions that accompany a number of malignancies. PEL cells express VEGF at high levels, and VEGF is present at high concentrations in PEL effusions. In a preclinical model of PEL growing in the mouse peritoneal cavity, antibody neutralization of VEGF delayed PEL progression. In addition, the mTOR inhibitor rapamycin, which inhibits VEGF translation, was effective at reducing PEL growth in this preclinical mouse model. However, drug resistance developed rapidly, in part due to accelerated PEL secretion of the autocrine growth factor IL-10 (Gasperini and Tosato 2009). The combination of VEGF and IL-10 neutralization has been proposed but has yet to be tested. Besides IL-10, vIL-6 is an autocrine growth factor for PEL and an inducer of VEGF production, which is detected at high concentrations in PEL effusions (Sakakibara and Tosato 2011). Unlike human IL-6, which activates the common signal transducer gp130 only after associating with the non-signaling IL-6 receptor chain, vIL-6 binds directly gp130 and activates its phosphorylation

and downstream signaling. Since gp130 is expressed in virtually all cells, whereas the IL-6 receptor has a more limited cell distribution, vIL-6 has the potential to activate all cells in the body, thus potentially contributing directly or indirectly to PEL cell growth. Neutralization of vIL-6 by either monoclonal antibodies or soluble gp130 has been proposed to reduce PEL progression, particularly in situations in which PEL is associated with KSHV-associated MCD or related MCD-like syndrome, where vIL-6 is believed to play an important pathogenetic role. Another experimental treatment approach to PEL has been based on the observation of the importance of the STAT3 signaling pathway, which is active in PEL cells at least in part due to PEL activation by the autocrine growth factors IL-10 and vIL-6 (Aoki et al. 2003). Expression of a dominant-negative form of STAT3, which serves as a competitive inhibitor of STAT3 binding to target DNA sequences, not only prevented STAT3 activity in PEL but also induced prominent apoptosis *in vitro*. Consistent with a role of active STAT3 in PEL survival, the JAK2 synthetic inhibitor tyrphostin AG490, which inhibits STAT3 phosphorylation, promoted PEL cell death *in vitro*.

Conclusion

In summary, PEL is a rare malignancy usually occurring in patients with AIDS characterized by KSHV-infected large-cell lymphoma cells. Despite chemotherapy, the prognosis is poor. It is hoped that an improved understanding of the role of KSHV in PEL pathogenesis and of the biochemical pathways sustaining PEL progression will identify new targets for treatment.

Definition

Progressive multifocal leukoencephalopathy (PML) is an opportunistic infection of the central nervous system (CNS), caused by the reactivation of the polyomavirus JC (JCV) and the infection of brain cells, and characterized by progressive focal demyelination and necrosis (Hirsch et al. 2013). Despite diagnosis can be achieved promptly, there is no specific therapy for PML, and, before the introduction of combination antiretroviral therapy (cART), the disease was almost invariably fatal within a few months. Nowadays, cART-induced immune reconstitution is able to halt disease progression in more than half of the cases, although PML survivors will most often retain disabling neurological deficits (Cinque et al. 2009).

Epidemiological Aspects

Before the advent of cART, PML developed in 3–7% of patients with AIDS, and it was the cause of up to 18% of fatal CNS diseases (Cinque et al. 2009). In the cART era, the incidence of PML has decreased of about tenfold, from 0.7 to 0.07 per 100 person year of follow-up in the period 1994–2002, representing, however, the lowest decrease of incidence among all opportunistic infections of the CNS (D'Arminio Monforte et al. 2004). While median CD4 count at diagnosis

of PML was around 50 cells per μL in the pre-cART era, it is around 100 cells per μL in recent years (Casado et al. 2014), and PML can also develop in patients with CD4 counts greater than 200 cells per μL , in the setting of initiating cART and immune reconstitution and, although more rarely, in long-term-treated patients with full viral suppression.

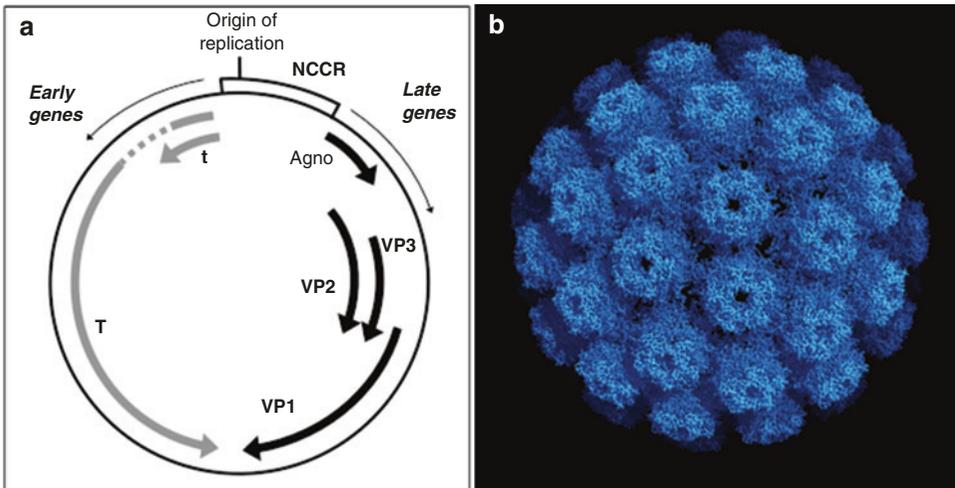

Etiology and Pathogenesis

JCV is a small DNA virus belonging to the family of human polyomaviruses (Fig. 1). JCV infection is ubiquitous, with a seroprevalence among healthy people of 39–69%, depending on the sensitivity of serologic assays. Primary infection occurs without identified symptoms, and ingestion of contaminated water or food has been suggested as major mode of transmission. Following primary infection, JCV may establish a chronic asymptomatic carrier state, with

persistence in the urinary tract and excretion of viral DNA in urine of 20–30% of healthy adults. Because JCV has been found in the bone marrow and CNS of subjects without PML, these tissues have also been suggested as possible sites of JCV persistence (Hirsch et al. 2013).

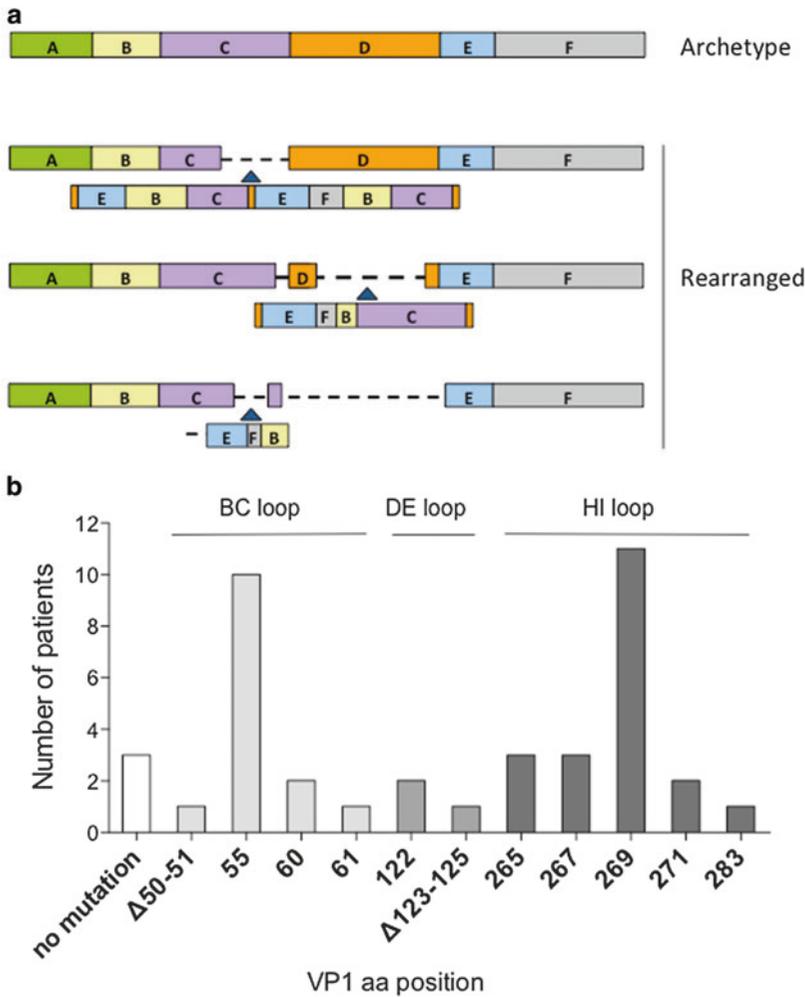

The loss of the immune control against JCV is essential in favoring JCV reactivation, either in the periphery or in the CNS, and allowing viral propagation in the CNS with consequent brain disease. The importance of immune defenses is clear from both the context of PML in patients with immune defects and its remission after reversion of the immune defect with cART. Indeed, remission of PML after cART is often associated with increased JCV-specific T-cell and B-cell responses in blood and cerebrospinal fluid (CSF) (Hirsch et al. 2013; Gheuens et al. 2011).

Beyond the immune defect, virus factors are also involved in the development of PML. These involve rearrangements of the JCV noncoding control region (NCCR) and mutations in the

Progressive Multifocal Leukoencephalopathy and HIV, Fig. 1 The polyomavirus JC (JCV) (a) Schematic representation of JCV genome. The noncoding control region (NCCR) contains the origin of replication, viral promoter-enhancing sequences, and binding sites for cell transcription factors. The early genes encode the large T antigen (T-Ag), which initiates viral DNA replication and regulates early and late gene transcription, and the small T antigen (T-Ag). The late genes code for the major

viral capsid protein-1 (VP-1), which mediates cell entry and is likely the main target of both humoral and cellular immune responses, the minor capsid proteins VP-2 and VP-3, and the agnoprotein (agno). (b) Three-dimensional atomic-level structure of the major capsid protein VP-1 of simian virus 40 (SV40), closely related to JCV and fully resembling JCV structure at picture resolution (Courtesy of Thilo Stehle, University of Tübingen, Tübingen, Germany)

Progressive Multifocal Leukoencephalopathy and HIV, Fig. 2 Genomic organization of the JC virus noncoding control region (NCCR) and frequency of viral protein-1 (VP-1) mutations in clinical specimens. (a) Schematic representation of JC virus NCCR. In “archetype” NCCR (found in urine of all healthy subjects and PML patients), there is an ordered sequence of six genomic fragments, designated with the alphabet letters from A to F (total length 267 bp). In “rearranged” NCCRs (found in brain tissues, cerebrospinal fluid

(CSF), and plasma of PML patients), the archetype sequence is completely reorganized with deletions, insertions, duplications, and mutations, and each PML case will present a unique pattern of rearrangement (figure shows three examples). (b) Frequency of VP-1 mutations in CSF samples of 40 PML patients (Adapted from Gorelik et al., Ref. 5). 37/40 PML cases presented one of these mutations. The numbers on the x-axis denote the amino acid substitution position in VP-1; BC, DE, and HI loops denote the outer VP-1 loops

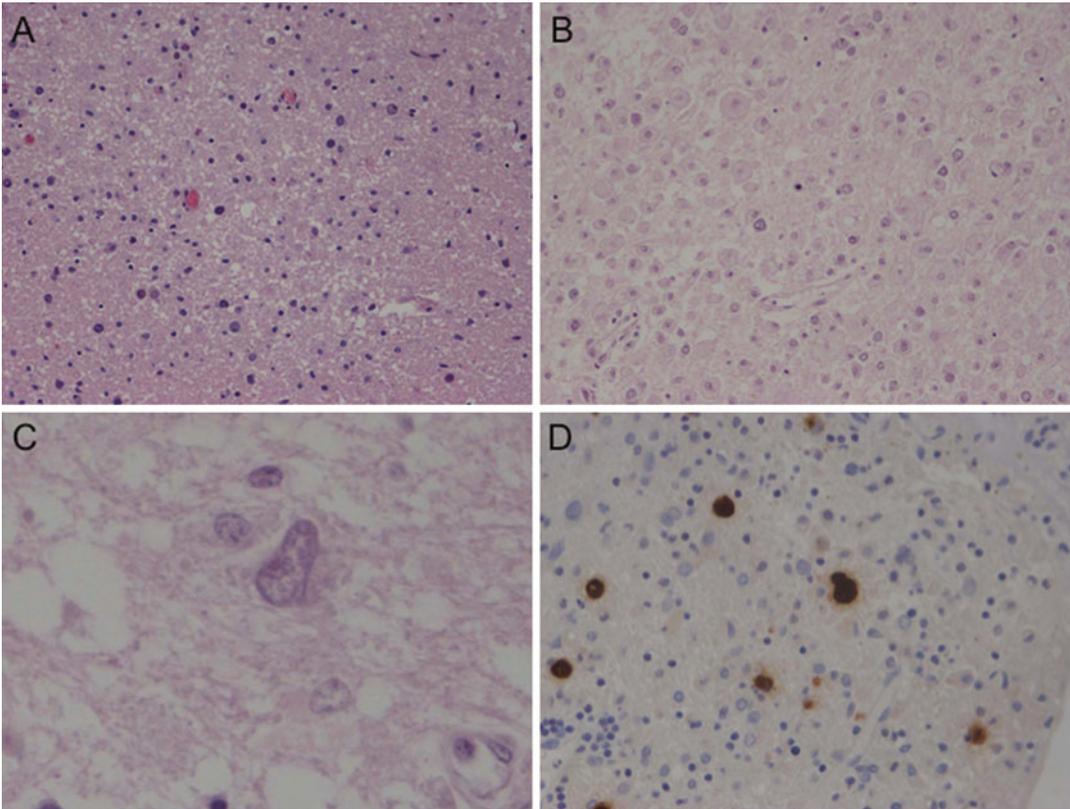

region coding for the major surface protein VP-1 (viral protein-1) (Fig. 2). Whereas JC virus NCCR sequences are conserved (“archetype”) in wild-type JC virus, i.e., the virus excreted in urine from both healthy subjects and PML patients, sequences are completely subverted (“rearranged type”) in the virus found in brain tissue and CSF

of patients with PML. Because NCCR contains sequences that regulate virus transcription as well as binding sites for cell proteins, it has been suggested that DNA rearrangements in this region may affect both virus replication and its tropism for host cells (Hirsch et al. 2013). In addition to NCCR rearrangements, the virus found in the brain

tissue and CSF of patients with PML also contains one of several amino acid mutations of the external capsid protein VP-1. These “PML-specific” mutations are located in the external VP-1 loops, which are both part of the JCV binding pocket for the sialic acid cell receptors, and involved in immune recognition. Therefore it is likely that VP-1 mutations affect cell binding and might also be involved in mechanisms of viral immune escape. Of note, these mutations are not present in wild-type viruses, including the virus excreted in urine from PML patients, indicating that these are selected within the patient upon JCV reactivation at the time of PML (Gorelik et al. 2011).

Neuropathology

PML is characterized by multiple areas of demyelination, varying in size and stage of development. Initial foci of demyelination expand and might coalesce into larger areas that can evolve into cavitory necrosis. All CNS regions can be involved, although spinal cord lesions are rare. Classically, oligodendrocyte nuclei are enlarged and densely basophilic, filled with eosinophilic inclusions, and stained by immunocytochemistry and in situ hybridization for JCV proteins and nucleic acid, indicating productive lytic infection (Fig. 3). Astrocytes also appear enlarged,

Progressive Multifocal Leukoencephalopathy and HIV, Fig. 3 Histopathological findings in PML. (a) Early progressive multifocal leukoencephalopathy (PML) lesion: white matter vacuolization, enlarged oligodendrocytes with viral nuclear inclusions, and no inflammatory infiltrate (hematoxylin–eosin, $\times 100$). (b, c) Late PML lesion: diffuse demyelinating lesion with abundant lipid-laden macrophages and few infected

oligodendrocytes (b, hematoxylin–eosin, $\times 100$) and a bizarre astrocyte with atypical multilobated, or “pseudoneoplastic,” nucleus (c, hematoxylin–eosin, $\times 40$). (d) In situ hybridization with JCV-specific probe: nuclear staining of infected oligodendrocytes (JC Virus BioProbe, hematoxylin counterstaining, $\times 100$) (Courtesy of Manuela Nebuloni, University of Milan, Italy)

sometimes with multiple or multilobate hyperchromatic nuclei, resembling neoplastic cells, the so-called “bizarre” astrocytes, and also harbor JCV gene products. Foamy macrophages, though not specific to PML, are present in many cases as a response to myelin breakdown. Very recently, the use of a novel animal model of PML, i.e., a chimeric mouse engrafted with human glial progenitor cells and infected intracerebrally with JCV, has shown that astrocytes and glial progenitor cells were the principal CNS targets for infection, with demyelination occurring only secondarily, due to JCV T antigen-triggered apoptosis of oligodendrocytes (Kondo et al. 2014).

One of the classic pathological features of PML is the presence of little or no inflammation. However, “inflammatory” forms can be observed. These usually occur at onset of PML in patients with relatively high CD4 cell numbers or, more typically, develop after starting cART, in the context of immune reconstitution. The inflammatory forms are characterized by either diffuse or focal perivascular mononuclear infiltrates. These consist mostly of CD8+ T lymphocytes and monocytes or macrophages; B lymphocytes, plasma cells, and CD4 T cells are also present, but usually in smaller numbers (Martin-Blondel et al. 2013).

JCV has also been identified in cerebellar granule cells, either together with other PML lesions or as unique neuropathology in the context of cerebellar atrophy. This picture characterizes the so-called cerebellar granulopathy, which is associated with a progressive cerebellar degeneration. Recently, an encephalitic form with JCV infection of cortical neurons and a meningitis, with JCV infiltration of subarachnoidal space, have also been described in HIV-negative patients (Miskin and Koralnik 2015).

Clinical Manifestations

The classical presentation of PML is with focal neurological deficits, usually with insidious onset and steady progression. Deficits vary depending on the location of the lesion, including visual field loss and hemianopsia (due to involvement of occipital lobes or optic radiations), hemisensory

defects or hemiparesis (frontal and parietal lobes), aphasia (language-dominant hemisphere), dysmetria and ataxia (cerebellar hemispheres and peduncles), or as a more diffuse encephalopathy, with cognitive deficits or behavioral alterations. Focal symptoms often begin as partial deficits that worsen with time (e.g., arm weakness evolving to hemiparesis), which reflect the spread of individual lesions concentrically or along white matter tracts. Seizures develop in nearly 20% of PML patients, usually in association with lesions adjacent to the cortex, while headache and fever are usually absent.

The inflammatory forms described above, if sufficiently severe, can be accompanied by additional symptoms and signs, which characterize the so-called immune reconstitution inflammatory syndrome (PML-IRIS). In general, IRIS is defined by the presence of immune reconstitution, tissue inflammation, and new onset or worsening of clinical disease that would not be expected from the natural course of the disease itself. The immune reconstitution develops in the context of a decrease of plasma HIV-1 RNA, most often with an increase of CD4+ T cells, following initiation of cART. As with other cART-associated IRIS events, PML-IRIS is also observed either as “paradoxical” or “unmasking.” In paradoxical PML-IRIS, inflammation and clinical worsening develop in relation to existing lesions a few weeks to months after cART initiation. In this setting, it is important to distinguish the clinical worsening associated with IRIS from classical progressive PML without inflammation, since the former may be ameliorated by treatment with corticosteroids. In the unmasking form, PML emerges in previously asymptomatic patients after the start of cART with an inflammatory picture on MRI. Unmasking PML-IRIS is presumed to represent the effects of a restored immune response to subclinical JCV brain infection, with resultant local inflammatory responses and clinical symptoms.

Before the introduction of cART, PML was almost invariably fatal. Median survival from diagnosis was of a few months, although continuous progression over a year or more was observed occasionally in patients with high CD4+ T-cell counts. In the cART era, the survival of PML has

increased substantially, with 38–62% survival rates at 1 year (Cinque et al. 2009). However, mortality remains ten times higher than the combined mortality of all AIDS-related diseases making PML the second most lethal AIDS defining opportunistic disease, after non-Hodgkin lymphoma (Antiretroviral Therapy Cohort Collaboration ART-CC et al. 2009).

Diagnosis and Monitoring

The diagnosis of PML is based on three subsequent steps: recognition of symptoms, radiological identification of the lesions, and confirmation of JCV etiology by CSF analysis or, more rarely, brain biopsy (Table 1).

The clinical recognition involves the identification of the above-described focal or, more rarely, diffuse, neurological deficits with steady progression. The time course of the disease, over several weeks, may provide a diagnostic clue because the other major opportunistic focal brain disorders (cerebral toxoplasmosis and primary CNS lymphoma primarily) usually progress within hours to days.

Neuroimaging

Magnetic resonance imaging (MRI) enables the detection and characterization of distinct white matter lesions in CNS areas corresponding to the clinical deficits. CT scan is less sensitive in detecting PML and less useful in delineating its characteristic anatomic pathology. PML lesions are most common in the subcortical white matter, the white matter of the cerebellar peduncles or hemispheres, and in the brain stem. However, they can involve any part of the central nervous system, including the deep gray matter and very rarely the spinal cord. Because the lesions involve demyelination, these are typically hyperintense (white) on T2-weighted and fluid-attenuated inversion recovery (FLAIR) sequences, but hypointense (dark) on T1-weighted sequences, which indicate tissue destruction (Fig. 4). At onset of PML, there is classically either no or only minimum contrast enhancement, and, unlike other major CNS-OIs, primarily toxoplasmosis and

Progressive Multifocal Leukoencephalopathy and HIV, Table 1 Diagnostic criteria and definitions in PML

Criteria for PML diagnosis

a. Confirmed:

Clinical picture consistent with PML

MRI findings consistent with PML

JCV-DNA detected in CSF or the presence of specific pathology at brain biopsy or postmortem examination (with identification of JCV proteins by immunohistochemistry, of JCV or cross-reacting polyomavirus DNA by in situ nucleic acid hybridization, or of JC virions by electron microscopy)

b. Presumptive:

Clinical picture consistent with PML

MRI findings consistent with PML

JCV-DNA not detected in CSF (either nondetectable or lumbar puncture not performed) and brain pathology not available

PML outcome

a. PML progression:

Worsening of clinical picture

Enlargement of old MRI lesions and appearance of new lesions, with persistent activity (hyperintense signal in T2 and FLAIR sequences and high-signal intensity rim at lesion periphery on DWI sequences)

b. PML remission:

Improvement or stabilization of clinical picture

Loss of activity of MRI lesions (disappearance of the hyperintense signal in T2 and FLAIR sequences and of the high-signal intensity rim at lesion periphery on DWI sequences)

JCV-DNA not detected in CSF

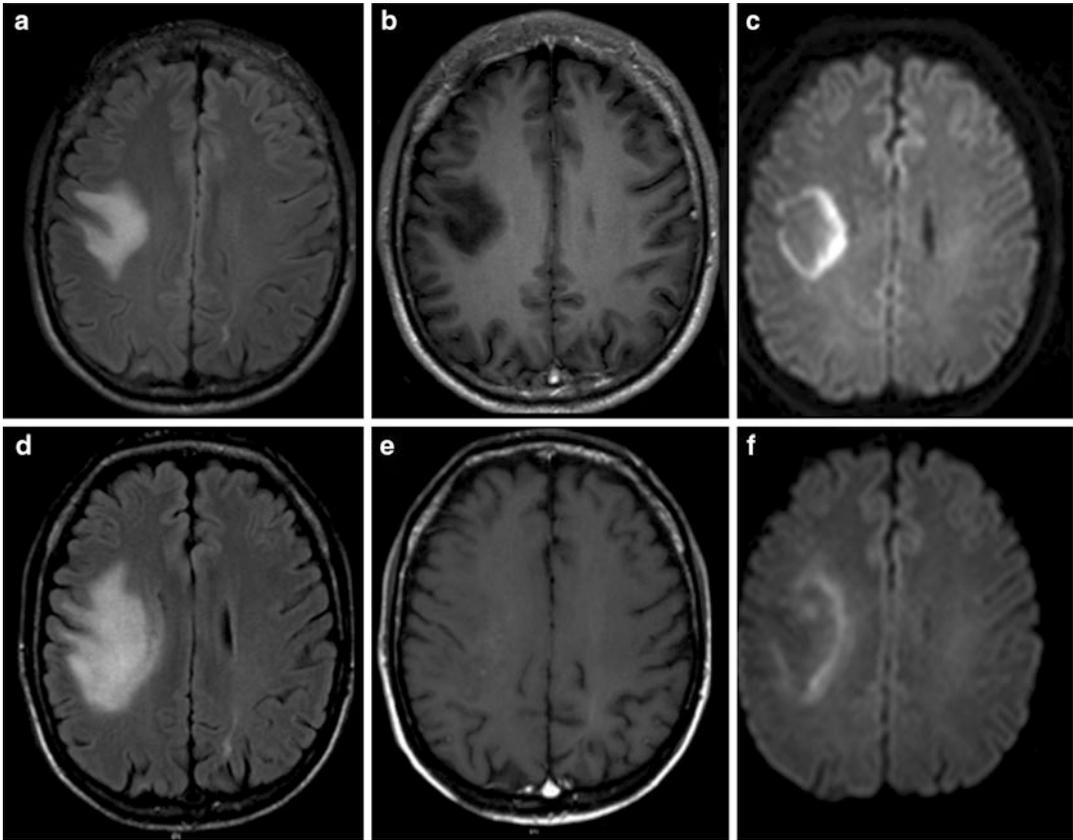

PML-immune reconstitution inflammatory syndrome (IRIS)

Immune reconstitution following cART initiation, with a decrease of plasma HIV-1 RNA, and usually also an increase of CD4+ T cells

Signs of brain inflammation by MRI or at brain biopsy

New onset (unmasking IRIS) or worsening (paradoxical IRIS) of clinical disease that would not be expected from the natural course of PML

primary CNS lymphoma, there is no mass effect or displacement of brain structures. Lesion appearance at MRI may also help distinguish PML from other white matter diseases, in particular HIV encephalitis, which is characterized by more diffuse and symmetrical central white matter changes that are either not detected or resulting only in a subtle signal alteration on T1-weighted sequences.

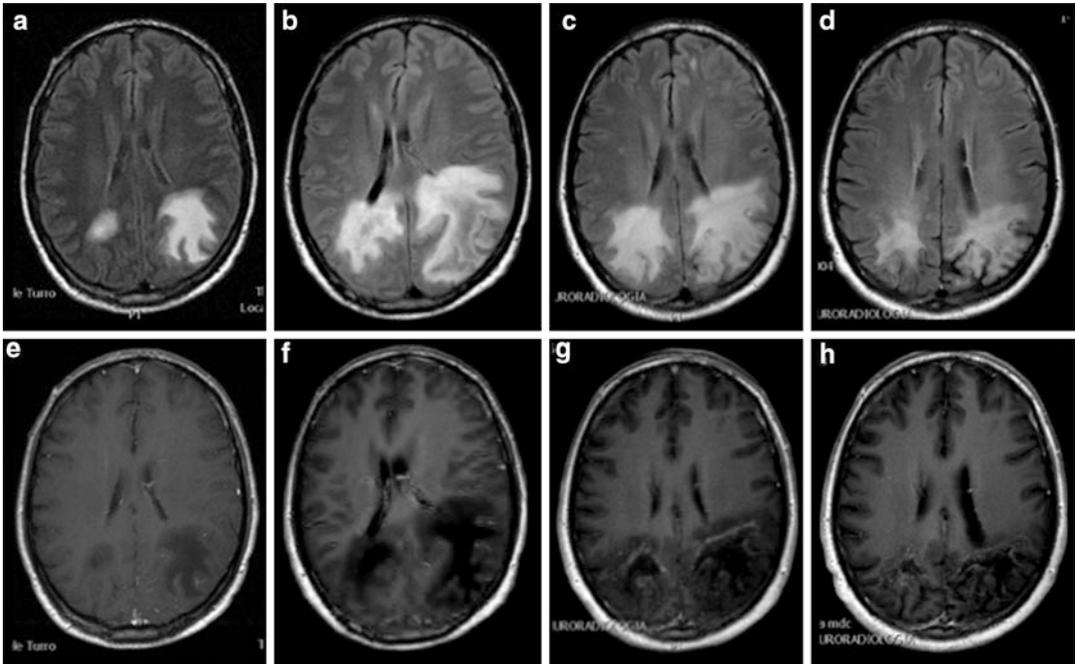

Progressive Multifocal Leukoencephalopathy and HIV, Fig. 4 Progression of disease by magnetic resonance imaging (MRI) in PML. Axial brain images at the time of PML diagnosis (a–c) and showing lesion evolution after 4 weeks (d–f). (a, d) Fluid-attenuated inversion recovery (FLAIR) sequences, showing focal hyperintense signal alteration in the subcortical white matter of

the right frontal region; (b, e) T1-weighted sequences showing hypointense signal alteration (*black*), with no enhancement after gadolinium administration; (c, f) diffusion-weighted images (DWI), showing high-signal intensity at the advancing edge of the active lesion and low-signal intensity in the center of the lesion

P

Contrast enhancement of PML lesions becomes more frequent after cART initiation with immune reconstitution and disease remission. This type of contrast enhancement is frequently described as “dot-like” perivenular, with a thin or reticulated appearance adjacent to the edge of the lesions. However, contrast enhancement may also present with a thick peripheral component, which is associated with the inflammatory forms (PML-IRIS), and can be accompanied by edema, mass effect, with or without displacement of brain structures (Post et al. 2013; Fig. 5). In these cases the distinction from the other CNS-OIs may be more difficult.

Advanced neuroimaging techniques, such as diffusion-weighted imaging (DWI), diffusion tensor imaging (DTI), and proton MR spectroscopy (MRS), may provide additional diagnostic information (Shah et al. 2010). DWI shows the degree of diffusion of water molecules in brain structures; thus more recent lesions and the advancing edges of established lesions show high-signal intensity (low water diffusion), reflecting active infection and cell swelling. By contrast, older lesions and the centers of larger lesions show low-signal intensity (high water diffusion), reflecting areas of necrosis and/or reparative gliosis. Diffusion tensor imaging (DTI) also shows the degree of

Progressive Multifocal Leukoencephalopathy and HIV, Fig. 5 Inflammatory PML by magnetic resonance imaging (MRI). Three different aspects of inflammatory PML observed at different time points in a patient with a simultaneous diagnosis of HIV infection and PML. (A–D), Axial fluid-attenuated inversion recovery (FLAIR); E–H, axial T1-weighted sequences after gadolinium administration. (a, e) At PML diagnosis, cART-naïve (CD4 cell count, 323/ μ L; HIV-RNA 5810 c/mL) left parieto-occipital and right parietal lesions with surrounding edema determining mass effect; there is no contrast enhancement of the lesions. (b, f) After 18 days of cART (clinical worsening): increase of lesion size, with edema and mass effect; intravenous dexamethasone is started at 8 mg tid for 10 days followed by oral taper,

followed by reduction of the perilesional edema. (c, g) After 12 weeks of cART (clinical worsening following previous improvement; CD4 cell count, 402/ μ L; HIV-RNA <1 c/mL): gadolinium T1-weighted sequences show the presence of thick contrast enhancement on the periphery of the lesions; intravenous methylprednisolone 1 g/day for 5 days is started, followed by clinical improvement and reduction of the enhancement. (d, h) After 18 weeks of cART (clinical stabilization; CD4 cell count, 344/ μ L; HIV-RNA <1 c/mL): gadolinium T1-weighted sequences show the presence of dot-like contrast enhancement within and in the periphery of the lesions; FLAIR images show reduction of lesion size and signal intensity and atrophy

white matter fractional anisotropy (FA), which reflects the tendency of water molecules to move preferentially in one direction of the space, in an asymmetric fashion. This is a sensitive tool for the assessment of myelination and white matter integrity with the potential to detect white matter injury before conventional MR imaging and DWI. By MRS, PML lesions typically show decreased N-acetylaspartate (NAA), or NAA to creatine ratio, reflecting neuronal and axonal damage, and increased choline, or choline to creatine ratio, related to the myelin breakdown, with the greatest changes at the center of lesions. The NAA

to creatine ratio is usually lower in PML than in other white matter lesions, and it might help in the differential diagnosis with HIV-1 encephalitis. Lactate and lipid signals, related to necrosis, may also be high in PML lesions.

Laboratory Assessment

The definite etiological diagnosis of PML is obtained, in the appropriate clinical and radiological context, through polymerase chain reaction (PCR) analysis of CSF for the presence of JCV-DNA or, more rarely, by brain biopsy (Table 1). Among cART-untreated patients with

neurological disease, the diagnostic sensitivity of JCV-DNA PCR in CSF is of 72–92% and specificity of 92–100%. Because the ability to detect JCV-DNA increases with PML progression, lumbar puncture is usually repeated if the first PCR analysis is negative, but diagnostic suspicion remains high. However, the likelihood of detecting JCV in CSF is reduced in patients on cART. The JCV-DNA load in CSF varies greatly, between the lower limit of detection (usually at around 50–100 copies/mL) to over 10 million copies/mL. This likely reflects the degree of JCV replication in the brain and in cART-untreated patients that may provide information on the patient's prognosis, with higher copy numbers predicting shorter survival. Measuring JCV-DNA copy number in the CSF can also be useful for monitoring disease progression during cART, with JCV-DNA clearance being associated with PML remission (Cinque et al. 2009).

At brain biopsy, PML is identified by the characteristic tissue cytopathology, including oligodendrocytes with intranuclear inclusions, bizarre astrocytes, and lipid-laden macrophages, with identification of JCV proteins by immunohistochemistry, of JCV or cross-reacting polyomavirus DNA by *in situ* nucleic acid hybridization, or of JC virion electron microscopy. In IRIS-PML histopathology typically demonstrates perivascular mononuclear inflammatory infiltration, with rare JCV-positive cells.

Other Laboratory Assessments

By the use of PCR, JCV-DNA can also be detected in blood, including peripheral blood mononuclear cells (PBMCs) and plasma. In PBMCs, JCV-DNA can be found in both PML patients (in 10–60% of cases) and in subjects without the disease (in up to 20% of cases); therefore this test is unlikely to provide a sensitive and specific diagnostic method. In plasma, on the contrary, JCV is detected in about one half of HIV-positive PML patients, with highly variable levels, but only occasionally and at low copy numbers in controls without PML, thus providing, in case of a positive result, a useful tool for disease monitoring. In urine, JCV-DNA is detected in about 20–30% of both healthy and

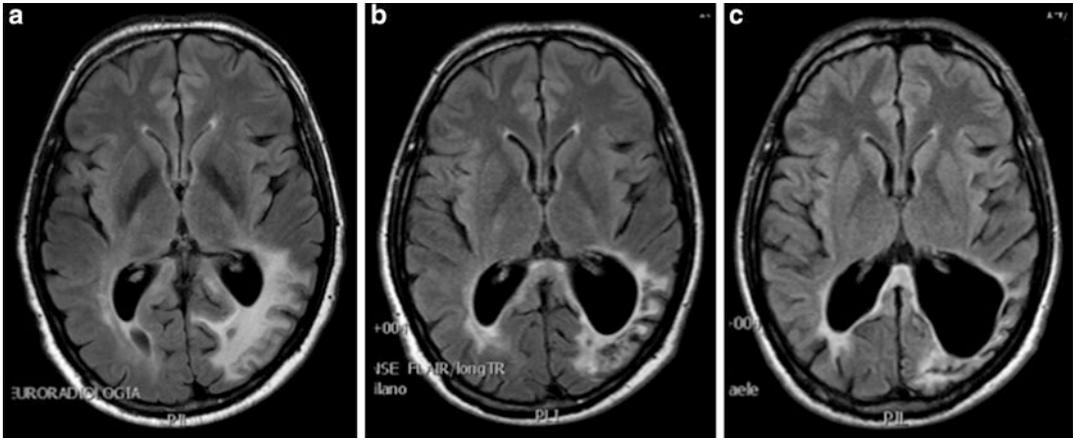

immunocompromised individuals without PML, at a wide range of copy numbers and with no differences between patient status, and therefore it is not useful in diagnosis (Hirsch et al. 2013).

Serologic testing is not diagnostically useful because of high anti-JCV IgG prevalence in the general population. Finding a JCV-specific intrathecal antibody, synthesis might provide additional diagnostic support, especially in patients with undetectable JCV-DNA in CSF; however this approach has not yet entered the clinical practice.

JCV-specific CD4+ and CD8+ T-cell immune responses have largely been assessed in PML, mainly in the context of research studies. Laboratory approaches have involved *ex vivo* stimulation of patient's blood cells with JCV or virus peptides, either individually or as peptide pools, more often covering the external capsidic, highly immunogenic VP1 region. A number of methodologies have been used including among the others, the functional cytokine secretion and ELISPOT assays. At the time of diagnosis, most of the patients with HIV-1-related PML show low or undetectable responses, which increase in frequency and magnitude during cART immune reconstitution. The diagnostic sensitivity and specificity of these assays has not been formally assessed, but the large variability of responses suggests that these assessments are unlikely to become diagnostically useful. Nevertheless, they may prove valuable for monitoring immune reconstitution following cART initiation.

Treatment

There is no specific therapy for JCV infection or PML, and, at present, cART remains the only proven effective approach to treatment of HIV-1-related PML (Panel on Opportunistic Infections in HIV-Infected Adults and Adolescents 2013). By reversion of the immunosuppression, cART stops progression of PML in about half of patients. Unfortunately, neurological deficits frequently persist following PML remission, because of irreparable loss of brain tissue, with approximately half of PML survivors retaining moderate to severe disability. Although several factors may

Progressive Multifocal Leukoencephalopathy and HIV, Fig. 6 Lesion evolution following PML remission. Axial fluid-attenuated inversion recovery (FLAIR) images following PML remission show progressive atrophy of the brain areas with PML lesions and

secondary, ex vacuo, enlargement of lateral ventricles in the case illustrated in Fig. 5: after 7 months (a), 13 months (b), and 36 months (c) from the diagnosis of PML

be associated with worse prognosis, including low CD4+ T cells, high plasma HIV-RNA levels, high CSF JCV-DNA level, and the presence of lesions in the brain stem, the prognosis is usually unpredictable at disease onset. In clinical practice, cART should be started immediately in untreated patients with PML and be optimized for virologic suppression in patients with PML who have received ART but remain HIV viremic. There is no evidence supporting cART intensification for PML or the use of antiretroviral drugs that better penetrate the CNS. On the other hand, it is reasonable to use drug combinations that achieve the fastest and most effective control of HIV-1 replication and immune reconstitution (Panel on Opportunistic Infections in HIV-Infected Adults and Adolescents 2013).

Untreated PML or progressive disease despite cART is characterized by continuous neurological worsening usually within weeks to months, in parallel with enlargement of initial lesions and onset of new ones. JCV-DNA levels in CSF may either increase or remain stable. On the contrary, disease remission is achieved with stabilization or improvement of clinical symptoms and clearance of JCV-DNA from the CSF, likely reflecting suppression of viral replication in brain lesions. The dynamics of JCV-DNA decay in CSF varies

largely among patients, likely depending on the amount of JCV-DNA at diagnosis and the degree of immunological restoration. MRI improvement usually follows clinical and virological changes, showing loss of activity of old lesions, with a decrease of the hyperintense signal in T2 and FLAIR sequences and disappearance of the high-signal intensity rim at the lesion periphery on DWI sequences, and frequent appearance of contrast enhancement. The formation of scar tissue that follows disease remission is associated with progressive atrophy of the brain structures (Fig. 6). By MRS, disease stabilization is associated with decreasing choline to creatine, increasing NAA to creatine, and increasing myoinositol to creatine ratios, the latter signaling glial activation and resolution of the lipid and lactate signals.

Corticosteroids are used in PML-IRIS to reduce local inflammatory reactions, and it is justified in patients with both progressing clinical deficits and signs of inflammatory disease. PML patients who initiate cART with evidence of immune reconstitution at MRI, such as contrast enhancement, might not need steroid treatment if they are clinically stable or improving. The dosage and duration of corticosteroid treatment for PML-IRIS are not established. One common approach, based on treatment of multiple sclerosis flares, is to begin

Progressive Multifocal Leukoencephalopathy and HIV, Table 2 Drugs used for treatment of PML

Drug name	Rationale for use	Highest clinical evidence of efficacy/nonefficacy	Current recommendations or status of development
Cytarabine	Anti-JCV in vitro activity	No survival benefit of IV or intrathecal administration in a controlled clinical trial. Significant toxicity	Not recommended
Cidofovir	Anti-JCV in vitro activity	No survival benefit from a meta-analysis of five published studies. Significant toxicity	Not recommended
Brincidofovir/ CMX001 (hexadecyloxypropyl- cidofovir)	Anti-JCV in vitro activity	Disease remission in one patient with ICL with subsequent administration of IL-7	Requires additional investigation
Mefloquine	Anti-JCV in vitro activity	No virological or clinical benefit in a phase I/II clinical trial	Not recommended
Mirtazapine, risperidone (5HT2a receptor inhibitors)	Serotonergic 5HT2a receptor can serve as cellular receptor for JCV in glial cell culture	No survival benefit from retrospective analyses and large clinical experience	Not recommended
Topotecan (Topoisomerase inhibitor)	Anti-JCV in vitro activity	No survival benefit from evaluation of individual case reports. Significant toxicity	Not recommended
Interferon-alpha	Immunomodulatory effect	No survival benefit from large retrospective analysis	Not recommended
Interleukin-7 (IL-7)	Immunomodulatory effect (thymic development and post-thymic survival, proliferation and maturation of T cells)	Disease remission in individual PML patients with ICL or receiving immunosuppressive drugs	Clinical trial planned in lymphocytopenia-related PML
Adoptive cell transfer	Improves JCV-specific T-cell immunity	Disease remission in a single patient with PML receiving immunosuppressive drugs	Requires additional investigation
Viral protein-1 (VP-1) as therapeutical vaccine	Improves JCV-specific B- and T-cell immunity	Disease remission in three PML patients (two ICL, one receiving immunosuppressive drugs) with simultaneous administration of IL-7	Requires additional investigation

Notes

ICL idiopathic CD4+ lymphocytopenia

with a 3–5-day course of intravenous (IV) methylprednisolone at 1 g per day, followed by an oral prednisone taper (Panel on Opportunistic Infections in HIV-Infected Adults and Adolescents 2013). The possible development of systemic and immune effects should be monitored carefully during steroid therapy. Contrast-enhanced MRI may be helpful in documenting resolution of

inflammation and edema and control for IRIS recrudescence. Importantly, cART should be continued during this period.

The history of specifically targeted treatments for PML is disappointing. Indeed, developing a treatment for PML is challenging, because of the lack of availability, in the past, of an animal model for the disease and of the difficulties to design and

carry out a clinical trial – due the low incidence of PML, its rapid progression, and its potential response to immune reconstitution interventions. A number of known drugs are effective in inhibiting JCV replication in cell culture systems, and several of these have also been administered to patients with PML, either in the context of structured clinical studies or of uncontrolled clinical practice. However, there is no drug that can influence substantially the natural history of PML (Table 2). Recently, more promising approaches have been suggested with the aim to restore either general or JCV-specific host immunity. These have included human recombinant interleukin-7 (IL-7), a cytokine that induces thymic T-cell development and post-thymic proliferation and maturation of both naive and memory T cells (Alstadhaug et al. 2014; Sospedra et al. 2014), adoptive infusion of JCV-specific cytotoxic T cells (Mani et al. 2014), and a JCV-VP1-based “vaccine,” which may be able to stimulate both T- and B-cell-specific responses (Sospedra et al. 2014).

Conclusion

PML remains a relevant opportunistic disease in persons with HIV infection. The only effective way to prevent the disease is to prevent progression of HIV-related immunosuppression with cART, and this is achieved in most of patients with HIV infection. Despite its currently low incidence, however, PML carries a high morbidity and mortality burden. Although cART will reverse immunodeficiency in most of the cases, PML remission may not be achieved in time to avoid death or irreversible brain damage. In the absence of drugs targeting JCV replication, strategies aiming to fasten immune reconstitution, e.g., IL-7 or a therapeutical vaccine, are a potential promising approach in HIV-related PML, which require evaluation in clinical trials.

Protease Inhibitor

Cecile Delille Lahiri, Jeffrey Lennox and Ighovwerha Ofotokun
Department of Medicine, Division of Infectious Diseases, Emory University School of Medicine, Atlanta, GA, USA

Definition

Protease inhibitors (PIs) belong to a class of anti-retroviral medications used to treat HIV-1 infection by acting as competitive inhibitors of aspartyl protease, an enzyme used to cleave precursors of HIV into functional enzymes and structural proteins. These medications are given orally and are metabolized by the liver through cytochrome P450 enzymes. One advantage of using PIs in

combination antiretroviral therapy (cART) is that they have a higher genetic barrier to resistance compared to other classes of medications. Disadvantages include the potential for multiple drug-drug interactions and high frequency of side effects and toxicity.

Introduction

HIV protease inhibitors (PIs) are a class of medications approved for treatment of HIV infection when given as a component of combination antiretroviral therapy (cART). The earliest PIs received Food and Drug Administration (FDA) approval for use in the treatment of HIV infection in 1995; currently, there are nine PIs available on the market (Pokorna et al. 2009). As an advantage over other antiretroviral drug classes, most PIs have a higher genetic barrier to resistance. However, PIs are also plagued by poor oral bioavailability, high pill burden, and frequency of unpleasant side effects (Tsibris and Hirsch 2015). This entry will give an overview of PIs including their drug characteristics, clinical use, side effects and toxicity, and mechanisms of resistance.

Characteristics of Protease Inhibitors

Mechanism of Action

Aspartyl protease is the HIV enzyme necessary to cleave polyprotein precursors of the virus (Gag and Gag-Pol) into mature, functional viral enzymes and structural proteins (Pokorna et al. 2009; Tsibris and Hirsch 2015). As competitive inhibitors of aspartyl protease, PIs prevent the process of HIV “viral maturation,” an essential step in the production of infectious viral particles (Pokorna et al. 2009). In the presence of PIs, therefore, viral particles formed remain non-infectious, preventing the spread of HIV to other cells. This mechanism of action differentiates PIs from all other antiretroviral classes because it occurs post-integration of HIV DNA into the host (human) DNA rather than pre-integration.

Pharmacokinetics

Absorption and Distribution

All PIs currently used in clinical practice are only approved for oral administration. Absorption in the gastrointestinal tract and diffusion through anatomical compartments overall is poor to moderate for the PIs, largely due to their extensive plasma protein binding (90–99%) and their affinity for the efflux pump transporter, p-glycoprotein (Pokorna et al. 2009). Both of these characteristics are thought to play a role in the overall poor penetration of PIs into HIV reservoir sites, including the central nervous system and genital tracts. One notable exception, the PI indinavir, has been found to have good CNS penetration, thought to be due to its lower degree of plasma protein binding (60%) compared to all other PIs.

Metabolism

The PIs are hepatically metabolized by the cytochrome P450 isoenzyme CYP3A4. Commonly, pharmacologic “boosters” that inhibit this metabolic pathway (e.g., ritonavir) are coadministered with PIs to overcome poor absorption and increase systemic drug concentrations. Originally approved as an antiretroviral drug, ritonavir’s utility was limited due to high frequency of side effects, and it is now exclusively used as a boosting agent due to its potent inhibition of CYP3A4. Ritonavir-boosted PIs have led to higher drug exposures and lower pill burden, thereby simplifying dose schedules without decreasing efficacy (Larson et al. 2014). PIs that may be given unboosted (e.g., nelfinavir, atazanavir, and fosamprenavir) are alternatives to first-line therapy due to their higher risk of virologic failure with drug resistance compared to boosted PIs (Shafer and Schapiro 2008). As an inhibitor of multiple CYP enzymes in addition to 3A4, ritonavir can induce many drug-drug interactions, particularly with immunosuppressant medications, antiarrhythmics, antimycobacterials, other antiretrovirals, oral contraceptives, and the statin class of lipid-lowering agents (Pokorna et al. 2009). Cobicistat, a more selective inhibitor of the CYP3A4 enzyme, is a newer pharmacokinetic enhancer without antiretroviral activity. Due

to its lower risk of drug-drug interactions, cobicistat is an attractive alternative to ritonavir for enhancement of PIs in adults with HIV infection (Larson et al. 2014) and is now used to enhance drug concentrations of two commonly used PIs, atazanavir and darunavir, in co-formulated fixed dose drug combinations.

Excretion

Excretion of PIs is predominantly through feces and partially in the urine. Two PIs, indinavir and atazanavir, have been found to have pH-dependent solubility in the urine, leading to increased crystallization and the development of urinary stones at higher pH (Pokorna et al. 2009).

Barriers to Resistance

A major advantage of PIs over other classes of antiretroviral medications is that they generally have a higher genetic barrier to developing resistance. Unlike non-nucleoside reverse transcriptase inhibitors (NNRTIs) or integrase inhibitors, PIs typically require multiple mutations to lose substantial antiviral activity (Tsibris and Hirsch 2015). Mechanisms of resistance will be described in greater detail in section “[Side Effects and Toxicity](#)”.

Side Effects and Toxicity

Although the introduction of the PIs has revolutionized HIV therapy, the dramatic improvement in treatment outcomes associated with their use has been tampered by treatment-limiting toxicities. Side effects observed with the earlier PIs included nausea, vomiting, and diarrhea, in addition to circumoral paresthesia with high-dose ritonavir and nephrolithiasis with indinavir. Laboratory abnormalities such as elevations in serum bilirubin, glucose, triglycerides, and cholesterol were also noted, although these were initially considered not to be clinically significant.

Within two years of their introduction into clinical practice, the US Food and Drug Administration (FDA) received over 80 reports of cases of diabetes mellitus, among HIV-infected patients on PI-based therapy, and subsequently issued a

warning regarding PI use; however, they noted that a causal relationship between PI use and hyperglycemia had not been established. Concurrently, anecdotal reports of increases in abdominal fat, loss of upper and lower extremity fat, and unusual fat accumulation at the base of the neck (dorsocervical fat pad) were emerging.

These observations were initially puzzling as the HIV PIs were designed based on detailed knowledge of the tertiary and quaternary structure of their target molecule, the HIV protease enzyme. These compounds have strong affinity and great degree of specificity for the HIV protease, an enzyme that catalyzes the cleavage of the HIV gag and gag-pol polyproteins in a critical step in the viral replication cycle necessary for maturation and budding of the new virion. Unlike the human proteases, the HIV protease belongs to a group of enzyme known as “aspartyl endopeptidase” that possesses unique specificity for Phe-Pro and Tyr-Pro sequences. Because human proteases do not recognize these sequences, it was thought that blocking this molecule that is vital for HIV replication but unique to the virus would have minimal effects on human cellular processes.

It is now clear from abundance of empiric evidence and more than two decades of clinical experience that the PIs are variably associated with a broad range of metabolic abnormalities. These observations have raised questions about the molecular specificity of these drugs and generated wide speculations about the mechanisms underlying their unwanted effects. For example, to what extent does the virus (apart from the drugs) contribute to the observed metabolic abnormalities? Do HIV disease reversal and correction of the underlying chronic pathologic processes following sustained suppression of viral replication lead to fat gain that may be abnormally distributed? Are the drug-associated metabolic abnormalities that mimic Cushing’s syndrome related to enhanced sensitivity of the body to cortisol? To what extent do genetic or familial factors play a role?

For the purpose of this discussion and to address some of these issues in greater details, we have grouped the PI associated toxicities into

the following commonly observed clinical syndromes: (a) lipodystrophy, (b) hyperlipidemia, (c) glucose intolerance, (d) hepatic injuries, and (e) others.

Lipodystrophy

Lipodystrophy is changes in body fat distribution arising from derangement in fat production, uses, and storage. It was among the most publicized of the PIs’ metabolic abnormalities and was originally referred to as the “Crix belly” because many of the earlier reports were associated with indinavir. Similar body changes have been observed with all FDA-approved PIs although to a lesser extent with the newer agents such as atazanavir and darunavir. Fat redistribution occurs early in therapy, and rates can be as high as 30–50%. Two patterns are recognized: fat loss and fat gain; in general, men tend to lose fat, while women tend to build fat. Subcutaneous fat loss, also referred to as lipatrophy, occurs more commonly when PIs are used in combination with the older nucleoside reverse transcriptase inhibitors such as stavudine, didanosine, or zidovudine. It manifests as fat loss in the face (leading to sunken cheeks, temples, or eyes), buttocks, and arms and legs (resulting in prominence of the peripheral veins). Fat buildup, often referred to as lipohypertrophy or lipoaccumulation or hyperadiposity, is associated with fat accumulations in the abdomen (central obesity), breasts (particularly in women), back of the neck and shoulder (dorsocervical fat pad), and lipomas (fatty growth) in various parts of the body. Lipodystrophy is a major clinical concern and has led some patients to seek liposuction or surgical removal of superficial fat deposits and others to discontinue therapy entirely. While the mechanism underlying this disorder remains unclear, some investigators have proposed a direct drug effect due to a high degree of similarity between a segment of the HIV protease enzyme and a lipoprotein receptor-like protein, which is involved with the transport of circulating lipids. Some of the cases – particularly those involving the dorsocervical fat pad – appeared similar to Cushing’s syndrome; however, serum cortisol levels or dexamethasone suppression tests are often normal in affected patients with buffalo

hump. Tesamorelin, a growth hormone-releasing factor analog, is currently the only FDA-approved drug shown to reduce excess abdominal fat in HIV-infected patients with lipodystrophy.

Hyperlipidemia

Elevation in serum lipids is among the most prevalent laboratory abnormalities seen with the PIs. Prevalence of 8–42% for hypercholesterolemia and 13–80% for hypertriglyceridemia has been reported following PI-based therapy. The association appears to be stronger with ritonavir than for other PIs. Some studies attribute PI-related hyperlipidemia to enhanced very low-density lipoprotein (VLDL) production, whereas others blame this abnormality on impaired lipoprotein clearance. Whether these lipid changes translate into higher rates of coronary artery disease remains controversial; however, increased incidence of cardiovascular disease is reported in patients with HIV infection. Hyperlipidemia in this setting often responds to treatment with lipid-lowering agents although not all of these agents can be safely coadministered with the PIs because of concern for severe drug-drug interaction. A switch from a PI-based therapy to a less lipidogenic antiretroviral regimen has been successful in lowering serum lipids to normal in some cases (Munk 1998).

Glucose Intolerance

Reports of hyperglycemia and overt diabetes increased in the HIV/AIDS population following the introduction of the PI into clinical practice, raising the speculation that this class of drugs induced insulin resistance. Rates of new-onset diabetes ranging from 3% to 7% have been reported with the PIs. The incidence of new-onset diabetes was fourfold higher in HIV-infected men on highly active antiretroviral therapy in the Multicenter AIDS Cohort Study compared with HIV-seronegative men. This effect may be less pronounced with the newer PIs such as darunavir and atazanavir. Standard medical therapy is recommended for PI-induced diabetes. Some patients have been managed by switching to other classes of drug that are less diabetogenic (Hruz et al. 2001).

Hepatic Injuries

Reports of hepatitis or hepatic failure linked to PI therapy are common. Hepatotoxicity occurred at rates of 1–10% in registration trials conducted for the purpose of obtaining FDA approval for the PIs. The prescribing information for all PIs approved by the US FDA includes the following warning: (1) hepatitis, including cases resulting in hepatic failure and death, has been reported in patients taking PIs; and (2) there may be an increased risk for alanine aminotransferase and/or aspartate aminotransferase (ALT/AST) elevations in patients with preexisting liver disease or underlying hepatitis B virus (HBV) or hepatitis C virus (HCV) infection. An increased frequency of AST/ALT monitoring should be considered for these patients (Ogedegbe and Sulkowski 2003).

Others

Toxicities specific to or seen more commonly with certain members of the PI class include atazanavir induced hyperbilirubinemia and bilirubin kidney stones, intracranial bleeds associated with tipranavir, ingrown toenails with indinavir, and skin rashes seen occasionally with fosamprenavir and darunavir. Diarrhea and other gastrointestinal intolerance, though observed with all members of the class at variable rates, appear to be relatively more common with lopinavir/ritonavir.

Mechanisms of Resistance

Multiple protease mutations are often required in order to develop clinically significant HIV-1 resistance to ritonavir-boosted PIs. For example, the accumulation of at least six mutations was associated with reduced virological response in PI-experienced patients receiving ritonavir-boosted lopinavir (Masquelier et al. 2002). Within the protease gene, resistance mutations are classified either as “major,” those selected first when drug is present or substantially reducing susceptibility of the virus to drug, or “minor,” those that typically present later and alone do not have significant impact on phenotype (Wensing et al. 2015). In addition, mutations in the cytoplasmic tail of the HIV-1 *Env* protein or cleavage sites of

the *Gag* protein may emerge before protease mutations and can confer resistance to all PIs.

Major and Minor Mutations

Major mutations at 13 amino acid positions have been shown to confer reduced susceptibility to one or more PIs, including positions 30, 32, 46, 47, 48, 50, 54, 58, 82, 83, 84, 88, and 90 (see Table 1).

Protease Inhibitor, Table 1 Major protease inhibitor mutations causing clinically significant resistance

Amino acid position	Specific mutation ^a	Protease inhibitors affected
30	D30N	Nelfinavir
32	V32I	Lopinavir/ritonavir
46	M46 I/L	Indinavir/ritonavir
47	I47A I47V	Lopinavir/ritonavir Lopinavir/ritonavir Darunavir/ritonavir Tipranavir/ritonavir
48	G48 V	Saquinavir/ritonavir
50	I50L I50V	Atazanavir +/- ritonavir boosting Darunavir/ritonavir Fosamprenavir/ritonavir
54	I54M/L	Darunavir/ritonavir
58	Q58E	Tipranavir/ritonavir
82	V82A/F/ T/S	Indinavir/ritonavir Lopinavir/ritonavir
83	N83D	Tipranavir/ritonavir
84	I84V	Atazanavir +/- ritonavir boosting, darunavir/ritonavir Saquinavir/ritonavir Indinavir/ritonavir Fosamprenavir/ritonavir
88	N88S	Atazanavir +/- ritonavir boosting
90	L90 M	Nelfinavir, saquinavir/ ritonavir

Adapted from table “Mutations in the Protease Gene Associated with Resistance to Protease Inhibitors” in 2015 update of the drug resistance mutations in HIV-1, IAS-USA. *Top Antiv Med.* October/November 2015;23(4):132–41

^aMutations are named by listing the letter abbreviation for the wild-type amino acid, followed by the amino acid position, and then the amino acid substitution conferring resistance. Amino acid abbreviations: *A*, alanine; *C*, cysteine; *D*, aspartate; *E*, glutamate; *F*, phenylalanine; *G*, glycine; *H*, histidine; *I*, isoleucine; *K*, lysine; *L*, leucine; *M*, methionine; *N*, asparagine; *P*, proline; *Q*, glutamine; *R*, arginine; *S*, serine; *T*, threonine; *V*, valine; *W*, tryptophan; *Y*, tyrosine

Minor (or accessory) mutations can contribute to resistance by either compensating for the impaired replication that major mutations cause the virus or reduce susceptibility only in combination with other mutations. For example, minor mutations at positions 10, 20, 36, 63, and 71 cause an upregulation of protease processivity to compensate for the decreased viral fitness associated with major protease mutations. Furthermore, the effect of some mutations differs based on PI; for example, the I50L mutation grants resistance to atazanavir but improves the susceptibility to all other PIs (Shafer and Schapiro 2008). Similarly, for darunavir, one of the most commonly prescribed PIs, two mutations (E35D and V82A) were found to have a positive impact on virological response, possibly explaining the potency of ritonavir-boosted darunavir in PI-resistant HIV (Descamps et al. 2009).

Gag Cleavage Site and Env Cytoplasmic Tail Mutations

Many patients fail PI-containing regimens without any protease mutations. One theory as to why this may occur is that standard resistant assays may ignore other parts of the HIV genome that could contain mutations causing PI resistance. For example, preliminary data has shown that sequence changes in the cytoplasmic tail of the HIV *Env* protein (Rabi et al. 2013) and mutations within the *Gag* protein (Fun et al. 2012) contribute to PI resistance and would not be discovered on standard genotypic PI resistance testing.

Characteristics of the HIV PIs

HIV PIs currently in use in the order they were introduced into clinical practice include saquinavir, ritonavir, indinavir, nelfinavir, amprenavir, lopinavir/ritonavir, atazanavir, fosamprenavir, tipranavir, and darunavir. Lopinavir is co-formulated with ritonavir (Kaletra[®]); more recently, atazanavir and darunavir were both co-formulated with cobicistat (Evotaz[™] and Prezcobix[®], respectively). Due to toxicities associated with its therapeutic doses and the potential to induce clinically significant drug-drug interaction,

Protease Inhibitor, Table 2 Characteristics of HIV protease inhibitors and boosted doses in treatment naïve patients

Drug ^a	Year approved	^{c,d} Dosing schedule	^e Unique side effects/toxicities
^b Saquinavir	1995	1000 mg twice daily	<ul style="list-style-type: none"> • Buffalo hump • Possible increased bleeding episodes in patients with hemophilia • PR interval prolongation • QT interval prolongation
Ritonavir	1996	100 mg daily or twice daily when used as a booster	<ul style="list-style-type: none"> • Drug-drug interaction • Metabolic abnormalities • Paresthesia (circumoral and extremities) <ul style="list-style-type: none"> • Taste perversion • Possible increased bleeding episodes in patients with hemophilia
^b Indinavir	1996	800 mg twice daily	<ul style="list-style-type: none"> • Kidney stones • Hyperbilirubinemia • Possible increased bleeding episodes in patients with hemophilia
Nelfinavir	1997	1250 mg twice daily	<ul style="list-style-type: none"> • Possible increased bleeding episodes in patients with hemophilia • Serum transaminase elevation
Lopinavir/ritonavir	2000	400/100 mg twice daily	<ul style="list-style-type: none"> • Gastrointestinal side effects • Lipid abnormalities • Pancreatitis • PR interval prolongation • QT interval prolongation
^b Atazanavir	2003	300 mg daily	<ul style="list-style-type: none"> • Hyperbilirubinemia • Rarely kidney stones • PR interval prolongation
^b Fosamprenavir – prodrug of amprenavir	2003	1400 mg daily	<ul style="list-style-type: none"> • Rash • Possible increased bleeding episodes in patients with hemophilia • Kidney stone
^f Tipranavir	2005	500 mg (plus 200 mg of ritonavir) twice daily	<ul style="list-style-type: none"> • Intracranial hemorrhage (rare) • Rash • Possible increased bleeding episodes in patients with hemophilia
Darunavir	2006	800 mg daily	<ul style="list-style-type: none"> • Rash • Hepatic toxicity • Increase in serum creatinine (with cobicistat)

^aThe HIV PIs are metabolized by cytochrome P450 isoenzymes. With the exception of nelfinavir, all can be boosted with either ritonavir or cobicistat

^bAlthough preferable boosted, saquinavir, indinavir, fosamprenavir, and atazanavir can be administered unboosted

^cDosing adjustments for renal insufficiency are not indicated as HIV PIs are metabolized primarily in the liver

^dExcept for nelfinavir, dosing schedules listed in this table assume boosting with either ritonavir or cobicistat in patients that are treatment naïve and receiving initial antiretroviral therapy

^eTo variable degree, the use of drugs in this class is associated with gastrointestinal intolerance and metabolic abnormalities (insulin resistance, dyslipidemia, and/or lipodystrophy)

^fTipranavir is reserved for treatment-experienced patients

ritonavir is now solely used at lower doses for its pharmaco-enhancement properties to boost the systemic exposure of other PIs, and it is no longer used for its antiviral effect. Saquinavir, nelfinavir,

and amprenavir are currently rarely used in clinical practice because of their high pill burden, need for more frequent dosing, and higher rates of side effects and toxicities. Although indinavir has very

good tissue and compartmental drug penetration (including the central nervous system) presumably due to its relatively lower plasma protein binding (60% plasma protein bound), its clinical use has dropped significantly because of toxicities. Tipranavir, the only non-peptidomimetic PI, has activities against HIV strains with multiple PI-resistant mutations and is therefore effective in treatment-experienced patients with prior history of PI exposure; however, its clinical use is limited by toxicities including rare cases of intracranial hemorrhages and drug-drug interactions. Atazanavir and darunavir boosted with ritonavir or cobicistat can be dosed once daily, are better tolerated relative to the other PIs, and are therefore the two more commonly used PIs in cART in many resource-rich countries. Due to cost consideration, lopinavir/ritonavir is the more widely used PI in many resource-limited settings including sub-Saharan African where it is the main second-line agent for patients failing their initial antiretroviral regimen. Lopinavir/ritonavir is also frequently used in HIV-infected pregnant women due to its favorable pharmacokinetic profile in pregnancy. The profiles of individual drugs in the HIV PI class are summarized in Table 2.

Conclusion

By inhibiting the aspartyl protease enzyme, the PIs block viral maturation and prevent continuing productive infection of HIV-susceptible cells. As a class, they possess potent antiviral activities against most strains of the HIV virus and have high genetic barrier to the development of drug-resistant mutations. They are metabolized primarily in the liver by the cytochrome P450 isoenzyme system and as such are amenable to pharmacoenhancement either by ritonavir or cobicistat, thereby simplifying dosing scheduled and significantly improving oral bioavailability, systemic exposure, and clinical efficacy. Treatment-limiting side effects to these drugs are common and include gastrointestinal intolerance and metabolic abnormalities such as insulin resistance, dyslipidemia, and abnormal body fat distribution. Nevertheless, the PIs remain important in HIV

pharmacotherapy, and PI-based regimens are particularly attractive in clinical setting where adherence to therapy is less than optimal and a more forgiving antiretroviral regimen is desired.

Pyroptosis in HIV Infection: HIV Offense Meets a Fiery Host Defense

Gilad Doitsh

Gladstone Institutes, Institute of Virology and Immunology, San Francisco, CA, USA

Definition

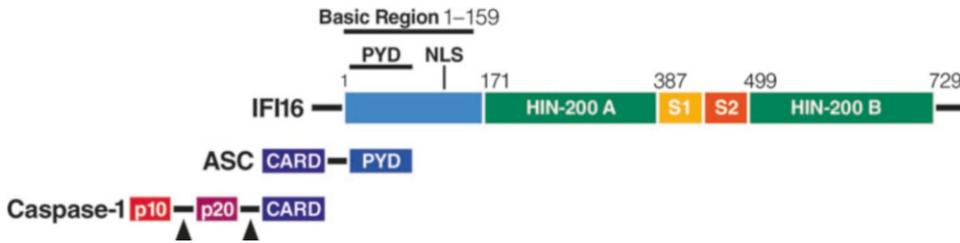

Cell death often occurs via morphological changes, which are typically described in two forms: apoptosis and necrosis. Apoptosis is an active, programmed process that causes cells to destroy themselves without stimulating inflammation. Necrosis is a passive, accidental process induced by environmental stress such as heat, physical force, or lack of oxygen, which causes the cell to uncontrollably release its inflammatory contents. Although apoptosis has received greater attention, because it is a regulated process that occurs during particular infections, both paradigms are widely accepted. However, there are a number of other cell death pathways that have been characterized. For example, in 2001, Dr. Brad Cookson discovered pyroptosis, a novel form of cell death induced by microbial infection with species of *Salmonella* and *Shigella* (Cookson and Brennan 2001). The term pyroptosis was taken from the Greek roots “pyro,” relating to fire or fever, and “ptosis” (pronounce “to-sis”), describing falling, which together describe this proinflammatory form of programmed cell death. This process uniquely depends on caspase-1, which processes the pro-forms of the inflammatory cytokines interleukin (IL)-1 β and IL-18 to their active form. Thus, distinct from apoptosis, which actively inhibits inflammation, pyroptosis involves an intense inflammatory form of programmed cell death that releases the cell’s cytoplasmic contents and proinflammatory cytokines.

Caspase-1 Is Activated in Inflammasomes

Caspases are cysteine-dependent **aspartate**-directed proteases that initiate or execute cellular

programs that cause cell death. They are synthesized as inactive proenzymes (zymogens) containing an N-terminal peptide (prodomain) and two subunits, one large and one small, separated by a linker peptide (Cohen 1997). The activity of caspases is tightly controlled by proteolytic activation. The crystal structures of caspase-3 and caspase-1 revealed that the active forms of caspases are heterotetramers containing two dimers of small and large subunits. These dimers contact each other between the small subunits, while the active site spans both the large and small subunits. Caspases also contain a prodomain that is recognized and bound by specific adapter molecules (such as apoptosis-associated speck-like protein containing a CARD (ASC) in the case of caspase-1), which recruit pro-caspase to the signaling complex (Fig. 1). Caspases are categorized as either proinflammatory or proapoptotic, depending on the outcome of their cell death programs. In humans, the proapoptotic caspases are caspase-3, caspase-7, and caspase-6, while the proinflammatory caspases are caspase-1, caspase-4, and caspase-5. Among the proinflammatory caspases, caspase-1 is the most fully characterized. Its catalytic activity is tightly regulated by signal-dependent recruitment and auto-activation within multiprotein complexes called **inflammasomes**. When activated, caspase-1 is released into the cytoplasm, where it stimulates the processing of proinflammatory cytokines and, ultimately, induces cell death by pyroptosis.

Pyroptosis is a programmed form of cell death that depends on caspase-1 but occurs independently of the caspases involved in immunologically silent apoptosis. Pyroptosis causes plasma membrane rupture, water influx, cellular swelling, osmotic lysis, and release of proinflammatory cellular content, features that are shared with caspase-independent necrosis. Pyroptosis also causes DNA cleavage and nuclear condensation. Because this process does not compromise nuclear integrity, it is distinct from the DNA laddering that occurs with apoptosis (Lamkanfi and Dixit 2010). However, the precise molecular events that regulate pyroptosis and whether pyroptosis plays a pathological role in genetic autoinflammatory diseases are not well defined.

Pyroptosis in HIV Infection: HIV Offense Meets a Fiery Host Defense, Fig. 1 IFI16 recruits caspase-1 to assemble a functional inflammasome. IFI16 is composed of an amino-terminal PYD and two carboxy-terminal DNA-binding HIN200 domains (A and B). After binding DNA, IFI16 assembles an inflammasome to which pro-caspase-1 enzymes are recruited via their CARD motifs. The bipartite adaptor protein ASC (apoptosis-associated speck-like protein containing a CARD) is then required to bridge the interaction and recruits caspase-1 to the IFI16 inflammasome complex. When the IFI16 inflammasome complex assembles, it promotes the proteolytic autoactivation of nearby caspase-1 (*black triangles*),

which releases the p20 and p10 subunits to form the activated caspase-1 heterotetramer. Next, activated caspase-1 converts its cytoplasmic substrates, pro-IL-1 β and pro-IL-18, into the secreted bioactive cytokines and triggers cell death by pyroptosis. The DNA-binding residues are largely conserved between the AIM2 HIN and IFI16 HIN domains (Jin et al. 2012). However, IFI16 preferentially binds to the stem-rich DNA motifs of HIV reverse transcripts generated by the internal folding of the ssDNA strand (Jakobsen et al. 2013). *HIN-200* hematopoietic interferon-inducible nuclear proteins with a 200-amino acid repeat, *CARD* caspase recruitment domain, *NLS* nuclear localization signal, *PYD* pyrin domain

Despite these gaps in knowledge, pyroptosis has emerged as a key defense mechanism against microbial infections. Researchers believe that pyroptosis stops the replication of intracellular pathogens by simultaneously eliminating infected immune cells and recruiting circulating phagocytes and neutrophils that promote inflammation and destroy surviving bacteria (Lamkanfi and Dixit 2014). Importantly, most reports characterizing inflammasomes have focused on the cells of the myeloid lineage, such as macrophages or dendritic cells; however, cells outside the myeloid compartment can also activate inflammasomes. For example, keratinocyte exposure to skin irritants or ultraviolet B (UVB) irradiation activates NLRP3 inflammasomes.

IFI16 Senses Intracellular DNA That Assembles Inflammasomes

Over the last decade, researchers have greatly advanced the existing knowledge of the molecular mechanisms that activate innate immune responses. For example, they discovered a highly conserved set of cellular sensors (pathogen-related receptors, or PRRs) that detect common viral and microbial motifs known as pathogen-

associated molecular patterns (PAMPs). Viral PAMPs are composed mainly of unique nucleic acids, such as double-stranded (ds)RNA, uncapped single-stranded (ss)RNA, and cytosolic DNA. Despite dramatic advances in how RNA is sensed, much less is known about how cytosolic DNA is sensed. To date, only four soluble (i.e., non-Toll-like receptors) cytosolic DNA sensors have been described. First, **DAI** (i.e., Z-DNA-binding protein (ZBP-1)) is a cytoplasmic DNA sensor that recognizes foreign dsDNA and induces a type-I IFN response that depends on interferon regulatory factor (IRF-3). DAI was the first putative DNA receptor discovered by researchers, who showed that it is required for the type-I IFN response to transfected viral, bacterial, and mammalian DNA in murine L929 cells. DAI is prominently expressed in lymphoid tissues, bone marrow, and small intestine, which are potential sites of interaction with pathogens. Next, the PYHIN protein **IFI16** (IFN- γ -inducible protein 16) and the helicase **DDX41**, which senses intracellular DNA, both induce IFN β by recruiting STING (stimulator of interferon genes), a critical mediator of IFN β responses (Barber 2011). IFN β induces the fourth dsDNA sensor, **AIM2**. AIM2 binds to dsDNA in the cytosol and then assembles and activates an

inflammasome complex. Interestingly, AIM2 has not been implicated in orchestrating innate responses against retroviruses that produce cytosolic DNA intermediates, such as HIV. Notably, the induction of type-I IFN induces additional innate antiviral factors, including the exonuclease **TREX1** and the phosphohydrolase **SAMHD1**. However, these factors do not act as sensors, but rather as host restriction factors that are active against HIV. In fact, a deficiency in TREX1 leads to an enhanced innate immunity response as it promotes the degradation of cytoplasmic DNA species (Yan et al. 2010).

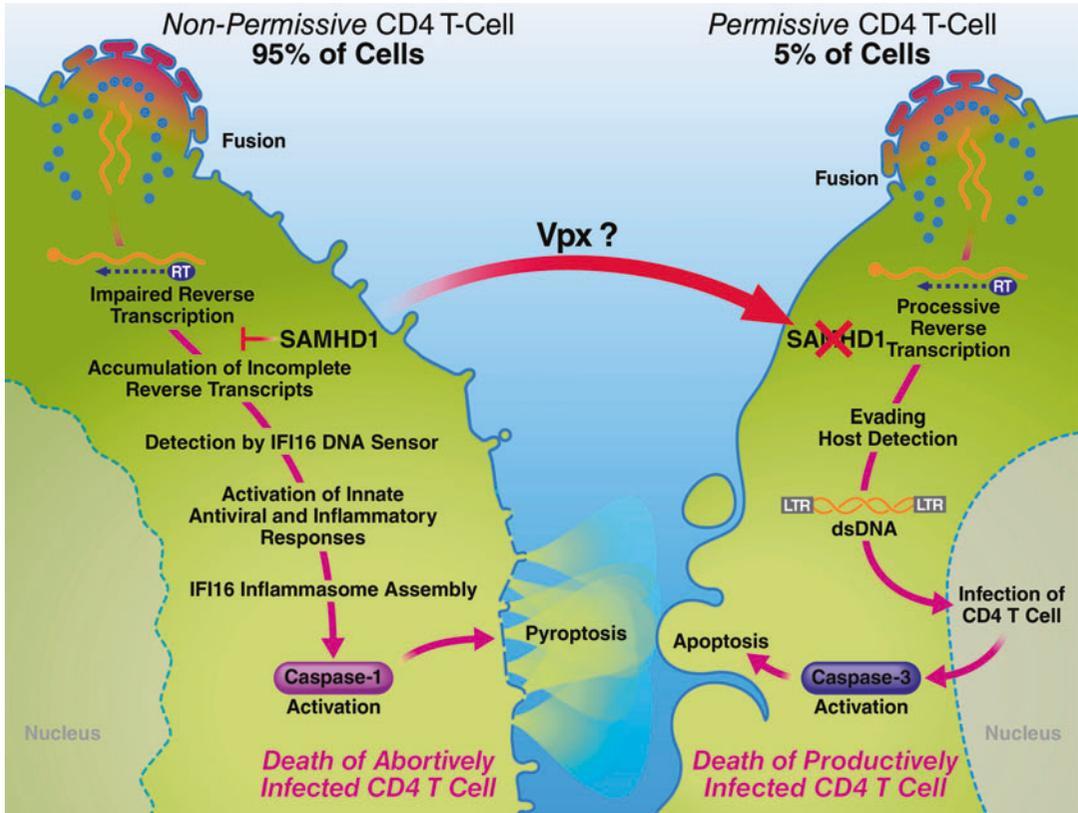

The DNA sensor protein **IFI16** is a PYHIN family member that harbors an N-terminal pyrin domain and two C-terminal HIN domains (Fig. 1). IFI16 is structurally and functionally related to AIM2 and was originally identified as an anti-proliferative protein that responds to DNA damage in the nucleus. In 2010, researchers showed that IFI16 and its mouse homologue p204 are cytosolic dsDNA receptors that induce interferon production. This process requires STING, a nucleotide sensor that resides in the endoplasmic reticulum (ER) and induces type-I IFN production. Importantly, in addition to directly binding and sensing DNA, IFI16 also forms inflammasomes in response to infection by Kaposi sarcoma-associated herpesvirus (Kerur et al. 2011).

Pyroptosis and Apoptosis in HIV Infection: Cell Permissivity Determines the Form of Programmed Cell Death

HIV pathogenesis is characterized by signature processes that deplete CD4 T cells and stimulate chronic inflammation (Deeks 2011). Despite more than three decades of study, the precise mechanisms generating these processes are poorly understood and remain key questions in HIV research (Thomas 2009). To investigate how CD4 T cells die during HIV infection, researchers took advantage of an ex vivo human lymphoid aggregate culture (HLAC) system formed with fresh human tonsil or spleen tissues (Glushakova et al. 1995). This system closely replicates the

conditions encountered by HIV in vivo and thus offers a biologically relevant approach for modeling molecular and cellular events during the HIV infection of human patients. HIV infection of these cultures extensively depletes CD4 T cells, but >95% of the dying cells are **abortively infected** with HIV-1 (Doitsh et al. 2010). Importantly, these cells do not die because of a toxic action of products encoded by HIV. Rather, death occurs as a consequence of a powerful suicidal defensive innate immune response elicited by the cells. Due to the viral nonpermissivity of these quiescent cells, the viral lifecycle attenuates during the chain elongation phase of reverse transcription, giving rise to incomplete cytosolic viral DNA transcripts. Cell death is ultimately triggered after sensing of these cytosolic DNA intermediates by **IFI16** (Monroe et al. 2014), leading to caspase-1 activation in inflammasome and **pyroptosis**, a highly inflammatory form of programmed cell death (Doitsh et al. 2014). These findings mechanistically connected for the first time CD4 T-cell death and chronic inflammation – the two key pathogenic processes of active HIV infection.

While the majority of CD4 T cells in lymphoid tissues are nonpermissive to HIV infection and die via abortive infection and pyroptosis, a small fraction of CD4 T cells become productively infected and die via caspase-3-mediated **apoptosis**. These observations provided the first integrated view of the relative roles of caspase-3-dependent apoptosis and caspase-1-dependent pyroptosis in CD4 T-cell death during HIV infection. They also demonstrated how the permissivity of the host cell determines the specific form of cell death elicited by HIV-1 – productive HIV infection in permissive cells causes a silent death involving caspase-3-dependent apoptosis, while abortive infection of resting, nonpermissive cells causes caspase-1-dependent pyroptosis with high inflammation. Importantly, in human lymphoid tissues such as tonsil and spleen, the activated and permissive subset of cells represents approximately 5% of total CD4 T cells, while nonpermissive quiescent cells represent nearly 95% of the targets encountered by HIV. Thus, contrary to the previous models, caspase-1-mediated pyroptosis

Pyroptosis in HIV Infection: HIV Offense Meets a Fiery Host Defense, Fig. 2 Host permissivity determines the specific form of lymphoid CD4 T-cell death elicited by HIV-1. When HIV infects permissive, activated CD4 T cells, cell death occurs silently through caspase-3-dependent apoptosis. Conversely, when HIV abortively infects nonpermissive, quiescent CD4 T cells from the lymphoid tissue, death occurs through caspase-1-

dependent pyroptosis. Blocking SAMHD1 activity by Vpx may relieve the restriction on viral reverse transcription in nonpermissive CD4 T cells, allowing both productive infection and the avoidance of pyroptosis. Thus, Vpx may have evolved to avoid the pathogenic consequences associated with abortive HIV infection by relieving the host restriction in nonpermissive lymphoid CD4 T cells

P

predominantly drives death of CD4 T cells in HIV-infected lymphoid tissues (Fig. 2).

Identifying pyroptosis as the predominant mechanism that depletes CD4 T cells during HIV infection provided novel targets, such as caspase-1, for potential therapeutic intervention. Indeed, pyroptosis can be blocked with the caspase-1 inhibitor VX-765, which is safe to use in humans (<http://clinicaltrials.gov/ct2/show/NCT01048255>). This finding raised the possibility that a new class of “anti-AIDS” therapies could target the host rather than the virus. These therapies could be used for a number of applications to treat HIV: (1) a salvage treatment for

individuals with broad-spectrum resistance or limited access to antiretroviral therapy; (2) a treatment to block the chronic inflammation that persists in patients treated for HIV and likely drives the earlier onset of age-related diseases; and (3) a potential component of an HIV cure, if the inflammation associated with persistent pyroptosis maintains the latent reservoir through cytokine dysregulation and increased homeostatic renewal.

In addition to the ex vivo analyses of HLACs, researchers have analyzed caspase-1 activation and IL-1 β secretion in lymph nodes following surgical removal from consenting HIV-infected

volunteers. These volunteers were chronically infected with an R5-tropic strain of HIV-1, were not taking antiretroviral therapy, and displayed high viral loads and low blood counts of CD4 T cells. Immunostaining of these tissues revealed a distinct area of HIV p24^{gag} expression between the mantle zone and germinal centers of the patient's lymph node, where activated CD4 T and B cells proliferate and interact in the follicles. In agreement with the findings from infected HLACs, caspase-1 staining revealed abundant activity in the surrounding paracortical zone (CD3), which is almost entirely composed of resting CD4 T cells, but not in the germinal centers, which consist mostly of B and activated T cells. Similarly, large amounts of bioactive IL-1 β were detected in the paracortical zone, particularly in the extracellular space between T cells, as well as the cell death marker annexin V. In sharp contrast, active caspase-3 localized explicitly to the areas in the germinal center where HIV-1 p24^{gag} expression was detected (Doitsh et al. 2014). These *in vivo* observations supported the findings obtained in infected HLACs, demonstrating that caspase-3 activity occurs in a distinct anatomical region that involves a set of productively infected cells separated from the majority of nonproductive cells undergoing caspase-1 activation, IL-1 β processing, and pyroptosis.

What Causes the Chronic Inflammation in HIV-Infected Subjects?

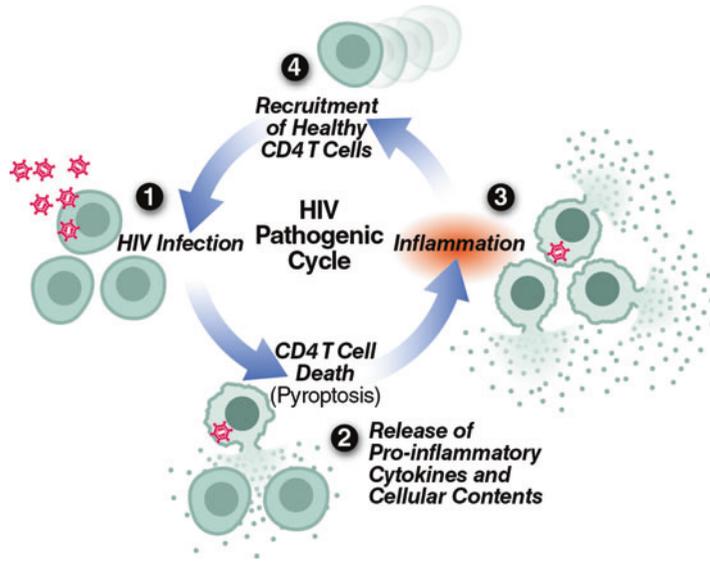

For decades, researchers have recognized that HIV infection is characterized not only by profound immunodeficiency but also by sustained inflammation and immune activation. Substantial evidence implicates chronic inflammation as a critical driver of immune dysfunction, premature appearance of aging-related diseases, and immune deficiency (Deeks 2011). In fact, these data profoundly changed the view of HIV infection, which is now classified as a chronic inflammatory disease. Animal studies also support the relationship between immune activation and progressive cellular immune deficiency. For example, simian immunodeficiency virus (SIV) infection of its

natural nonhuman primate hosts, the sooty mangabey, causes high-level viral replication but limited evidence of disease. This lack of pathogenicity is accompanied by a lack of extensive immune activation and cellular proliferation. Conversely, SIV infection in nonnatural hosts (i.e., rhesus macaque) produces immune activation and AIDS-like disease that closely mimics human HIV infection.

Many potential causes of chronic inflammation exist in HIV disease, including infection with Cytomegalovirus (CMV) and other copathogens, loss of regulatory CD4 T cells, and microbial translocation. Among these potential causes, microbial translocation was proposed as a key contributor that occurs when the barrier function of the gut mucosa breaks down following extensive CD4 T-cell depletion in the gut-associated lymphoid tissue (GALT). However, massive depletion of mucosal CD4 T cells cannot cause progression to AIDS unless significant depletion occurs in the peripheral lymph nodes. Moreover, depletion of mucosal CD4 T cells is also observed during SIV infection of natural hosts who do not progress to AIDS. Thus, further defining the mechanisms that cause immune activation and chronic inflammation remains a key issue in the field. Another more controversial issue pertains to patients who exhibit chronic inflammation despite undergoing long-term and effective combination antiretroviral therapy (cART) and maintain undetectable plasma HIV RNA levels. Some of these patients (defined as “immunological nonresponders”) cannot restore their cellular immunity and their pool of CD4 T-cell lymphocytes. Thus, paradoxically, systemic inflammation in HIV-infected patients may persist in a virus-independent manner.

Pyroptosis Links Chronic Inflammation and CD4 T-cell Death in Lymphoid Tissues

Pyroptosis likely evolved to rapidly clear bacterial infections by removing intracellular replication niches and releasing proinflammatory cytokines and endogenous danger signals that enhance the

Pyroptosis in HIV Infection: HIV Offense Meets a Fiery Host Defense, Fig. 3 Pyroptosis links CD4 T-cell death and inflammation and may affect HIV pathogenesis and disease progression. Abortive HIV infection causes caspase-1-mediated pyroptosis of lymphoid CD4 T cells (steps 1 and 2). Dying cells release large amounts of proinflammatory cytokines including

IL-1 β and cellular contents such as 5'-ATP into the extracellular milieu (step 2). These events promote local inflammation (step 3) that mediates the migration of new circulating CD4 T cells into the lymph node (step 4) to establish a vicious cycle of CD4 T-cell death and inflammation

host's defensive responses. However, in pathogenic chronic inflammation, such as with HIV infection, pyroptosis is not a protective response and does not clear the primary infection. Instead, pyroptosis appears to create a vicious pathogenic cycle, where dying CD4 T cells release inflammatory signals that attract more cells into the infected lymphoid tissue to die and produce more inflammation. This cycle of chronic inflammation likely fuels disease progression and tissue injury (Fig. 3).

Investigations of HLACs revealed that healthy, uninfected lymphoid CD4 T cells are naturally primed to mount inflammatory responses and constitutively express high levels of cytoplasmic pro-IL-1 β , as well as the caspase-1 adaptor ASC and NLRP3 inflammasome (Doitsh et al. 2014). It is therefore possible that the release of intracellular 5'-ATP by pyroptotic CD4 T cells may provide a second inflammatory stimulus to induce the activation of caspase-1 by the NLRP3 inflammasome in nearby CD4 T cells that are already primed. Thus, pyroptosis initiated by

HIV may result in an avalanche of new rounds of pyroptosis in primed CD4 T cells by the repeated release of intracellular 5'-ATP in a **virus-independent manner**. Such an "auto-inflammation" scenario could generate persistent rounds of pyroptosis, chronic inflammation, and loss of CD4 T cells even when viral replication is reduced by antiretroviral therapy.

Vpx May Reverse Caspase-1-Mediated Pyroptosis by Enhancing the Permissivity of Host Cells

HIV and SIV carry a unique set of accessory proteins (e.g., Vif, Vpx, Vpr, Vpu, and Nef) that enhance viral replication in the host. Of these accessory proteins, Vpx is the signature gene in HIV-2, SIVsmm (sooty mangabey), and SIVmac (rhesus macaques) viruses. These viruses carry both Vpx and Vpr genes, while HIV-1 carries only Vpr. Why do these HIV-2 and SIV encode these two similar proteins while HIV-1 carries

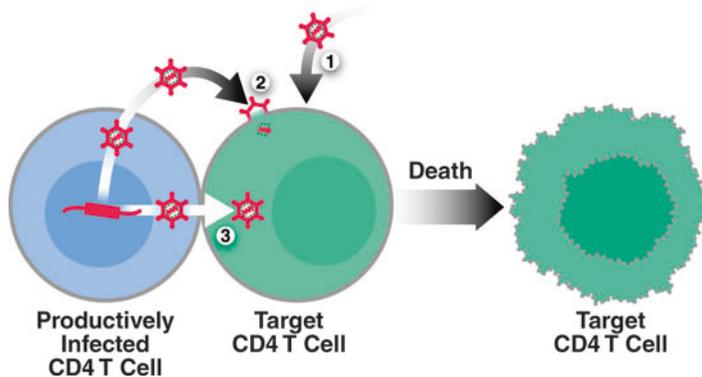

only one? The answer to this question lies in their functional details. A clue may be found in the fact that HIV-2 causes slower declines in CD4 T-cell levels, much longer periods of asymptomatic infection, and lower mortality rates than HIV-1. It is certainly possible that Vpx activity in HIV-2 relieves the SAMHD1-mediated restriction of infection in host target cells, thereby redirecting death from the caspase-1-mediated pyroptotic pathway toward the caspase-3-mediated apoptotic pathway (Fig. 2). The lack of chronic inflammation during apoptosis may underlie the milder clinical course of HIV-2 infection. Thus, Vpx may have not simply evolved to accelerate viral propagation but also to influence the particular cell death pathway utilized and to reduce the pathogenic outcomes of viral infection in the host. These hypotheses are now under active investigation.

The Mode of Viral Spread May Influence HIV Pathogenesis

Retroviruses disseminate between susceptible cells (i.e., cells that support fusion and entry) by cell-free infection or direct cell-to-cell spread. The pathway utilized can greatly affect the infectivity

yield. For HIV, the ratio of infective particles to free virions is low and calculated to be 10^{-3} to 10^{-4} . In contrast, the infectivity of virus-producing cells, as measured in coculture systems, is approximately 10^2 to 10^3 times higher than the infectivity of all the cell-free particles in the culture supernatant from the same infected cells. Although the superior efficiency of cell-to-cell spread, compared to cell-free infection, has been known for 20 years, the contributions of such modes of spread to HIV pathogenesis have never been directly demonstrated. Recent studies in HLACs now reveal that the mode of spread may determine the specific form of CD4 T-cell death elicited by HIV: **cell-free HIV particles mediate direct killing** of permissive CD4 T cells, but the death of nonpermissive cells by **abortive infection occurs only via cell-cell interaction with nearby HIV-producing cells** (Fig. 4). The molecular mechanisms that operate during cell-to-cell spread to kill nonpermissive cells remain unknown.

Because of the relatively low particle infectivity that characterizes retroviruses, cell-free virions might fail to generate an amount of cytoplasmic DNA intermediates sufficient to elicit an innate immune response in abortively infected cells. TREX1, a cellular 3' DNA exonuclease, may

Pyroptosis in HIV Infection: HIV Offense Meets a Fiery Host Defense, Fig. 4 Modes of HIV transmission affect the cytopathic outcomes in target cells. HIV can be transmitted into target CD4 T cells by cell-free infection or spinoculation (1), paracrine secretion from a nearby HIV-producing cell (2), or cell-to-cell spread from a neighboring productively infected cell (3). While HIV

transmission modes 1 and 2 promote productive infection and death in *permissive* target cells, mode 3 is required to promote death of *nonpermissive* target CD4 T cells by abortive infection and pyroptosis. Of note, 95% of CD4 T cells reside in lymphoid tissues, are nonpermissive, and die as a result of abortive HIV infection

further antagonize this process by degrading cytoplasmic reverse transcribed DNA products. Indeed, the intrinsic TREX1 activity in the cytoplasm may create a threshold of DNA products necessary either to achieve productive infection in permissive cells or, alternatively, to activate the pyroptotic pathway in abortively infected cells. Cell-to-cell spread across the virological synapse may overcome TREX1 restriction by rapid transfer of large quantities of viral DNA, facilitated by the concomitant clustering of adhesion molecules, lipid rafts, and viral entry receptors on the opposing target cell. These hypotheses are currently being investigated.

Conclusion

The very specific response that is so beneficial during host infection can contribute substantially to the pathogenesis of HIV-1. In this chronic disease, such protective response by the immune system goes into overdrive; the stimulus that triggers the inflammation is not easily cleared, causing inflammation to persist and become a substantial driver of the disease.

A number of experimental methods have been used to acquire results, test hypotheses, and formulate new models of HIV replication and pathogenesis. The differences between these methods greatly influence the conclusions that can be drawn from them. For example, accessory genes are often dispensable in facilitating viral growth in *in vitro* cell culture systems, which causes their loss during long-term propagation. Yet, these genes are strongly maintained and appear critical for viral replication in physiological systems with preserved natural conditions. The use of HLACs prepared from fresh tonsil and spleen tissues has proved to be instrumental in replicating the physiological outcomes of HIV infection, including the pyroptotic death of CD4 T cells, the generation inflammatory responses (i.e., expression and release of IL-1 β by lymphoid CD4 T cells), the requirement for cell-to-cell transfer of HIV-1 to trigger innate suicide response, and the function of Vpr promoting early steps of viral infection.

Interestingly, while cell death by abortive HIV infection is the predominant mechanism for killing CD4 T cells in lymphoid tissues, it is surprisingly not observed in the peripheral blood CD4 T cells. This result is especially surprising in view of the fact that HIV fuses and enters into quiescent blood and lymphoid CD4 T cells at equivalent levels. It is particularly important because peripheral blood cells have traditionally been used as the principal cells for modeling HIV infection and studying HIV pathogenesis. The routine use of blood, instead of lymphoid CD4 T cells, is likely the reason why previous studies entirely missed the pyroptotic cell death pathway through which many abortively infected cells die during HIV infection. Again, these observations highlight how the tissue microenvironment is a key determinant that governs how CD4 T cells die during HIV infection. They also distinguish AIDS as a disease of the lymphoid tissue, not the blood, and underscore striking biological differences between the blood and lymphoid-derived CD4 T cells that have important implications for HIV pathogenesis.

Definition

Genetic recombination, a mechanism through which large fragments of two viral genomes can be combined, accelerates the evolution of human immunodeficiency viruses (HIVs). Recombination thus has an extremely high potential to create new advantageous viral genotypes for effective transmission, to escape from host immune responses, for better replication capacity, and for the development of drug resistance (Ramirez et al. 2008). This chapter summarizes recent evidence on recombinant forms of HIV type 2 (HIV-2).

HIV-2 recombinant forms can be classified according to HIV-1 nomenclature (Robertson et al. 1999, 2000) into two categories: circulating recombinant form (CRF) and unique recombinant form (URF). The minimum requirement for declaring a new CRF is identification of the virus in at least three cases with no direct linkage,

accompanied by near full-length sequences showing the same mosaic genome structure (Robertson et al. 1999, 2000). Other recombinant forms whose identification does not meet the criteria are called URFs.

To date, eight genetic groups (A to H) have been identified in HIV-2 (Gao et al. 1992, 1994; Chen et al. 1997; Yamaguchi et al. 2000; Damond et al. 2004). Among these eight groups, A and B are the major strains circulating in HIV-2-endemic areas. Therefore, all five isolates of HIV-2 recombinant forms identified to date are chimeras of group A and B strains (Table 1). Among the five isolates, four are classified as a CRF and the remaining one is a URF.

HIV-2 CRF

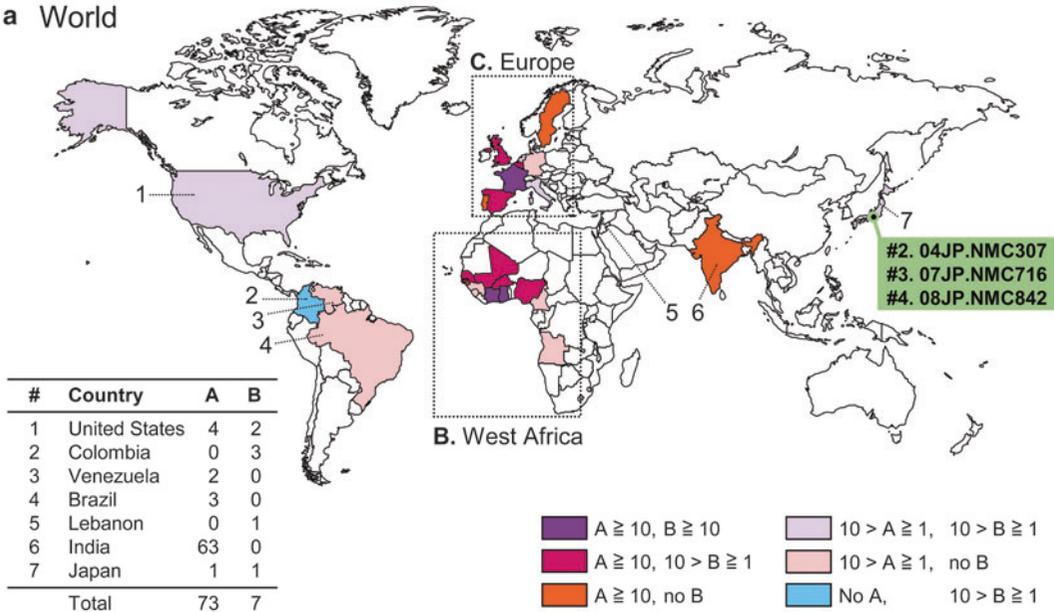

The first HIV-2 recombinant isolate 7312A had been identified through a blood sample obtained in 1990 from a 32-year-old male living in Abidjan, Côte d'Ivoire, inside the original HIV-2-endemic area of West Africa (Gao et al. 1992, 1994; Robertson et al. 1995) (Table 1 and Fig. 1b). Detailed analyses of the complete full-length genomic DNA sequence of 7312A clearly showed a mosaic genome structure consisting of HIV-2 groups A and B, along with four recombination breakpoints (Robertson et al. 1995). Although nearly two decades had passed since the discovery of 7312A, three more isolates were recently identified from epidemiologically

Recombinant Forms of HIV-2, Fig. 1 Geographical distribution of HIV-2 isolates registered as group A, B, and recombinant forms. HIV-2 nucleotide sequences ($N = 4,058$) were available with their genotype and sampling country information through the Los Alamos HIV Sequence Database on April 2012. After processing by

using 1 sequence/1 isolate, 1,131 group A and 144 group B isolates were used to make the distribution map. Countries are color-coded according to the number of HIV-2 group A and B isolates. Five isolates of HIV-2 recombinant forms are represented with a *green box*. (a) World, (b) West Africa, and (c) Europe

unlinked patients living in Nagoya, Japan, outside the HIV-2-endemic area (Ibe et al. 2010) (Table 1 and Fig. 1a). These three isolates, 04JP.NMC307, 07JP.NMC716, and 08JP.NMC842, were shown with their complete full-length genomic DNA sequences to have the same mosaic genome structure as that of 7312A, fulfilling the criteria for identifying the first CRF of HIV-2, named CRF01_AB (Ibe et al. 2010).

CRF01_AB has a group B genomic backbone and a chimeric *env* gene from groups A and B (Fig. 2a, b). In particular, the gp120 region contains a group A backbone and a partial group B C2V3 fragment, and the gp41 region contains group A extracellular and transmembrane domains and a group B cytoplasmic domain (Fig. 2c).

All four individuals infected with CRF01_AB were found with symptoms at the time of diagnosis. The host of 7312A presented with lymphadenopathy, cutaneous anergy, and recurrent skin abscesses (Gao et al. 1992). However, the pathogenicity of CRF01_AB was difficult to estimate in this case due to the presence of HIV-1 coinfection (Gao et al. 1994) (Table 1). In contrast, the three hosts of 04JP.NMC307, 07JP.NMC716, and 08JP.NMC842 were identified without HIV-1 infection (Ibe et al. 2010). It is important to note that, despite their young ages (28, 34, and 36 years old), all three cases were at advanced-stage AIDS with opportunistic infections, low CD4⁺ cell counts, and high plasma HIV-2 viral loads (Ibe et al. 2010) (Table 1), suggesting the high pathogenicity of CRF01_AB.

HIV-2 URF

The remaining isolate, CM-03-510-03, had been identified through a blood sample obtained in 2003 from a 47-year-old female living in Douala, Cameroon, in west Central Africa (Yamaguchi et al. 2008) (Table 1 and Fig. 1b). The near full-length genomic DNA sequence of CM-03-510-03 showed a unique mosaic genome structure different from that of CRF01_AB (Yamaguchi et al. 2008).

Like CRF01_AB, CM-03-510-03 has a group B genomic backbone and a chimeric *env* gene of

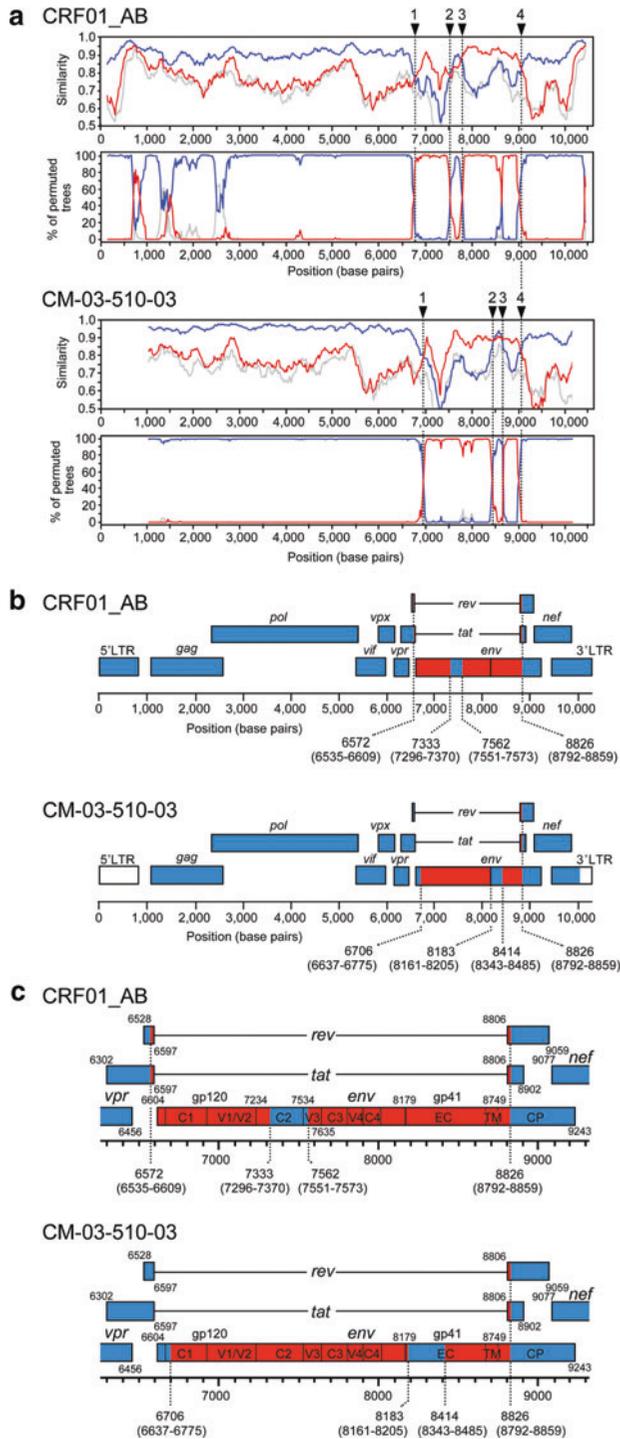

groups A and B (Fig. 2a and b). However, the gp120 region mostly contains group A fragments, and the gp41 region contains a chimeric extracellular domain of groups A and B, a group A transmembrane domain, and a group B cytoplasmic domain (Fig. 2c). As no additional isolate has been identified after the discovery of CM-03-510-03, this strain still remains identified as a URF.

Unfortunately, the host of CM-03-510-03 did not have enough clinical information to estimate the pathogenicity of this URF (Table 1).

Geographical Potential for the Emergence of HIV-2 Recombinant Forms

Coinfection with at least two different HIV-2 groups is essential for the emergence of HIV-2 recombinant forms. Therefore, overlapping areas with circulating HIV-2 groups A and B are the primary candidates for geographical hot spots for HIV-2 recombinant forms. Figure 1 shows the distribution of HIV-2 group A ($n = 1,131$) and B ($n = 144$) isolates available through the Los Alamos HIV Sequence Database in April 2012. Three major HIV-2-endemic areas have been confirmed worldwide: West Africa (also see “► Epidemiology of HIV-2 Infection in West Africa”), Europe (also see “► HIV-2 Infection in Europe, Epidemiology of”), and India in Asia, responsible for 99% (1,258/1,275) of registered HIV-2 isolates (Fig. 1a).

In the original HIV-2-endemic area of West Africa, two countries (Côte d’Ivoire and Ghana) had more than 10 group A and B isolates with nearly equal percentages; Côte d’Ivoire had 53% (45/85) group A and 47% (40/85) group B, and Ghana had 55% (16/29) group A and 45% (13/29) group B (Fig. 1b). Therefore, the southern coastal area of West Africa can be cited as a primary hot spot candidate for the emergence of HIV-2 recombinant forms. In fact, four of five individuals identified with HIV-2 recombinant forms originated from this area. The host of 7312A had been in Côte d’Ivoire, and the hosts of 04JP.NMC307 and 07JP.NMC716 had been in Nigeria before arriving in Japan (Table 1 and Fig. 1a, b). In addition,

Recombinant Forms of HIV-2, Fig. 2 Mosaic genome structures of HIV-2 recombinant forms. (a) Similarity plotting (*top*) and bootscanning (*bottom*) data for each case of HIV-2 CRF01_AB (7312A, 04JP.NMC307, 07JP.NMC716, and 08JP.NMC842) and CM-03-510-03. Plots

for consensus group A (from ALI, BEN, CAM2CG, and UC2 isolates), consensus group B (from D205, EHO, and UC1 isolates), and SIVmac239 are shown in *red*, *blue*, and *gray*, respectively. Both similarity plotting and bootscanning were performed with window and step

R

the host of CM-03-510-03 had been in Cameroon (Table 1 and Fig. 1b).

In Europe, several countries had previously developed strong socioeconomic ties with West African countries. Among them, France had abundant numbers of both group A and B isolates: 135 group A (73%) and 51 group B (27%) (Fig. 1c). The large number of group B isolates in France can be explained by a socioeconomic tie with Côte d'Ivoire. Although no HIV-2 recombinant forms have been reported in France to date, the country seems to have a higher potential for the emergence of HIV-2 recombinant forms than other European countries.

In Asia, India is known as an HIV-2-endemic country. However, as all 63 registered isolates belong to group A (Fig. 1a), the country is currently an unlikely candidate for the emergence of HIV-2 recombinant forms.

Future Studies on HIV-2 Recombinant Forms

Understanding the clinical and epidemiological impacts of HIV-2 recombinant forms will require a cohort study to assess the pathogenicity of HIV-2 recombinant forms, along with a parallel comparison of their parent HIV-2 groups A and B. To examine the feasibility of such a study, further molecular epidemiological studies are currently needed to clarify in detail the prevalence and geographical distribution of HIV-2 genotypes, especially in the southern coastal area of West Africa. Of note, the *env* gene is the only region that can specify both types of currently known HIV-2 recombinant forms (Fig. 2b). However, *env* sequencing appears to be not commonly

performed in HIV-2 studies, based on the number of *env* sequences in the public database. In other words, genotyping HIV-2 without the *env* gene risks incorrectly categorizing recombinant forms into group B. Indeed, some HIV-2 *pol* sequences suspected to be from recombinant forms have been deposited as group B sequences in the public database.

Another important future study will be in vitro approaches to the biological significance of recombination in HIV-2 recombinant forms. Research on HIV-1 recombinant forms has identified two hot spots for recombination: (1) the region (600 base pairs) from the first exons of *tat* and *rev* genes to the beginning of the *env* gene and (2) the region (400 base pairs) from the second exons of *tat* and *rev* genes to the end of the *env* gene (Magiorkinis et al. 2003; Fan et al. 2007). These two hot spots have also been identified as strong positive selection sites (Fan et al. 2007), suggesting that recombination breakpoints primarily function to escape from the host immune system. Interestingly, the first and fourth recombination breakpoints of HIV-2 CRF01_AB and CM-03-510-03 are just inside the regions corresponding to the two hot spots in the HIV-1 genome (Fig. 2c). Furthermore, the second and third recombination breakpoints are inside the C2V3 region of gp120 in CRF01_AB and inside the extracellular domain of gp41 in CM-03-510-03 (Fig. 2c), the major determinant sites for anti-envelope host immune responses. Immunological studies are thus needed to assess the ability of HIV-2 recombinant forms to escape from the host immune system. In addition, envelope proteins are essential for HIVs to attach and enter targeted cells at the beginning of the virus life cycle. Thus, virological studies are also needed

Recombinant Forms of HIV-2, Fig. 2 (continued) sizes of 300 and 20 nucleotides, respectively. Bootscanning was performed using the neighbor-joining algorithm with 500 replicates. Each recombination breakpoint is represented with an arrow head. (b and c) Schematic drawings for the genomic structures of HIV-2 CRF01_AB and CM-03-510-03. (b) Whole genomic structures and (c) details around the *env* gene are

represented. Regions belonging to groups A and B are shown in red and blue, respectively. Numbering positions were adjusted to the reference SIVmac239 sequence (Calef et al. 2001; Lin et al. 2007). Each position of recombination breakpoints is represented as the midpoint and range. *C* constant region, *CP* cytoplasmic domain, *EC* extracellular domain, *gp* glycoprotein, *TM* transmembrane domain, *V* variable region

to answer the question of whether unique chimeric envelope proteins of HIV-2 recombinant forms give any replication advantage.

Conclusion

Although few individuals to date have been identified with HIV-2 recombinant forms, ectopic discoveries and identification outside West Africa may alert clinicians, researchers, and public health authorities to the wider spread of the strains worldwide. Therefore, further molecular epidemiological studies will provide more accurate information in the near future on the prevalence and geographical distribution of HIV-2 recombinant forms.

Genetic recombination has an extremely high potential to create quite new viral genotypes by combining large fragments of two viral genomes (Ramirez et al. 2008). Current worldwide efforts to prevent further HIV spread are also important for interrupting the emergence of more pathogenic HIVs by reducing their chance for evolution.

Retention in Care Interventions

Andrew J. Wawrzyniak¹ and Allan E. Rodriguez²

¹Psychiatry and Behavioral Sciences, University of Miami Miller School of Medicine, Miami, FL, USA

²University of Miami, Miller School of Medicine, Miami, FL, USA

Definition

Retention in care is broadly defined as consistent primary HIV care visits after HIV diagnosis that leads to the initiation of an antiretroviral (ARV) medication regimen. Importantly, higher retention, as measured by higher rates of appointment attendance, is strongly associated with virological suppression and better health outcomes (Metsch et al. 2008; Mugavero et al. 2012a); individuals newly diagnosed with HIV should expect to live a normal life span and a highly preserved quality of life. This chapter will further define retention, provide an overview of outcomes associated with better retention, highlight interventions to improve retention, provide recommendations for achieving optimal retention based on evidence synthesized from existing research, and close with implications for future research.

Expanding the Definition of Retention in Care

The definition of retention must be expanded to incorporate previous research and reflect how retention has been implemented practically in a clinical setting; the practical usage guidelines have been delineated by the public health agencies and have also been demonstrated in practice.

Retention in care has been defined through best practice measures offered by the Centers for Disease Control and Prevention (CDC) and the Health Resources and Services Administration (HRSA). First, both the US National HIV/AIDS Strategy (NHAS; White House Office of National AIDS Policy 2016) and HRSA (Health Resources and Services Administration 2016) consider retention as the proportions of patients with two

or more medical visits at least 3 months or more apart in a calendar year. To calculate retention using this definition, NHAS and HRSA suggest using dates of CD4 and viral loads reported to surveillance. In that retention rates are commonly reported as a proportion of all patients who ever had any medical visits in a calendar year, specific guidelines are presented to determine this proportion. NHAS (2016) and HRSA (2016) provide specific guidelines to calculate retention rates by defining what proportion of patients were considered “retained” from patients who had a medical appointment; NHAS and HRSA guidelines define retention as the number of patients with two or more CD4 or viral load values at 3 or more months apart in one calendar year divided by the number of patients with one or more laboratory result in the same calendar year.

Research-Based Definitions of Retention in Care

Aside from the HRSA HAB clinic visit performance measure, there are other ways to measure retention; each way has strengths and limitations and is often dictated by who is trying to assess retention, namely, a clinician, an administrator, or a researcher (Mugavero et al. 2012b). Based on findings from previous research, retention has been defined based on kept visit frequency. The most efficacious means of calculating kept visits, however, has varying degrees of predictive validity in being associated with better health outcomes; retention has been measured by missed visits (number or any no show visits over a specified time), appointment adherence (proportion of kept visits from all scheduled visits), visit constancy (proportion of time intervals with at least one kept appointment), and gaps in care (time interval between kept appointments) (Mugavero et al. 2012b).

In clinical practice, the emphasis on calculating retention centers on missed visits and gaps in care in that those data are typically immediately available at the point of care and intuitively can indicate to the clinician disease prognosis. Administrators have a stronger focus on clinic performance, specifically clinic underutilization and revenue. Researchers tend to focus more on appointment adherence and visit constancy in

order to assess retention in a more refined, detailed manner that permits short- and long-term trend analyses. On a population level, engagement in care is defined as the proportion of patients with two or more CD4 or viral loads at three or more months apart in one calendar year (numerator) divided by all PLWHA living in a particular area of interest for that particular analysis in the same calendar year but excluding those whose first labs occurred in the second half of the year (denominator) (Dombrowski et al. 2012).

Some considerations should be noted in calculating retention. Determining kept visits is susceptible to practicality and data accessibility issues, primarily due to how attendance records and historical lab results, indicators of health outcomes in HIV-infected patients, are stored combined with the capabilities of the electronic medical record (EMR) that typically feeds surveillance data to health departments. Additionally, clinic scheduling practices along with computational issues, such as cutoff dates and spans of time in the analysis, can produce variance in retention rates (Mugavero et al. 2012b). Although variability exists between definitions of retention in care, irrespective of the formula used to calculate retention, research has indicated that retention is associated with health outcomes in HIV-infected patients.

Retention in HIV Care and Health Outcomes

Retention in HIV care has been found to be an integral factor of optimal health outcomes in HIV-infected patients; generally, better retention has been associated with better health outcomes due to increased rates of viral suppression and better immunity conferred by higher CD4 counts. Better retention is associated with greater antiretroviral medication adherence (Metsch et al. 2008; White House Office of National AIDS Policy 2016) and lower incidence of morbidity in that the patient's health is consistently monitored. The importance and implications of retention in care is reflected through improved clinical outcomes in patients with high retention.

Increased retention in care has been associated with better health outcomes, including reduced morbidity and mortality, better immunity, and,

importantly, less engagement in risky behaviors that increase HIV transmission (Metsch et al. 2008; Mugavero et al. 2012a). Furthermore, missed regular care visits have been associated with increased antiretroviral drug resistance (Sethi et al. 2003). Given the benefits to retaining patients in HIV care, there are evidence-based interventions that have been shown to improve retention rates.

Interventions to Improve Retention in Care

Retention in HIV care is part of the HIV Continuum of Care in the USA; notably, it is one of the key steps, after linkage to care, where patient numbers decline. In that retention directly impacts health outcomes, numerous interventions to improve retention have been published. The CDC has given providers a list of both best and good practice interventions based on the sustained effect of the interventions on retention rates.

Some interventions have been found to be designated as best practice for improving retention. Enhanced personal contact that establishes a personal relationship between providers and patients increased retention (Gardner et al. 2014). Additionally, interventions involving patient navigators, community and peer outreach, financial incentives, and case management have been found to improve retention (Higa et al. 2012, for a review; McCoy et al. 2013). Focusing on provider-based interventions, alerts for sub-optimal attendance in the EMR as part of a clinical decision support system have been found to be an effective evidence-based intervention to improve retention (Robbins et al. 2012).

Additionally, there are evidence-informed interventions that have shown improved retention and no noteworthy negative effects from pre- to post-intervention but did not have a comparison group. Bilingual care teams, consisting of a nurse practitioner, a Ryan White case manager, and a peer educator, have been found to improve retention in Hispanic/Latino patients (Higa et al. 2012, for a review). HIV-infected minority youth receiving care from adolescent care providers, youth-focused social workers, and case managers demonstrated increased retention (Davila et al. 2013). Better retention was seen in the long term in

out-of-care patients who were targeted to be relinked to care using clinical data and a linkage specialist (Bove et al. 2015). A comprehensive care plan, incorporating home- and field-based patient navigation, coordinated medical and social services, support and coaching for medication adherence, and patient education increased retention (Irvine et al. 2015). Print reminders and verbal reminders used by all clinic staff increase retention (Higa et al. 2012, for a review). Finally, an intervention for African American and Hispanic/Latino young MSM that linked newly diagnosed HIV-infected patients to a physician within 72 h of a positive result that offered ancillary support services such as group meetings, counseling, case management, assistance with appointment scheduling or medical questions by text or phone, and the development of an individual treatment plan designed to reduce that patient's barriers was found to increase retention (Higa et al. 2012, for a review). As with any intervention, their suitability depends partially on the resources available in the setting in which the intervention is deployed.

Recommendations for Retention

Systematic reviews have published guidelines that provide recommendations to optimize retention in HIV-infected patients (IAPAC 2015). Systematic monitoring of retention in care is strongly recommended for all patients, and the electronic medical record (EMR) is used to measure retention, necessitating EMRs that can handle these sorts of data queries. Along these lines, population-level data and HIV clinical monitoring using databases and surveillance systems is recommended.

Second, IAPAC has recommended providers disseminate information and implement communication technologies centered around supporting patient self-care. More specifically, IAPAC recommends using mobile health technology, such as text messaging. Importantly, the IAPAC strongly recommends patient education underscoring the importance of keeping clinic appointments (IAPAC 2015).

Finally, steps to reengage patients with low retention should be proactive. Specifically,

IAPAC recommends targeting patients who frequently miss clinic appointments to the same extent as ensuring new patients are engaged in care. Although resource heavy, IAPAC provides a moderately strong recommendation to provide case management to retain patients in care and to facilitate transportation to clinic visits (IAPAC 2015).

Conclusions

Given the importance of retention on health outcomes in HIV-infected patients along with the varying effectiveness of existing interventions, future research and clinical management should integrate appropriate interventions to optimize retention for specific patient populations. Interventions have differential levels of success depending on the type of patient; efforts taken to improve retention should take these patient characteristics into account.

The International Advisory Panel on HIV Care Continuum Optimization suggests that future retention in care research focuses on the following elements: a validated core set of metrics, ideally sourced from the EMR; comparisons of interventions in high- versus low-resource settings; the impact of technology; the effect of in-person contact; the impact of various forms of appointment reminders; the role of financial incentives; the effect of reducing food instability; reducing transportation barriers; alternative models of HIV care (visit with pharmacist or nurse only); community adherence through peer support; and home-based HIV care (IAPAC 2015). Finally, best practices to improve retention should be widely disseminated to improve population-wide rates of optimal retention in care.

Reverse Transcriptase-Catalyzed HIV-1 DNA Synthesis

Jennifer T. Miller and Stuart F. J. Le Grice
RT Biochemistry Section, Basic Research
Laboratory, Frederick National Laboratory for
Cancer Research, National Cancer Institute,
Frederick, MD, USA

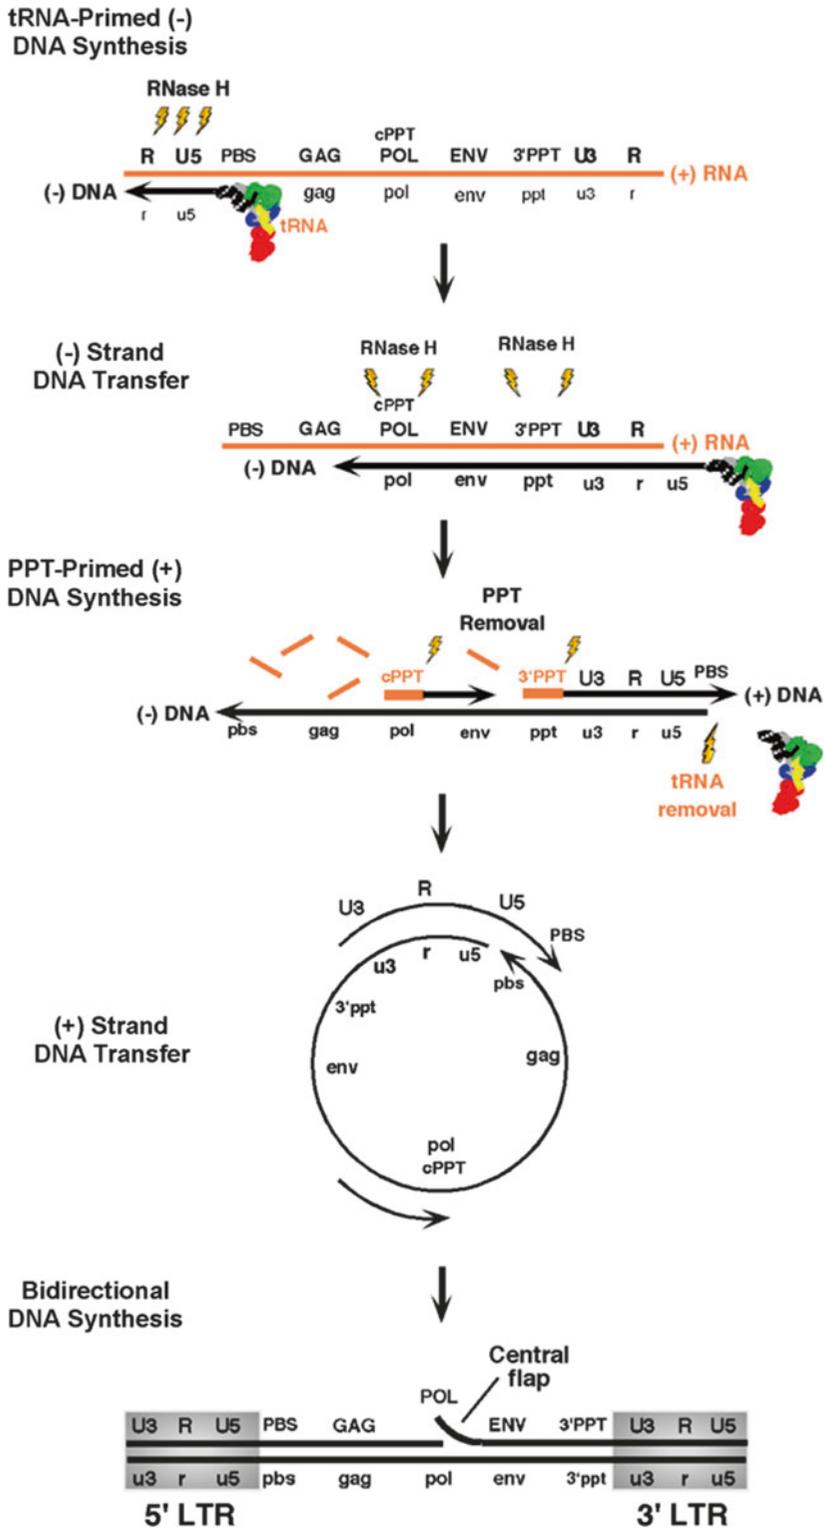

Definition: Reverse Transcription

Reverse transcription, more appropriately described as HIV-1 cDNA synthesis, describes a multi-step process through which the virus-coded reverse transcriptase (RT) converts the single-stranded (+) RNA genome into an integration-competent double-stranded DNA uninterrupted by ribonucleotides (“► [Integration](#)”). It is, however, important to note that while the integrated provirus is flanked by the hallmark long terminal repeat (LTR) elements, these encode sites for initiation and termination of transcription (“► [Transcription \(Initiation, Regulation, Elongation\)](#)”). The (+) RNA genome from which the provirus is synthesized therefore harbors incomplete LTR copies at its 5' and 3' termini, requiring their regeneration through a combination of RNA- and DNA-templated DNA synthesis. Individual steps of HIV-1 DNA synthesis (Telesnitsky and

Goff 1997; Arts and Le Grice 1998) are outlined in Fig. 1 and described in the following sections.

HIV-1 Reverse Transcriptase (RT): Structure and Function

HIV-1 RT is encoded by a single 66 kDa open reading frame of the Gag-Pol precursor polypeptide. However, the biologically relevant enzyme is a heterodimer of 66 and 51 kDa polypeptides, the latter resulting from cleavage of p66 by virus-coded protease cleavage between residues Phe440 and Tyr441 (Fig. 2). Both RT subunits therefore share four similar subdomains, designated (by analogy to a right hand) fingers, palm, thumb, and connection, while p66 retains the C-terminal, 133-residue RNase domain (amino acids 427–560). Despite primary sequence identity, subdomains of the p66 and p51 subunits adopt significantly different folds, i.e., the p66 DNA polymerase domain exhibits an open, extended structure with a large active site cleft, while the equivalent p51 subdomain adopts a closed, compact structure that lacks catalytic activity. DNA polymerase and ribonuclease H (RNase H) activities are encoded by domains at either terminus of the p66 subunit, and proposed roles for p51 include providing a structural support and facilitating p66 loading onto nucleic acid. In contrast to p66, which undergoes large-scale motions, the p51 subunit is essentially rigid. The p66 nucleic acid binding cleft comprises its fingers, palm, and thumb subdomains, and X-ray crystallography has identified numerous contacts with both strands of the duplex, primarily between the sugar-phosphate backbone and highly conserved motifs of the DNA polymerase and RNase H domains (Huang et al. 1998). Helix α -H of the thumb forms extensive contacts with the primer strand in the DNA minor groove. The β 12– β 13 hairpin (Pro227-His235) is designated the DNA polymerase “primer grip” and is proposed to maintain the primer terminus in the appropriate orientation for nucleophilic attack on the incoming dNTP. Contact with the template strand involves the p66 “template grip,” which includes elements of its palm and finger subdomains.

R

Reverse Transcriptase-Catalyzed HIV-1 DNA Synthesis, Fig. 1 (continued)

A high-resolution co-crystal structure of an HIV-1 replication complex (i.e., enzyme, nucleic acid, and the incoming dNTP) depicts the template overhang ahead of the DNA polymerase active site bending to interact with the p66 fingers, contacting nucleobases +1, +2, and +3.

The p66 palm houses the DNA polymerase active site, characterized by the Asp110, Asp185, and Asp186 catalytic triad, a common feature of DNA and RNA polymerases. Among nucleic acid polymerase families, palm subdomain architecture is highly conserved, comprising a four- to six-stranded β -sheet flanked on one side by two α -helices. Asp185 and Asp186 are part of the conserved -Tyr-Met-Asp-Asp- active site motif that adopts an unusual β -turn conformation, possibly to promote their positioning for catalysis, while Tyr183 is involved in hydrogen bonding with nucleobase -2. Structures of HIV-1 RT reveal significantly different conformations for the active site motif, indicating a high degree of structural flexibility. The incoming dNTP is tightly coordinated by p66 finger residues Lys65, Arg72, Asp113, and Ala114, and its ribose occupies a pocket lined by Asp113, Tyr115, Phe116, Glu151, and Arg72. dNTP insertion fidelity is critically influenced by interactions of its γ -phosphate with Lys65. Finally, Tyr115 has been coined the “steric gate,” providing the critical discrimination between deoxy- and ribonucleoside triphosphates.

RNase H-mediated hydrolysis of the RNA/DNA reverse transcription intermediate is two-metal catalyzed (metals ions A and B), with a preference for Mg^{2+} . Divalent metal coordination is substrate dependent, i.e., at physiologically relevant concentrations, productive binding occurs only in its presence. The catalytic cycle can be summarized as follows:

- In a “resting” state, metal ions A and B are separated by ~ 4 Å. During catalysis, their

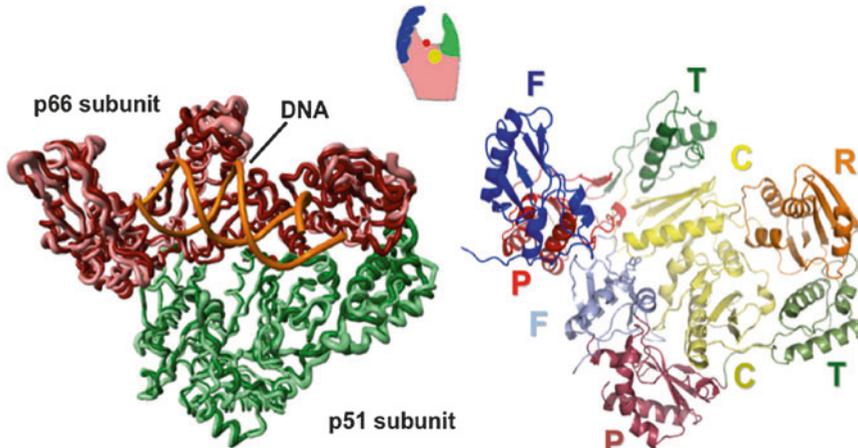

position and separation vary according to the coordination environment.

- Hydrolysis proceeds via an SN2 mechanism, involving a penta-coordinated intermediate, resulting in inversion of configuration at the phosphorus.
- Metal ion A (coordinated by Asp443 and Asp549) coordinates a water molecule, reducing its pKa and aligning this for in-line nucleophilic attack on the phosphodiester backbone.
- In turn, metal ion B, coordinated by Asp443, Glu478, and Asp498, stabilizes the transition state to facilitate the leaving of the 3' oxyanion group.

Crystallographic studies show extensive contacts between RT and the RNA/DNA hybrid several base pairs ahead the RNase H active site. This motif, designated the “RNase H primer grip,” interacts with the DNA primer upstream of the scissile phosphodiester bond of the RNA strand. By interacting with DNA bases of the RNA/DNA hybrid near the active site, the RNase H primer grip is proposed to impose the appropriate trajectory on the RNA strand for catalysis. Two general modes of RNase H-mediated catalysis have been identified, namely, polymerization dependent and polymerization independent. The former cleaves the RNA/DNA hybrid 17–18 nt downstream of the primer 3' terminus and is consistent with the distance spanning the DNA polymerase and RNase H active sites. In contrast, polymerization-independent RNase H activity cleaves the RNA/DNA hybrid 8–10 nt downstream of the primer terminus by an RT relocation mechanism that remains to be fully elucidated. Despite this, polymerization-independent RNase H activity plays a pivotal role in both strand transfer steps of HIV-1 DNA synthesis (see later).

tRNA-Primed Initiation of (–) DNA Synthesis

Reverse transcription of the HIV-1 (+) RNA genome is initiated from a host-coded tRNA molecule (tRNA^{Lys,3}), whose 18 3'-terminal nucleotides are hybridized to a sequence immediately adjacent to the U5 region of the viral genome designated the primer binding site (PBS) (Wilhelm and Wilhelm 2001; Le Grice 2003). tRNA^{Lys,3} is selectively packaged into the budding virion, i.e., tRNA^{Lys} isoacceptors (tRNA^{Lys,3} and tRNA^{Lys1,2}) constitute ~50–60% of the population of small RNA species in the virion, whereas they represent at most 5–6% of the cellular tRNA population. The viral Gag-Pol polyprotein precursor is necessary for this enrichment, evidenced by data indicating an interaction between its RT coding region and the tRNA molecule.

Since virus particles lacking an RNA genome contain wild-type levels of tRNA^{Lys} isoacceptors, an interaction of the tRNA primer with the PBS of the (+) viral RNA template appears unnecessary to mediate its sequestration. Instead, tRNA^{Lys,3} is packaged into virions complexed with a component of the host translational machinery, namely, lysyl-tRNA synthetase (LysRS). Catalytically inactive LysRS retains the ability to facilitate

packaging of tRNA^{Lys} isoacceptors, indicating that the tRNA does not have to be covalently linked to the synthetase for its enrichment in the virion. LysRS has been shown to interact through an association between a region involved in its contact with HIV-1 Gag, specifically the C-terminal capsid (CA) dimerization region. While this is mostly likely the primary mechanism through which the LysRS/tRNA complex is sequestered into the virus, an interaction between the C-terminal RT domain of the Gag-Pol polyprotein may make an additional contribution. Although virus containing truncated Gag-Pol proteins from which this domain had been removed continued to selectively package their tRNA RNA primer, this was not annealed to the (+) RNA genome, suggesting a conformational change may be required to correctly position tRNA^{Lys,3} on viral RNA subsequent to packaging. Whether the primer is annealed pre- or post-virus assembly and budding remains a matter of speculation. Since tRNA^{Lys,3} is annealed to the RNA genome of viruses whose protease gene has been inactivated, the nucleocapsid (NC) domain of Gag, not the mature NC protein, most likely mediates its hybridization to the PBS. The host-coded RNA helicase A has also been suggested to play an auxiliary role in tRNA annealing by modifying viral RNA conformation.

Reverse Transcriptase-Catalyzed HIV-1 DNA Synthesis, Fig. 3 Alternative models of long-range interactions between the HIV-1 $tRNA_{Lys,3}$ replication primer and the 5' region of the viral RNA (vRNA) genome that control

initiation of (–) strand DNA synthesis. Individual tRNA arms are color coded. *A/C* anticodon, *Var* variable loop, *Acc* 3' acceptor stem, *P* primer binding site. Viral RNA is represented in magenta

Establishment of a productive reverse transcription initiation complex occurs subsequent to binding of the p66/p51 RT heterodimer to the tRNA/viral RNA duplex. A combination of chemical and enzymatic probing studies suggests this RNA/protein complex assumes a complex tertiary structure that controls early events of the initiation process. Besides an absolute requirement for the $tRNA^{Lys,3}$ /PBS interaction, several regions in subtype B HIV-1_{HXB2} RNA influence initiation of (–) strand DNA synthesis. One such interaction (Fig. 3a) involves the 3' portion of the $tRNA^{Lys,3}$ anticodon stem and the U5-IR region upstream of the PBS (Isel et al. 2010). Deleting these viral RNA sequences creates a reverse transcription defect in vitro, although virus replication is not significantly impaired. Another important regulatory interaction proposes that a primer activation sequence (PAS) on the viral RNA genome, and present in an extended stem downstream of the PBS, interacts with an “anti-PAS” sequence located in the tRNA TΨC stem (Fig. 3b). In contrast, studies with HIV-1_{Mal}, a subtype A virus, provided an alternative model where an A-rich viral RNA sequence in the U5-IR stem interacts with the U-rich $tRNA^{Lys,3}$ anticodon domain. Although the structures of these complexes are significantly different, both share a common property of controlling early steps of (–) strand DNA synthesis.

Initial steps of tRNA-primed (–) strand DNA synthesis, i.e., addition of the first five dNTPs, are characterized by pausing and premature termination of the replication machinery and are followed by a transition into a productive polymerization mode. Single-molecule spectroscopy with fluorescently labeled enzymes has elegantly illustrated that these premature termination events correlate with multiple inversions of enzyme orientation that have the consequence of positioning the C-terminal RNase H domain over the polymerization site. Productive reverse transcription follows incorporation of the fifth dNTP, which is paralleled by disruption of RNA secondary structural elements immediately ahead of the PBS. This initiation “program,” variations of which can be demonstrated for the related feline immunodeficiency and equine infectious anemia viruses, may provide a means of avoiding premature reverse transcription prior to virus budding. In support of this model, HIV-1 virion-associated $tRNA^{Lys,3}$ has been demonstrated to contain a 2–3 deoxynucleotide extension at its 3' terminus.

(–) Strand DNA Synthesis and Transfer

Subsequent to tRNA-primed DNA synthesis from the PBS, RT copies the U5 and R regions until it

reaches the 5' terminus of the (+) genome, producing the hallmark (−) strand strong-stop DNA. The RNA/DNA hybrid created by this process is hydrolyzed by RNase H activity of both the polymerizing enzyme and additional enzymes that reassociate with the substrate, producing short oligoribonucleotide stretches that can spontaneously dissociate from nascent (−) strand DNA. During RNA-dependent DNA synthesis and RNase H-mediated template hydrolysis, the Gag-coded NC protein aids in unwinding areas of secondary structure and dissociation of larger RNA hydrolysis products.

In the terminal R region, complementarity between nascent (−) DNA and the R region at the 3' end of the viral genome facilitates the first DNA strand transfer event. (−) strand DNA transfer is both intramolecular, i.e., between termini of the same RNA genome, and intermolecular, via two different RNAs. Inter-strand DNA transfer can facilitate recombination between different viral genomes, a process that is essential for maintenance of virus diversity and fitness. (−) strand DNA transfer has been shown to proceed via two distinct mechanisms. In one scenario, transfer takes place between the termini of the full-length (−) strand DNA and the 3' end of the viral RNA genome. An alternative mechanism invokes a strand invasion process, where an internal stretch of single-stranded DNA is accessed by the corresponding complement in the vRNA, followed by branch migration and subsequent completion of (−) strand strong-stop DNA synthesis (Basu et al. 2008).

(+) Strand DNA Synthesis: PPT Primer Utilization and Removal

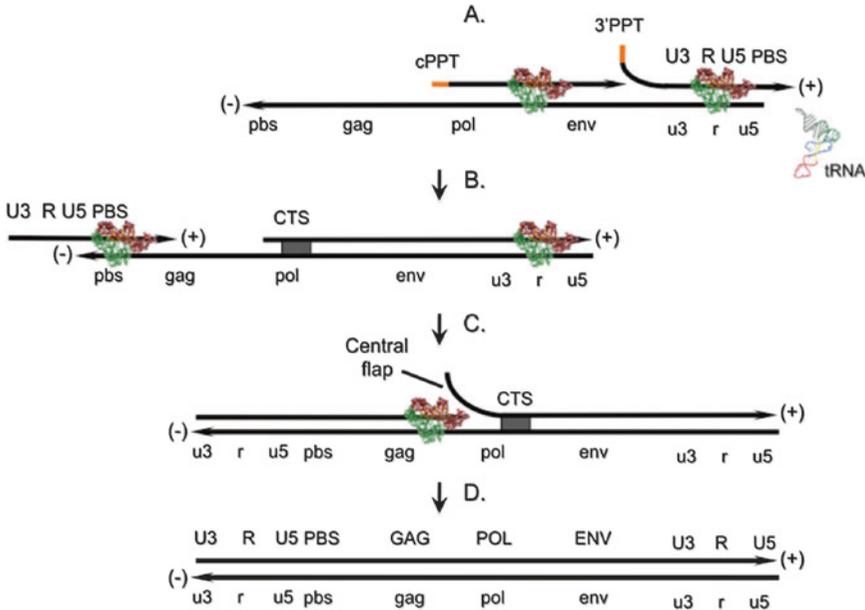

Following (−) strand DNA transfer, RNA-dependent DNA synthesis resumes, accompanied by hydrolysis of (+) RNA of the ensuing RNA/DNA hybrid. However, two polypurine tracts (PPTs), located at the center (cPPT) and in the vicinity of the genome 3' terminus (3' PPT), are refractory to hydrolysis and provide the RNA primers for (+) strand, DNA-dependent DNA synthesis. The cPPT, a unique feature of several

lentiviral genomes, will be discussed in detail later, and therefore only 3' PPT-mediated DNA synthesis is discussed here.

Since 3' PPT-primed (+) strand DNA synthesis defines 5' LTR sequences essential for integration of the full-length double-stranded viral DNA (Fig. 1), its selection from the RNA/DNA replication intermediate and subsequent removal from newly synthesized (+) DNA requires a considerable degree of precision (Rausch and Le Grice 2004). Although the structural basis for selection of the PPT 3' terminus is not completely understood, crystallographic analysis indicates a local and altered pattern of base pairing, an observation that has been supported by chemical footprinting of PPT RNA and its (−) DNA complement. Together, these independent lines of evidence suggest the PPT-containing RNA/DNA hybrid assumes a unique geometry, possibly to promote an “induced” fit with RT to correctly position the scissile phosphodiester bond in the RNase H active site. Initiation of (+) strand DNA synthesis has the consequence of producing a PPT RNA/(+) DNA chimera hybridized to (−) DNA, and the unique architecture of the RNA/DNA junction (demonstrated by NMR spectroscopy) may likewise provide a means of recognition by the RNase H domain that ensures accurate primer removal.

tRNA Primer Removal and (+) Strand DNA Transfer

Prior to second or (+) strand DNA transfer, PPT-primed (+) strand DNA synthesis is templated by both DNA and RNA, namely, U3, R, and U5 DNA, together with 18, 3' nucleotides of the covalently linked tRNA^{Lys,3} primer (Fig. 1). At this point, the replication complex encounters a modified tRNA^{Lys,3} base, 1-methyladenosine 58 (M¹A58), whose modification results in pausing of the replication machinery. Based on the 17–18 bp spatial separation of the DNA polymerase and RNase H active sites of HIV-1 RT demonstrated by X-ray crystallography, pausing at this position places the (−) DNA-tRNA junction in the RNase H active site, facilitating removal of the (−) strand primer.

Reverse Transcriptase-Catalyzed HIV-1 DNA Synthesis, Fig. 4 Central termination of HIV-1 (+) strand DNA synthesis and generation of the “central flap.” cPPT and 3' PPT RNA primers are depicted in orange and (+) DNA in

black, respectively. HIV-1 RT is represented by the 2-color cartoon. CTS central termination sequence. Individual steps (a–d) are described in detail in the text

Although the tRNA-DNA junction might be the logical RNase H target site, HIV-1 RT cleaves the penultimate ribonucleotide bond, the rationale for which remains elusive. Polymerization-independent RNase H activity subsequently removes additional ribonucleotides from the tRNA 3' terminus, promoting its dissociation and freeing homologous (+) and (-) strand PBS sequences for second or (+) strand DNA transfer. Confirmation that arrest of DNA synthesis at M^{158A} is critical to (+) strand DNA transfer has been provided in vitro, where substituting tRNA^{Lys,3} with a variant that cannot be methylated at A58 interferes with virus infectivity. Finally, in contrast to (-) strand DNA transfer, which can be either intra- or intermolecular, (+) strand DNA transfer is exclusively intramolecular.

Central Termination of Proviral DNA Synthesis

In principal, (+) strand DNA transfer and ensuing bidirectional DNA-dependent DNA synthesis

should suffice to produce the double-stranded, integration-competent HIV-1 DNA flanked by hallmark LTRs and uninterrupted by ribonucleotides. Surprisingly however, a discrete (+) strand discontinuity was discovered that mapped near the center of the genome and within the integrase (IN) open reading frame (“► Integration”). These observations suggested that *cis*-acting sequences in the IN gene specified (a) a second (+) strand initiation site and (b) a unique mechanism to halt (+) strand DNA synthesis in its immediate vicinity. Since the IN coding region contains a duplication of the 3' PPT sequence (designated the central or cPPT), this provided a rationale for the second initiation site, while the mechanism for terminating (+) strand DNA synthesis was explained by the nearby *central termination sequence* or CTS (Fig. 4).

Describing sequence-specific termination of HIV-1 DNA synthesis mechanistically requires understanding the fate of (+) DNA synthesized simultaneously from the 3' and cPPTs, which is illustrated schematically in Fig. 4. As outlined previously, initiation from the 3' PPT leads to

accumulation of (+) strong-stop DNA containing the PBS sequence necessary for (+) strand DNA transfer. In contrast, cPPT-primed (+) strand synthesis proceeds to the genome 3' terminus (most likely displacing (+) strong-stop DNA in the process), but the absence of a PBS sequence precludes its involvement in strand transfer, thereby establishing one component of the discontinuous (+) strand.

Following (+) strand DNA transfer and resumption of DNA-dependent DNA synthesis, the replication complex ultimately reaches the duplex product of cPPT-primed DNA synthesis. After displacing ~100 nucleotides, RT encounters the CTS in the form of duplex DNA, a prominent feature of which is phased dA:dT tracts. Since dA:dT tracts have been characterized structurally to induce minor groove compression, such successive elements of the HIV genome, in the context of strand displacement synthesis, result “dislocation” of the replication complex and enzyme dissociation. Figure 4 also indicates that the central termination step produces a “flap” of displaced DNA that must be precisely removed and repaired by host-coded enzymes to create the replication-competent DNA provirus. While the function of the central flap remains controversial, several reports indicate that (a) its mutation or deletion is deleterious to virus replication, (b) incorporation of the CTS into lentiviral vectors improves transduction efficiency, and (c) equivalent elements are present in the genomes of equine infectious anemia and feline immunodeficiency virus.

HIV-1 RT Inhibitors and Microbicide Development

Since the approval of AZT in 1987, several nucleoside RT inhibitors (NRTIs) are in clinical use (“► [Clinical Trials: Past, Present and Future](#)”), including lamivudine (3TC), emtricitabine (FTC), abacavir (ABC), didanosine (ddI), and stavudine (d4T). Once phosphorylated to the triphosphate by cellular kinases, NRTIs are incorporated into the growing DNA chain, and the absence of a ribose 3' OH prevents subsequent dNTP incorporation. The related nucleotide RT

inhibitors (NtRTIs), e.g., tenofovir (TFV), function similarly but require only two phosphorylation steps to their active derivative. In contrast, nonnucleoside RT inhibitors (NNRTIs), such as nevirapine and efavirenz, occupy a site at the base of the p66 thumb, “locking” this subdomain in a configuration incompatible with catalysis. Additional mechanistic features of NNRTIs revealed by single-molecule spectroscopy include inducing relaxed contact of RT with nucleic acid (leading to dislocation and “sliding” from the polymerization site) and promoting an inversion of configuration on the PPT. Lastly, indolopyridones represent a new class of RT inhibitors with a unique mechanism that specifically traps the enzyme at a specific stage of translocation.

Despite the requirement of retroviral RNase H for virus infectivity, RNase H inhibitors have not advanced toward clinical trials, possibly reflecting toxicity concerns due to lack of specificity. In particular, inactivating eukaryotic RNase H has been associated with failure to accumulate mitochondrial DNA in model systems. These issues notwithstanding, a considerable body of biochemical and structural data on RNase H inhibitors has accumulated. Chelation of the catalytic divalent metal at the active site is a shared feature of many RNase H inhibitors, which include N-hydroxyimides, hydroxylated tropolones, diketo acids, and pyrimidinol carboxylic acids. Allosteric inhibition of RNase H activity, exemplified by thienopyrimidinones, is also currently under investigation. These compounds occupy a site at the interface between the p51 thumb subdomain and p66 RNase H domain, presumably altering subunit geometry in a manner that is inconsistent with catalysis.

Finally, antiretroviral agents targeting specific enzyme functions of the HIV replication cycle, and reverse transcription in particular, are emerging as promising vaginal and rectal microbicides (“► [Pre-exposure Prophylaxis \(PrEP\)](#)”) (Lewi et al. 2012). Prominent among these is the NtRTI TFV, demonstrated in clinical trials to be safe and well tolerated in a study on HIV-negative women receiving a vaginal gel applied for 24 weeks. Repeated TFV application also produced low

plasma levels and, importantly, failed to select for drug-resistant mutations. NNRTIs such as dapivirine (DPV) also show promising virucidal properties, and long-term constant DPV release has been obtained from a variety of intravaginal rings. However, HIV microbicide development still faces considerable formidable challenges, including conclusive demonstration of efficacy in nonhuman primates, selection of drug-resistant virus in clinical settings (“► [Clinical Trials: Past, Present and Future](#)”), cultural acceptability, and affordability.

Conclusion

HIV-1 DNA synthesis is a multi-step process catalyzed by the viral enzyme reverse transcriptase that creates a double-stranded DNA copy of the plus-sense single-stranded RNA genome. During the course of creating a double-stranded provirus competent for integration into the host chromosome, RT must recognize a variety of different nucleic acid substrates. This multi-functionality offers several stages that can and are being targeted for drug intervention, both therapeutic and prophylactic.

Risk of Sexual HIV-1 Transmission: Coinfections Associated with Risk

Janneke van de Wijgert

Department of Clinical Infection, Microbiology and Immunology, Institute of Infection and Global Health, University of Liverpool, Liverpool, UK

Definition

For sexual transmission of HIV-1 to occur, a susceptible host has to be exposed to a transmissible virus originating from a transmitter. The transmission risk depends on the frequency and dose of HIV-1 exposure and host susceptibility. The presence of coinfections in the transmitter or in the host influences transmission risk in multiple ways. Coinfections include mucosal coinfections (such as viral and bacterial/protozoal sexually transmitted infections (STIs), altered mucosal microbiota, and genital schistosomiasis) and systemic infections (such as acute malaria and active tuberculosis).

Sexual Transmission of HIV-1

For sexual transmission of HIV-1 to occur, a susceptible host has to be exposed to a transmissible virus originating from a transmitter (Haase 2010). The transmission risk depends on the frequency of exposure and, when exposed, on the plasma and genital HIV-1 viral load in the transmitter. The plasma viral load depends on disease stage and use of combination antiretroviral therapy for HIV

(cART) and can be increased by systemic coinfections. The genital viral load mostly correlates with the plasma viral load, but local genital factors can increase it independently. These include lack of male circumcision and the presence of genital coinfections. Transmission risk also depends on the type of sexual exposure (from highest to lowest risk: receptive anal intercourse, insertive anal intercourse, male-to-female vaginal intercourse, female-to-male vaginal intercourse, and oral intercourse) and host susceptibility.

HIV is not transmitted easily. Even in the case of receptive anal intercourse between men who have sex with men (MSM), only 1 in 70 sex acts results in transmission (Jin et al. 2010). The reason for this is that HIV typically encounters several barriers to infection at the mucosal surfaces of the genital tract, rectum, or oropharynx. The healthy lower female genital tract is lined by multilayered, stratified, and keratinized epithelial cells that form a mechanical barrier and are capable of producing chemokines and antimicrobial compounds. This epithelium is colonized by lactobacilli that produce lactic acid and antimicrobial compounds. Furthermore, it is covered with vaginal exudate and cervical mucus that trap pathogens and distribute the compounds produced by the epithelial cells and lactobacilli. The penis is also protected by epithelium and is bathed in cervicovaginal secretions that are mixed with pre-ejaculate and semen during vaginal sex. Semen has properties that can either enhance or block HIV-1 transmission, but the mixture of cervicovaginal secretions and semen mostly inhibits HIV-1 infectivity. In the rectum, fewer protective barriers exist. The epithelium consists of a fragile single layer of columnar cells, but these cells do produce chemokines and other protective soluble factors. In the oropharynx, transmission mostly occurs via the gingiva and tonsils, which are protected by saliva.

HIV-1 uses a CD4 receptor and either a CCR5 or CXCR4 coreceptor to enter its target cells (mostly lymphocytes and macrophages), but the majority of HIV-1 transmissions involve only a single CCR5-tropic virus (Grivel et al. 2010). HIV-1 can also be captured by dendritic and

Langerhans cells using the cell surface molecules DC-SIGN and other C-type lectins, which is usually followed by transfer of the virus to CD4+ T cells. However, Langerhans cells are capable of degrading HIV-1, but this mostly seems to occur in noninflammatory circumstances when few activated CD4+ T cells are present (de Witte et al. 2007). After HIV-1 has infected its target cells in the mucosa, infected cells are transported to the draining lymph nodes where the virus undergoes rapid replication before being disseminated throughout the body. Innate and adaptive immune responses try to interfere with this sequence of events. The virus is recognized by pathogen-associated molecular pattern (PAMP) receptors on mucosal epithelial cells, which upregulate their production of chemokines, defensins, and other antimicrobial compounds. The complement cascade is activated, more immune cells are recruited, and HIV-1-specific antibodies and cytotoxic T cells are eventually produced. While these defense mechanisms are capable of keeping HIV transmission rates low, they do not always succeed in blocking the virus completely.

From this description of how HIV transmission usually occurs, it becomes clear that host susceptibility increases when the exposed mechanical barrier is weakened or disrupted, protective mucosal fluids are diminished in quantity or altered in consistency or composition, the mucosal microbiome is altered, large numbers of HIV-1 target cells are within reach, and protective innate and adaptive immune responses are insufficient to block the virus. The presence of coinfections in the host can influence all of the above.

Viral STIs: Herpes and Human Papillomaviruses

Herpes simplex virus type 2 (HSV-2) is the etiological agent of genital herpes and the most common cause of genital ulcer disease (GUD). Globally, 16% of the 15- to 49-year-old population is estimated to be living with HSV-2. This amounts to 536 million people, compared to 34 million people living with HIV (Looker

et al. 2008). HSV-2 enters its host via disrupted epithelia, causes blisters at the site of infection due to viral replication in epidermal or dermal cells, and causes a lifelong chronic latent infection of the dorsal root ganglia. Persons infected with HSV-2 alternate between latency and reactivation of viral replication, which causes recurrence of blisters or asymptomatic genital HSV-2 shedding. While the frequency of blister recurrences typically wanes over time, infected persons continue to shed virus for about 25% of days with about half of the shedding episodes lasting less than 12 h (Barnabas and Celum 2012). The HSV-2 viral load produced in these short bursts of viral replication is sufficient for transmission to take place.

Epidemiological studies have shown that prevalent HSV-2 infection (defined as the presence of HSV-2 antibodies in blood) and incident HSV-2 infection increase HIV acquisition risk two- to threefold and sevenfold, respectively, in women (Freeman et al. 2006). Positive HSV-2 serology is also associated with increased HIV acquisition risk in heterosexual men and MSM and with increased HIV-1 RNA in the genital tract of HIV-positive women and men. The mechanisms by which HSV-2 infection might increase HIV-1 transmission include epithelial disruption and recruitment of HIV-1 target cells to the site of HSV-2 replication, but also direct stimulation of HIV-1 replication by HSV-2 in coinfecting individuals (Barnabas and Celum 2012). HSV-2 upregulates HIV-1 replication through different pathways including transactivation of the HIV-1 long terminal repeat. Plasma HIV-1 RNA levels in coinfecting individuals prior to initiation of cART are about 0.2 log₁₀ copies/ml higher than in those without HSV-2 infection, which may translate to higher rates of onward HIV transmission during sexual intercourse and intrapartum. While cART is the most efficient way to reduce plasma HIV-1 RNA levels, acyclovir treatment for HSV-2 also has a modest effect. The mechanism of action is still to be elucidated. In vitro studies suggest that (val)acyclovir may directly inhibit HIV-1 reverse transcriptase. It should be noted that cART in coinfecting patients does not completely eliminate HSV-2 reactivation.

Between 2007 and 2010, three randomized controlled trials (RCTs) of daily oral acyclovir (800 mg) for HIV prevention were conducted (Barnabas and Celum 2012). Two of these showed a reduced incidence of GUD but not of HIV-1 in the study participants. The third one also showed a reduced incidence of GUD as well as a median reduction of 0.25 log₁₀ copies/ml in plasma HIV-1 RNA in index cases, but this was insufficient to lower the HIV transmission rate to their HIV-negative partners. Poor adherence with the acyclovir regimen may be one reason why these RCTs showed no effect. However, since then it has also become clear that HSV-2-infected persons are in an almost continual state of disease reactivation and viral shedding which is not completely suppressed by standard acyclovir treatment. Furthermore, HIV-1 target cells remain present at the site of healed HSV-2 lesions for a surprisingly long time. Current research focuses on development of HSV-2 vaccines and vaginal microbicides that inhibit both HIV-1 and HSV-2. Vaccine candidates to date (most of them using the HSV-2 entry receptor glycoprotein D as the immunogen) have not been successful, and live-attenuated HSV-2 vaccines are currently in early development (Halford et al. 2011). In contrast, 1% tenofovir vaginal gel was shown to reduce HIV-1 acquisition (by 39% over 30 months) and HSV-2 acquisition (by 51% over 30 months) in young South African women in the CAPRISA 004 trial using the so-called BAT24 dosing regimen (first application within 12 h before sex and second application within 12 h after sex) (Abdool Karim et al. 2010). The gel achieved high vaginal levels of tenofovir resulting in direct inhibition of local HSV DNA polymerase. The same gel and BAT24 dosing strategy are currently being retested in another South African RCT (the FACTS 001 trial), which is due to report in 2015. Daily dosing of the gel independent of sex acts was also evaluated in a RCT (the VOICE trial), but this trial was prematurely terminated because of lack of efficacy in reducing HIV-1 acquisition; efficacy against HSV-2 has not yet been determined.

Other highly prevalent herpes viruses may also play a role in HIV-1 transmission but are less well studied in that context. These include HSV type

1 (which mostly causes facial cold sores but can also cause genital herpes), cytomegalovirus (CMV), Epstein-Barr virus (EBV), and human herpesvirus 8 (HHV-8) (Gianella et al. 2013).

Between 1995 and 2009, prior to large-scale introduction of human papillomavirus (HPV) vaccination, the global HPV prevalence in women was estimated to be 12% (Bruni et al. 2010). More than 100 types of mucosal HPV viruses have been identified. High-risk types are associated with cervical, anal, and other anogenital cancers and low-risk types with warts. Worldwide, the high-risk types 16, 18, 31, 52, and 58 are the most common. HPV viruses are sexually transmitted and infect the basal epithelial cells of the anogenital mucosa via microabrasions in the epithelial lining (Veldhuijzen et al. 2010). They evade the immune system by only inducing viremia in terminally differentiated epithelial cells, which are already programmed for apoptosis. Nevertheless, 90% of infections are cleared within 2 years by cell-mediated immune responses. A 2012 systematic review and meta-analysis concluded that HPV infection by both high-risk and low-risk types increases HIV-1 acquisition in women and men about twofold (Houlihan et al. 2012). Several mechanisms of action have been proposed, such as epithelial breaches, increased density of CD4+ CCR5+ T lymphocytes, and a reduced capacity of Langerhans cells to kill HIV-1 in HPV-infected tissues. HPV has also been associated with increased genital HIV-1 RNA in coinfecting women and men.

Two highly effective HPV vaccines were licensed by the US Food and Drug Administration in 2009 (Gardasil and Cervarix, both including high-risk types 16 and 18 and Gardasil also including low-risk types 6 and 11). These vaccines are currently being rolled out in several countries worldwide. A vaccine including HPV types 6, 11, 16, 18, 31, 33, 45, 52, and 58 is currently completing Phase III efficacy testing. An obvious question is whether HPV vaccination, and particularly vaccination with the 9-valent vaccine, does not only reduce incidence of HPV and cervical cancer but also of HIV-1. This will most likely be investigated in future studies.

Bacterial/Protozoal STIs: Gonorrhea, Chlamydia, Syphilis, and Trichomoniasis

The sexually transmitted bacteria *Neisseria gonorrhoeae* (NG) and *Chlamydia trachomatis* (CT) cause endocervical infection in women that can spread to the upper genital tract, sometimes resulting in pelvic inflammatory disease (PID) and/or infertility. NG and CT cause urethritis and balanitis in men. While both infections can cause an inflammatory response with recruitment of HIV-1 target cells, gonorrhea is almost always highly inflammatory, whereas chlamydia is often asymptomatic (Jarvis and Chang 2012). The sexually transmitted spirochete *Treponema pallidum* causes syphilis; primary syphilis is often characterized by GUD and later stages of syphilis by neurological involvement. *Trichomonas vaginalis* (TV) is a sexually transmitted anaerobic, flagellated protozoa. It can infect the ectocervix and vagina in women and urethra in men and is usually asymptomatic or mildly symptomatic. All four STIs are curable with antibiotic treatments, but reinfections are common because sexual partner(s) of index cases are often not treated. The 2005 World Health Organization incidence estimates among women and men aged 15–49 were 88 million new cases per year for gonorrhea, 101 million for chlamydia, 11 million for syphilis, and 248 million for trichomoniasis (World Health Organization 2005). Several epidemiological studies have demonstrated that each infection is associated with increased HIV-1 acquisition in HIV-negative patients and increased genital HIV-1 RNA detection in HIV-positive patients.

NG binds to and invades mucosal epithelial cells using several different surface proteins (Jarvis and Chang 2012). These proteins also activate toll-like receptors (TLR) 2 and 4, thereby initiating cytokine expression and inflammatory cascades, including the recruitment of HIV-1 target cells. NG is also associated with the induction of human defensins that can enhance HIV-1 entry into target cells by promoting HIV-1 attachment. In chronic HIV-1 infection, NG has been associated with transient HIV-1 viremia in plasma and genital secretions. In vitro, NG enhances HIV-1 replication in primary resting CD4+

T lymphocytes, and its surface proteins modulate the degree of this enhancement via TLR-2 activation.

CT serovars D-K infect the genital tract. CT is an obligate intracellular bacterium which alternates between two forms: a metabolically inactive but infectious elementary body (EB) and a metabolically active, noninfectious intracellular reticulate body (RB). EBs enter host cells via receptor-mediated endocytosis; the CT proteins involved in this process have not been completely described. EBs within endosomes then differentiate into RBs that escape host defenses. Like other genital pathogens, CT infection reduces epithelial integrity and induces recruitment of HIV-1 target cells to the genital mucosa. In vitro studies have shown that some CT serovars also increase the expression of HIV-1 primary and coreceptors on epithelial cells, thereby allowing productive infection of epithelial cells by HIV-1. These infections occur via binding of the HIV-1 protein gp41 to the epithelial cell receptor GalCer, instead of the usual binding of HIV-1 protein gp120 to CD4 (Schust et al. 2012).

Syphilis and other GUDs were among the first STIs to be linked to enhanced HIV-1 acquisition and transmission. The explanation was thought to be simple: the genital ulcers caused by these diseases provide a large portal of entry for HIV-1 with plenty of HIV-1 target cells immediately available (Karp et al. 2009). Later on, *T. pallidum* lipoproteins were shown to induce the expression of CCR5 on macrophages in syphilitic lesions and *T. pallidum* itself to increase HIV-1 viral load. The research focus eventually shifted to genital herpes due to its much higher prevalence worldwide.

TV is highly prevalent but was always thought to be a minor STI due to the lack of severe morbidity. However, it has received more attention in recent years due to accumulating epidemiological evidence of its enhancement of both HIV-1 acquisition and transmission (Kissinger and Adamski 2013). TV reduces the mechanical barrier to HIV-1 by causing punctuate mucosal hemorrhages (referred to as “strawberry cervix”) and by breaking down the cervical mucus. TV causes a proinflammatory response but has also been

shown to dampen innate immunity by decreasing secretory leukoprotease inhibitor (SLPI) and other genital innate immune factors. This may allow other genital pathogens to flourish. Perhaps related to this, TV often occurs together with bacterial vaginosis (BV). The two conditions may have synergistic effects on HIV transmission (see further).

Between 1995 and 2007, the results of six RCTs were reported examining the effect of improved management of the abovementioned curable STIs on HIV transmission (Hayes et al. 2010). Disappointingly, only one of these (the Mwanza trial) showed a statistically significant reduction in HIV incidence in the intervention communities. The potential reasons for this have been extensively debated in the literature and include differences in HIV epidemic phases in the study populations (an expanding epidemic in Mwanza and mature epidemics in the other study populations), differences in STI prevalence in the study populations (higher prevalence in Mwanza), the implementation of STI control activities in the control groups (at a minimum, standard STI control practices were allowed to continue), and perhaps the fact that other important genital coinfections (such as viral STIs, BV, and candidiasis) were not included in the interventions. Smaller studies that evaluated the effect of various STI treatments on genital HIV-1 viral load did generally show a reduction in genital viral load after treatment.

Cervicovaginal, Penile, and Oral Microbiota

A healthy cervicovaginal microbiome consists predominantly of lactobacilli, which are thought to restrict growth of pathogenic bacteria and yeasts by keeping the vaginal pH low and by other mechanisms. Several clinical conditions associated with an imbalanced cervicovaginal microbiome have been described, including BV, vaginal candidiasis, and more recently “aerobic vaginitis.” BV has traditionally been associated with anaerobic bacteria, candidiasis with *Candida* yeasts, and aerobic vaginitis with aerobic bacteria, such as streptococci and *Escherichia coli*.

In the last 20 years, several prospective cohort studies have shown significant associations between BV (diagnosed by microscopy) and subsequent HIV acquisition in women. A meta-analysis of individual participant data of 13 African prospective cohort studies showed that intermediate vaginal microbiota (Nugent score 4–6) and BV (Nugent score 7–10) were each associated with HIV acquisition in multivariable models (adjusted hazard ratios of 1.54 and 1.69, respectively) (Low et al. 2011). In addition, four studies have shown a positive association between vaginal candidiasis and HIV acquisition, with adjusted relative risks ranging from 1.8 to 3.3 (reviewed in 19). Taken together, current evidence suggests that any deviation from a normal lactobacilli-dominated vaginal microbiome increases women's susceptibility to HIV. Similarly, studies have shown an association between BV and genital HIV-1 RNA levels, which declined after successful BV treatment (Wang et al. 2001).

In the last decade, new molecular techniques that can characterize the composition of the vaginal microbiome in much more detail (such as next-generation sequencing and DNA microarrays) have become accessible. Published data so far mostly report on smaller, exploratory studies of the cervicovaginal microbiome, but data are accumulating fast. They are showing that the bacterial communities in the vagina are more complex and less stable over time than previously thought. Pioneering work with asymptomatic women of reproductive age in the USA identified five microbiome clusters: four clusters were dominated by *Lactobacillus iners*, *L. crispatus*, *L. gasseri*, and *L. jensenii*, respectively, and the fifth cluster by other BV-associated anaerobic bacteria (Ravel et al. 2011). African studies are finding fewer women with *L. crispatus*-, *L. gasseri*-, or *L. jensenii*-dominated microbiota and more women with *L. iners* or mixed anaerobes. Studies in women with BV worldwide identified multiple BV-associated clusters that were dominated by anaerobic bacteria other than lactobacilli but never a single taxon. No clear patterns have emerged yet. A recent study showed that African sex workers with *L. crispatus*-dominated microbiota were

significantly less likely to be infected with HIV-1, HSV-2, any HPV type, or bacterial/protozoal STIs than women with other types of microbiota, including microbiota dominated by *L. iners*. Furthermore, women with *L. crispatus*- or *L. iners*-dominated microbiota who were already HIV infected were less likely to have detectable HIV-1 RNA levels in their genital tract than women with BV-associated microbiota, even after adjusting for CD4 count. In both cases statistically significant trends were found: the prevalence of STIs or detectable HIV-1 RNA increased with increasing total bacterial load and microbiota biodiversity. Other studies have found that certain types of BV-associated bacteria in particular can have a profound impact on HIV-1 expression in the genital tract.

It has been hypothesized that the effects of vaginal bacterial communities on HIV-1 transmission are due to differences in lactic acid production and vaginal acidity, the production of antimicrobial compounds (such as H₂O₂ and antimicrobial peptides), the production of enzymes (such as sialidases, proteases, and glycosidases) that break down mucins and innate antimicrobial factors, and the extent to which a proinflammatory vaginal environment is induced (potentially resulting in direct damage to the vaginal mucosa and recruitment of HIV-1 target cells) (Mirmonsef et al. 2012). Recently, it has been shown that the bacterial species associated with BV can produce small-chain fatty acids (SCFA; such as butyric acid) that stimulate inflammatory cascades and cell migration and inhibit innate immunity. SCFAs have also been shown to reactivate latent integrated HIV-1 DNA. The wide-ranging effects of individual SCFAs remain to be elucidated.

Studies have also begun to characterize the penile microbiome. The direct influence of the penile microbiome on HIV-1 acquisition in and transmission by men has not yet been determined, but a pioneering study showed that male circumcision reduced the total bacterial load and microbiota biodiversity of the coronal sulcus (Liu et al. 2013). In particular, 12 anaerobic bacterial taxa decreased significantly. Most of these are also frequently found in the microbiota of women with BV, although it should be noted that several

important BV-associated bacteria (such as *Gardnerella*, *Atopobium*, *Megasphaera*, and *Sneathia* species) were not significantly altered in the coronal sulcus by male circumcision. Lactobacilli were found in about a third of men regardless of circumcision status but in low abundance. Male circumcision reduces HIV-1 acquisition by about 60% and also reduces other viral STIs in men and STI transmission to their female partners. The authors hypothesize that the microbiota changes and accompanying reduction of HIV-1 target cells may contribute to the reduction of HIV-1 risk by male circumcision.

Changes of the oral microbiome seem to increase transmission risk during oral sex in a similar fashion as described above for the cervicovaginal microbiome and vaginal sex. The periodontal pathogenic bacteria *Porphyromonas gingivalis*, for example, increases CCR5 expression on oral keratinocytes, induces inflammation, and produces SCFAs (Pretorius et al. 2007). These effects are not generalizable to all oral bacteria.

Schistosoma and Other Helminths

Schistosoma and other helminths influence HIV-1 acquisition and transmission in multiple ways, with the clearest detrimental effects when the infection includes the urogenital tract (as is frequently the case with *Schistosoma haematobium* and sometimes with *S. mansoni*). Cross-sectional studies have shown a positive association between urogenital schistosomiasis and HIV-1 prevalence, but data on other helminth infections and HIV-1 are inconsistent, and longitudinal data are lacking (Webb et al. 2012). Helminths have coexisted with humans for a long time and cause minor pathology, but HIV-1 is a relatively new infection that has disrupted this stable parasitic relationship between helminths and hosts. Helminths induce a T-helper type 2 (Th2)-biased immune response, the extent of which depends on the phase of helminth infection. Regulatory T cells are induced that dampen generalized immune activation (thereby reducing the number of target cells for HIV-1), but most likely also dampen HIV-1-specific immune responses. On the one hand,

schistosomes have been shown to increase CCR5 coreceptor expression and to stimulate CD4+ T cells, which could facilitate HIV-1 entry and replication. On the other hand, competitive binding of helminth antigens to DC-SIGN receptors on dendritic cells in mucosal surfaces presumably hinders HIV-1 entry into these cells. Genital schistosomiasis clearly does increase risk of HIV-1 acquisition: it induces vascularization and granuloma formation around schistosoma eggs in the genital mucosa, thereby impairing the mucosal barrier and increasing the number of HIV-1 target cells. These effects have been shown to last for more than 12 months after successful treatment. HIV-1 transmission has also been shown to occur through lesions in the intestinal mucosa caused by gut-associated helminths.

No clear benefits of antihelminthic treatments on HIV-1 transmission (including mother-to-child transmission) have been shown thus far. In contrast to the hypothesized beneficial effects of all other coinfection treatments, the effects of deworming could be beneficial or detrimental. The gut is regarded as a major site of HIV-1 replication and studies have been done to determine the effect of deworming of HIV-positive patients on HIV-1 viral load. However, about half of the studies found no effect, and the other half were split between beneficial and detrimental effects. Therefore, no consensus has been reached about the potential usefulness of deworming as an HIV prevention tool.

Malaria and Tuberculosis

HIV-1, malaria, and tuberculosis are among the most important global health problems, and they overlap geographically. HIV-1 and malaria seem to interact bidirectionally and synergistically with each other (Alemu et al. 2013). HIV-1 infection and associated immune depression increase the malaria parasite burden, which facilitates malaria transmission. The malaria parasites, on the other hand, induce apoptosis of CD4+ and CD8+ cells during blood stage infection, but they also activate the remaining CD4+ cells; the net effect seems to be more efficient spread of HIV-1 among CD4+

cells and reduced cellular immunity. A systematic review of six studies showed an increase in HIV-1 viral load in acute malaria infection, which partially decreased after antimalaria treatment (Barnabas et al. 2011). In vitro, this enhancement was shown to be mediated by tumor necrosis factor-alpha (TNF- α), which can upregulate HIV-1 replication by acting directly on the HIV-1 long terminal repeat. In vitro studies have also shown mononuclear cell activation by malaria antigens through interferon gamma (IFN- γ), rendering these cells more susceptible to HIV-1 and reactivating integrated HIV-1 DNA.

Mycobacterium tuberculosis (and other pulmonary pathogens) can cause lung-specific expansions of CD4+ CCR5+ T lymphocytes that are highly susceptible to HIV-1, thereby increasing the possibility of HIV-1 transmission via the lower respiratory tract mucosa (Santucci et al. 2004). However, HIV-1 transmissions across the pulmonary tract are exceedingly rare. A systematic review of 19 studies showed that active tuberculosis is associated with an increase in plasma HIV-1 viral load, but tuberculosis treatment did not reduce the viral load (Barnabas et al. 2011). Others have linked *M. tuberculosis* infection with HIV-1 reactivation from latency (and vice versa), thereby increasing onward HIV-1 transmission risk.

Conclusions

Most of the coinfections described in this entry cause significant morbidity and mortality in their own right and deserve to be targeted in public health programs. While this is generally the case for malaria and tuberculosis, STI control is often neglected and has not been successful. While individual RCTs to date have not consistently shown that STI control reduced HIV transmission, the basic concept that STIs increase HIV-1 transmission remains strong and has only strengthened over time. The HIV prevention field is currently moving toward comprehensive HIV prevention approaches to reduce transmission (Vermund and Hayes 2013). While most of the proposed programs to date call for STI control as one of the components, it is not clear which interventions are

likely to have the biggest impact in specific populations and whether screening and treatment of other coinfections (such as genital schistosomiasis and altered mucosal microbiota) should also be included. Furthermore, some of the interventions that are likely to have the biggest impacts are still in development (e.g., HSV-2 and 9-valent HPV vaccines and pre- or probiotics to achieve and maintain a *L. crispatus*-dominated cervicovaginal microbiome). Finally, new approaches to STI screening (rapid point-of-care diagnostic tests, self-sampling, and testing strategies), and improved routine STI surveillance, are also needed. Our understanding of the role of coinfections in HIV-1 transmission is still improving, and this will hopefully eventually result in better tools and better prevention programs.

Role of Antibodies in HIV Transmission

Keshet Ronen, Caitlin Milligan and Julie Overbaugh
Fred Hutchinson Cancer Research Center, Seattle, WA, USA

Definition

An antibody is a soluble protein that recognizes and binds a specific target, known as its antigen. The region of an antigen bound by an antibody is

known as an epitope. Antibodies are produced and secreted by B cells (► [HIV & SIV, B Cell Responses to](#)) following exposure to their cognate antigens in the presence of appropriate activating signals. Antibodies are members of the immunoglobulin protein superfamily and are made up of four subunits – two heavy chains and two light chains – that come together to form a Y-shaped protein with two functionally distinct regions on opposite ends of the molecule. On one end, the two-headed variable region (the Fab fragment) mediates interaction with the antigen and varies enormously in sequence between antibodies with different antigen specificities. On the other end, the constant region (the Fc fragment) mediates recruitment of other components of the immune system, including innate immune cells and complement. The Fc portion can be one of five main forms, which determine the antibody's isotype (IgA, IgD, IgE, IgG, or IgM). Different isotypes have different binding partners and thus mediate different effector functions. Isotypes also differ in their tissue distributions, as a result of differences in diffusion rates and isotype-specific active transport.

Introduction

Antibodies are key effectors of humoral immunity against pathogens, helping to block transmission, control spread in the body, or clear infection. Following infection, a repertoire of pathogen-specific antibodies of numerous specificities and multiple isotypes is generated. These antibodies bind extracellular pathogens and infected cells, targeting them for destruction. The mechanisms by which this destruction is achieved vary depending on the antibody isotype and epitope and can be divided into two main types: neutralization and non-neutralizing functions. Antibodies that bind extracellular pathogens, and in so doing, sterically block infection, are referred to as neutralizing antibodies. In addition to neutralization, which relies solely on binding of a structurally relevant region of the pathogen to the antibody's variable region, antibodies with bound antigen can mediate other effector

functions by recruiting various cells or molecules through their Fc portion. Antibodies that act through Fc-mediated functions can target infected host cells as well as free pathogens. For example, IgM and some IgG antibodies fix complement, leading to the formation of cytolytic pores by the membrane attack complex. A number of innate immune cells can also be recruited to antibody-antigen complexes, either through fixed complement or through direct interaction of cellular receptors (Fc γ receptors) with the Fc portion of antigen-bound IgG. Upon interaction of their Fc γ receptors (Fc γ Rs) with an antibody-antigen complex, macrophages, neutrophils, dendritic cells, and mast cells phagocytose the coated antigen (by a process known as antibody-dependent cellular phagocytosis, ADCP). Fc γ R engagement on NK cells, macrophages, neutrophils, and eosinophils also results in the release of cytotoxic granules that induce death of antibody-coated infected cells (by antibody-dependent cellular cytotoxicity, ADCC). Fc γ R-bearing cells can also release pro-inflammatory cytokines upon receptor engagement, potentiating other arms of the immune response.

Which of these antibody functions are most important in infection control varies between pathogens, and several mechanisms are likely to play in any given infection. This entry focuses on the roles of antibodies in preventing transmission of HIV. Investigation of these roles is critical to characterizing the immune responses that provide protection from HIV and designing a prophylactic vaccine that elicits such responses.

Most antibodies developed in response to HIV infection target the envelope glycoprotein (Env). Env is expressed on the surface of infected cells during viral budding and is present on the virus particle that is released (cell-free virus), where it facilitates viral entry (► [Life Cycle Overview](#)). Though the antibodies generated in HIV infection mediate a number of effector functions that impact viral replication (described below), they are not able to clear infection. This is largely due to HIV's extremely high rate of evolution and consequent immune evasion (Immune Evasion by HIV). Within a single individual, the virus readily mutates in response to antibody pressure,

generating escape variants resistant to antibody recognition and binding. While escape is sometimes the result of a change within the target epitope, it is also often due to acquisition of additional glycans and conformational changes that shield conserved epitopes. These escape variants in turn elicit a new response – a process that leads to continued evolution of both HIV and the antibody response to it. Given the capacity of HIV to evolve away from immune pressure, the generation of antibodies that can recognize and protect against the vast diversity of HIV variants that an individual might be exposed to is an enormous challenge in vaccine development.

It is important to distinguish the role that antibodies play in established infection – where antibodies are elicited well after significant virus replication and amplification – from their potential role in blocking a new infection, where relatively few virus particles and/or infected cells must be blocked. A number of antibody functions could theoretically be important in blocking HIV transmission: cell-free virions could be bound by neutralizing antibodies that would prevent infection of target cells; infected cells expressing viral proteins could be bound by antibodies and recruit NK cells ([▶ NK cells responses to HIV](#)) to perform ADCC; and antibody-coated infected cells or free virions could recruit macrophages or neutrophils to perform ADCP. Experimentally, a number of different assays can be used to measure antibody inhibition of HIV, and the antibody functions measured vary depending on the assay. Assays may measure neutralization exclusively, ADCC exclusively, or overall antibody-dependent cell-mediated virus inhibition (ADCVI), which accounts for not only ADCC activity but also release of soluble antiviral factors (cytokines and chemokines) that inhibit viral spread. Many of these Fc-mediated functions are dependent upon antibody avidity, which measures the overall strength of the interaction between antibodies and their antigens. Avidity may therefore be an important surrogate measure for such activity (Robinson 2013).

Elucidating which antibody functions are most important in blocking HIV transmission can only be achieved by empirical investigation of the

antibody responses in various models of HIV exposure and protection. This entry will review current knowledge of the role of neutralizing and non-neutralizing antibody functions in preventing HIV transmission. Evidence will be discussed from several settings of transmission in which HIV-specific immune responses exist prior to viral exposure.

HIV-Specific Neutralizing Antibody Function

The expectation that neutralizing antibodies are important in protecting from HIV stems from the fact that almost all successful vaccines for other pathogens elicit strong neutralizing antibody responses. Indeed, HIV-infected individuals generate neutralizing antibody responses targeting Env that persist throughout infection. Although these neutralizing antibodies are not able to clear infection, there is evidence that they do exert a selective pressure on the virus (Overbaugh and Morris 2012). Plasma from an individual can neutralize the individual's own (autologous) viral strain *in vitro* starting as early as a few months after infection, but, as discussed, the virus readily mutates in response to the antibody. Broader responses capable of blocking *in vitro* infection by heterologous viral strains develop in 10–30% of individuals after 2–3 years of infection (Stamatatos 2012).

It has been hypothesized that if neutralizing antibody responses could be elicited by a prophylactic vaccine and be present at or within a few days of HIV exposure, infection could be prevented or halted before establishment of a latent reservoir or outgrowth of escape variants. Evidence from passive immunization studies of non-human primates ([▶ Models for HIV-1 transmission; non-human primates](#)) supports this hypothesis (Lifson and Haigwood 2012). Prophylactic administration of high concentrations of neutralizing antibodies (either human monoclonal antibodies or polyclonal IgG from infected humans or chimpanzees, referred to as HIVIG or CHIVIG, respectively) to nonhuman primates at the time of viral challenge or a few hours later

resulted in dose-dependent protection from infection. While these studies provided proof of concept for the ability of neutralizing antibodies to block HIV or SIV transmission, their interpretation is limited. Nonhuman primate models do not entirely mimic the natural history of human HIV infection, and experimental infections and passive immunizations do not fully replicate the characteristics of human HIV transmission – higher concentrations of antibody, less diverse viral stocks, and closer matching between the antibody specificity and the challenge virus are typically used in nonhuman primate experiments than observed in natural human infection.

A more clinically relevant understanding of the role of neutralizing antibodies in HIV transmission has been afforded by studies of humans naturally exposed to HIV. A number of studies have compared preexisting neutralizing antibody activity in individuals exposed to HIV in various settings who do or do not acquire infection. This section will review the conclusions drawn from such studies.

Mother-to-Child Transmission

Mother-to-child transmission (MTCT) (► [Prevention HIV-1 MTCT](#)) of HIV, which occurs in utero, during delivery, and via breastfeeding, provides one setting in which to study the role of preexisting HIV-specific antibodies in transmission. Maternal IgG crosses the placenta while the infant is in utero and provides protection against a variety of diseases. In HIV-infected mothers, HIV-specific antibodies are passed to their infants and may provide protection while in utero or during delivery. These passively acquired antibodies persist for many months and thus may also guard against infection during the breastfeeding period when infants are continually exposed to the virus. Breastfed infants receive additional HIV-specific IgA and IgG from maternal breast milk, which may coat the virus present in breast milk and thus protect from infection at infant mucosal surfaces.

Early studies showed that neutralizing antibodies exert a selective pressure on viral variants in MTCT. During MTCT, a bottleneck occurs in which only one or a few maternal virus variants

are transmitted to the infant. It has been shown that these infant viruses are generally more resistant to neutralization than their corresponding maternal variants and the most highly neutralization sensitive variants are typically not transmitted (reviewed in Overbaugh and Morris 2012). These findings suggest that variants that are able to escape the neutralizing antibody response are transmitted and support the idea that maternal antibodies may be at least partially protective.

However, when comparing infants who become infected to those who do not, the direct impact of maternal and infant neutralizing antibodies on MTCT is unclear (reviewed in Overbaugh and Morris 2012). A number of studies have suggested that mothers with higher neutralizing antibody activity are less likely to transmit than those with lower activity. Other studies, however, have only seen a protective effect during certain stages of pregnancy and infancy or not at all. Similarly, although studies specifically focused on infant passively acquired antibodies are limited, the largest study of this type observed no protective effect mediated by these antibodies (Lynch et al. 2011). The inconsistency in these results may be partially explained by differences in methodology, discussed below, but highlight the current debate in the field and need for more studies.

Similar to passive immunization studies in macaques, HIV-specific antibodies have been tested as preventative therapies for MTCT. In two different clinical trials, polyclonal HIVIG was administered to pregnant HIV-infected women and their infants at birth (Mofenson 2011). Similar infection rates were seen among infants who received HIVIG and control groups in both studies. However, all study participants were also given antiretrovirals, resulting in overall low infection rates, which may have limited ability to detect an additional protective effect of HIVIG. In addition, HIVIG has only moderate neutralization activity against diverse HIV viruses, whereas some more recently identified broadly neutralizing antibodies have been shown to neutralize the vast majority of circulating variants (Stamatatos 2012). It remains unknown whether these broadly neutralizing antibodies may provide additional

protection over that of antiretrovirals and could be used as a successful immunotherapy to prevent MTCT.

HIV-Infected Individuals Exposed to Superinfection

Another setting in which HIV exposure occurs in the presence of an immune response to HIV is in infected individuals who are continually exposed to the virus. These individuals are at risk of acquiring another HIV infection, a process referred to as superinfection. Superinfection has been reported at relatively high frequencies in cohorts of individuals at risk of transmission through sexual contact and intravenous drug use (reviewed in Waters and Smit 2012). Comparison of the immune responses of individuals who acquire superinfection with those who do not despite continued exposure has offered insight into whether a strong neutralizing antibody response protects from infection. Three studies have compared plasma neutralizing activity of superinfected individuals prior to superinfection to that of singly infected individuals at a matched time after initial infection (Smith et al. 2006; Blish et al. 2008; Basu et al. 2012). The findings differed, with two studies reporting weaker neutralizing antibody responses in superinfected individuals, while the other reported no difference. Similar to MTCT studies, these conflicting results in the setting of superinfection may be due to experimental differences, outlined below. Thus, the ability of neutralizing antibody responses to protect from superinfection remains unclear and additional studies are needed.

Highly Exposed, Persistently Seronegative Individuals

Another setting that indicates a potential role for neutralizing antibodies is individuals who remain HIV negative despite repeated exposure to the virus (highly exposed, persistently seronegative). A number of studies have shown that individuals with repeated HIV-1 exposure more frequently develop mucosal HIV-specific neutralizing IgA than controls (reviewed in Hirbod and Broliden 2007). This association has been shown in

multiple populations, including serodiscordant couples and female sex workers, and suggests a potential protective effect of mucosal neutralizing IgA antibodies. At this time, however, these intriguing results are still somewhat controversial as there is limited precedent for the development of pathogen-specific antibodies in the absence of infection.

HIV Vaccine Trials

Data from human vaccine trials have yet to show support for a role for neutralizing antibodies in preventing transmission. While most vaccines that incorporate HIV Env have been shown to elicit neutralizing antibodies, these antibodies are often not very potent or effective against diverse HIV isolates (Mascola and Montefiori 2010). The elicited antibodies typically target variable regions of Env, rather than conserved epitopes that are the target of broadly neutralizing antibodies.

Of the phase IIb/III human vaccine trials to date, the RV144 trial, completed in 2009, is the only one to show a statistically significant decline in the rate of HIV infection among vaccinated recipients, and this effect was modest (~31%) (Rerks-Ngarm et al. 2009). In this trial of a canarypox vector prime and gp120 protein boost vaccine, HIV-specific neutralizing antibody levels were low and did not differ between vaccinated individuals who became infected and those who remained uninfected (Haynes et al. 2012). However, there was some evidence of a role for non-neutralizing antibodies, as discussed below.

HIV-Specific Non-neutralizing Antibody Function

In the last few years, there has been increased interest in non-neutralizing antibody functions in HIV infection. Most studies to date have focused on ADCC. Like neutralizing antibodies, antibodies capable of inducing ADCC have been detected in HIV-infected individuals. These antibodies arise earlier in infection than neutralizing antibodies, usually within days or weeks. Interest

in non-neutralizing antibody functions in HIV protection stems from the known role of such antibodies in protective vaccines against other pathogens, such as *Haemophilus influenza* and *Streptococcus pneumonia* (Robinson 2013). An important role for non-neutralizing antibody function in blocking HIV transmission is supported by evidence from passive antibody transfer and vaccine studies in nonhuman primates (Robinson 2013). In one passive transfer study (Hessell et al. 2007), a broadly neutralizing monoclonal antibody known to protect macaques from SHIV challenge was engineered to have reduced Fc γ R binding. Macaques given the form lacking Fc-mediated effector functions were more susceptible to infection than those given the original antibody, despite no difference in neutralizing activity between the two forms. Recent vaccine studies reporting partial protection of macaques from SIV acquisition have shown a correlation between the number of low-dose SIV challenges required for infection and the avidity, but not neutralizing activity, of the antibody response mounted (Lai et al. 2011; Barouch et al. 2012). These findings in nonhuman primates have promoted the idea that a protective HIV vaccine will need to elicit non-neutralizing antibodies, and prompted investigation of non-neutralizing functions in studies of HIV infection in humans. Evidence of non-neutralizing antibodies, predominantly ADCC, as correlates of protection in transmission settings is presented below.

Mother-to-Child Transmission

Limited data exist on the role of non-neutralizing antibodies in mother-to-child transmission. Early studies suggested no association between antibodies capable of mediating ADCC in mothers or their infants and risk of infant infection, though some did observe a correlation with delayed progression in infected infants, suggesting a protective effect of ADCC (reviewed in Farquhar and John-Stewart 2003; Huber and Trkola 2007). Additionally, in a recent study of breast milk-derived antibodies from HIV-infected mothers, ADCC was found to correlate with protection from infection (Mabuka et al. 2012). In this

small study, mothers who transmitted the virus to their infants had lower ADCC activity than those whose infants remained uninfected. This study was the first to examine the impact of HIV-specific ADCC activity in maternal breast milk and requires further follow-up to determine if the association is observed in larger cohorts and, if so, the mechanism of protection.

HIV Vaccine Trials

Perhaps some of the best evidence for non-neutralizing antibodies in protection comes from recent human vaccine trials. While the RV144 trial showed no evidence of protection due to neutralizing antibody activity, protection in vaccinated individuals correlated with binding of IgG antibodies to the V1V2 loop of HIV-1 Env and inversely correlated with Env-specific IgA (Haynes et al. 2012). The increased risk of infection seen with Env-specific monomeric IgA is thought to be due to IgA competing with IgG for binding rather than antibody-dependent enhancement of infection. Such competition limits non-neutralizing effector functions mediated by the Fc portion of IgG as the Fc portion of IgA is displayed instead. Indeed, in a secondary analysis of vaccinated individuals with low IgA, ADCC activity was correlated with reduced risk of infection, supporting the hypothesis that IgG binding to V1V2 mediated protection through non-neutralizing antibody function.

An additional level of support for non-neutralizing antibodies in protection is from one of the first large-scale HIV vaccine trials, Vax004. Although this vaccine was not efficacious, higher ADCVI activity and antibody avidity were associated with lower infection risk among vaccinated individuals (Forthal et al. 2007). The combination of results from RV144 and Vax004 suggests a role for Fc-mediated effector functions in protection. However, given that the Vax004 trial showed no vaccine efficacy and the associations observed in the RV144 trial were detected in a hypothesis generating study design (a design that does not account for multiple statistical comparisons), these findings represent promising leads for future studies, rather than definitive correlates.

The Contribution of Methodological Differences to Study Findings

The role neutralizing and non-neutralizing antibodies play in protection from HIV infection remains unclear, despite years of study. This is in part because the results of studies in exposed human populations have often been conflicting, as highlighted above. A number of technical differences may contribute to such conflicting data and are important considerations when designing new studies and drawing conclusions from previous research.

First, differences in cohort and sample size may limit conclusions and comparisons across studies. For example, the three studies of neutralizing antibodies and superinfection were all relatively small (ranging from 3 to 12 superinfected individuals). With such small sample sizes, the power to detect any statistical significance is reduced.

Differences in the virus(es) against which antibody activity is assayed may also confound results and limit comparisons across studies. Older studies, including the studies of ADCC in MTCT discussed above, typically used lab-adapted viruses such as HIV III_B and RF. Newer work has revealed that these lab-adapted viruses do not mimic the majority of transmitted viruses, particularly with respect to co-receptor usage and epitope masking. Primary isolates, obtained directly from infected individuals rather than passaged in the lab, are now more commonly used. Additionally, while some studies test antibodies against autologous viruses, others quantify activity against a panel of heterologous variants. Both approaches provide valuable information, but differ in the questions they answer and their interpretations. For example, in studies of MTCT, infant antibody responses against heterologous viruses may not be relevant to the biological effect of these antibodies against autologous maternal virus. On the other hand, in settings of sexual exposure to diverse viruses, such as human vaccine studies and individuals at risk of superinfection, antibody activity against heterologous viruses will likely be a more relevant measure of protection. Furthermore, the degree of

sequence similarity between immunogens (the antigens that provoke immune responses) and challenge viruses in these contexts will influence interpretation of results and comparison across studies.

Another major consideration is the timing of sampling of the virus and/or antibody. As described above, the virus continually evolves to evade host immune responses. Thus, antibodies are often capable of neutralizing historical, but not contemporaneous, variants. This detail is important when measuring antibody responses against autologous virus – matching sampling time points of viruses and antibodies is important to obtain a complete, relevant picture of the humoral response at the time of transmission or protection. Similarly, timing of virus exposure relative to the development of the antibody response may influence results. For example, it is difficult to compare studies of individuals superinfected very early after initial infection when the neutralizing response has not yet fully developed with studies of individuals superinfected late; or likewise infants infected early after birth when passively transferred antibodies circulate at high concentrations with those infected later in life when they have begun to decay.

Conclusion

Antibodies are central components of the immune response to HIV and will likely be essential in a protective vaccine-induced response. A key question in the HIV antibody field has therefore been what antibody specificity and effector functions correlate with protection from infection. The studies described in this entry suggest that both neutralizing and non-neutralizing antibodies have the potential to provide protection, but which responses do so in natural transmission remains unclear.

More studies are needed to continue to characterize all antibody-mediated effector functions in HIV transmission and their potential role in protection. For example, the roles of antibodies that mediate phagocytosis, complement fixing, and viral trapping in mucus need to be clarified.

Some preliminary studies have reported that these functions are associated with reduction in viral load, which would reduce infectiousness and thus may help prevent transmission, but the direct impact of preexisting antibodies with these effector functions has not been determined. Another feature of the antibody response that is garnering greater attention is tissue distribution. The majority of HIV transmission events occur at mucosal surfaces (► [Mucosal Immunity](#) and ► [Infection in the female genital](#); ► [transmission blocks to HIV-1](#)), but for technical reasons, studies to date have mostly focused on plasma samples. Consequently, local responses at the site of virus exposure might not have been adequately assessed. Finally, the lack of protective effect seen in the majority of vaccine studies to date may be due to inadequate stimulation of the antibody response by the immunogens used. Research is therefore needed to determine how immunogens can be designed to generate high-titer, long-lived responses that mediate protection against transmitted variants (► [HIV-1 Transmission blocking vaccines; how feasible are they?](#), ► [HIV-1 transmission blocking vaccines; new designed immunogens](#)). The studies presented in this entry and future research into other antibody effector functions and their elicitation will help us understand how to harness the humoral immune response to ultimately prevent HIV infection.

Definition

Dendritic cells (DC) are fundamental components of the response to infection, and it has become clear that these cells play a key role in HIV/AIDS pathogenesis.

This chapter focuses on how DC may contribute to the immunopathogenesis of HIV-2 infection, a relatively “benign” form of HIV/AIDS. The current situation regarding the global HIV epidemic will be addressed first, along with a brief review of the known differences and similarities between HIV-1 and HIV-2 disease. Then, the role of various DC subsets that may functionally contribute to these differences will be discussed.

HIV: The Current Situation

The human immunodeficiency virus (HIV) pandemic still represents one of the major healthcare problems to be faced in the twenty-first century. Approximately 33 million people are estimated to be living with HIV infection, with the latest

reported figure for AIDS deaths of 1.8 million (www.unaids.org/globalreport), with African countries bearing an inordinate share of the burden. The introduction of effective antiretroviral therapy (ART), the development of drug provision, and worldwide health education programs, although bringing marked benefits, are still unable to significantly reduce viral transmission and, thus, control the rate of new infections (2.6 million in 2009 as compared to 3 million in 2001) and HIV prevalence (remaining approximately 0.8% among adults).

Achieving a “functional cure” relies on a better understanding of HIV/AIDS pathogenesis. As HIV-2 infection can be viewed as a naturally occurring attenuated form of HIV/AIDS, it offers a unique opportunity to reveal important clues regarding the determinants of a protective host response to HIV (Grossman et al. 2002).

HIV-1 and HIV-2

HIV is a member of the *Lentivirus* genus, belonging to the *Retroviridae* family of viruses, all of which feature single-stranded ribonucleic acid (ssRNA) as their genetic material. There are currently two viruses associated with HIV infection: HIV-1, discovered in 1983, is the one responsible for the pandemic, while HIV-2 (► [HIV2: Identification of the second AIDS virus, a historical perspective](#)), isolated in 1986, is associated with geographically confined epidemics, mainly in West Africa (► [The epidemiology of HIV-2 infection in West Africa](#)), but also in India and in Europe (► [Epidemiology of HIV-2 infection in Europe](#)), particularly in Portugal, due to the latter connections with its African ex-colonies (de Silva et al. 2008).

The overall gross structure (► [HIV-2: viral structure, sequence variation and pathogenesis](#)) of the viruses is very similar (Reeves and Doms 2002). A protein core, constructed from the viral capsid protein, encapsulates two copies of the unspliced ssRNA genome, which is stabilized as a ribonucleoprotein complex with the virally encoded nucleocapsid protein. In addition to the diploid viral genome (► [Molecular biology of](#)

Russell B. Foxall and Rita Tendeiro contributed equally to this work

HIV-2), the capsid contains six virally encoded molecules: the enzymes protease, reverse transcriptase and integrase, and the accessory proteins Nef, Vif, and Vpr/Vpx (HIV-1 and HIV-2 specific, respectively). The protein core is surrounded by a host-cell-derived lipid bilayer, or envelope (► [The HIV-2 envelope: structure, diversity and evolution](#)). This envelope is characteristically modified by the insertion of two viral glycoproteins which heterodimerize and subsequently associate to form trimeric complexes, sometimes referred to as “spikes,” which extend beyond the envelope’s surface and mediate virus-cell interactions.

HIV-2 Infection: Why Is It Less Severe?

It is well-documented that HIV-2 infection results in a markedly different disease course (► [Natural history and clinical features of HIV-2 infection](#)), with limited impact on the mortality of the majority of infected adults (de Silva et al. 2008). Two main features set HIV-2 apart from HIV-1 infection. The first one is the much slower rate at which CD4+ T-cell depletion, the hallmark of HIV/AIDS, occurs; the second is the typically undetectable to low levels of circulating virus (► [HIV-2 diagnosis and viral load measurements](#)) (plasma viremia) that are observed throughout disease in the majority of infected patients (Table 1).

At first sight, such differences could suggest an impaired ability of HIV-2 to replicate (► [HIV-2: viral replication](#)) and/or destroy its primary

cellular target, the CD4+ T cell. However, both HIV-2 and HIV-1 have been shown to have comparable in vitro replication and cytopathicity (Sousa et al. 2002).

Assuming that HIV-2 can replicate and destroy cells at similar levels as HIV-1, what other factors could then account for the distinct rates of disease progression?

One straightforward explanation would be that the immune response to HIV-2 infection (► [The antibody response to HIV-2](#) and ► [The cellular immune response to HIV-2 infection](#)) is in some way more effective. Thus, in HIV-2-infected individuals, the overall immune response may be somehow more appropriate, and, possibly, more sustainable (de Silva et al. 2008). DC likely play a role in these processes.

Natural History of HIV-2 Infection

In order to understand the potential role of DC in HIV-2 disease, it is first necessary to discuss the natural history of HIV infection. Whether resulting from HIV-1 or HIV-2 transmission, the ensuing infection is typically subdivided into three phases: an acute period, associated with the dissemination of the virus and establishment of the infection, followed by a chronic phase that ultimately results in the collapse of the infected individual’s immune system, and the consequent development of acquired immune deficiency syndrome (AIDS) and death (Fig. 1).

There is a great deal of interest in the events that occur in the hours and days following HIV exposure, particularly in the context of the genital mucosa, given the relevance of heterosexual transmission to the pandemic. Resident DC in the tissues have been shown to capture HIV and transport the virus to regional lymph nodes contributing to both the dissemination of the infection and promotion of the initial, HIV-specific T-cell response (Wu and KewalRamani 2006). It is possible that disparities between HIV-1 and HIV-2 infection in terms of dissemination of the virus and establishment of infection could play a role in determining the different rates of subsequent disease progression. Acute HIV-1 infection may be

Role of Dendritic Cells in HIV-2 Pathogenesis,

Table 1 Comparison of disease parameters of HIV-1 and HIV-2 infection

	HIV-1	HIV-2
Rate of CD4+ T-cell decline ^a	−49 cells/μl per year	−9 cells/μl per year
Time to AIDS (years)	≤ 10	≥ 20
Viremia (HIV RNA copies/ml)	10 ⁴ –10 ⁶	Undetectable to 10 ⁴
Transmission	Common	Rare
Geographical distribution	Global	Restricted (West Africa)

^aDrylewicz et al. 2008

Role of Dendritic Cells in HIV-2 Pathogenesis,

Fig. 1 Natural history of HIV-2 and HIV-1 infection

associated with flu-like symptoms. There are no clinical reports of HIV-2-associated "acute-phase syndrome." Thus, it would appear that this initial disease phase is asymptomatic in HIV-2-infected individuals. It is also possible that this apparent lack of an "acute-phase syndrome" is indicative of differences in the establishment of infection and/or the subsequent degree of virus dissemination.

Chronic/asymptomatic HIV infection is characterized by a gradual increase in plasma viral load and concomitant decrease in CD4+ T cells over time. Importantly, despite the lack of major clinical manifestations, this disease stage is characterized by a progressive immune dysregulation. As previously mentioned, the rate of CD4+ T-cell loss is much slower in HIV-2- than HIV-1-infected individuals, typically resulting in this phase lasting more than 20 years in HIV-2+ patients (Drylewicz et al. 2008). Nevertheless, when HIV-1- and HIV-2-infected individuals are matched for the degree of CD4+ T-cell depletion, they feature similar levels of immune activation (► [HIV-2 infection: the role of immune activation in pathogenesis](#)), a well-established hallmark of HIV disease which has been shown to better

correlate with disease progression than plasma viral load (Sousa et al. 2002). Although, a progressive increase in viremia also occurs during the chronic phase in HIV-2-infected individuals, it is typically low throughout the disease. Notably, more than half of the patients reaching the AIDS phase have undetectable plasma viral load (Drylewicz et al. 2008).

The clinical spectrum (► [Natural history and clinical features of HIV-2 infection](#)) of the AIDS stage is similar in both infections. Notably, immunological recovery upon antiretroviral therapy (ART) (► [Immunological response to ART](#)) is usually poorer in HIV-2 than in HIV-1-infected patients (Drylewicz et al. 2008), which may explain some reports of worse outcomes of opportunistic infections during HIV-2 infection. Hence, although HIV-2-infected individuals with low CD4+ T-cell numbers may remain asymptomatic for long periods, when opportunistic infections develop their prognosis is frequently poor (de Silva et al. 2008). Thus, there is no reason to believe, once this final stage of disease has been reached, that DC, like many other cells of the immune system, are not severely impaired in their ability to function normally.

Dendritic Cells: A Brief Overview

Dendritic cells (DC) constitute a large and heterogeneous leukocyte population, of differing origins and functional abilities. They are considered the main orchestrators of the immune system. Briefly, they serve a dual purpose. Firstly, as part of the innate immune system (Innate immunity in HIV-2 infection), they respond directly to pathogens by producing a variety of pro-inflammatory effector molecules, such as cytokines, interferons (IFN), and chemokines, which can, in turn, enhance the function of other innate immune cells, such as natural killer cells (► [Natural killer cells and innate immunity in HIV-2 infection](#)). Secondly, they provide a vital link between innate and adaptive immunity, through their induction of T-cell responses and modulation of their quality. Both of these functions result, in part, from the ability of DC to recognize molecular patterns which are common to a variety of pathogens.

It is possible to distinguish several DC subpopulations, based on a combination of localization, migratory properties, molecular markers, and functional abilities. This chapter will focus on two main subsets found in humans that have been implicated in HIV infection: myeloid (Piguet

and Steinman 2007) and plasmacytoid DC (Fitzgerald-Bocarsly and Jacobs 2010).

Myeloid DC (mDC)

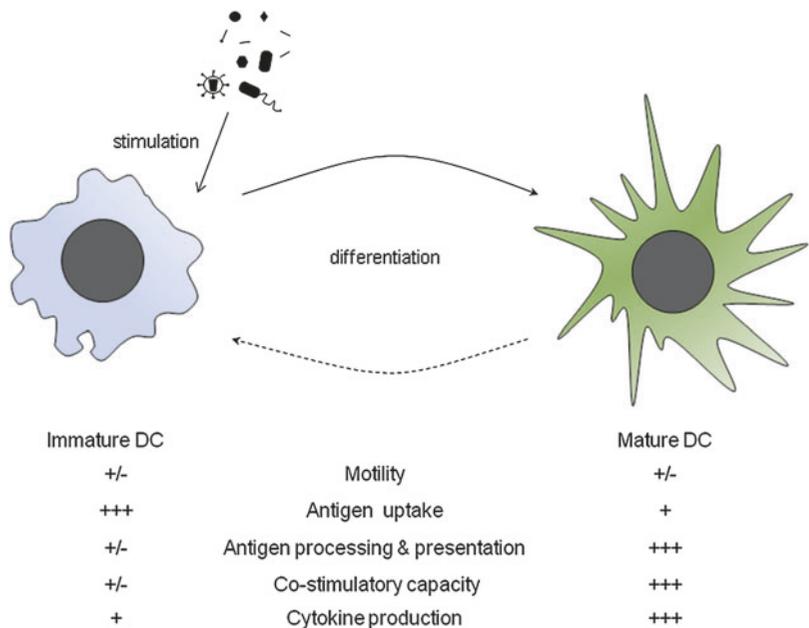

mDC are thought to be mainly produced in the bone marrow but can also result from differentiation of monocytes. A population of mDC can be found in the peripheral blood and has been the main target of investigation in HIV/AIDS (Piguet and Steinman 2007). These cells, also referred to as “conventional DC,” represent “professional” antigen-presenting cells (APC) and are characterized by their ability to recognize foreign pathogens and ingest, process, and subsequently present peptides to cells of the adaptive immune system.

Tissue-resident mDC, located in all body tissues, constitute “peripheral sentinels,” which are able to survey their environment for the presence of foreign molecules. Upon interaction with such molecules, these immature DC become activated and engage a coordinated program of differentiation (Fig. 2).

These functional and phenotypic alterations ultimately allow them to efficiently home, via the afferent lymphatics, to the draining lymph nodes. There they serve as APC, presenting

Role of Dendritic Cells in HIV-2 Pathogenesis,

Fig. 2 Schematic overview of myeloid dendritic cell maturation

antigens sampled in the tissues to T cells circulating through the lymphoid tissues. Within the secondary lymphoid organs, mDC are also thought to contribute to the homeostasis of lymphocyte subsets.

Plasmacytoid DC (pDC)

These cells are thought to be of lymphoid origin, although there may be some degree of developmental plasticity. They are mainly restricted to peripheral blood and lymph nodes but can, nevertheless, be recruited to sites of inflammation. pDC are the major producers of type I interferons (IFN), a family of proteins with multiple antiviral functions. This is considered their primary function in response to pathogen exposure. Nevertheless, they can also serve as APC, although at a lower efficiency than mDC.

Orchestrating DC Activation Through HIV Pattern Recognition

Despite the fairly specialized function of each DC subset, it is important to note that some degree of functional overlap exists between mDC and pDC. Thus, while the former can produce a range of pro-inflammatory mediators, on exposure to pathogens, the latter are able to differentiate into APC, albeit less efficient ones than those differentiated from their mDC counterparts, upon receiving the appropriate signals. Of note, the regulation of the immune function also depends on the flexibility with which each cell responds to distinct stimuli and on the interaction between DC subsets.

DC, like other cells, expresses a specialized, but heterogeneous, group of receptors, referred to as pattern-recognition receptors (PRR). These germ-line encoded receptors are able to recognize structurally repetitive elements associated with a variety of pathogens, the so-called pathogen-associated molecular patterns (PAMP). PAMP are associated with either genomic and/or structural elements of a pathogen, which can be recognized by PRR expressed on the surface and/or in the cytosol of DC.

Surface-expressed PRR include members of the toll-like receptor (TLR) and C-type lectin receptor (CLR) families. The latter consist of membrane-associated receptors able to bind to

carbohydrates/sugars, such as dendritic cell-specific intercellular adhesion molecule-3-grabbing non-integrin (DC-SIGN). Both virally encoded glycoproteins, gp120 in HIV-1 and gp105 in HIV-2, that extend beyond the surface of the viral envelope (► [The HIV-2 envelope: structure, diversity and evolution](#)) and attach to the viral receptor CD4 and chemokine co-receptors, are able to bind a variety of CLR, particularly DC-SIGN (Reeves and Doms 2002). Thus, the fact that both pDC and mDC express DC-SIGN is of critical importance for their contribution to HIV-2 as well as HIV-1 immunopathogenesis.

Some TLR family members, such as TLR3, TLR7, and TLR9, are located within the endosomal compartment of DC, whereas cytosolic PRR include the nucleotide-binding oligomerization domain (NOD)-like receptor (NLR) and retinoic acid-inducible gene-I (RIG-I)-like receptor (RLRs) families. Of note, TLR expression patterns are distinct and complementary in the two aforementioned DC subsets. pDC selectively express TLR7 and 9, which recognize single-strand RNA molecules and un-methylated DNA, respectively (Fitzgerald-Bocarsly and Jacobs 2010). mDC, on the other hand, preferentially express TLR1-6 and TLR8, a characteristic that allows them to recognize distinct stimuli (Piguet and Steinman 2007). Additionally, both subsets express members of the CLR family, as well as a various members of the cytosolic nucleic acid-sensing PRR.

When HIV interacts with a cell, it can engage a variety of PRR. Which particular receptors are involved and the eventual outcome are determined partly by the subcellular localization this interaction occurs in, and by the cell-type involved. Both HIV-1 and HIV-2 genomes consist of ssRNA, which can bind directly to TLR7. This has a particular bearing on determining the virus' interaction with pDC (Fitzgerald-Bocarsly and Jacobs 2010).

It is important to note that neither interactions between HIV-derived PAMP and endosomal TLR nor CLR require viral replication. However, should productive infection of either of these DC subsets occur, then the replication intermediates

and/or end products would themselves be able to activate various cytosolic PRR resulting in the activation and subsequent maturation of these cells.

HIV-2 Infection of mDC and pDC

Several reports indicate that both DC subsets express CD4 (► [CD4, Receptors](#)), the primary receptor utilized by HIV-1 and HIV-2, together with various members of the chemokine receptor family (► [CXCR4, Co-receptors](#) and CCR5) that serve as co-receptors for these viruses, and thus, should be potential targets for infection (Wu and KewalRamani 2006).

In the case of HIV-1, both ex vivo-isolated pDC and mDC have been shown to be able to be infected with lab-adapted viral strains. However, HIV-1 replication is generally markedly less productive in DC as compared to that in CD4+ T cells (Wu and KewalRamani 2006).

There is only very limited data regarding the ability of HIV-2 to infect and replicate in mDC and pDC. Peripheral blood mDC and pDC have been shown to be less susceptible to ex vivo infection with HIV-2 than HIV-1, independently of whether lab-adapted strains or viruses isolated from HIV-2 infected individuals were used (Duvall et al. 2007). Others have shown that HIV-2 could infect, replicate, and subsequently produce virions in monocyte-derived DC in vitro, the commonly used in vitro model of mDC, although with kinetics distinct from HIV-1 (Marchant et al. 2006).

Does Vpx Make a Difference?

A large amount of effort has been made to understand the reduced ability of HIV-1 to replicate in pDC, mDC, and other myeloid cells such as monocytes and macrophages (► [Macrophages in HIV immunopathogenesis](#)). It has been recently proposed that the restriction of HIV-1 replication in these cells is due to SAM- and HD-domain-containing protein 1 (SAMHD1) (Laguette et al. 2011). Intriguingly, this molecule is targeted by Vpx, a protein only encoded by HIV-2 and a

subset of simian immunodeficiency viruses (SIV), but not HIV-1 (Reeves and Doms 2002).

Thus, HIV-2 should be able to circumvent the SAMHD1-imposed restriction to viral replication (► [Interactions between HIV-2 and host restriction factors](#)) in DC via the action of Vpx. However, it is possible that other HIV-2 accessory proteins are unable to fully antagonize additional pathways that are likely activated upon viral infection and limit HIV-2 replication in DC, resulting in the failure to produce infectious virus. This does not rule out the possibility that HIV-2 remains able to establish a pool of latently infected DC.

On the other hand, it has been suggested that the putative Vpx-mediated increase in permissiveness of myeloid cells to HIV-2 infection may result in an augmented DC processing and presentation of HIV-2 antigens and, in this way, promote the induction of HIV-2-specific T-cell responses.

mDC in HIV-2 Infection: Contribution to Viral Dissemination and Promotion of Specific T-Cell Responses

The ability of HIV to be taken up by mDC allows the virus to exploit their migratory potential and, thus, use them as “Trojan horses,” allowing delivery of the virus to the draining lymph nodes (Wu and KewalRamani 2006). Once there, it can be transmitted to CD4+ T cells via a process called “trans-infection,” consequently establishing the lymph node as the main site of viral production.

Initial in vivo and in vitro studies suggested that intraepithelial and submucosal mDC were among the first cellular targets of HIV/SIV after intravaginal infection. Although, more recently, CD4+ T cells have been suggested to be the initial HIV targets, mDC are still thought to play an important role in the amplification of viral replication and subsequent viral dissemination to lymphoid tissues. Thus, it is generally accepted that mDC play a crucial role in sexual HIV transmission (► [HIV-2 transmission](#)). It is likely that these mechanisms also underlie HIV-2 infection, although there are no studies formally addressing this.

HIV capture by mDC may be mediated by several receptors, of which DC-SIGN is the best studied. This molecule has been shown to be equally capable of interacting with HIV-2 and HIV-1, suggesting that both viruses are similarly disseminated by and/or transferred to susceptible T cells (Reeves and Doms 2002). In agreement, both viruses preferentially infect HIV-specific CD4⁺ T cells, a subset known to be particularly vulnerable to DC-mediated trans-infection, despite mDC's limited ability to transfer HIV-2 to autologous CD4⁺ T cells (Duvall et al. 2007). Moreover, the total number of infected T cells has been shown to be similar in HIV-2- and HIV-1-infected patients, in spite of the low-to-undetectable HIV-2 viremia, suggesting that cell-to-cell transmission may play a significant role in HIV-2 infection. This process occurs when a CD4⁺ T cell encounters an HIV-loaded mDC. The virus is recruited to the site of cell interaction, together with CD4 on the T cell, and this strong cell adhesion facilitates HIV infection. This "infectious synapse" may be particularly critical in the establishment of HIV-2 reservoirs.

HIV-1 infection is associated with quantitative and qualitative alterations in mDC, which may contribute to the overall dysregulation of the immune system. A progressive decline in the number of peripheral blood mDC and increased differentiation/maturation are characteristic of HIV-1 infection and are linked to the generalized state of chronic immune activation (Piguet and Steinman 2007).

The limited data available suggest that mDC disturbances during HIV-2 infection mimic those observed in the context of HIV-1 disease. mDC depletion and increased activation during HIV-1 disease seem to be intimately related to the degree of CD4⁺ T-cell depletion and, more importantly, the increased levels of immune activation. As this parameter is known to be comparable in HIV-2+ and HIV-1+ individuals with the same degree of CD4⁺ T-cell depletion (Sousa et al. 2002), it is plausible that similar mDC disturbances are observed during HIV-2 infection, even though the kinetics involved may be much slower.

Of note, in contrast to what has been reported for HIV-1, HIV-2 envelope proteins per se do not

appear to enhance DC differentiation and maturation (Cavaleiro et al. 2009a). This may help restrain immune activation (► [Chronic immune activation](#)) in the context of HIV-2 infection and to a better maintenance of mDC function.

pDC in HIV-2 Infection: Low IFN- α Production In Vivo

pDC are depleted in the peripheral blood of HIV-2 infected patients to levels similar to those observed in HIV-1+ individuals (Cavaleiro et al. 2009b). This depletion occurs throughout infection and is likely associated with pDC homing to secondary lymph nodes, although impairments in their production and/or destruction by the virus are yet to be addressed. Moreover, the differentiation state of circulating pDC is remarkably similar in HIV-2 and HIV-1 infected individuals despite the differences in viremia. Importantly, a clear up-regulation of the inhibitory molecule, programmed death ligand 1 (PD-L1), also occurs on pDC in HIV-2 infection, which may play a role in restraining the rate of increase of immune activation. Activated pDC that have migrated to lymphoid tissues are known to be key modulators of immune responses. One of the implicated mechanisms involves tryptophan catabolism via induction of indoleamine 2, 3-dioxygenase (IDO). This has been linked with the generation of CD4⁺ regulatory T cells and, in this way, the suppression of immune responses. Notably, HIV-2+ patients feature a relative expansion of regulatory T cells (► [Regulatory T cells](#)) in the peripheral blood during disease progression similar to that found in HIV-1 (Foxall et al. 2011).

Importantly, IFN- α production, the hallmark of pDC function, is significantly different in HIV-2 and HIV-1 infection despite the aforementioned similarities regarding pDC depletion and differentiation state. It is known that the contribution of pDC to HIV-1 immunopathogenesis stems from their status as "natural interferon-producing cells" (Fitzgerald-Bocarsly and Jacobs 2010). This capacity results from two features that are unique to these cells: the presence of TLR7 and TLR9 in the endosomal compartment and the constitutive

expression of a key factor in the activation of the interferon (IFN) response, interferon response factor 7 (IRF7). Hence, upon endosomal TLR stimulation, pDC are able to quickly produce large amounts of type I IFN, inducing an antiviral program that impacts upon HIV replication. IFN are known to induce the expression of a range of genes, collectively termed interferon-stimulated genes (ISG), such as *MxA*, that target various phases of the HIV life-cycle.

HIV-1 infection is associated with chronic IFN- α production that likely contributes to immune activation. HIV-2-infected patients, in contrast with HIV-1-infected patients, feature no increase in the expression levels of *MxA*, a known interferon-inducible gene, providing evidence of a lower in vivo activation of pDC in the context of HIV-2 infection (Cavaleiro et al. 2009b). The lower levels of in vivo IFN- α production in HIV-2 infection may be beneficial, contributing to the slower rate of progression.

Why HIV-2 would be less able to induce an interferon response in pDC than HIV-1 remains unknown. Both viruses have ssRNA able to stimulate TLR7, and both can enter the endosomal pathway of these cells, via CLR- or CD4-mediated endocytosis. An intriguing possibility may be related to differences in viral accessory proteins. HIV-1 encodes Vpu that is known to target the ISG product tetherin, whereas HIV-2, lacking this gene, relies instead on Env to perform this function (Evans et al. 2010). HIV-1 Vpu and HIV-2 Env differ in their ability to target tetherin, which serves the dual function of inhibiting the release of enveloped viruses from the cell surface of infected cells and regulating the IFN-pathway via a negative-feedback mechanism. Thus, it is possible that the limited ability of HIV-2 Env to target tetherin may result in a preserved capacity to down-modulate the IFN-pathway and ultimately lead to its better preservation.

Chronic in vivo stimulation of pDC has been suggested to result in the induction of a refractory state, where these cells' ability to produce IFN- α upon in vitro stimulation with the appropriate ligands is severely impaired. In agreement with reduced in vivo IFN activity, pDC from HIV-2+

patients have a relatively preserved ability to produce IFN- α ex vivo. Nevertheless, this ability is impaired in patients with detectable viremia (Cavaleiro et al. 2009b). These data support the idea that viremia, even at the low levels observed in HIV-2-infected patients, has a major impact on pDC.

Conclusion

DC play a central role in HIV immunopathogenesis and could potentially contribute to the slower course of HIV-2 infection. The HIV-2 accessory protein, Vpx, has been shown to counteract an intrinsic host-factor receptor, SAMHD1, thus, possibly, facilitating DC infection and presentation of HIV-2 antigens. Despite the major imbalances in circulating pDC that were found in HIV-2+-infected patients, there is evidence of lack of significant increase in IFN- α production in chronic HIV-2 infection, contrasting with HIV-1 infection. Given the major role of IFN- α in the activation of several components of the immune system, it is possible that limiting its in vivo production may help slow the stepwise increase of immune hyperactivation that is linked to AIDS progression.

Overall, despite the potential importance of HIV-2 to the understanding of HIV immunopathogenesis, many areas of the immune response to this infection remain to be explored in detail. The understanding of the role of DC in this naturally occurring model of attenuated HIV infection may significantly aid in the identification of key pathways of the immune response to HIV that could, in turn, lead to the identification of novel therapeutic targets or help advance areas of existing research such as vaccine development.

Role of Histone Deacetylases 1 and Yin Yang 1 Protein in Proviral Latency

Bojana Lucic and Marina Lucic

Department of Infectious Diseases, Integrative Virology, University Hospital Heidelberg and German Centre for Infection Research, Heidelberg, Germany

Definition

HDAC1 is a member of the HDAC family of proteins, whereas YY1 is a ubiquitously expressed transcriptional factor with both repressive and activating functions. Cooperatively, these two proteins have been shown to repress transcription from the viral LTR promoter and have been proposed to contribute to the state of post-integration latency.

Introduction

After the integration into the host cell chromatin, the HIV-1 genome can be reversibly silenced through multiple mechanisms, establishing a state of post-integration latency. Although different posttranscriptional mechanisms participate in maintaining the latent state, it is usually a block at the transcriptional level that gives a major contribution to the establishment of latency (Lucic and Giacca 2014).

The establishment of latency, according to a now prevailing theory, foresees the infection of activated CD4⁺ T cells prior to their natural reversion to a quiescent memory state; this is also compatible with the finding that latent HIV-1 resides predominantly in the memory subset of resting CD4⁺ T cells (Siliciano and Greene 2011). During the reversion from an activated into a quiescent state, the availability of certain cellular factors becomes limited, and they can no longer bind to the viral long terminal repeat (LTR) promoter, while at the same time, transcriptional repressors present in the cell may have a

facilitated access to the viral LTR promoter (Lusic and Giacca 2014; Siliciano and Greene 2011).

Control of HIV-1 Gene Expression

The regulation of HIV-1 transcription is a complex event of significant pathological relevance, which recapitulates general concepts of cellular transcription with some peculiarities. In CD4⁺ T cells, a rapid and effective replication of the HIV-1 genome occurs through a concerted action of cellular transcriptional activators, which bind the 5' LTR of the viral genome and the viral Tat protein, which binds the trans-activation-responsive region (TAR) mRNA sequence. HIV-1 expression is initiated from the 5' LTR region, at the single transcription start site (TSS). The HIV-1 promoter and adjacent regulatory elements in the U3 region of the LTR are both involved in the recruitment of RNA polymerase 2 (RNA Pol 2). The TAR sequence, found within the R region in the 5' end of all viral transcripts, contains important regulatory motifs, and so does the U5 region (Ott et al. 2011). Basal transcription from the viral promoter is controlled by the Sp1 protein, whose binding sites are located upstream of the TATA element in the "core" promoter. Other transcription factors (TFs), mostly inducible by cell activation with cytokines or similar stimuli, bind the enhancer region that lies upstream of the core promoter. Activator protein-1 (AP-1), nuclear factor of activated T cells (NFAT), and cytokine-inducible nuclear factor κ B (NF- κ B) are among the best-characterized TFs that regulate HIV-1 transcription. However, multiple TFs are associated with repression of viral transcription, such as Yin Yang 1 (YY1), the p50 subunit of NF- κ B, chicken ovalbumin upstream promoter transcription factor (COUP-TF)-interacting protein-2 (CTIP2), and specificity protein 1 (Sp1).

A Role of Chromatin in Transcriptional Silencing of the Provirus

When analyzed *in vitro*, as naked DNA, HIV-1 5' LTR exhibits very strong promoter activity, but as

any other eukaryotic promoter, it is embedded into chromatin that imposes a significant level of control of gene expression (Colin and Van Lint 2009). Nuclease digestion of intact nuclei of infected cells under basal conditions showed the presence of at least three precisely positioned nucleosomes, called nuc-0, nuc-1, and nuc-2 and their intervening nucleosome-free regions (Verdin et al. 1993). As with other promoters, both activation and silencing of the HIV 5' LTR are governed by the acetylation status of histones in the nucleosomes. In a simplified model, chromatin is accessible for transcription factors when histones positioned at the gene promoters are acetylated; conversely, chromatin compaction is achieved by histone deacetylases (HDACs) through deacetylation of specific lysines within the N-terminal tails of histones. This promotes high-affinity binding between the histones and DNA backbone and reduces the accessibility of underlying DNA to transcriptional activators. Nucleosome remodeling (especially of nuc-1) is an early event in the reactivation of latent HIV-1, and histone acetylation induced by treatment with an HDAC inhibitor might lead to activation of latent HIV-1 (Shirakawa et al. 2013).

Histone Deacetylases (HDACs)

Based on their homology to the yeast prototype deacetylases, HDACs are grouped into four classes: class I and IV show homology to reduced potassium dependency 3 (RPD3) and class II to HDAC1, while class III HDACs have homology to the Sir2 yeast deacetylase (Shirakawa et al. 2013).

Class I HDACs include HDAC1, HDAC2, HDAC3, and HDAC8 and represent a subset of mostly nuclear and ubiquitous enzymes. Different members of this family have been shown to be recruited to the HIV-1 promoter and to participate in transcriptional silencing of the provirus. HDAC1 has initially been brought in connection with the proviral latency when its recruitment to the 5' LTR promoter by Yin Yang 1/late SV40 factor (LSF) complex was described (Coull et al. 2000). Multiple cellular factors that associate with the viral promoter during proviral latency

also recruit HDAC1 to the viral promoter. HDAC1 partners identified during HIV-1 LTR transcriptional silencing include the NF- κ B p50 homodimer, CTIP2, C-promoter-binding factor-1 (CBF-1), Sp1, and c-Myc (Shirakawa et al. 2013). HDAC1 comprises of the N-terminally positioned catalytic domain and the HDAC association domain (HAD) important for the homodimerization, while the C-terminal part encodes for the nuclear localization domain (NLS). Class I HDACs have generally been considered transcriptional silencers; however, several recent studies challenged this view by showing that histone deacetylases play a role in the activation of certain genes and that class I HDACs have preferences for active genes (Moser et al. 2014). In support of their complex regulatory functions is the fact that these enzymes also acetylate nonhistone proteins and are hence implicated in different aspects of cellular metabolism aside from transcription. In fact, HDAC1 has also been shown to be involved in integration, where in complex with KRAB-associated protein-1 (KAP-1) HDAC1 deacetylates HIV integrase (IN) and restricts integration (Allouch et al. 2011). Despite multiple studies and a number of different interactors, a specific transcription factor crucial for HDAC1 recruitment to the HIV-1 promoter during silencing has not been revealed to date.

Yin Yang 1

Yin Yang 1 protein is a fascinating example of the inherent complexity of the regulation of gene expression in eukaryotes. As one of the most intriguing players in gene regulation, YY1 has found its part in a plethora of cellular processes, such as regulation of B-cell development, malignant transformations, apoptosis, gene dosage, and viral latency. The first reports about the factor, today widely known as YY1, came 30 years ago when specific binding of the YY1 protein in the intronic enhancer of the immunoglobulin heavy-chain (IgH) locus was reported. YY1 was cloned and characterized as a zinc finger protein initially known as NF-E1 that binds to a DNA sequence within the negative-acting segment during B-cell

development. Soon after, the protein was shown to cause not only transcriptional repression but was demonstrated to act as a transcriptional activator as well. Based on its dual property to repress and activate transcription depending on the context of *cis* elements and interacting proteins, this transcription factor was named YY1 for “yin and yang 1.” Further studies supported both positive and negative roles of this transcription factor. The complex role that YY1 has inside the cell is also demonstrated by the finding that it is crucial for embryonic development: homozygous mutation of the *yy1* gene results in peri-implantation lethality. YY1 is implicated in a wide number of processes such as in cardiac and skeletal lineage development and in the cell growth control, as well as in disease pathways such as dystrophic muscle disease (see the recent review from Atchison (2014)).

The YY1 gene is highly conserved between different species, showing a remarkable similarity (greater than 98%) to its mouse homologue NF- δ . After several attempts to position human YY1 gene to its chromosomal location, YY1 was finally mapped to the telomere region of chromosome 14 by fluorescence in situ hybridization (FISH). YY1 gene consists of five highly conserved exons and is alternatively spliced into eight different isoforms whose functions still remain elusive. Although an estimated molecular weight of the protein, based on 414 amino acids, is 44 kDa, YY1 migrates at a molecular weight of 68 kDa in SDS–polyacrylamide gels which is probably due to its protein structure. The hallmark of Yin Yang 1 protein is four zinc finger motifs located in its carboxyl terminus (amino acids 298–414) which are responsible for the recognition of a consensus DNA sequence. Of interest, in addition to its DNA binding activity, YY1 also binds Xist RNA through different sequence motifs during X chromosome inactivation process. Functionally, part of the C-terminally located zinc fingers (amino acids 333–397) and a more centrally positioned region (amino acids 170–200) harbor transcriptional repression activity. In contrast, residues involved in transcriptional activation are positioned closer to the amino terminus (Atchison 2014). A region

defined between residues 201 and 226 forms the recruitment of polycomb (REPO) domain which is implicated in polycomb group repression. More recently, a higher oligomer form of YY1 was purified, suggested to facilitate sequence independent association with DNA and protein–protein interactions during homologous recombination-mediated DNA repair (Atchison 2014).

A Role for HDAC1:YY1 in Proviral Latency

Repression of HIV-1 transcription has been ascribed to multiple TFs that directly bind the viral LTR promoter. Almost all of these factors, including Yin Yang 1, the p50 subunit of NF- κ B, COUP-TF-interacting protein-2, CBF1, Sp1, and c-Myc, recruit HDACs to the viral promoter to attenuate viral transcription (Shirakawa et al. 2013). Initial studies identified YY1 as a cellular partner that binds the AAV P5 promoter, contributing to the silent state of this promoter. Since then, YY1 was identified as a critical host cell transcription factor for numerous viral promoters. Interestingly, in almost all cases it was connected to the phenomenon of viral latency (Shi et al. 1997), proposing that this TF might be a general regulator of the latent phenotype in different viruses. One such example shows that YY1 represses the BZLF1 gene, the gene product of which is necessary for the latent Epstein-Barr virus (EBV) to enter the lytic state in B cells. YY1 also represses HIV-1 transcription, and in fact, it was one of the first host cell transcription factors demonstrated to be involved in repression of the HIV-1 LTR. Studies in HeLa cells by David Margolis and his group showed that YY1 binds to the position -16 to $+27$ of the HIV-1 LTR ($+1$ marks the start site of transcription) and that over-expression of YY1 inhibits viral transcription and virion production (Margolis et al. 1994). By using nuclear extracts from the physiologically more relevant CEM cells (a T-cell line), they showed later that YY1 acts together with the transcription factor late simian virus 40 (LSF)/leader binding protein-1 (LBP-1) to form a transcriptionally repressive complex (Romerio et al. 1997). This YY1 and LSF

complex copurified with HDAC1, while deletion of a glycine/alanine-rich domain of YY1 responsible for YY1 and HDAC interaction diminished the ability of YY1 to silence the HIV-1 LTR. A similar effect on the LTR was observed after treatment with deacetylase inhibitor trichostatin A, reinforcing the role of HDAC1 in transcriptional silencing of HIV-1 (Coull et al. 2000).

In addition to LSF-mediated interaction near the core promoter, YY1 was recently shown to bind an upstream binding site called RBEIII (-120 to -140) in a highly conserved RBF-2 (USF1/2-TFII-I) region of the LTR enhancer in Jurkat cells. The association of YY1 with this upstream sequence in the LTR promoter was confirmed by ChIP experiments in unstimulated Jurkat cells but unfortunately the contribution of this site to YY1-mediated repression of the LTR promoter remained unclear (Bernhard et al. 2013).

More recent work of Margolis and colleagues showed that upon YY1 and c-Myc depletion in Jurkat 2D10 and J89 cell clones, HDAC1, HDAC2, and HDAC3 occupancy of the LTR remains unchanged (Barton and Margolis 2013). Surprisingly, levels of viral mRNA increased upon YY1 removal, but remained the same upon c-Myc silencing contradictory to the previous reports. Moreover, expression of latent HIV-1 drastically increased in combination with an HDAC inhibitor vorinostat (or SAHA) treatment, with higher transcriptional induction than upon HDAC inhibition alone (Barton and Margolis 2013). These findings underline the existence of multiple repressor mechanisms involved in transcriptional silencing of the provirus. Indeed, HDACs were shown to participate in different repressive complexes at the viral promoter which in turn require selective targeting to effectively activate quiescent proviruses from latency (Shirakawa et al. 2013).

Conclusions and Future Directions

Association between YY1 and HDAC1 represents the basis of the first epigenetic mechanism found to repress the LTR promoter during HIV-1 latency. The highly heterogenic interactome of YY1,

together with a number of reports that suggest a more global role in long-distance interactions across the eukaryotic genome, is putting this factor in the limelight of HIV-1 latency regulation. In this context, one could envisage a mechanism according to which YY1 contributes to the latent phenotype by establishing long-range interactions between the LTR and the chromosomal regions either on the same or on different chromosomes. In fact, such mechanism was previously reported to take part in proviral silencing in at least one fraction of a latent Jurkat cellular clone J-Lat A1 (Dieudonne et al. 2009). In support of this hypothesis, the requirement for YY1 in the long-distance DNA interactions and loop formation was proposed based on several lines of evidence. In particular, YY1 interaction with PcG proteins and its recruitment to DNA as well as interactions with cohesin, condensin, and lamin proteins could all contribute to the formation of long-distance contacts that lead to contraction and silencing of the provirus (Atchison 2014, #51). HDAC1 could also participate in such interactions, possibly together with other chromatin modifiers and scaffolding proteins.

Despite the described mechanisms, the role of YY1 in the establishment and maintenance of latency in primary CD4⁺ cells still remains to be determined (Barton et al. 2013, Bernhard et al. 2013, Coull et al. 2000).

Definition

LEDGF/p75 is a chromatin-associated cellular protein with roles in embryonic development, transcriptional regulation, and cell survival that

has been implicated in autoimmunity, carcinogenesis, and HIV replication. A key feature is its ability to act as a molecular adapter to tether proteins to the chromatin. Recent studies have uncovered its role in leukemia, cell survival, and DNA repair. Biophysical characterization of its dynamic interaction with chromatin sheds light on how a single protein can exert so many functions. The function of LEDGF/p75 in HIV replication has been further elaborated, and the insight in the interaction between LEDGF/p75 and IN has resulted in a new class of inhibitors (LEDGINs) blocking HIV replication.

Introduction

LEDGF/p75 has been identified on four different occasions in association with transcriptional regulation, cell survival, autoimmunity, or virology (Ge et al. 1998; Singh et al. 2000; Ochs et al. 2000; Cherepanov et al. 2003). LEDGF/p75, together with LEDGF/p52, co-purified with the general transcriptional coactivator positive cofactor 4 (PC4) (Ge et al. 1998) and was termed p75, due to its apparent mass of 75 kDa. Since both proteins enhanced activity of the general transcription machinery, they were hence referred to as transcriptional coactivators p75 and p52. Later, a cDNA clone coding for a protein identical to p75 was isolated from a lens epithelium cell (LEC) library (Singh et al. 2000), and the protein was coined lens epithelium-derived growth factor or LEDGF/p75. In 2000, screening of a cDNA library with human serum reactive against the nuclear autoantigen dense fine speckled protein of 70 kDa (DFS70) revealed DFS70 to be identical to LEDGF/p75 (Ochs et al. 2000). Finally, LEDGF/p75 was reported as a binding partner of HIV-1 IN by isolating complexes of ectopically expressed IN from the nuclei of HEK293T cells (Cherepanov et al. 2003).

LEDGF/p75 is a ubiquitously expressed nuclear protein that associates with mitotic chromatin. The protein interacts with various nuclear proteins and is generally regarded as a molecular adapter. It binds chromatin with its N-terminal

chromatin/DNA-interacting domains and interacts with proteins via its C-terminal region, thereby tethering these interacting proteins to the chromatin.

The *PSIP1* Gene and the Genomic Organization

The 530 amino acid (aa) protein LEDGF/p75 is encoded by *PSIP1* (PC4 and SFRS1 interacting protein), a gene located at chromosome 9p22.2 which also gives rise to a smaller splice variant encoding the 333 aa protein LEDGF/p52. LEDGF/p52 shares a region of 325 residues with LEDGF/p75 at the N-terminus but contains only 8 additional C-terminal amino acids.

LEDGF/p75 is a member of the hepatoma-derived growth factor (HDGF)-related protein (HRP) family. HRPs are characterized by a conserved N-terminal region, also known as HATH (homologous to amino terminus of hepatoma-derived growth factor) or PWWP domain. This 90- to 135-amino acid domain is found in a variety of nuclear proteins. Seven human HRP family members have been described: HDGF, HRP-1, HRP-2, HRP-3, HRP-4, LEDGF/p75, and LEDGF/p52. Recently, the transcriptional control of *PSIP1* itself has been scrutinized. Expression is probably initiated from different transcription start sites (TSS) in different cell types, an important source of regulatory diversity, and regulated mainly by the transcriptional protein specificity protein 1 (Sp1) next to other regulatory proteins such as TGF-beta1. A region within the promoter has been suggested to regulate the ratio of LEDGF/p75 over LEDGF/p52 expression. Sp1 was shown to bind to multiple (5) sites in the promoter region of LEDGF/p75 and to differentially regulate expression. Also a TGF-beta1-inhibitory-element-like sequence and other regulatory element responsive sequences were proposed. TGF-beta1 has been shown to decrease the LEDGF/p75 promoter activity. Oxidative stress, hyperthermia, TNF- α , heat shock protein (Hsp) 70-2, and gonadotropins have all been reported to induce LEDGF/p75 expression.

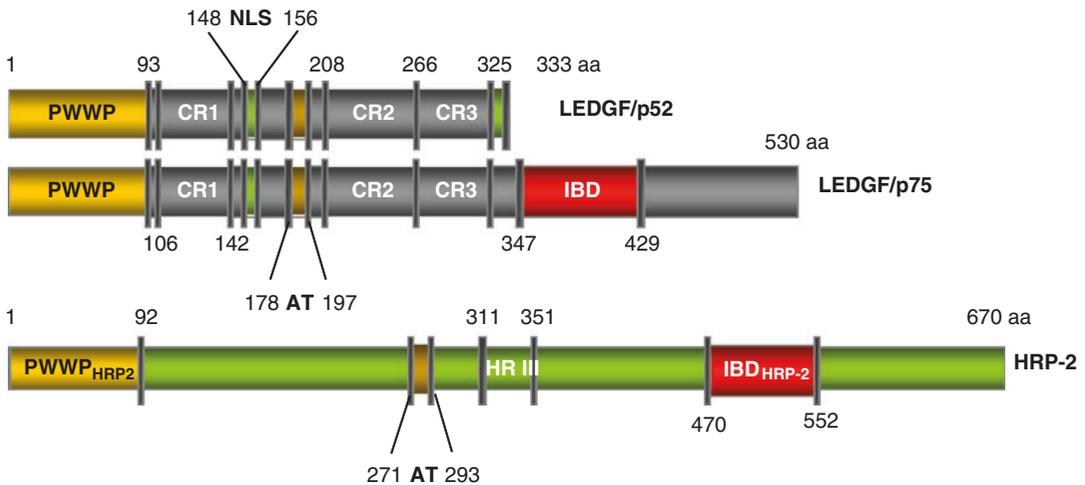

Structure and Distribution of LEDGF/p75

Domains in LEDGF/p75

LEDGF/p75 contains the following functional domains: (1) a PWWP domain (aa 1–93) in the N-terminal part of LEDGF/p75 that functions as a chromatin interaction domain; (2) a functional nuclear localization signal (NLS) [23]; (3) two AT-hook-like motifs; (4) four charged regions (CR1–4) of which recently CR2–4 were described to contain a supercoiled DNA recognition domain (SRD, aa 200–336); (5) a C-terminal integrase-binding domain (IBD) of approximately 80 amino acids (aa 347–429) that is responsible for the interaction with HIV integrase (IN) but is absent in the LEDGF/p52 splice variant (Fig. 1).

The N-terminal PWWP domain, named for a conserved Pro-Trp-Trp-Pro motif, is present in all HRP family members. PWWP domains are members of the Tudor domain “royal family” consisting of Tudor, chromodomain, malignant brain tumor, and PWWP domains. The PWWP domains are currently regarded as chromatin-interacting domains capable of binding methyl-lysine residues on histones and DNA, probably without sequence specificity. They are present in diverse chromatin-associated proteins involved in DNA repair, histone modification, transcriptional

regulation, and DNA methylation. NMR structures and more recently crystal structures of related PWWP domains demonstrate the presence of a five-stranded antiparallel beta-barrel core responsible for the interaction between methyl-lysine residues on histones and two C-terminally located alpha-helices. An insertional third motif between the second and third beta-strand is not present in the PWWP domain of HRPs. The PWWP domain of LEDGF/p75 (aa 1–93) alone interacts with chromatin, not with naked DNA. Detailed mapping of the chromatin-binding profile of LEDGF/p75 using DamID technology in the highly annotated ENCODE region revealed an association with histone modification marks associated with active transcription such as H3 or H4 acetylation, H3K4me1, RNA polymerase II and a disfavoring of promoter regions, and H3K27me3, a determinant of heterochromatin. Recent work indicated that H3K36me3, H3K4me1, and to a lesser extent H3K36me2 and H3K36me1, associated with active chromatin, efficiently co-immunoprecipitated with LEDGF/p75, while H3K9me3 and H3K27me3, markers of inactive chromatin, did not (Daugaard et al. 2012). Pradeepa et al. also suggested a direct interaction of the PWWP domain with H3K36me3, although this was only

Role of LEDGF/p75 in Cell Biology and Disease Pathogenesis, Fig. 1 Structure of LEDGF/p52, LEDGF/p75, and HRP-2. Cartoon representation of LEDGF/p52, LEDGF/p75, and HRP-2: PWWP domain (*PWWP*),

charged regions 1–3 (*CR1–3*), nuclear localization signal (*NLS*), AT-hook-like sequence (*AT*), homology region III (*HR III*), and integrase-binding domain (*IBD*) are indicated

demonstrated for the PWWP domain of LEDGF/p52 and not for the identical domain in LEDGF/p75 (Pradeepa et al. 2012). The PWWP domain in LEDGF/p75 is also important for its nuclear distribution. A PWWP-truncated protein (Δ N93-LEDGF/p75) lost its interaction with condensed mitotic chromatin and was no longer excluded from nucleoli, contrary to LEDGF/p75. Since LEDGF/p75 has been demonstrated to tether and target HIV integration, the integration pattern itself provides valuable clues of the interaction of LEDGF/p75 with the chromatin. HIV-1 integration favors genomic regions enriched with histone modifications associated with active transcription (such as H3K4me1, H3K9me1, H3K36me3). Notably, when the PWWP domain of LEDGF/p75 was swapped with other PWWP domains from HRPs and the HIV integration pattern near histone marks was compared, the PWWP of HDGF increased integration near H3K36me3, while the PWWP of HRP-2 increased the likelihood of integrating near other marks associated with active transcription (i.e., H2BK5me1, H3K4me3, H3K9me1, H3K27me1, H3K36me3). However, not all LEDGF/p75 chromatin-binding sites correlated with the HIV-1 integration pattern. Next to the PWWP domain, a tripartite motif consisting of a functional NLS, GRKRKA EKQ (aa 148–156), and two AT-hook-like domains (aa 178–198) capable of binding DNA *in vitro* can be distinguished. NLS deletion leads to cytoplasmic localization of newly synthesized LEDGF/p75. In dividing cells, however, LEDGF/p75 is trapped to the mitotic chromatin, rendering the NLS dispensable for its nuclear localization. In line, mutations of the NLS region reduced but did not abolish the interaction of LEDGF/p75 with naked DNA.

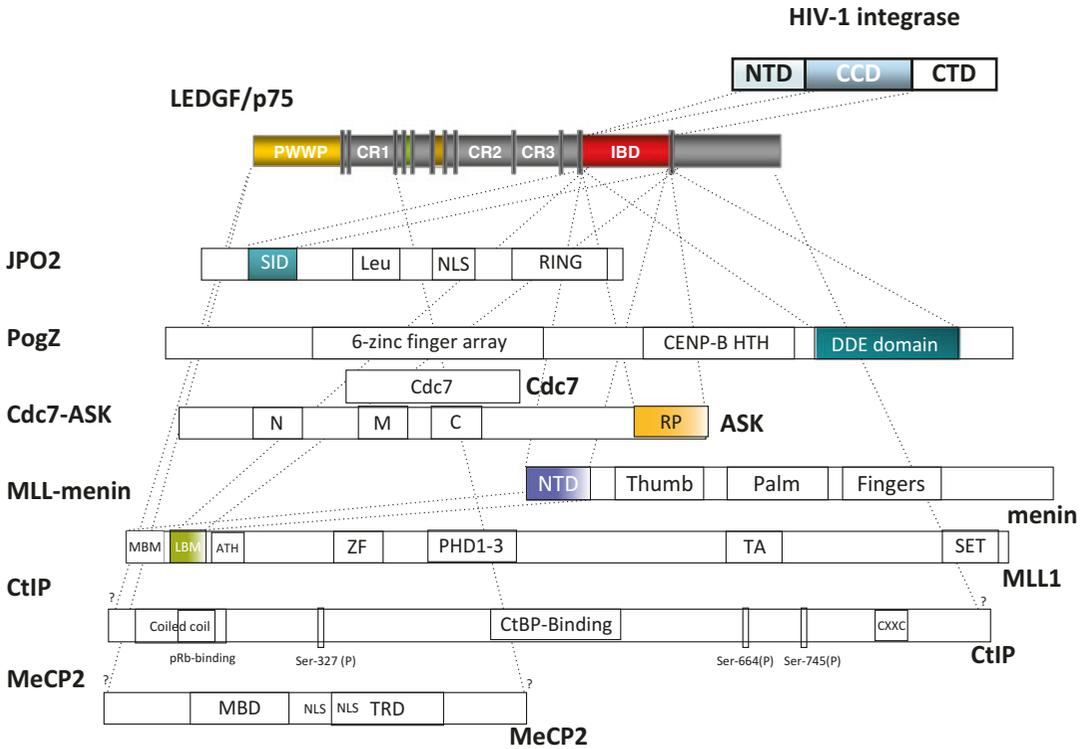

Four relatively charged regions (CR1–4) are interspersed between the different domains; CR2 and CR3/4 to a lesser extent were recently shown to bind supercoiled DNA. This so-called supercoiled DNA recognition domain (SRD) in LEDGF/p75 (aa 200–336) was also capable of binding to relaxed DNA, consistent with observations that LEDGF/p75_{226–471} has minor DNA-binding properties and LEDGF/p75_{326–471}, containing the IBD, has none.

The C-terminus of LEDGF/p75 contains the IBD (aa 347–429), capable of interacting with HIV integrase (IN). The IBD is formed by a compact right-handed bundle composed of five α -helices [based on a NMR solution structure of the IBD and a co-crystal structure of the IBD with the catalytic core domain (CCD) of IN (Cherepanov et al. 2005)] that is topologically similar to a pair of HEAT repeats. Binding IN is obviously not the natural function of this domain as it has been shown to bind other cellular partner proteins as well: c-Myc-interacting protein JPO2, mixed-lineage leukemia (MLL)/menin complex (Yokoyama and Cleary 2008), a domesticated transposase PogZ (pogo transposable element-derived protein with zinc finger), and Cdc7 activator of S-phase kinase (Cdc7/Ask). Thus, the IBD probably functions as an adapter, associating divergent factors and enabling them to be tethered to chromatin through interactions with the N-terminus of LEDGF/p75 (Fig. 2).

After translation, LEDGF/p75 can be a substrate of posttranslational modifications such as phosphorylation and SUMOylation by SUMO1 (small ubiquitin-like modifier 1). LEDGF/p75 phosphorylated at Ser206 by Cdc7/Ask was recovered during the S-phase. A fraction of endogenous LEDGF/p75 is SUMOylated, and four SUMOylation sites, Lys-75, Lys-250, Lys-254, and Lys-364, were identified, of which only Lys-364 was located in a conserved consensus motif. SUMOylation does not affect the cellular localization of LEDGF/p75 but negatively regulates its half-life and transcriptional activity. Mutating Lys-364 to arginine abolished SUMOylation and increased the capacity of LEDGF/p75 to bind naked DNA in EMSA.

Cellular Localization of LEDGF/p75

LEDGF/p75 is a nuclear protein that binds to chromatin during mitosis. Initial studies suggested that GFP-LEDGF/p75 was secreted into the culture medium of lens epithelial cells and that temperature influenced the location of LEDGF/p75 in these cells, with LEDGF/p75 in the cytoplasm at 4 °C to 28 °C and in the nucleus at 37 °C. Next, exogenous GSP-LEDGF/p75 was reported to be taken up by lens epithelial cells

Role of LEDGF/p75 in Cell Biology and Disease Pathogenesis, Fig. 2 LEDGF/p75 interacts with HIV integrase and various cellular proteins. Cartoon representation of the different interaction partners of LEDGF/p75: HIV-1 integrase, JPO2, PogZ, Cdc7/Ask, MLL-menin, CtIP, and MeCP2. Dashed lines indicate the interacting domains. Abbreviations: N-terminal domain (NTD), catalytic core domain (CCD), C-terminal domain (CTD), PWWP domain (PWWP), charged region 1–3 (CR1–3), integrase-binding domain (IBD), specific interaction domain (SID), putative leucine zipper (Leu), nuclear

localization signal (NLS), RING-finger-like zinc-binding motif (RING), helix-turn-helix (HTH), N-motif (N), M-motif (M), and C-motif (C), C-terminal regulatory peptide (RP), menin-binding motif (MBM), LEDGF-binding motif (LBM), ZF_CXXC motif (ZF), PHD fingers (PHD1–3), SET domain (SET), retinoblastoma protein-binding motif (pRb-binding), C-terminal-binding protein binding motif (CtBP-binding), CXXC motif (CXXC), methyl-CpG-binding domain (MBD), transcriptional repression domain (TRD)

where it is transported through the cytoplasm into the nucleus. These observations could not be reproduced independently. Recently, in a series of biophysical experiments in cell culture, Hendrix et al. proposed a chromatin scan-and-lock model for LEDGF/p75 in the nucleus (Hendrix et al. 2011). LEDGF/p75 is for 98% of the time bound to chromatin and moves in the remaining 2% to other sites on the chromatin. In the chromatin-bound fraction, a slow moving, scanning state, and a smaller more tightly bound or locked state could be distinguished. A comparable phenomenon, a scanning/hopping mechanism, was previously described for

transcription factors. In the scan-and-lock model, the N-terminal PWWP domain plays a pivotal role. Mutating the PWWP domain (R74D) considerably increased the nuclear mobility of LEDGF/p75, suggesting a decreased chromatin interaction. However, it did not completely abrogate the binding of LEDGF/p75 to chromatin as suggested by the remaining slower-moving and presumably chromatin-bound fraction of the mutant LEDGF/p75 compared to freely diffusing eGFP. The PWWP domain in LEDGF/p75 was proposed to constitute a “protein lock,” docking LEDGF/p75 and its potential cargo at specific sites on the chromatin.

Cellular Binding Partners of LEDGF/p75

Several cellular interaction partners of LEDGF/p75 have been identified. JPO2 and PogZ have been identified by Y2H and the interaction with JPO2 was independently confirmed by co-IP. Although, like integrase, they each interact with the IBD domain of LEDGF/p75, the interaction differs considerably. The interaction of JPO2 with the IBD is not inhibited significantly by mutating the Ile-365, Asp-366, and Phe-406 residues in the IBD that abrogate the interaction with IN. JPO2, also known as R1, RAM2, or CDC7L, is a c-Myc interactor and potentiates c-Myc transforming capacity in medulloblastoma cells. JPO2 is a repressor of human monoamine oxidase A and B expression. Contrary to JPO2, PogZ shares more interacting IBD amino acids with IN and mutation of Ile-365 or Phe-406 abrogates its interaction with the IBD. The Asp-366 mutation in the IBD is however exclusively linked to a loss of interaction with lentiviral integrases. PogZ binds heterochromatin protein 1, essential in the formation of heterochromatin and mitotic progression, through its zinc-finger-like motif and destabilizes the heterochromatin protein 1-chromatin interaction enabling normal mitotic progression.

LEDGF/p75 has also been implicated in oncogenesis and acts as a chromosomal tether for the mixed-lineage leukemia (MLL) histone methyltransferase protein complex through menin (Yokoyama and Cleary 2008) via interaction with its IBD. LEDGF/p75 is required for both MLL-dependent transcription and leukemic transformation.

LEDGF/p75 interacts with cell division cycle 7-related protein kinase (Cdc7) activator of S-phase kinase (ASK) through its IBD. Cdc7/ASK phosphorylates LEDGF/p75 *in vitro*, with Ser-206 being the major target, and LEDGF/p75 stimulates the enzymatic activity of Cdc7/ASK *in vitro* by relieving autoinhibition of Cdc7/ASK, imposed by the C-terminus of ASK.

MeCP2, a methylation-associated transcriptional modulator, is a common interaction partner of both LEDGF/p75 and LEDGF/p52. The interaction was demonstrated *in vitro* and in various cancer cell lines using a wide array of techniques (transcription factor protein arrays, pull-down,

AlphaScreen assays, co-IP, nuclear co-localization studies using confocal microscopy) and was mapped to the N-terminal region, particularly the PWWP-CR1 domains, shared by both LEDGF/p75 and LEDGF/p52.

Endogenous LEDGF/p75 co-immunoprecipitated with C-terminal-binding protein interacting protein (CtIP), a component of the homologous recombination repair machinery (Daugaard et al. 2012).

Physiological Roles of LEDGF/p75

LEDGF/p75 as a Transcriptional Regulator Affecting Stress Response

Initial work attributed a role to LEDGF/p75 in transcriptional regulation after its co-purification with the transcriptional coactivator PC4 (Ge et al. 1998). Addition of the protein to the culture medium of LECs stimulated their growth and prolonged cell survival (Singh et al. 2000). LEDGF/p75 was shown to be a stress response protein promoting cell survival in multiple cell lines (i.e., LECs, mouse keratinocytes, monkey kidney cos7 cells, human fibroblasts, retinal pigment epithelial cells, HepG2 cells) in the presence of environmental stress stimuli such as hyperthermia, serum starvation, or UVB radiation. LEDGF/p75 is proposed to activate stress-related genes in response to environmental stress stimuli, and LEDGF/p75 expression itself is upregulated upon oxidative and thermal stress or via TNF- α -induced oxidative stress. Genes known to be transactivated by LEDGF/p75 are Hsp27, peroxiredoxin-6 (also known as antioxidant protein 2), involucrin, alcohol dehydrogenase, aldehyde dehydrogenase, α B-crystallin, gamma-glutamylcysteine synthetase, vascular endothelial growth factor C (VEGF-C), and interleukin 6 (IL-6). In a "human oxidative stress and antioxidant defense" qPCR array in PC-3 cells, only 5 out of 84 genes were differentially regulated by LEDGF/p75 (albumin, cytoglobin, phosphoinositide-binding protein commonly known as IPCEF-1, superoxide dismutase 3, and thyroid peroxidase), and Hsp70-2 depletion resulted in LEDGF/p75 depletion in HeLa cells

but did not differentially alter the expression of the previously reported target genes of LEDGF/p75 (including Hsp27, α B-crystallin, peroxiredoxin-6). Recent studies indicated that LEDGF/p75 binding to chromatin is not necessarily restricted to STRE or HSE in the genome but predominantly associated with active chromatin markers. It remains, however, possible that under conditions of stress, LEDGF/p75 interacts with specific transcription factors and tethers them to active chromatin regions, thereby promoting expression of specific stress and antioxidant genes. However, potent LEDGF/p75 knockdown (KD) or over-expression in HeLa and various T-cell lines including MT4, SupT1, and PM1 cells, or even LEDGF/p75 knockout (KO) in pre-B Nalm-6 cell lines used to study the role of LEDGF/p75 in HIV replication, did not alter growth kinetics of the cells, although introduction of incidental compensatory mechanisms or clonal selection cannot be excluded. LEDGF/p75 depletion in HEK293T cells was reported to hamper cell growth and viability. Homozygous *PSIP1* KO mice lacking the expression of the C-terminal part of LEDGF/p52 and LEDGF/p75 had expected birth rates but exhibited a higher incidence of early postnatal death. Most of these *PSIP1* KO mice had a failure to nurse early after birth, for yet unknown reasons, whereas a reduced cell survival or stress responsiveness remains speculative.

A Role of LEDGF/p75 in Embryonic Development

The importance of *PSIP1* for embryonic development was demonstrated by the disruption of *PSIP1* using a gene trap screen in embryonic stem cells in mice. The gene trap resulted in fusion proteins that retained a part of the N-terminus of LEDGF/p52 or LEDGF/p75 (aa 1–152 in case the gene trap was inserted between exon 6 and 7 or aa 1–208 in case insertion occurred between exon 8 and 9) but abolished expression of the remaining part of LEDGF/p52 or LEDGF/p75, the latter containing the C-terminally located IBD. Although the number of littermates was not decreased, the majority of homozygous *PSIP1* knockout mice died early after birth due to a

failure to nurse. Mice that did survive also demonstrated a low fertility, tendency for blepharitis, and diverse motor and/or behavioral defects including reduced grip strength and locomotor activity. Almost all mice demonstrated craniofacial and skeletal abnormalities such as brachycephaly and small rib cages. The homeotic skeletal transformations suggested a role for *PSIP1* in homeobox (Hox) gene expression. LEDGF/p75 KD in HEK293T cells resulted in the upregulation of 358 and downregulation of 479 genes, among which Hoxa5, Hoxa6, Hoxa9, Hoxa10, and Hoxa13. Next, LEDGF/p75 has been shown to be essential for constitutive Hoxa9 gene expression via MLL-fusion proteins and possibly regulates Hox gene expression under physiological conditions via interaction with normal menin/MLL proteins (Yokoyama and Cleary 2008). In the *PSIP1* knockout MEFs, no obvious effect on Hox gene expression could be noticed. Notably, heterozygous *PSIP1* knockout mice were indistinguishable from wild type. The study in *PSIP1* KO mice, however, did not allow to differentiate the impact of LEDGF/p75 and LEDGF/p52 since both were deleted.

Role of LEDGF/p75 in Disease Pathogenesis

A Role of LEDGF/p75 in Tumor Cell Survival

Based on recent publications, LEDGF/p75 should be regarded as an oncoprotein that is over-expressed in a considerable number of cancer cells, providing a survival advantage to rapidly proliferating cells and promoting resistance against chemotherapy. In addition, Nup98-LEDGF/p75 fusions have been reported in chronic myeloid leukemia (CML), acute myeloid leukemia (AML), and myelodysplastic syndrome, and LEDGF/p75 tethers mixed-lineage leukemia (MLL)-fusion proteins resulting in a malignant transformation (Yokoyama and Cleary 2008). LEDGF/p75 expression was reported to be elevated in several tumor cell lines, consistent with earlier data in prostate cancer, breast cancer, bladder cancer, and blasts from chemotherapy-resistant acute myeloid leukemia.

Recently, LEDGF/p75 has been shown to be a component of the effective homologous recombination DNA-repair machinery. Repair of DNA double-strand breaks via the homologous recombination repair pathway is restricted to S and G2 phases and involves the recruitment of DNA-repair factors such as BRCA1, the Mre11–Rad50–Nbs1 (MRN) complex, and C-terminal-binding protein-interacting protein (CtIP) to the site of damage. These factors cooperate to catalyze DNA resection of DNA double-strand breaks, an initial 5′–3′ DNA resection of the broken DNA ends generating 3′ single-stranded DNA overhangs. LEDGF/p75 depletion reduced the repair of DNA double-strand breaks by the homologous recombination repair pathway and hampered the recruitment of CtIP to the site of damage. Endogenous LEDGF/p75 also co-immunoprecipitated with endogenous CtIP, an interaction that was enhanced by DNA damage. However, LEDGF/p75 is not an absolute requirement for a functional homologous recombination-mediated repair, as suggested by the milder phenotype of *PSIP1* KO mice compared to mice depleted for known components of the homologous recombination pathway (e.g., CtIP, Rad51, or RPA KO mice). LEDGF/p75, binding to specific methyl-lysine histones associated with active transcription, probably enhances the recruitment of CtIP to the site of DNA damage in LEDGF/p75-decorated parts of the chromatin. In this context, depletion of LEDGF/p75 abolished the ability to co-immunoprecipitate H3K36me3 via CtIP. The observations provide an additional explanation how LEDGF/p75 can protect cancer cells from chemotherapy (e.g., anthracycline-induced DNA damage) or ionizing irradiation. These findings however probably also relate to the physiological role of LEDGF/p75.

LEDGF/p75 is cleaved during apoptosis by caspase-3 and caspase-7 at three sites (DEVPD³⁰↓G, WEID⁸⁵↓N, and DAQD⁴⁸⁶↓G) generating fragments of 65 and 58 kDa. Interestingly, while full length LEDGF/p75 promoted tumor cell survival, overexpression of caspase cleavage fragments (LEDGF/p75_{1–486}) abrogated this effect or resulted even in a proapoptotic effect (LEDGF/p75_{86–486})[75]. Overexpression of the

smaller splice variant LEDGF/p52 (or its caspase-mediated variant with a truncated PWWP domain) induced apoptosis in several tumor cell lines, suggesting a regulation of the survival/apoptosis balance via alternative splicing. In turn, transient expression of LEDGF/p751–326 increased the viability of mutant rhodopsin expressing human retinal pigment epithelial cells, although this study lacked essential controls.

LEDGF/p75 as a Molecular Tether for MLL Fusions in Leukemia

Increasing evidence suggests that LEDGF/p75 is involved in the pathogenesis of acute leukemia. A significant fraction of acute leukemia is associated with translocations involving the mixed-lineage leukemia (MLL) gene. Over 50 different MLL translocation partner genes have been described, all retaining the N-terminal region of MLL. The most prevalent MLL alterations are t(4;11), t(9;11), and t(11;19), resulting in MLL-AF4, MLL-AF9, and MLL–ENL fusions, respectively. The MLL gene encodes for MLL-1, a H3K4 methyltransferase that acts as a regulator of *hox* genes (such as *Hoxa9*, *Hoxc6*, and *Hoxc8*) and is essential for adult hematopoiesis and body plan formation. C-terminal fusion partners AF4, AF9, and ENL orchestrate aberrant transcriptional elongation. Expression of MLL-fusion genes in hematopoietic progenitor cells blocks normal differentiation and provides a malignant self-renewal capacity. LEDGF/p75 has been shown to bind MLL-fusion proteins through interaction of its IBD with a surface formed by MLL1 and the adaptor protein menin. Menin is the gene product of *MEN1* (multiple endocrine neoplasia 1) and an essential oncogenic cofactor for malignant transformation by MLL fusions in vitro and in vivo. LEDGF/p75 tethers the menin/MLL or menin/MLL-fusion complex to the chromatin, the latter resulting in constitutive activation of *Hox* genes and malignant transformation. Knockdown of LEDGF/p75 revealed that LEDGF/p75 is required for both MLL-dependent transcription regulation in nonpathogenic conditions and leukemic transformation by MLL fusions. The transforming properties of the tripartite complex of

LEDGF/p75 and menin/MLL fusion could be bypassed by fusing the PWWP domain of LEDGF/p75 to the N-terminus of a MLL-fusion protein. Conversely, mutating the evolutionary conserved Trp-21 to alanine in the fused PWWP domain disrupted the transformation potential. A crystal structure revealed the LEDGF/p75 IBD alpha-helix E being sandwiched between MLL1 and menin and provides valuable information for future therapeutic strategies targeting this interaction.

LEDGF/p75 as an Autoantigen

The presence of antibodies against LEDGF/p75 has been reported in a variety of diseases as well as in healthy individuals, and its exact role in pathogenesis or its diagnostic value remains uncertain. Initially immunohistochemistry using sera from Japanese patients with atopic dermatitis and interstitial cystitis revealed a dense fine speckled pattern during interphase in combination with chromatin staining during mitosis. The responsible antigen was termed dense fine speckles 70 kd (DFS70) and turned out to be identical to LEDGF/p75 (Ochs et al. 2000). Since then, anti-LEDGF/p75 (or anti-DFS70) antibodies have been recovered in patients with atopic dermatitis [14%, 29.7% (Ochs et al. 2000), or 71.4%, Japanese patients], interstitial cystitis [9% (Ochs et al. 2000)], asthma [16%, patients from the USA (Ochs et al. 2000)], psoriasis (Ochs et al. 2000), Sjögren (Ochs et al. 2000), Behçet, sarcoidosis, chronic fatigue syndrome (16%, Japanese patients), alopecia areata (20%, Japanese patients), and patients with prostate cancer (18.4%).

A Role of LEDGF/p75 in HIV Replication

The function of LEDGF/p75 has been studied most in the context of HIV. LEDGF/p75 has been shown to be a cofactor of HIV and more specifically of HIV integrase. For successful replication, HIV and other retroviruses rely on the virally encoded IN enzyme to orchestrate insertion of their reverse transcribed genomes into the host cell DNA. The active site of IN catalyzes two

distinct reactions. First, IN removes a conserved dinucleotide from the 3' ends of the viral DNA, a process termed 3'-processing. This reaction takes place in the cytoplasm of the host cell in the context of a large nucleoprotein complex, termed the preintegration complex (PIC). The second reaction takes place in the nucleus and involves a pair of coordinated transesterification reactions that cuts both strands of target DNA and joins them to the exposed reactive 3' hydroxyl groups of the invariant CA dinucleotides of the viral DNA molecule, a process termed the strand transfer reaction. Following the concerted strand transfer step, host enzymes presumably repair the remaining gap. During its replication cycle, HIV is dependent on cellular proteins, so-called cofactors. LEDGF/p75 is such a cofactor of HIV replication that tethers the viral preintegration complex toward the host cell chromatin thereby promoting integration and determining the HIV integration site distribution pattern. Although initial work led to contentious results, from a hindsight due to limitations of emerging RNAi technology, recent work using a human somatic LEDGF/p75-specific knockout cell line clearly established the crucial role of LEDGF/p75 in HIV replication (Cherepanov et al. 2003, 2005; Hendrix et al. 2011; Gijssbers et al. 2010; Schrijvers et al. 2012; Llano et al. 2006; Christ et al. 2010; Ciuffi et al. 2005). The interaction between LEDGF/p75 and HIV IN has been well characterized (Cherepanov et al. 2003, 2005) and enabled the generation of a new class of antiretroviral agents that block HIV replication by docking at the LEDGF/p75 binding pocket in HIV IN (Christ et al. 2010). In this entry we first focus on the characterization of the LEDGF/p75-IN interaction, continue with its role in HIV replication and lentiviral targeting, and conclude with its potential as an antiviral target.

The HIV Integrase-LEDGF/p75 Interaction

Cherepanov et al. first reported on LEDGF/p75 as a binding partner of HIV-1 IN by isolating complexes of ectopically expressed IN from nuclei of HEK293T cells (Cherepanov et al. 2003). The interaction of IN-LEDGF/p75 was confirmed by *in vitro* pull-down assays using recombinant

proteins and was shown to be specific for *Lentivirinae* and not a general characteristic of all retroviral integrases. Co-localization studies of different HIV-1 eGFP-IN deletion mutants in the absence or presence of LEDGF/p75 revealed that both the N-terminal zinc-binding domain and the core domain of HIV-1 IN are involved in the interaction with LEDGF/p75. The core domain proved to be the main determinant for the interaction since overexpression of LEDGF/p75 was able to restore nuclear/chromosomal localization of the IN core domain but not that of the N-terminus. Information about the interacting amino acids in the IN-LEDGF/p75 interface came from a crystal structure of the HIV-1 IN CCD in complex with the IBD (Cherepanov et al. 2005) and a later crystal structure comprising the HIV-2 IN NTD-CCD in complex with the IBD and was supported by several mutagenesis studies. Critical interacting residues of the IBD, Ile-365, Asp-366, Phe-406, and Val-408 are located on two interhelical loops of the IBD and contact two regions in a pocket formed by an IN CCD dimer. In the first interhelical loop ($\alpha 1/2$ connector), Asp-366 makes hydrogen bonds with the main amino groups of IN residues Glu-170 and His-171, and LEDGF/p75 Ile-365 makes van der Waals interactions with Met-178, Leu-102, Ala-128, Ala-129, Trp-131, and Trp-132. In the second interhelical loop ($\alpha 4/5$ connector), Phe-406 and Val-408 pack against a hydrophobic patch on IN formed by Ala-128 and Trp-131. A second crystal structure containing the NTD and CCD of HIV-2 IN in complex with the IBD elucidated additional charge-charge interactions between the IN NTD, i.e., Glu-6, Glu-10, Glu-13, and the IBD, i.e., Lys-401, Lys-402, Arg-404, and Arg-405. Of note, although all lentiviral integrases can interact with LEDGF/p75, not all key amino acids in HIV-1 integrase, such as Ala-128, Trp-131, and Gln-168, are conserved between primate and non-primate lentiviral integrases.

LEDGF/p75 functions as a molecular tether, binding chromatin with its N-terminal region and IN with its C-terminally located IBD. Several lines of evidence support this theory. Integrase is known to localize predominantly in the nucleus

and the distribution of nuclear IN perfectly matches with that of LEDGF/p75. Knockdown of LEDGF/p75 using RNAi abolished the nuclear localization of HIV-1 IN as well as its association with chromosomes in cells transiently transfected with IN fused to eGFP. Recent work indicated that IN affects the dynamics of LEDGF/p75 in cells. When LEDGF/p75 was co-expressed with IN, a possible binding partner, the complex moved 75-fold slower compared to LEDGF/p75 alone (Hendrix et al. 2011). Vice versa, depletion of LEDGF/p75 significantly increased the mobility of IN. The reduction of LEDGF/p75 mobility was only sixfold when PWWP-mutated LEDGF/p75 (R74D), retaining wild type affinity for IN, was co-expressed with IN, suggesting that increased viscosity of the complex could not explain these observations. An allosteric effect of IN on the chromatin-binding properties of LEDGF/p75 was deemed unlikely, since the IBD and chromatin-binding domains of LEDGF/p75 are located in distinct structural parts of the protein. Instead the PWWP domain in LEDGF/p75 probably constitutes a “protein lock” that strongly tethers IN to chromatin. McNeely et al. corroborated the tethering function of LEDGF/p75 in an in vitro assay. While the interaction of IN and DNA was much weaker compared to the interaction of LEDGF/p75 and DNA, adding LEDGF/p75 increased the apparent affinity of IN to DNA 10- to 32-fold by tethering of IN to DNA. The interaction was outcompeted by LEDGF/p75₃₂₆₋₅₃₀ but not by LEDGF/p52 or LEDGF/p75_{D366N}, incapable of interacting with IN. LEDGF/p75 with mutated NLS and AT-hook-like domains, preserving binding to IN but reducing DNA binding, likewise did not result in a stimulation of the IN-DNA interaction. Finally, LEDGF/p75 affects the lentiviral integration site distribution and changing the N-terminal chromatin-binding domains with other chromatin-interacting proteins enables retargeting of integration (see section “[The Role of LEDGF/p75 in Targeting Lentiviral Integration](#)”), again alluding to the tethering role of LEDGF/p75.

LEDGF/p75 has been shown to be an allosteric stimulator of HIV IN catalytic activity and stimulates HIV-1 integration into chromatinized templates. LEDGF/p75 stimulates both the

3'-processing and strand transfer. LEDGF/p75 was shown to stimulate half-site (insertion of only one viral DNA into template DNA) but not full-site concerted integration (insertion of both viral DNA ends in a template DNA) *in vitro*. This discrepancy between half- and full-site integration stimulation was not seen with another LEDGF/p75-dependent lentiviral IN, EIAV IN, and proved to be dependent on the concentration and molar ratios of LEDGF/p75 and IN used in these experiments. McNeely et al. observed a stimulation of overall IN activity by LEDGF/p75 as measured using ELISA, yet this activity most pronounced upon preincubation of IN with donor DNA. LEDGF/p75 also stabilizes IN subunit to subunit interactions and promotes IN tetramer formation. Using FRET, two distinct IN conformations were observed upon preincubation of IN with DNA or LEDGF/p75, respectively. These findings suggest that premature binding of LEDGF/p75 to IN precludes the formation of a functional IN-viral DNA complex. How these findings relate to the *in vivo* situation and when LEDGF/p75 is exactly engaged in the viral PIC remains unanswered.

Earlier work indicated that the presence of LEDGF/p75 increased the stability of ectopically expressed IN and protected IN from ubiquitination and proteasomal degradation. LEDGF/p75 disabled efficient immunoprecipitation of C-terminally tagged IN from whole-cell extracts 8 h after transduction with a HIV-derived viral vector, suggesting that the C-terminus of IN in the PIC is masked in the presence of LEDGF/p75.

The Role of LEDGF/p75 in HIV-1 Replication

Depletion of LEDGF/p75 significantly hampers HIV-derived lentiviral vector transduction and HIV replication in different cell lines (Schrijvers et al. 2012; Llano et al. 2006) as well as in primary CD4⁺ T cells or macrophages. In hindsight, the initial controversy surrounding the potential role of LEDGF/p75 in HIV replication, with RNAi-mediated knockdown of LEDGF/p75 failing to affect HIV replication, was caused by unknown limitations and misinterpretation of the RNAi technology. These observations, however, also support the notion that minute amounts of LEDGF/p75 are

already sufficient for HIV replication and explain why LEDGF/p75 was not withheld in different RNAi screens for host factors of HIV, despite its currently established role in HIV replication.

In early LEDGF/p75 KD experiments, a reproducible two to fourfold reduction in HIV-1 replication was shown. The residual HIV-1 replication observed in LEDGF/p75 KD cells was attributed to the remaining chromatin-bound LEDGF/p75. Luciferase reporter gene expression was more than tenfold reduced in *PSIP1* KO mouse embryonic fibroblasts (MEFs) compared to wild type levels. Reintroduction of human LEDGF/p75 in these cells alleviated the block in transduction, whereas LEDGF/p75 with a D336N mutation, defective for interaction with integrase, or LEDGF/p52 did not. Deletion mutants of LEDGF/p75 demonstrated that both the N-terminal domains, containing the PWWP, AT-hook, and NLS region, and the C-terminal region containing the IBD were required to rescue the observed block. Deletion mutants of LEDGF/p75 lacking the PWWP domain rescued HIV transduction and/or replication only up to 17% of wild type levels, while AT-hook-like-domain deletions or mutations alone had no effect. One report suggested the PWWP domain to be dispensable for single-round HIV-fluc transduction. A similar transduction block was observed in *PSIP1* KO MEFs generated using a gene trap. Although the domains in LEDGF/p75 important for its function in HIV-1 replication are 100% conserved in the murine orthologue, HIV is not a murine virus, and studies in MEFs were restricted to single-round VSV-G-pseudotyped lentiviral vectors. Recently a human somatic LEDGF/p75 knockout cell line was generated enabling the study of multiple-round HIV replication in a human context (Schrijvers et al. 2012). Here, the exons encoding the C-terminal region of LEDGF/p75 were specifically knocked out via homologous recombination in Nalm-6 cells, leaving the smaller splice variant LEDGF/p52 unaltered. HIV replication was significantly hampered in the absence of LEDGF/p75 and could only be observed using laboratory-adapted HIV strains. In the absence of LEDGF/p75, HRP-2, the only known other cellular protein harboring a PWWP

domain and a functional IBD besides LEDGF/p75, was shown to mediate HIV replication. Previous attempts to demonstrate a role for HRP-2 in HIV replication were probably obscured by the remaining LEDGF/p75 or premature RNAi technology. The observations explain the residual replication observed in potent RNAi-mediated LEDGF/p75 KD cell lines and probably as well the residual transduction observed in *PSIP1* KO MEFs. Since clinical HIV isolates demonstrated futile to no replication in the absence of LEDGF/p75 (Schrijvers et al. 2012), in vivo LEDGF/p75 is probably essential, although relative expression levels of LEDGF/p75 and HRP-2 in relevant cell lines remain unknown.

The block opposed by LEDGF/p75 depletion on HIV-derived vector transduction or HIV replication was pinpointed using qPCR analysis of HIV-1-derived DNA intermediates. Equal amounts of late reverse transcripts but lower amounts of integrated copies, ranging from a two to tenfold reduction, were observed. The number of 2-LTR circles, suggested to rise in the nucleus upon abortive integration and to decrease in case of a block in nuclear import, was 1.5- to 2.5-fold increased at 24 h postinfection upon RNAi-mediated LEDGF/p75 KD or was equal to modestly increased in case of LEDGF/p75 or *PSIP1* KO. Cytoplasmic PICs isolated from *PSIP1* KO MEFs also demonstrated equal IN enzymatic activity in vitro, suggesting a role of LEDGF/p75 downstream of PIC formation. Together these data suggested a block at the integration step, after reverse transcription and nuclear import. LEDGF/p75 KD did not affect production or infectivity of progeny virus in initial experiments. These observations have yet to be confirmed in more potent LEDGF/p75 KO cell lines. Of note, introducing IN W131A, Q168A, or A128T/E170G mutations, abolishing or reducing the interaction with LEDGF/p75, in HIV impaired reverse transcription and integration capacity, suggesting a role of LEDGF/p75 upstream of integration. In this context, functional PICs that were precipitated from the cytoplasm using anti-LEDGF/p75 antibodies and wild-type IN, but not IN Q168A, could be immunoprecipitated with anti-LEDGF/p75

antibodies using whole-cell extracts 8 h post-infection, although these observations were not confirmed in another study. Together these RNAi, knockout, and mutagenesis experiments thus point to a crucial role of LEDGF/p75 in HIV replication with LEDGF/p75 tethering the viral PIC toward the host cell chromatin thereby promoting integration.

Different studies have shown that genomic variation of *PSIP1* and LEDGF/p75 expression levels affects HIV acquisition and progression to AIDS. The link between several single-nucleotide polymorphisms (SNPs) in *Psip1*, few of them resulting in non-synonymous mutations, and disease outcome has been recently evaluated (Madlala et al. 2011). Madlala et al. mapped four known synonymous and one non-synonymous SNP resulting in the polymorphism Q472L in *PSIP1*, in the prospectively followed acutely HIV-infected, chronically HIV-infected, or uninfected South African people. The noncoding SNP (rs2277191) was associated with a higher likelihood of HIV-1 acquisition and more rapid disease progression, and another noncoding SNP (rs12339417) with slower CD4⁺ T cell decline and lower mRNA levels of LEDGF/p75. Recently, two non-synonymous SNPs, resulting in S436I and T473S mutations in LEDGF/p75, were described in HIV-infected long-term non-progressors ($N = 2$ out of 149), while these mutations could not be retrieved in a population of HIV progressors ($N = 92$) or healthy controls ($N = 1,500$, only T473S was evaluated), suggesting a possible role of these mutations in disease progression. However, a causal relationship or an effect of these mutations on the cellular functions of LEDGF/p75 has not yet been established. Expression levels of LEDGF/p75 in PBMCs also matter. In the prospectively followed South African CAPRISA cohort, higher LEDGF/p75 mRNA levels were associated with an increased likelihood of HIV infection (Madlala et al. 2011), and LEDGF/p75 protein levels in CD4⁺ lymphocytes were lower in HIV-exposed but seronegative individuals compared to healthy controls in a Senegalese cohort, although differences were only subtle. LEDGF/p75 was previously reported to be upregulated in HIV-infected

cells in vitro, and PBMCs from untreated HIV-1-infected individuals in vivo had higher expression levels of LEDGF/p75. Contrary, Madlala et al. found lower expression levels of LEDGF/p75 in PBMCs from seropositive compared with seronegative individuals in South African cohorts, and longitudinal data suggested a downregulation of LEDGF/p75 expression in seroconverters (Madlala et al. 2011).

The Role of LEDGF/p75 in Targeting Lentiviral Integration

LEDGF/p75 is clearly required for HIV replication. Interestingly this tethering factor also determines the integration site distribution. HIV-1 integration was demonstrated to occur preferentially in the body of actively transcribed transcription units in contrary to the gamma-retroviral integration pattern in which a less pronounced preference toward transcriptionally active regions and a preference to integrate near transcription start sites and CpG islands were observed and avian sarcoma leukocytosis virus (ASLV) or human T-cell leukemia virus (HTLV) is displaying a much weaker preference for these features. Integration site preferences of other lentiviruses, such as EIAV and SIV (SIVmne), correspond well with those observed for HIV-1.

Knockdown or knockout of LEDGF/p75 alters this integration pattern (Ciuffi et al. 2005), supporting the hypothesis that LEDGF/p75 targets HIV-1 integration toward transcriptionally active genes. Interestingly, LEDGF/p75 KD already affects the HIV integration site distribution pattern even in the absence of inhibition of HIV transduction (Ciuffi et al. 2005), and the effect in integration site selection becomes more outspoken upon KO of LEDGF/p75 (Schrijvers et al. 2012). LEDGF/p75 depletion reduced integration in active genes and increased integration near CpG islands, although still not in a range observed with the *Gammaretrovirus* MLV. Recently, the PWWP domain was demonstrated to be critical for targeting integration to regions enriched in specific histone posttranslational modifications. Interestingly, although integration events shifted toward a random distribution, random HIV integration was not observed even in LEDGF/p75

KO cells, suggesting alternative targeting mechanisms to play a role in the absence of LEDGF/p75. Transportin-SR2, a nuclear import factor for HIV, and RANBP2 also affected the integration site distribution pattern, suggesting a role for nuclear trafficking in target site selection.

Chromatin-binding sites of LEDGF/p75, mapped by DamID technology in the ENCODE region, revealed a chromatin-binding profile of LEDGF/p75 reminiscent to that of HIV-1 integration. Correlation of binding sites of LEDGF/p75 with known genomic features revealed a high correlation with markers of active chromatin. LEDGF/p75 binds active genes and disfavors promoter regions, although not all LEDGF/p75-binding sites correlated with HIV-1 integration.

Next, LEDGF/p75 hybrids in which the N-terminus was replaced by an alternative chromatin interaction domain, such as the heterochromatin-binding element CBX1, have been shown to retarget HIV-1 integration out of transcription units and toward heterochromatic regions (Gijsbers et al. 2010). These observations were independently confirmed using various other chromatin-binding domains. These studies therefore provide an in vitro proof of principle for redirecting retroviral integration, leading to the generation of safer lentiviral vectors that can selectively be targeted to regions of choice in the chromosome.

The LEDGF/p75–HIV Integrase Interaction as a Target for Antiretroviral Therapy

The LEDGF/p75–IN interaction can be targeted to tackle HIV using various approaches. First, overexpression of the IBD of LEDGF/p75 was shown to have a dominant negative effect on HIV-1 replication and was further exploited as a potential gene-therapeutic approach for HIV/AIDS. Next, small molecules targeting IN at the pocket formed by the IN dimer and responsible for the interaction with LEDGF/p75 were developed. They display potent antiviral activity (Christ et al. 2010). These compounds form a new class of antiretrovirals, are considered as allosteric HIV–integrase inhibitors, and termed LEDGINs (Christ et al. 2010). They are currently tested in phase 1 clinical trials. Lastly, also LEDGF/p75

itself can be targeted. In proof-of-concept studies, peptides were shown to block the LEDGF/p75-IN interaction and hamper HIV replication.

LEDGF/p52

Despite the shared N-terminal 325 amino acids, LEDGF/p52 seems to have distinct cellular functions compared with LEDGF/p75. In contrast to LEDGF/p75, the smaller LEDGF/p52 has been attributed a stronger and more general transcriptional coactivator activity (Ge et al. 1998). LEDGF/p52 interacts with the essential splicing factor ASF/SF2 (Ge et al. 1998) and was proposed to modulate alternative splicing. LEDGF/p52 is, contrary to LEDGF/p75, not implicated in HIV replication nor repair of double-strand breaks. While LEDGF/p75 overexpression seems to increase cell survival, overexpression of LEDGF/p52 or its caspase-mediated variant with a truncated PWWP domain induced apoptosis in several tumor cell lines.

HRP-2

HRP-2 (also known as HDGF2) is a 670 aa basic protein encoded by *Hdgfp2*, located on chromosome 19p13.3. It is structurally highly related to LEDGF/p75. Like LEDGF/p75, it contains a PWWP domain and AT-hook-like sequences at its N-terminus, next to a C-terminal IBD (48% identical and more than 70% similar to the IBD of LEDGF/p75). The remaining part of HRP-2 is estimated to be unstructured. HRP-2 is a nuclear protein, but has a more homogenous distribution when compared to the speckled pattern observed with LEDGF/p75, and does not bind to mitotic chromatin.

Fluorescence polarization, NMR titration experiments, and crystal structures suggest that the PWWP domain of HRP-2 also binds methyl-lysine residues on histones. HRP-2 bound best to peptides derived from H3K36me2 and weakly to H3K36me3, H3K79me2, H3K79me3, H4K20me2, and H4K20me3. In another study where the PWWP of LEDGF/p75 was changed for that of

HRP-2, an increased likelihood of integration near marks associated with active transcription, i.e., H2BK5me1, H3K4me3, H3K9me1, H3K27me1, and H3K36me3, was observed.

Little is known of the cellular role of HRP-2. Most observations were made in parallel with studies evaluating the role of LEDGF/p75. Interestingly, HRP-2 was shown to bind as well to the cellular LEDGF/p75-interacting proteins JPO2, PogZ, and Cdc7/ASK, although the relative contribution of HRP-2 in these interactions remains unknown. Much alike LEDGF/p75, the IBD of HRP-2 was sufficient to bind and stimulate the enzymatic activity of Cdc7/Ask. HRP-2 was also attributed a crucial role in the recruitment of CtIP to DNA DSBs, paralleling observations with LEDGF/p75.

HRP-2 also binds HIV IN via its IBD. HRP-2 overexpression relocated HIV-1 IN from the cytoplasm to the nucleus in LEDGF/p75 depleted cells. Although HRP-2 was investigated previously as a potential alternative for LEDGF/p75, no effect in multiple-round HIV-1 replication was observed after HRP-2 KD alone or in combination with LEDGF/p75 KD. However, these observations may have been obscured by the remaining LEDGF/p75 after incomplete RNAi-mediated KD. Recently, both single-round transduction and multiple-round replication were shown to be additionally hampered upon HRP-2 KD in LEDGF/p75 KO cells (Schrijvers et al. 2012). HIV-1 engages HRP-2 as an alternative for LEDGF/p75, but this low affinity IN binding partner can only substitute for LEDGF/p75 after depletion of the latter, suggesting a dominant role for LEDGF/p75 over HRP-2. The inferior role for HRP-2 compared with LEDGF/p75 is probably due to its lower affinity for HIV-1 IN. Considerably less IN could be co-immunoprecipitated by HRP-2 than LEDGF/p75; flag-LEDGF/p75 but not flag-HRP-2 co-immunoprecipitated IN from cell lysates, and AlphaScreen technology estimated that the IBD of HRP-2 has a 13-fold lower affinity for HIV-1 IN compared to the IBD of LEDGF/p75. The fact that HRP-2 does not bind to mitotic chromatin is probably irrelevant for HIV replication since LEDGF/p75 depletion for instance also affects HIV replication in nondividing cells.

Conclusion

LEDGF/p75 is a nuclear protein that acts as a molecular adapter to tether proteins to the chromatin. Besides a crucial role in tethering the HIV PIC to the chromatin, recent studies have uncovered a role for LEDGF/p75 in leukemia, cell survival, and DNA repair. The protein can thus be considered as a hub protein and an interesting target to treat multiple diseases. Knowledge on the interaction between LEDGF/p75 and IN has resulted in a new class of inhibitors (LEDGINS) blocking HIV replication that are in advanced preclinical and early clinical studies. LEDGINS are now being used as research tools to unravel HIV integration. They provide a good example of translating basic research findings into novel therapeutics.

Role of Regulatory T Cells During HIV Infection

Claire A. Chougnet, Maria E. Moreno-Fernandez and Cesar M. Rueda
 Department of Immunobiology, Cincinnati Children Hospital Medical Center, Cincinnati, OH, USA

Definition

Human immunodeficiency virus (HIV) causes a gradual loss of immune competence, leading to acquired immunodeficiency syndrome (AIDS). HIV-associated defects in cell-mediated immunity (CMI) are of particular importance, as these impairments lead to poor control of HIV replication and of other pathogens whose clearance depends on CMI. Importantly, a number of immune deficits caused by HIV infection can be

partially restored *in vitro*, suggesting the existence of active regulatory mechanisms. Several mechanisms are involved in the regulation of the immune system; among these is the pivotal role of regulatory T cells (Treg), a subset of CD4⁺ T cells, which has been recognized for several years. In addition to their role in controlling peripheral tolerance, Treg promote the establishment of persistent infections (viral, bacterial, parasitic, and fungal). Treg may thus contribute to inefficient CMI during chronic HIV infection. However, Treg may also play a beneficial role, because their control of immune activation may limit the availability of cellular targets for HIV infection, as well as decrease the pathology associated with immune activation. The mechanism(s) underlying the accumulation and role of Treg during HIV/SIV infection remain poorly understood. The aim of this entry is to discuss the recent findings on Treg origin and function in the setting of HIV infection.

Regulatory T Cells

Treg are a subpopulation of CD4⁺ T cells that originate from either the thymus (tTreg) or the peripheral conversion of conventional CD4⁺ T cells (Tcon) (pTreg). tTreg are positively selected in the thymus through MHC class II-dependent T-cell receptor (TCR) interactions resulting from a high-avidity selection. Multiple pathways of peripheral conversion have been described. The most studied involves TCR stimulation in the presence of the immunosuppressive cytokine, transforming growth factor beta (TGF- β). In addition, dendritic cell (DC)-mediated signals such as indoleamine 2,3-dioxygenase 1 (IDO) or retinoic acid (RA) induce or stabilize Treg conversion. Treg, regardless of their origin, are characterized by a high and constitutive expression of the IL-2 receptor alpha chain (CD25), the low expression of IL-7 receptor (CD127), and expression of the transcription factor, FOXP3. Unfortunately, so far, no single marker allows for a reliable phenotypic comparison between tTregs and pTregs.

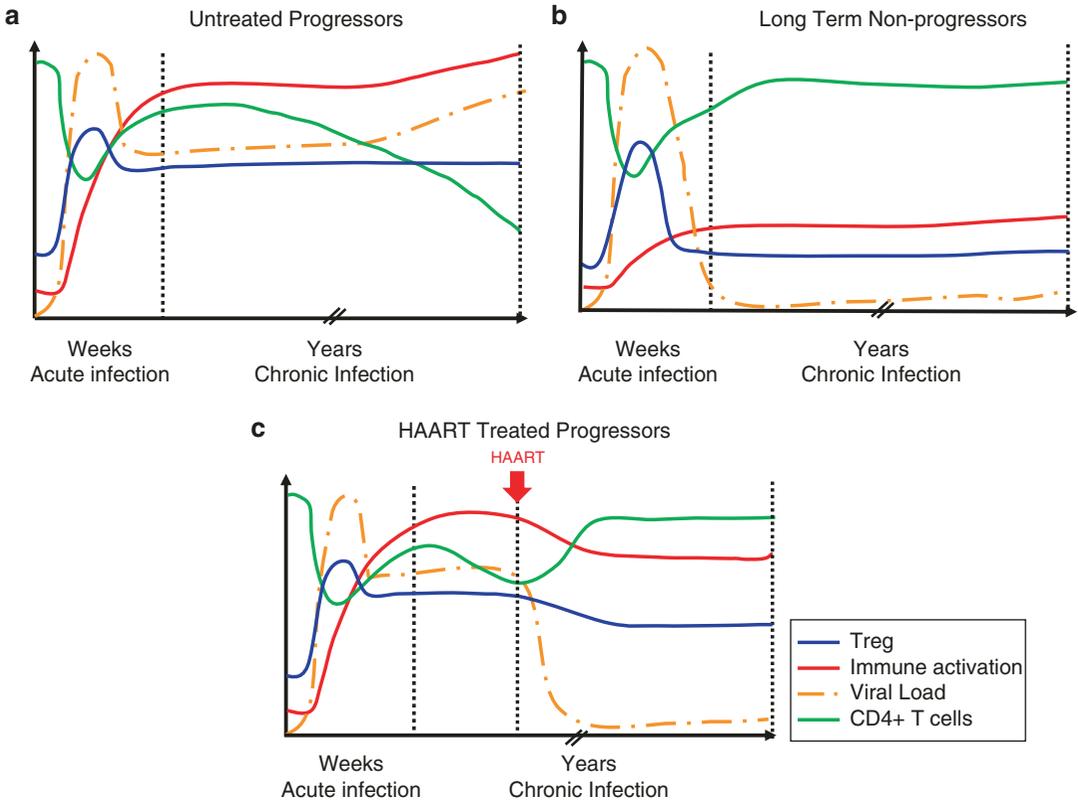

Immune Control by Regulatory T Cells

Treg are key regulators of the immune system. During viral infections, Treg are essential to prevent exacerbated inflammatory processes. However, in excess, Treg can impair the development of effector immune responses, thus promoting the establishment of chronic infections. Treg have been shown to suppress both innate and adaptive immune responses, based on their ability to produce immunomodulatory cytokines such as TGF- β and IL-10, as well as their capacity to mediate suppression through cell contact-dependent mechanisms. Among these, the interaction of lymphocyte antigen 4 (CTLA-4) with CD80/CD86 in DCs promotes the production of IDO.

Treg also contain high levels of cyclic adenosine monophosphate (cAMP), which inhibits T-cell differentiation and proliferation and which can be transferred to target cells through the formation of gap junctions (GJ) between Treg and their targets. Additionally, Treg express the ectonucleotidases CD39 and CD73, enzymes that hydrolyze extracellular adenosine triphosphate (ATP) and adenosine diphosphate (ADP) into adenosine monophosphate (AMP) and then into adenosine, respectively. Adenosine consequently activates adrenergic receptors which increases intracellular cAMP.

Regulatory T Cells During Acute HIV Infection

Little is known about Treg dynamics during the acute phase of HIV infection. In this setting, Treg expansion was reported and the percentage of circulating Treg inversely correlated with CD8⁺ T-cell activation (Ndhlovu 2008). During the non-pathogenic SIV infection in the African green monkey, Kornfeld et al. observed a very early (24 h post infection) and strong induction of FOXP3 mRNA expression and an increased percentage of circulating CD4⁺CD25⁺ T cells in the blood (Kornfeld 2005). In the context of pathogenic SIV infection in rhesus macaques, relative Treg accumulation occurred 2 weeks

Role of Regulatory T Cells During HIV Infection, Fig. 1 Treg kinetics during HIV infection. Change in peripheral Treg frequency over the course of HIV infection and its relationship with the levels of immune hyperactivation, HIV viral load, and CD4+ T-cell counts. **(a)** Untreated typical progressor: during the acute phase of HIV infection, the viral load (dotted yellow line) rapidly rises, the CD4+ T-cell count (green line) rapidly falls, while markers of immune activation (red line) and Treg frequency (blue line) start to rise. During the late acute and early chronic phase, the viral load is controlled, CD4+ T-cell levels increase, immune hyperactivation persists, and Treg frequency declines but remains higher than normal levels. During the late chronic phase, the viral loads as

well as immune hyperactivation gradually increase; Treg frequency also increases despite a progressive loss of CD4+ T cell. **(b)** Long-term nonprogressors: during the late chronic phase, viral loads decrease to very low levels and immune activation is low. CD4+ T-cell counts and frequency increase and can reach normal levels. Treg frequency remains comparable to that observed in healthy individuals. **(c)** HAART-treated HIV progressor: viral loads quickly fall to undetectable levels, and CD4+ T-cell counts and frequency are rapidly reestablished but not to levels comparable to uninfected individuals. HAART ameliorates Treg frequency and immune activation; however, Treg frequency never normalizes completely

postinfection in both mucosal tissues and peripheral lymph nodes (Allers 2010; Ji 2009). Importantly, macaques vaccinated by an attenuated vaccine showed significantly higher levels of Treg after SIV challenge than control animals (Genesca 2012). However, important differences exist depending on the model employed, as rapid loss of Treg occurred in the highly pathogenic model of SIV infection of pigtailed macaques, suggesting that the effect of acute HIV/SIV on

Treg frequency is dependent on multiple factors (Fig. 1a).

Regulatory T Cells During Chronic HIV Infection

High frequency of circulating Treg has consistently been found during progressive HIV infection (Presicce 2011; Rueda 2013). Increased Treg

percentages were also detected in lymph nodes, tonsil, gastrointestinal mucosa, and thymus (Nilsson 2006; Rueda 2013). In addition, chronically SIV-infected rhesus macaques with high viral loads had higher FOXP3 expression in the spleen, lymph nodes, and gut than macaques with a lower viral load (Boasso 2007). Despite this relative accumulation of Treg, their absolute numbers decrease over the course of infection (Presicce 2011; Rueda 2013; Fig. 1a).

In contrast, the majority of studies in long-term nonprogressors (LTNP), particularly elite controllers, reported decreased Treg frequency in peripheral blood and rectal mucosa compared to HIV progressors. Taken together, these data suggest that Treg imbalance is associated with progressive infection and uncontrolled viral replication (Fig. 1b).

Regulatory T Cells in HAART-Treated Patients

Discrepant results have been reported concerning the effect of HAART treatment on circulating Treg. HAART treatment was shown to either decrease (Presicce 2011) or not to modify (Lim 2006) the frequency of circulating Treg, although Treg frequency is not fully normalized by HAART (Presicce 2011; Fig. 1c). Differences between studies could come from the heterogeneity of HAART-treated patients. Indeed, recent studies comparing patients with immunological and non-immunological response to HAART suggest that Treg frequency was reduced only in patients with immune reconstitution (Rueda 2013). Treg absolute counts also increase post HAART, although they remain lower than in healthy donors (Presicce 2011; Rueda 2013). This alteration was associated with the persistent mucosal barrier dysfunction and activation (Rueda 2013).

Treg Susceptibility to HIV Infection

Although all studies agree that Treg can be infected by HIV, their relative susceptibility to

infection compared to Tcon remains controversial. Some studies have shown that activated Treg were more susceptible to infection by an HIV R5 strain than memory T cells, but Treg replicated the virus to a similar extent. Conversely, Treg have been shown to be less susceptible to infection with HIV R5 strains than Tcon but were more susceptible to X4 viruses (Moreno-Fernandez 2009). Data on Treg infection by HIV in vivo are scarce. In chronically HIV-infected patients, Treg were not preferentially infected compared to non-Treg (Chase 2008). During SIV infection of rhesus macaques, productive infection was detected in some FOXP3⁺ cells present in the gut-associated lymphoid organs and in the mucosal surface, but relatively less than in non-Treg. This suggested that Treg may be selectively spared from SIV/HIV-mediated cell death (Allers 2010). Additional work is needed to address the role of different viral factors in the dynamics of Treg infection by HIV.

Another unanswered question is whether Treg constitute a reservoir for HIV infection. In chronically infected HIV patients on suppressive HAART, the frequency of HIV DNA harboring cells is higher in resting Treg than in resting non-Treg. Similar results were found in mucosal Treg from SIV-infected macaques (Allers 2010), thus suggesting that Treg could contribute to viral reservoir.

Mechanisms of Treg Accumulation During HIV Infection

Preferential survival. As mentioned above, Treg are susceptible to HIV infection both in vitro and in vivo. However, their low susceptibility to productive infection compared to that of non-Treg could lead to their preferential survival. In the same line, Treg exposure to HIV selectively promoted their survival via a CD4-gp120-dependent pathway (Nilsson 2006).

Increased proliferation. Increased expression of Ki67, a marker of cell cycle, was found in mucosal and blood Treg from SIV-infected macaques and in circulating Treg from HIV-infected patients, suggesting that local

expansion of Treg could contribute to increased Treg frequency in lymphoid tissues and blood (Allers 2010; Presicce 2011). Of note, HIV may directly induce Treg expansion, as in vitro interaction of HIV with Treg induced their expansion and increased the expression of FOXP3, CD25, and CTLA-4 (Amarnath 2007).

Tissue redistribution. Some authors hypothesized that redistribution of Treg from blood to lymphoid tissues could explain the increased tissue frequency. Ji et al. showed that HIV-1 binding upregulated expression of the homing receptor CD62L and integrin $\alpha 4\beta 7$ by CD4⁺CD25⁺ Treg, which in turn could result in more rapid Treg migration to peripheral and mucosal lymphoid tissues where HIV replication occurs (Ji 2009). In agreement with this hypothesis, Treg prevalence correlated better with tissue viral load than with plasma viremia (Boasso 2007). However, using flow cytometry characterization of Treg, increased Treg frequency have been found in the peripheral blood of infected compared to uninfected subjects (Chase 2008; Presicce 2011), which does not support increased Treg homing as a mechanism for their accumulation in tissue.

Increased peripheral conversion. Several results suggest a contribution of peripheral conversion to the increased Treg pool. First, HIV-exposed plasmacytoid dendritic cells (pDC) convert allogeneic non-Treg into CD4⁺CD25⁺FOXP3⁺ Treg, while unexposed pDC do not (Manches 2008). Second, lymph node DC from untreated HIV-infected subjects induced a Treg phenotype in normal allogeneic T cells, an ability that was lost after ART. Third, tissue myeloid dendritic cells (mDC) from chronic SIV-infected rhesus macaques were more efficient at inducing the expression of CD25 and FOXP3 in autologous non-Treg than mDC from uninfected macaques (Presicce 2012). However, the contribution of this mechanism to increased Treg frequency may depend on the stage of infection and/or the body compartment, as blood mDC infected in vitro with HIV were not able to convert non-Treg into Treg (Presicce 2012).

Mechanisms that could be involved in increased DC-mediated peripheral conversion during HIV are not well characterized.

HIV-exposed pDC induced Treg through IDO (Manches 2008), and IDO levels are high in many organs of SIV-infected macaques (Boasso 2007). Another molecule involved in Treg conversion is TGF- β . During HIV infection, TGF- β levels are high (Estes 2007). Interestingly, although CD103⁺ mDC are considered critical for Treg conversion in GALT, the enhanced capacity of mDC from SIV-infected macaques to induce FOXP3 was not directly associated with the presence of CD103⁺ DC, suggesting that other molecules such as PD-L1 may be involved in this conversion (Presicce 2012).

Phenotype and Functional Activity of Treg During HIV Infection

During chronic HIV infection, Treg express high levels of activation markers, cell cycle, and regulatory molecules, such as CD69, PD-1, GITR, CTLA-4, and CD39, compared to healthy controls (Presicce 2011; Rueda 2013). Expression of most of these molecules is normalized in individuals with an immunological response to HAART but not in those without a response (Chase 2008; Presicce 2011). In vitro, Treg exposed to HIV or gp120 maintained their suppressive activity (Moreno-Fernandez 2009). Treg from HIV-infected individuals can suppress proliferation, cytotoxicity, and cytokine production in response to HIV proteins, but no marked difference in suppression is observed between acute and chronic HIV infection (HAART-treated or untreated HIV patients) or between progressors and elite controllers (Chase 2008; Kared 2008; Ndhlovu 2008; Rueda 2013). HIV-driven Treg expansion also appears to hamper immune control of other persistent pathogens, as Treg from HIV-infected individuals suppress immune responses to recall antigens such as CMV and PPD, suggesting that Treg may contribute to the clinical reactivation of CMV in untreated AIDS patients as well as attenuate the immune response to vaccines.

In the past years, new observations have suggested that Treg act as a double-edged sword during HIV-1 infection and that Treg may also play

a beneficial role during HIV infection by controlling immune activation. During SIV acute infection, CTLA-4 blockade decreases the level of IDO1 and paradoxically increased the viral replication in mucosal tissue due to intense immune activation, suggesting that the suppressive action of Treg is necessary to control the pathogenic process induced by SIV (Hryniewicz 2006). Likewise, SHIV-vaccinated rhesus macaques were protected from uncontrolled viral replication after SIV challenge, and this protection was associated with increased Treg frequency and decreased immune activation (Genesca 2012). Similarly, because the frequency of CD4⁺CD25^{high} Treg positively correlated with CD4 T-cell count and inversely correlated with CD4 T-cell activation during primary infection, Treg were postulated to play a largely beneficial role during the acute phase of HIV-1 infection (Kared 2008). In utero, activation of Treg may contribute to a lack of vertical transmission by decreasing T-cell activation (Legrand 2006). Moreover, individuals with strong HIV-specific Treg function in vitro had significantly lower levels of plasma viremia and higher CD4:CD8 ratios than individuals in whom Treg activity could not be detected (Kinter 2004).

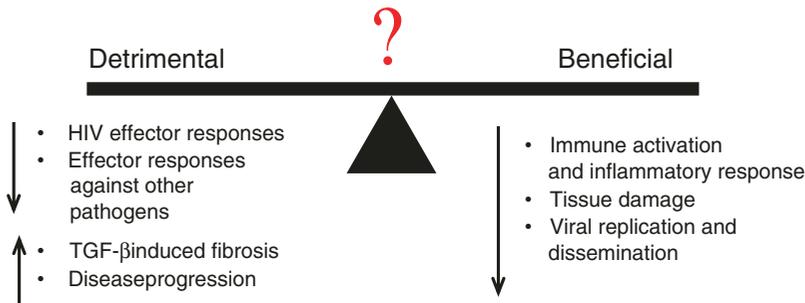

Consistent with these in vivo findings, Treg can control the frequency of HIV-infected Tcon cells in an in vitro model of acute infection by a process independent of their effect on Tcon cell proliferation. Cyclic AMP was critical for this antiviral effect, acting either by direct transfer of cAMP through gap junctions or by the extracellular pathway, which involves CD39 activity (Moreno-Fernandez 2011). Recently, Treg were shown to decrease HIV infection in dendritic cell-Tcon clusters using both CTLA-4 and cAMP mechanism, suggesting that Treg could reduce HIV dissemination, which would be beneficial to the host in the early stages of infection (Moreno-Fernandez 2014). In addition, Treg have been shown to decrease infection of murine macrophages by a pseudotyped HIV virus and, consequently, to attenuate HIV-associated neurodegeneration (Liu 2009).

On the other hand, Treg also play a detrimental role during HIV infection. Treg have been shown

to be a major source of TGF- β . Treg contributed heavily to the development of fibrosis in SIV-infected rhesus macaques as TGF- β exacerbates collagen deposition within T-cell zones that destroys the lymphatic tissue architecture and hampers CD4 reconstitution in the lymphoid tissues of infected animals (Estes 2007). In addition, as described above, Treg suppress HIV-specific immune responses. Depletion of Treg from mononuclear cells enhanced the T-cell response to HIV/SIV antigens, and their activity contributed to the diminution of HIV-specific immune responses in the early stages of HIV infection (Hryniewicz 2006; Kinter 2004). Rhesus macaques acutely infected with SIV have increased Treg frequency that correlated with inefficient SIV-specific CD8⁺ responses. Furthermore, a high-perforin/FOXP3 ratio was associated with nonprogressive disease, suggesting that the immune control of virus replication represents a balance between CMI and Treg-mediated counter regulation of such responses (Nilsson 2006). Confirming this hypothesis, an important study recently showed that HIV-specific CD8⁺ T cells bearing protective HLA alleles (HLA B*27 and B*57) are able to evade Treg suppression (Elahi 2011). This suggests that alternative mechanisms to evade Treg suppressive activity have emerged to counteract their deleterious effect on HIV-specific immune responses.

Treg could decrease HIV-specific responses via several mechanisms. The role of CTLA-4 is suggested by the fact that in vivo CTLA-4 blockade increased CD4⁺ and CD8⁺ T-cell effector function during the chronic phase, when given in combination with ART (Hryniewicz 2006). Blockade of CD39 partially decreased the suppressive effect of Treg on effector T cells (Nikolova 2011). Of note, a CD39 gene polymorphism that leads to low CD39 expression is associated with the relative protection against development of AIDS (Nikolova 2011). Together these data demonstrate that Treg activity may contribute to the inability of the host to clear HIV infection both in vivo and in vitro.

Potential role of Tregs during HIV infection

Role of Regulatory T Cells During HIV Infection, Fig. 2 Role of Treg during HIV infection. Treg have both a detrimental and beneficial role during the acute and chronic phases of HIV infection. Increased Treg frequency during the early acute phase of HIV infection (*right side*) may have an overall beneficial effect, by controlling T-cell activation, inflammation, and tissue damage and by decreasing the availability of target cells for HIV

replication. During the late acute and chronic phase (*left section*), the increased frequency of Treg is likely deleterious as they dampen specific immune responses against HIV and other pathogens. Treg also contribute to lymphoid tissue fibrosis by secreting large amounts of TGF-β. At this stage, increased Treg frequency likely favors disease progression. However, protection against tissue damage may persist

In vivo studies directly evaluating the role of Treg during HIV/SIV infection are scarce. One study in chronically SIV-infected African green monkeys treated with Ontak (a fusion protein that combines a recombinant IL-2 and a cytotoxic diphtheria toxin moiety that depletes CD25⁺ cells) showed that treated animals had significantly higher levels of immune activation and a significant increase in viral replication compared to control animals suggesting that Treg can control virus infection in vivo. However, it is important to note that the data from this study are difficult to interpret, as the frequency of FOXP3⁺ cells was not significantly decreased in the Ontak-treated animals, suggesting that Ontak may have acted through another mechanism. Notably, the higher levels of immune activation induced by Ontak treatment may have increased the numbers of available cellular targets for HIV infection.

Conclusion

Excessive activation and regulatory processes coexist through the entire course of HIV infection. As HIV infection progresses, a relative expansion of Treg cells occurs in the early stages when viral replication is high and before severe damage of

the GALT occurs. At this stage, Treg might control Tcon activation, reducing the proliferation and the number of target cells for the virus (Fig. 2, right section). This effect of Treg is thought to result in decreased HIV replication and limited disease progression. At the post-acute stage when the viral load is reduced and HIV-specific immune responses are established, the balance between regulatory and effector cells is lost and the increased frequency of Treg may become deleterious due to their suppression of HIV-specific immune effector mechanisms (Fig. 2, left section). In addition, Treg inability to suppress systemic hyperactivation and their promotion of tissue fibrosis may potentiate their role in HIV pathogenesis (Fig. 2, left section). Gaining a better understanding of the mechanisms regulating Treg dynamics and their role during HIV infection remains an important question, as this knowledge will help in determining whether Treg function or number can be successfully manipulated to the advantage of the infected host.

Definition

TRN-SR2 (TNPO3, transportin-3) is a karyopherin of the importin- β superfamily. As such it imports protein cargos from the cytoplasm

into the nucleus. Alike for all members of this family, the import of cargos is driven by the GTP/GDP gradient between the cytoplasm and the nucleus of the cell and therefore regulated by RanGTP-induced release of the cargo in the nucleus. TRN-SR2 is known to import SR-rich proteins in to the nucleus and has been proposed to be responsible for PIC nuclear translocation essential for provirus formation and a bottleneck in HIV replication.

Nuclear Import, a Critical Step in HIV Replication

Lentiviruses, such as the human immunodeficiency virus type 1 (HIV-1), are unique among the retroviruses because of their capacity to infect nondividing cells. The lentiviral DNA, packed in the nucleoprotein pre-integration complex (PIC), is recognized by the cellular nuclear transport machinery and traverses the nuclear envelope in an active- and energy-dependent manner to integrate into human chromatin. Gammaretroviruses, however, such as murine leukemia virus (MLV) require nuclear envelope breakdown during mitosis to gain access to the cellular chromatin and efficiently integrate. Although this process has been studied over decades, implementing different viral components and cellular nuclear import factors in the process, only recently the importin- β like karyopherin TRN-SR2 (transportin-3, TNPO3 (Lai et al. 2000, 2001, 2003; Yun et al. 2003)) has been proposed to play an important role in HIV nuclear import. In 2008 three independent reports using either siRNA screening (Brass et al. 2008; Konig et al. 2008) or yeast two-hybrid (Christ et al. 2008) identified TRN-SR2 as an important cellular factor for HIV replication. In the yeast two-hybrid approach, HIV integrase was identified to interact with TRN-SR2 (Christ et al. 2008), indicating a role of TRN-SR2 in the nuclear import of the viral PIC.

TRN-SR2 (Transportin-3, TNPO3) an Importin of the Importin- β Family

TRN-SR2 (Lai et al. 2000) shuttles essential splicing factors, the serine-/arginine-rich proteins

(SR proteins), between the cytoplasm and the nucleus of cells and therefore is involved in the regulation of mRNA splicing. The recognition of the SR proteins by TRN-SR2 relies on the conserved RS domain and requires phosphorylation (Lai et al. 2000, 2001). Yun et al. showed that TRN-SR2 like its splicing variant TRN-SR1 is encoded by *TNPO3* and is expressed via alternative splicing (Yun et al. 2003). In most tissues and in all cell lines analyzed so far, only TRN-SR2 is expressed, whereas the TRN-SR1 isoform is undetectable (Yun et al. 2003). By yeast two-hybrid screening, multiple non-SR proteins have been identified as binding partners of TRN-SR2. The most prominent binding partner is the RNA-binding motif protein 4 (RBM4), a zinc finger protein involved in splicing regulation (Lai et al. 2003). TRN-SR2 is a member of the importin- β family of nuclear importins and therefore depends on the RanGTP/RanGDP gradient between cytoplasm and nucleus for efficient nuclear import of its cargos. Despite the lack of knowledge regarding the structure of TRN-SR2, its close relation and homology with importin- β proteins suggests that its three-dimensional structure consists of stacked HEAT domain repeats containing two antiparallel α -helices linked by a flexible loop. No clear independent domains can be assigned, but overlapping functional domains can be defined: (1) the N-terminal RanGTP-binding domain, (2) the central nuclear pore-binding domain, and (3) the C-terminal cargo-binding domain. Indeed the C-terminal domain of TRN-SR2 was shown to be involved in cargo binding (Lai et al. 2000).

TRN-SR2 and HIV Replication

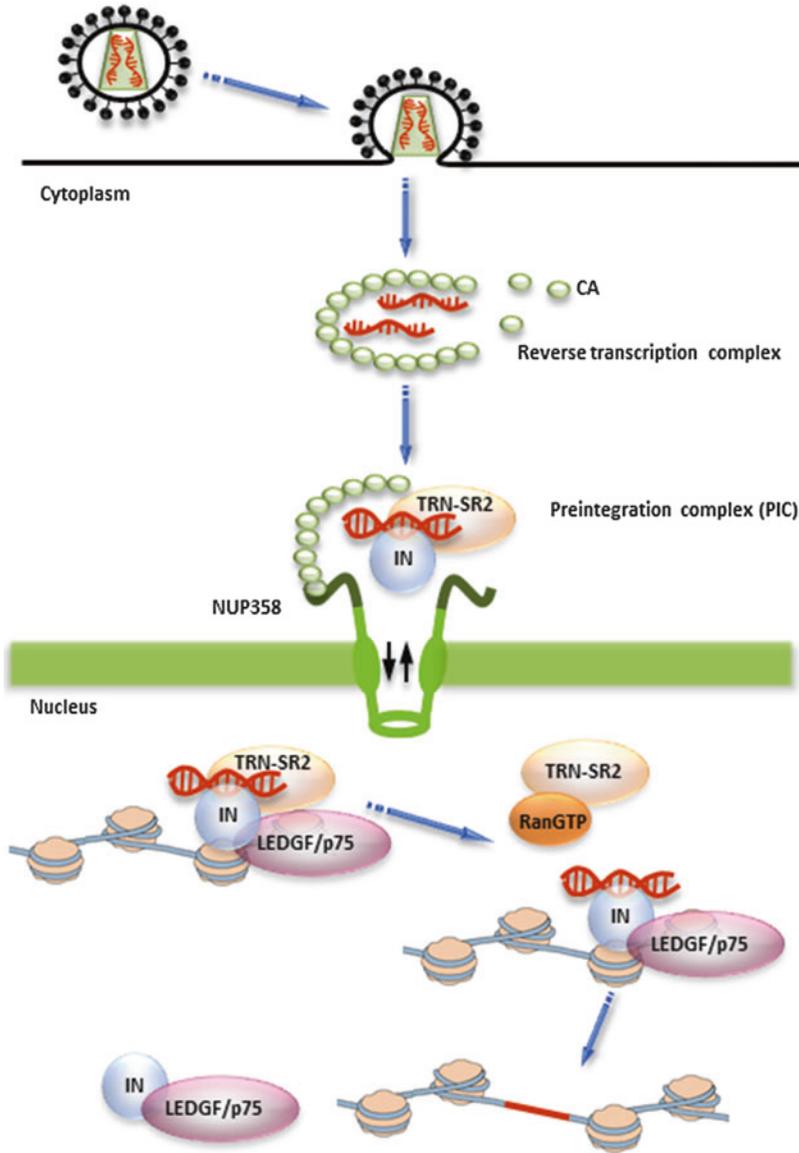

Between the first reports of the involvement of TRN-SR2 in HIV replication (Brass et al. 2008; Konig et al. 2008; Christ et al. 2008) in 2008 and today, multiple groups have been elaborating on its function in HIV replication (Christ et al. 2008; Cribier et al. 2011; De Iaco and Luban 2011; Krishnan et al. 2010; Lee et al. 2010; Logue et al. 2011; Ocwieja et al. 2011; Schaller et al. 2011; Thys et al. 2011; Valle-Casuso

et al. 2012; Zhou et al. 2011). Although consensus is reached that TRN-SR2 indeed is an important cofactor of early HIV replication acting prior to provirus establishment in the host chromatin, the detailed underlying mechanism is still controversial. TRN-SR2 was identified as an interaction partner of the viral protein integrase in yeast two-hybrid screening (Christ et al. 2008). A reverse screen confirmed the exclusive interaction between both proteins excluding interactions with other viral proteins under these experimental settings. The high-affinity interaction was independently confirmed by others (Krishnan et al. 2010). Two groups though demonstrated that the *in vitro* interaction with TRN-SR2 is not exclusive for lentiviral integrases (Krishnan et al. 2010; Thys et al. 2011) but is also observed with other retroviral integrase such as MLV and RSV that do not depend on TRN-SR2 for viral replication (Krishnan et al. 2010; Logue et al. 2011; Thys et al. 2011). Thus the lentiviral specificity of the TRN-SR2 phenotype does not depend on the integrase but must be determined by at least one second viral determinant. The early report that a mutant, N74D, of the viral capsid protein apparently rendered HIV independent of TRN-SR2 knockdown brought the capsid protein into the picture (Lee et al. 2010). The N74D mutant had been selected to be resistant for the overexpression of a deletion mutant (385) of the cleavage and polyadenylation specific factor 6 (CPSF6) which is in turn a SR-rich protein and therefore a likely cargo of TRN-SR2. Although to date no direct evidence has been provided that CPSF6 is indeed a cargo of TRN-SR2, the CPSF6_385 deletion mutant, lacking the SR-rich domain, does not translocate to the nucleus and stays in the cytoplasm where it most likely binds to the viral capsid and slows down the cytoplasmic uncoating of the viral particle (Lee et al. 2010). Even though the detailed mechanism underlying the link between both processes is not understood, the data suggest coupling between nuclear import and uncoating of the viral particle. In further support of this notion, the TRN-SR2 requirement for viral replication was shown to be associated with the viral entry pathway into the cell (Thys et al. 2011). VSV-G-pseudotyped HIV

vectors enter the cell through endocytosis, whereas HIV enters through membrane fusion. These different entry pathways likely affect the uncoating process. This underlines the care to be taken when analyzing the early steps of HIV replication (prior to ► [integration](#)) with pseudotyped vectors instead of HIV-enveloped replication competent viruses. In fact the initial finding that the N74D capsid mutant replicates independently from TRN-SR2 (Lee et al. 2010) needs to be revised after analyzing the replication of the N74D molecular clone. The replication competent virus with N74D capsid is still dependent on TRN-SR2 (Thys et al. 2011).

Different groups have studied the physical interaction of TRN-SR2 with capsid but no consensus on the functional implications has been reached (Valle-Casuso et al. 2012; Zhou et al. 2011). *In vitro* interaction studies of capsid protein with potential binding partners might be biased by the multimeric state of capsid and therefore should be interpreted with care unless a specific high-affinity interaction with reconstructed core particles can be demonstrated. Independent confirmation in literature will be needed to further support the interaction between capsid and TRN-SR2 and to clarify the underlying mechanism.

During HIV replication not all reverse transcribed cDNAs are integrated in the cellular chromatin, but nonproductive byproducts, the 2-LTR circles, are formed. The general belief is that such circles are formed in the nucleus and therefore they are taken as a measure of nuclear import. Interpretation of the absolute number of 2-LTR circles has to take into account that additional blocks of ► [integration](#) will lead to an increase of circles that can mask any reduction caused by a nuclear import defect. Several groups have studied how knockdown of TRN-SR2 affects the number of 2-LTR circles. In 2008 a 2- to 3-fold decrease in 2-LTR circles after siRNA-mediated knockdown of TRN-SR2 was reported (Christ et al. 2008). Although several studies confirmed this initial finding (Logue et al. 2011; Schaller et al. 2011), other groups could not detect the decrease (De Iaco and Luban 2011; Valle-Casuso et al. 2012; Zhou et al. 2011). Although final word

Role of Transportin-SR2 (Transportin-3, TRN-SR2, TNPO3) in HIV Replication, Fig. 1 Schematically drawing of the early steps of HIV replication. After fusion to the cell membrane, the viral core is released into the cytoplasm. While the RNA is reverse transcribed into a cDNA copy and the reverse transcription complex and later the PIC travels through the cytoplasm in direction to the nucleus, uncoating progresses. Eventually uncoating has reached a state where the inner structure of the PIC is accessible to other cellular cofactors, such as TRN-SR2 (Christ et al. 2008). CA then docks the PIC to the nuclear

pore basket via its interaction with Nup358 (Schaller et al. 2011) and enables the nuclear import factor to interact with the nuclear basket leading to the passaging of the PIC into the nucleus where TRN-SR2 draws the PIC in the proximity of the preferred integration sites of HIV (Ocwieja et al. 2011), RanGTP displaces the PIC from TRN-SR2, and, via the interaction of IN with LEDGF/p75, the PIC is tethered to the host chromatin leading to provirus formation. More experimental evidence is needed to support and test the proposed hypothesis of HIV-PIC nuclear import

needs to be spoken regarding the formation of 2-LTR circles, all reports confirm that knockdown of TRN-SR2 leads to a decreased provirus formation confirming the importance of TRN-SR2 for early steps of the replication cycle (Christ et al. 2008; Cribier et al. 2011; De Iaco and Luban 2011; Logue et al. 2011; Ocwieja et al. 2011; Schaller et al. 2011; Valle-Casuso et al. 2012; Zhou et al. 2011). Analyzing the cellular localization of fluorescently labeled PICs in cell culture supports the notion that TRN-SR2 is directly involved in nuclear import. Knockdown of TRN-SR2 with siRNA or shRNA excludes the fluorescently labeled PICs almost completely from the nucleus (Christ et al. 2008). The Bushman group demonstrated that depletion of TRN-SR2 alters the ► [integration](#) site distribution of HIV but not MLV, pointing toward a direct or indirect role of TRN-SR2 in ► [integration](#) site selection (Ocwieja et al. 2011). Although several questions remain unanswered, it is clear today that TRN-SR2 is an important cofactor of HIV replication (Christ et al. 2008; Cribier et al. 2011; De Iaco and Luban 2011; Logue et al. 2011; Ocwieja et al. 2011; Schaller et al. 2011; Valle-Casuso et al. 2012; Zhou et al. 2011). As the single steps which lead to provirus formation (uncoating of the incoming viral particle, reverse transcription, nuclear import, and integration) are interdependent, the detailed understanding of the TRN-SR2 mechanism is a challenging task. In any case it has become clear that nuclear import is very tightly linked to uncoating and even that uncoating might only be completed through nuclear import since CA promotes the docking of the PIC to the nuclear pore protein, NUP358 (Schaller et al. 2011). Future work will help to elucidate the interplay of TRN-SR2 with integrase and/or capsid and will shed light on the function of TRN-SR2 in lentiviral replication.

Conclusions

TRN-SR2 (TNPO3, transportin-3) is a classical importin- β like nuclear import factor present in all cell types. Multiple lines of evidence suggest an important role of TRN-SR2 in HIV

replication, although the detailed underlying mechanism still needs to be understood. The interaction of TRN-SR2 with HIV-IN seems at least partially responsible for the nuclear import of the PIC. Other tightly associated viral processes such as uncoating are rate limiting for the nuclear import and are therefore tightly linked to the nuclear import of the HIV-PIC (Fig. 1).

S

Salmonellosis and Other Bacterial Enteric Infections and HIV

Christine Wanke¹ and Andrew Chandranesan²

¹Department of Medicine and Infectious Diseases, Tufts University School of Medicine, Boston, MA, USA

²Infectious Diseases, Tufts University School of Medicine, Boston, MA, USA

Definition

Enteritis by definition is inflammation of the intestinal wall; this inflammation could be small intestine or large intestine or both. Inflammation may be infectious or noninfectious in origin. Among infectious etiologies, bacterial organisms are most commonly associated with acute infectious enteritis. In this entry enteric bacterial infections in persons living with HIV are discussed as they have been an important cause of morbidity and mortality in this vulnerable population. The rates of gram-negative bacterial infections are at least tenfold higher in persons living with HIV than in the general population. The risk of symptomatic disease varies according to the immune status (as measured by CD4 count) of the host. The greatest risk is in individuals with CD4 count less than 200 cells/mm³. In this entry we aim to provide a concise review of the enteric bacterial pathogens that play a very important role in

causing enteritis in the HIV patient population. The first, historical perspective about the enteric bacterial infections during the late 1980s and 1990s when immune compromised HIV patients were the norm will be presented. This will be followed by data on enteritis from the current era of widespread use of antiretroviral therapy which may alter the presentation and frequency of these pathogens. While emerging bacterial pathogens will be discussed, pathogens such as mycobacteria, parasites, or viruses will not be discussed.

Overview

The most commonly encountered enteric bacterial pathogens are salmonella, shigella, and campylobacter and the diarrheagenic *Escherichia coli*. There has been a recent emergence of *Clostridium difficile* and enteroaggregative *Escherichia coli* infections among persons living with HIV. Infection with any of the above pathogens can have differing clinical presentations depending on the region of the gut infected and the patient's immune status. Infections of the small bowel present as watery, often dehydrating, diarrheal illnesses, and infections of the colon are more likely to be associated with smaller volume often bloody or inflammatory stool. Colitis in persons living with HIV may be complicated by bacteremia with extra-intestinal manifestations (AIDS info 2016).

Salmonella

Early in the AIDS pandemic, salmonella was recognized as an important opportunistic pathogen. Patients with AIDS had a 20–100-fold increased incidence of salmonellosis (Angulo and Swerdlow 1995). Salmonellosis heralded the development of other opportunistic infections and is an AIDS-defining condition (Celum 1987). The incidence of salmonella bacteremia is high in persons living with HIV, and recurrence is common due to the intra-macrophagic persistence of salmonella organisms (Casado 1999). With the institution of antiretroviral therapy in the 1990s, mortality from nontyphoidal salmonella bacteremia decreased significantly (Arthur 2001).

Microbiology

Salmonella is a motile gram-negative bacilli that is oxidase and lactose negative and produces hydrogen sulfide. Salmonella grows well in both aerobic and anaerobic conditions. Salmonella grows on XLD (xylose lysine deoxycholate) agar. All of the clinically relevant salmonella fall under *Salmonella enterica* subsp. *enterica*. This is further subdivided into multiple serotypes each causing a different clinical disease (Tindall 2005).

Serotype (serogroup)	Clinical syndrome
<i>S. paratyphi A</i> (A)	Enteric fever
<i>S. paratyphi B</i> (B)	Gastroenteritis or enteric fever
<i>S. typhimurium</i> (B)	Gastroenteritis
<i>S. paratyphi C</i>	Enteric fever
<i>S. choleraesuis</i> (C)	Bacteremia
<i>S. newport</i> (C)	Gastroenteritis
<i>S. typhi</i> (D)	Enteric fever
<i>S. enteritidis</i> (D)	Gastroenteritis
<i>S. dublin</i> (D)	Bacteremia

Epidemiology and Transmission

Typhoidal Salmonella Typhoid and paratyphoid are major public health problems in the resource-limited setting. In 2010 there was an estimated 13.5 million cases of typhoid fever globally. Incidence (episodes per 100,000 person years) of typhoid fever was highest in the sub-Saharan Africa (724.6), followed by South Asia (394.2), and East and South East Asia (29.2). With

regard to paratyphoid fever, the incidence was highest in sub-Saharan Africa (77.4) and South Asia (394.2) followed by East and South East Asia (29.2). North America had an incidence of 0.1 for typhoid fever (Buckle 2012).

Typhoid is endemic in regions of the world which are overcrowded with poor sanitation (Crump 2004). Humans are the only reservoir of *S. enterica serotype typhi*. So contact with a known typhoid case or carrier is needed to cause transmission. History of travel to typhoid endemic areas with poor sanitation is also one of the major causes of typhoid in United States (Lynch 2009).

Nontyphoidal Salmonella The global burden of nontyphoidal salmonellosis was estimated to be 93 million in 2006 with an incidence of 1140 per 100,000 person years (Majowicz 2010). Outbreaks of nontyphoidal salmonellosis were most commonly associated with poultry and eggs. Reptiles and amphibians especially when they were pets can also carry and transmit salmonellosis (Bennett 2015).

Clinical Syndrome

Clinically, *Salmonella* can present in one of the following five ways (Bennett 2015; Cohen 1987):

- Asymptomatic chronic carrier state
- Gastroenteritis
- Enteric fever
- Bacteremia and endovascular infections
- Extraintestinal focal infections

Typhoidal *Salmonella* (*S. typhi*, *S. paratyphi A*, *S. paratyphi B*, and *S. paratyphi C*) causes enteric fever. Typical enteric fever is characterized by onset of symptoms, 5–21 days after the ingestion of the causative microorganism. During the first week, a patient may experience rigors from bacteremia often with a relative bradycardia or a pulse temperature dissociation. During the second week, the patient may develop “rose spots” which are faint salmon-colored macules on the trunk and abdominal pain. During the third week, if left untreated patients can develop intestinal bleeding or intestinal perforation due to the

ileocecal lymphatic hyperplasia of the Peyer patches (Stuart and Pullen 1946). HIV infection in itself does not change the course of enteric fever. But in AIDS patients, enteric fever may have an atypical presentation, have an increased rate of relapse, and develop into a chronic carrier state (Gutuzzo 1991).

Nontyphoidal *Salmonella* (NTS) cause gastroenteritis with or without bacteremia. Presence of NTS bacteremia in the absence of any other immunodeficiency can be an early sign of HIV infection. Also HIV confers a significant risk for bacteremia (primary and secondary) and focal extraintestinal infections. The extraintestinal sites of infections are the urinary tract, lung, pleura, joints, bones, heart, and central nervous system (Rodriguez 2006; Cohen 1987). NTS bacteremia has a predilection to seed the vasculature especially the large vessels with atherosclerotic plaques and may cause mycotic aneurysms of the aorta (Benenson 2001).

Shigella

Microbiology

Shigella species are a major cause of bacterial dysentery worldwide. *Shigella* are facultative anaerobes and are gram-negative rods. There are four species of *Shigella*: *S. dysenteriae*, *S. flexneri*, *S. boydii*, and *S. sonnei*. *Shigella* are nonflagellated, indole positive, and urea and oxidase negative, ferment glucose, and don't produce hydrogen sulfide. They grow well in MacConkey agar.

Epidemiology and Transmission

The global burden of shigellosis was estimated to be 165 million each year (Kotloff 1999). In the resource-limited setting, most cases are transmitted by the fecal–oral route from people with symptomatic infection. In the resource-sufficient world, outbreaks of shigella infection have been reported among MSM. In the person living with HIV, raw vegetables traced to a common supplier, cold salads, and day care centers and areas with crowded living condition are all risk factors for shigellosis (Niyogi 2005; Aragon et al. 2007). Men who have sex with men (MSM) have an increased risk of shigellosis due to direct oral–anal contact (Aragon et al. 2007).

Clinical Syndrome

Shigellosis, also known as acute bacillary dysentery, is an infectious inflammation of the colon. The disease is characterized by a prodrome of fatigue, malaise, and anorexia followed by diarrhea. Initially, diarrhea can be watery (*S. sonnei*), and then it can progress to bloody diarrhea with tenesmus (*Shigella dysenteriae* 1 or *Shigella flexneri*) (Khan 2013). In a normal host, the course of the disease is generally self-limited and will resolve within 7 days if left untreated. HIV infection in itself is not clearly associated with increased risk of *Shigella* gastroenteritis (Angulo and Swerdlow 1995). Intestinal complications include intestinal perforation, toxic megacolon, and rectal prolapse (Bennish 1991). *Shigella* bacteremia is a rare occurrence in the general population. But it has been more prevalent in the HIV patient population, occurring both in the early and later course of HIV infection with increased mortality (Keddy 2012). Recurrent shigella bacteremia was also found among AIDS patients (Angulo and Swerdlow 1995). Other systemic complications include encephalopathy manifesting as seizures, electrolyte abnormalities from dehydration, microangiopathic hemolytic anemia, and post-infectious inflammatory arthritis (Niyogi 2005).

Campylobacter

Microbiology

Campylobacters are motile gram-negative bacteria which can be of spiral, rod, or curved shape. They are microaerophilic and nonspore forming (Mandell 2015). *Campylobacter jejuni* and *Campylobacter coli* are the most important species to cause human infections. *Campylobacter* spp. multiply slowly, and isolation of these organisms requires growth in a blood-based, antibiotic-containing media (Bennett 2015). *C. upsaliensis* and *C. concisus* are emerging pathogens in patients with gastroenteritis (Man 2011).

Epidemiology and Transmission

The incidence of campylobacter cases has been increasing globally over the past decade. Incidence in the United States in 2012 is 14.3 per 100,000 population. In Europe, incidence ranges

from 0.92, in Poland from 2011 to 2012 to a maximum of 81.4 per 100,000 population in Germany from 2005 to 2011 among reported studies. The prevalence of campylobacter gastroenteritis in China and India ranges from 5% to 16% in the last decade (Kaakoush 2015). Risk factors for campylobacteriosis are international travel, exposure to animals, and contaminated food and water (Kaakoush 2015). With regard to international travel, the greatest risk for acquiring infection is travel to Asia, Africa, Latin America, and the Caribbean (Mughini-Gras et al. 2014). Among foods, consumption of poultry products especially broiler chicken and unpasteurized milk is associated with infection. Domesticated animals like cattle, sheep, pigs, dogs, and cats are known reservoirs of campylobacter and have been implicated in human infections (Kaakoush 2015).

Clinical Syndrome

Campylobacter enteritis is characterized by a prodrome of fever, malaise, and abdominal pain which lasts for about 12–24 h. This is followed by diarrhea, which can range from loose watery stools to bloody stools. Diarrhea can last for up to 7 days, but the organism can be shed in the stool for several weeks (Bennett 2015). In the HIV patient population, the disease tends to be severe and persistent. HIV patients are also at risk of developing recurrent episodes of enteritis, extra-intestinal campylobacter infections, and long-term carriage. The incidence of campylobacter bacteremia has not consistently been increased in patients with AIDS (Angulo and Swerdlow 1995; Molina 1995).

Escherichia coli (*E. coli*)

E. coli infection which has acquired diarrheagenic virulence factors is a common cause of diarrheal illness worldwide. *E. coli* are a part of the normal flora of the human gut. But the acquisition of genes for virulence factors such as adhesins or toxins by *E. coli* allows *E. coli* to cause different kinds of diarrheal illness in humans. The currently recognized pathotypes are enterotoxigenic *E. coli* (ETEC), enteropathogenic *E. coli* (EPEC), enterohemorrhagic *E. coli* (EHEC), enteroinvasive *E. coli* (EIEC), and enteroaggregative *E. coli*

(EAEC). Among these enteroaggregative *E. coli* is associated with an increased risk in patients with HIV. In HIV patients especially those who are immunocompromised, infection with EAEC causes chronic diarrhea and malnutrition (Mayer and Wanke 1995). There has been an association of EAEC in the stool of chronic diarrheal patients with low CD4 counts and weight loss. Thus it may be easier for an immunocompromised host to develop EAEC infection (Wanke 1998).

Clostridium difficile Infection in HIV

Clostridium difficile infection (CDI) was found to be the most common cause of bacterial diarrhea in a study among persons living with HIV from 1992 to 2002 (Sanchez 2005). In another study from 2003 to 2011 among the persons living with HIV, clinical manifestations among persons living with HIV did not differ significantly from the disease in non-HIV patients. A CD4 count of less than or equal to 50 cells/mm³ was identified as an independent risk factor for acquisition of CDI. Other risk factors for acquisition of CDI were the use of gastric acid suppressants, the use of antibiotics, a recent hospital stay, and the use of immunosuppressive medications (Haines 2013).

Proctitis

The most common bacterial causes of infectious proctitis are *Neisseria gonorrhoea*, *Chlamydia trachomatis*, and *Treponema pallidum* (Hoentjen and Rubin 2012). The most common cause of proctitis is anal-receptive intercourse from an individual infected with gonorrhoea or chlamydia; the most common etiology is gonorrhoea followed by chlamydia. More than one infectious agent may occur concurrently in proctitis at the same time (Klausner 2004). Rectal inflammation in proctitis is associated with an increased risk of acquiring HIV infection (Craib 1995).

Evaluation

The evaluation of diarrhea in a person living with HIV does not need to be fundamentally different than the evaluation of diarrheal illness in the general population. Thorough history taking is a

crucial part of the initial evaluation; questions related to characterization of diarrhea should be gathered in detail and should include duration of diarrhea, associated symptoms, quality of diarrhea (is blood present), frequency of diarrhea (stooling), and presence of tenesmus. Weight loss, if present, should be noted. Then, specific emphasis should be focused on exposures: animals, pets, recent travel, and sick contacts. Dietary history including consumption of raw foods, salads, and green leafy vegetables, method of food preparation, dining at restaurants, and travel history is important. A detailed review of medications the patient is taking currently or in the recent past is also important. It is important to keep in mind that antiretroviral therapy in itself can cause diarrhea as a side effect.

Laboratory evaluation should begin with complete blood count and renal function tests to assess hydration status in the person living with HIV; CD4 count should be determined to assess which pathogens may occur. In the person living with HIV, blood cultures should also be drawn as incidence of salmonella, and campylobacter bacteremia is high in this patient population. Stool microscopy, ova and parasite screen, and stool cultures should be part of the standard evaluation for diagnosis. Specification of which pathogens are being sought will allow the microbiology lab to perform the appropriate stains or tests. Stool testing for *Clostridium difficile* toxin by EIA or PCR should be added to patients who are at risk of *Clostridium difficile* infection. The Widal test which detects *Salmonella* antibodies has been used for the diagnosis of salmonellosis, but it has limited clinical utility due to insufficient sensitivity and specificity. Additional workup to look for nonbacterial causes of diarrhea is also important. Other possible differential diagnoses in this patient population would be *Cytomegalovirus*, *Mycobacterium avium complex* infections, and malignancies like Kaposi's sarcoma and lymphoma. Endoscopic evaluation would be beneficial in cases in which the standard evaluation is uninformative. Based on the symptomatology, upper gastrointestinal endoscopy or colonoscopy or both are done to evaluate the intestinal mucosa (Wilcox and Saag 2008; AIDS info 2016).

Prevention and Prophylaxis

Regular handwashing with soap and water or alcohol-based cleaners is the best way to prevent enteric bacterial infections. The MSM patient population should be advised to avoid unprotected sexual practices such as anal sex and oral–anal contact as there is a risk of oral exposure to feces. People recovering from typhoid fever or those who have become chronic carriers of *Salmonella* should be excluded from food preparation activities. Killed or live vaccine is available for typhoid prevention.

Routine antimicrobial prophylaxis is not recommended to prevent enteric bacterial infections in HIV patients. Fluoroquinolones, azithromycin, or rifaximin can be considered as antimicrobial prophylaxis for travelers with severe immune compromise. Patients who are already taking trimethoprim–sulfamethoxazole benefit from limited protection for travelers' diarrhea, although many pathogens have become resistant to trimethoprim–sulfamethoxazole.

Treatment

The cornerstone of treatment of infectious diarrhea is adequate rehydration. The use of sufficient fluid and electrolytes, whether given by the oral or intravenous route, is crucial. Most patients can take fluid in the form of oral rehydration fluid. Calculating the loss of total body water and matching that with the rate of water and fluid repletion can have a beneficial impact on outcomes. Below are the individual antibiotic regimens to pathogens in HIV patients.

Salmonella

Typhoid fever: All persons infected with HIV who are diagnosed with typhoid fever should be treated. This is due to the increased risk of salmonella bacteremia in this patient population. The choice of the empiric antibiotic regimen depends on the clinical setting, susceptibility testing of the bacteria, severity of illness, and ability of the patient to tolerate oral antibiotics. For the patient who is not severely ill, the preferred regimen is

ciprofloxacin 500–750 mg oral every 12 h for duration of 5–7 days. For patients in areas of increased incidence of resistance to nalidixic acid or documented resistance to quinolones, azithromycin or cefixime is the preferred choice. Alternative regimens used in case of allergy or contraindications are co-trimoxazole, amoxicillin, or chloramphenicol.

In patients who are severely ill or not able to tolerate oral antibiotics, admission to the hospital and initiation of intravenous antibiotics are crucial (Bhan 2005). Given the increasing resistance of salmonella to quinolones, intravenous treatment with a cephalosporin such as ceftriaxone 2 g daily is often started until resistance testing is available.

The duration of therapy depends on the immune status of the patient, presence or absence of bacteremia, and presence of metastatic foci of infection. When the CD4 count is <200 cells/mm, a 2–6-week course is recommended. When CD4 count is >200 cells/mm, a 7–14-day course is recommended. A longer duration is recommended when bacteremia persists or if there is a metastatic foci of infection. Recurrent salmonella bacteremia in itself constitutes an AIDS-defining illness. Management of HIV with antiretroviral therapy and suppression of the viral load lead to decreased risk of recurrence. Secondary prophylaxis is warranted for patients who have a CD4 count of <200 cells/mm with severe diarrhea and patients with recurrent gastroenteritis with or without bacteremia. Secondary prophylaxis can be discontinued when the CD4 count is >200/mm and sustained viral suppression is achieved (AIDS info 2016).

Management of chronic carrier state is based on the presence of abnormal biliary anatomy like the presence of gallstones. Preferred antibiotic regimen for the eradication of chronic carrier state is the use of ciprofloxacin 750 mg oral twice daily for 28 days or norfloxacin 400 mg orally twice daily for 28 days. Cholecystectomy is required for patients with gallstones in addition to antibiotics (Bhan 2005).

Nontyphoidal Salmonella (NTS)

Gastroenteritis caused by NTS is usually self-limiting and needs supportive care. But in HIV

patients, a short-course treatment of 3–7 days with quinolones is helpful to diminish symptoms and prevent long-term carriage. Quinolones are the preferred first-line antibiotics. Alternatives are ceftriaxone, cefotaxime, trimethoprim–sulfamethoxazole, and ampicillin. Carbapenems are the drug of choice when multidrug resistance is encountered. HIV patients are at an increased risk of NTS bacteremia and metastatic foci of infections. NTS can seed large vessels leading to mycotic aneurysm and rupture. Seeding of an aneurysm can be a source of recurrent bacteremia (Benenson 2001). Management of endovascular infections involves a combination of prolonged antibiotic therapy and surgical procedures including endograft placements. Duration of antibiotic therapy will depend on the immune status of the patient (CD4 count), presence of metastatic foci of infection, adequacy of source control, and retained foreign material. Duration can range anywhere from 4 weeks to 12 weeks, and sometimes the patient will need oral antibiotic suppression after completion of the treatment course.

Shigella

Treatment of shigellosis in HIV patients is recommended to shorten the duration of illness and prevent the spread of infection to others. The preferred regimen is fluoroquinolone like ciprofloxacin 500–750 mg PO Q12 hourly. Alternative regimens especially in areas of quinolone resistance are trimethoprim–sulfamethoxazole and azithromycin. Typical duration of treatment for gastroenteritis in immunocompromised patients is 7–10 days. When oral azithromycin is used, duration can be shortened to 5 days. But azithromycin is avoided when there is concomitant bacteremia. For shigella bacteremia treatment duration is extended to 2 weeks (Niyogi 2005; AIDS info 2016).

Campylobacter

Campylobacter gastroenteritis is a self-limiting disease, and no intervention is required in mild cases with intact immunity (Ternhag 2007). If there is persistent diarrhea, if the disease is moderate to severe, or if the patient is

immunocompromised, treatment is recommended. Ciprofloxacin 500–750 mg PO twice daily (7–10-day course) or azithromycin 500 mg PO daily (5-day course) is the preferred regimen. There is an increasing rate of fluoroquinolone resistance worldwide (Gupta 2004). Antibiotic therapy should be guided based on the susceptibility report. In patients with bacteremia, empiric ciprofloxacin and an aminoglycoside are used until the sensitivities are back. Duration of antimicrobial therapy in bacteremia is 14 days and recurrent bacteremia is treated for 2–6 weeks (AIDS info 2016).

Others

HIV patients infected with enteroaggregative *E. coli* gastroenteritis have been treated with a course of ciprofloxacin 500 mg oral twice daily for 7 days. This regimen leads to eradication of EAEC from the stool culture, decrease in frequency of diarrhea, and improved general sense of well-being (Wanke 1998). Treatment of gonococci or chlamydia proctitis is standard as in non-HIV patients. It is treated with a regimen consisting of ceftriaxone 500 mg IM one dose with azithromycin 1 g oral once. Treatment of *Clostridium difficile* infection in HIV patients is similar in the general population.

Conclusion

Salmonella and other enteric pathogens are an important cause of morbidity and mortality in the HIV patient population. The risk of acquiring these infections is significantly associated with the immune status of the patient. Thus initiating early antiretroviral therapy is an important part of management of these infections. As a patient develops symptoms, it is important to obtain the necessary cultures and sensitivities. Due to the emergence of multiple resistances to commonly used antibiotics, it is important to reevaluate if the patient is not responding to the empiric regimen. In bacteremic and metastatic infections, prolonging the course of antibiotics and adequate source control is needed to prevent relapses.

Definition

The phrase “sex work and HIV prevention” refers to any strategy undertaken to prevent the acquisition or transmission of HIV/AIDS in the context of commercial sex transactions (e.g., where there is exchange of sex for money between consenting adults). This may include HIV prevention among sex workers or their clients (sex buyers) or both, though the vast majority of programs and research to date have focused on sex workers alone. While HIV prevention within sex work typically focused on prevention of sexual acquisition or transmission of HIV among sex workers and their clients, it may also include drug-related transmission routes where there is overlap between sex workers and clients who use drugs. This entry will focus on HIV prevention through sexual contact but will

also discuss HIV prevention within sex work where there is overlap with drug use.

Global Burden of HIV Among Sex Workers

Worldwide, sex workers remain highly vulnerable to HIV in most settings, due to a complex interplay of structural and environmental factors (Shannon et al. 2015). Sex work remains hidden and marginalized in many countries, due to extreme gender-based discrimination and social stigmatization of sex work (UNAIDS 2009). Laws surrounding sex work further drive sex work underground, making it difficult for HIV prevention to reach sex workers and clients (UNDP 2012). While there are some examples of environments of sex work that have been conducive to implementing HIV prevention, treatment, and care, many other environments compromise sex workers' health and safety due to vulnerability to violence, coercive and exploitative management, debt bondage, economic insecurity, low pay, poor working and housing conditions, and insufficient access to health and social resources and services (e.g., male and female condoms and water-based lubricants, post-exposure prophylaxis following unprotected sex and rape, management of sexually transmitted infections (STIs), drug treatment) (UNAIDS 2009). Even if services are available to sex workers, use of services may be limited by stigmatization or coercive practices (UNAIDS 2009). The lack of availability of safe, supportive channels for sex workers to report rights abuses further exacerbates harm to sex workers (UNAIDS 2009). The vulnerability of sex workers to HIV is also affected by the local epidemic structures, including level of antiretroviral (ARV) coverage, STI epidemics, overlap with HIV epidemics among key populations (e.g., injection drug users, men who have sex work men), and the type of epidemic (e.g., "generalized" among general population or "concentrated" epidemics among most-at-risk populations (MARPS)).

A recent systematic review of the global HIV prevalence among sex workers in low- and

middle-income countries found that overall HIV prevalence was 11.8% (95% confidence intervals (CI): 11.6–12.0%) (Baral et al. 2012). Overall, sex workers had 13.5-fold higher odds of having HIV compared with general populations of women, irrespective of whether the HIV epidemic in that setting was a generalized or concentrated epidemic. Of note, two thirds of countries in this review had no HIV surveillance data, largely attributed to the same structural constraints (e.g., criminalization, stigmatization) that enhance HIV vulnerability in sex work (Baral et al. 2012).

HIV Prevention Approaches and Sex Work

Main Types of HIV Prevention Approaches

Different terms have been used to describe HIV prevention approaches among sex workers. A brief survey of some of the main types of approaches used is described here. "Large scale" and "small scale" are terms used to describe the size and coverage of the prevention program or intervention, usually with respect to the numbers or proportions of individuals served. "Core group" approaches refer to programs and interventions that are specifically designed for groups of individuals among whom the largest concentration of HIV infections is observed, most often including sex workers (and sometimes their clients) and men who have sex with men, as well as drug users and truck drivers, depending on the context.

Traditionally, HIV prevention in sex work has focused on biomedical and behavioral HIV prevention developed for sex workers, rather than by or along with sex workers. While sex workers have been wrongly portrayed as "vectors of disease" and "drivers" of HIV epidemics and sex work itself framed as a risk pathway, biological and behavioral factors (e.g., the use of condoms and type of sex acts within commercial transactions, high numbers of sex partners, presence or absence of STIs) more accurately shape HIV risk structures in sex work, as in sexual exchanges outside of sex work. "Biomedical" approaches typically focus on addressing HIV risk through biological factors that affect the transmission and acquisition of HIV (e.g., reducing

transmission probability by treatment of STIs or use of ARVs). “Behavioral” approaches have been influenced by a number of theoretical principles of behavior change and include an individual-level focus on changing behavior to reduce HIV risk (e.g., education to increase condom use).

There has been increasing recognition of the importance of structural and environmental factors (e.g., discrimination, stigmatization, gender inequality) in shaping increased risk for HIV within commercial transactions and along with this the development of HIV prevention interventions and programs that aim to reduce vulnerability to HIV within commercial sex transactions on structural levels (Shannon et al. 2015). Accordingly, the important roles of other individuals who are a part of commercial sex transactions besides sex workers, including clients and managers (e.g., pimps, madams, brothel owners), are beginning to be acknowledged as key in HIV prevention within sex work. In brief, “structural” approaches address upstream or root causes of HIV risk to sex workers, structural factors that shape or constrain the behavior of individuals. “Community-level” HIV prevention can describe HIV prevention implemented on a community or structural level and/or refer to an approach where HIV risk is considered an issue for communities rather than individuals to address. The integral role that sex workers should play in decisions regarding their own health, safety and well-being, and in particular to HIV prevention, has been cemented in recent years (UNAIDS 2009). “Sex worker-led” or “community-led” approaches are structural interventions that are initiated, developed, and/or implemented by relevant affected community of sex workers (e.g., sex worker organizations and/or collectives, including sex workers themselves). If a program or intervention is “peer-based,” sex workers themselves have been included as peers. “Comprehensive” approaches to HIV prevention typically refer to approaches that include multiple and different types of components. Comprehensive HIV prevention that is tailored for local contexts is increasingly identified as key in reducing sex workers’ HIV vulnerability (UNAIDS 2009). It is important to note that multiple terms are often used to describe the same type of approach and

many prevention programs can be best described as using multiple approaches (e.g., “community structural intervention” or “community-/sex worker-led structural interventions”).

- **Biomedical HIV prevention strategies**

Having an STI, including both ulcerative and nonulcerative, is thought to increase the probability that HIV will be transmitted upon sexual contact by causing lesions or inflammation that facilitates transmission of the virus (Wasserheit 1992). This relationship may exist in the other direction, with HIV amplifying the probability that STIs will be transmitted (Wasserheit 1992). Several main STI control strategies exist and have been integrated into comprehensive HIV prevention, particularly in resource-poor settings (Shahmanesh et al. 2008). These strategies include diagnosis and treatment based on observed STI symptoms (i.e., syndromic management) (Steen and Dallabetta 2003), regular screening of sex workers, and presumptive treatment (Steen and Dallabetta 2003). Rapid, point-of-care tests also exist now for many STIs (Peeling 2011). There has been little acknowledgement or research on how these approaches can constitute violation of sex workers’ rights, nor how these approaches can further marginalize and stigmatize sex workers (UNAIDS 2009; Shannon and Csete 2010; UNDP 2012). There have been increasing calls by international organizations (United Nations, World Health Organization) to not endorse the inclusion of regular screening or presumptive treatment of sex workers for these reasons. Moreover, results regarding the effectiveness of regular screening for STIs and periodic presumptive treatment of STIs on HIV among sex workers have been mixed, with strong evidence lacking regarding the effectiveness of STI screening and presumptive treatment alone (Shahmanesh et al. 2008).

Antiretroviral therapy (ART) has increasingly been accepted as part of comprehensive HIV prevention globally, particularly with the established role of treatment as prevention (TasP) (Montaner 2011). Suppressed viral

load drastically reduces the likelihood of onward transmission and can also substantially reduce HIV/AIDS-related morbidity and mortality among HIV-positive individuals (Montaner et al. 2006). While the role of TasP at a population level in onward transmission of HIV is now widely acknowledged, with strong global commitments to TasP at a policy level by international bodies, there remain limited data available on implementation across various settings (in part due to publication lag). Implementation research needs to evaluate and monitor role out of TasP on human rights of individuals and communities and ensure noncoercive practices (e.g., confidential, voluntary HIV testing) that are respected in all cases.

- **Behavioral HIV prevention strategies**

Inconsistent or non-condom use within the context of commercial sex transactions has historically been the primary means through which sex workers contract HIV through sexual transmission. Research suggests that lower condom use with intimate or other nonpaying male partners could increasingly be a key means by which sex workers contract HIV, especially in settings where interventions have shown success in increasing condom use in commercial sex transactions (Deering et al. 2011). Male condom use is thought to be the primary means with which HIV can be prevented through reducing the probability of transmission during sex contact, with condom use decreasing the per-contact probability of male-to-female transmission of HIV to about 5% when used correctly. Increased numbers of sex contacts also plays a role in increasing the likelihood that individuals will come into sexual contact with person living with HIV.

Sex workers have typically been expected to shoulder the responsibility for correct and consistent use of condoms and having reduced numbers of sex contacts to prevent the spread of HIV. In terms of HIV prevention, condom use and numbers of sex contacts have historically been conceptualized in terms of “behavior,” on an individual level, with behavioral HIV prevention influenced by a number of

theoretical principles of behavior change, including social cognitive theory and the theory of reasoned action (Fishbein and Middlestadt 1989). Aspects of social cognitive theory include knowledge, self-efficacy, and outcome expectancy, with behavior change thought to occur through activities such as observation, role modeling, performance, positive feedback, and social support. Under the theory of reasoned action, individuals’ intentions to act are thought to play the largest role in determining behavior. Individuals’ attitudes, perceptions of social norms, and personal beliefs about the consequences of behavior are thought to influence intentions. Increased education, risk reduction counseling, and condom promotion, including that provided by peers (e.g., condom demonstrations, social support), are key components of behavioral HIV prevention and have been effective at reducing HIV risk through increased condom use (Patterson et al. 2008).

Behavioral HIV prevention is mostly directed toward sex workers instead of clients, with little acknowledgement of the role that clients play in determining the use of condoms. However, HIV prevention programs and interventions have increasingly been including clients. For example, the *Avahan Indian AIDS Initiative* (“Avahan”) included a behavior change communication program that aimed to increase consistent condom use (i.e., 100%) among male clients of sex workers in four southern Indian states through the use of outdoor static promotional materials, interpersonal communication, and mid-media activities, with evidence suggesting that this program increased condom use over two years (Lipovsek et al. 2010).

- **Decriminalization of sex work as HIV prevention**

There are several main legislative approaches to sex work globally, with decriminalization of sex work increasingly cited as being a critical issue to address in HIV prevention for sex workers. In most settings most aspects of sex work either criminalized or quasi-criminalized (UNDP 2012). In brief, sex work can be

criminalized, where the buying and selling of sex itself are illegal (e.g., China, the United States, many African countries), although it is still practiced in some if not all cases (UNDP 2012). Sex work can be quasi-criminalized (e.g., Canada, India, United Kingdom) where some but not all aspects of sex work are criminalized, effectively making the practice of sex work nearly impossible without breaking laws (UNDP 2012). Another variation of quasi-criminalized approach to sex work adopted in Sweden and Iceland is the “Nordic model” where the selling of sex is legal (e.g., being a sex worker) but the purchasing of sex is criminalized (e.g., being a client/sex buyer) (UNDP 2012). In relatively few countries, sex work is legalized (e.g., sex work is legal and regulated), often in specific contexts such as Victoria, Australia, and Nevada, USA, where sex work is legal in brothels. Sex work can also be decriminalized (e.g., criminal laws prohibiting sex work are removed – e.g., New Zealand, Senegal, and parts of Australia (UNDP 2012)).

Criminalization of sex work is highly tied to stigmatization and increased HIV risk to sex workers (Shannon et al. 2015). Under criminalized and quasi-criminalized legislative frameworks, sex workers may experience police harassment as well as physical and sexual violence as part of police crackdowns, from which they have no legal protection or means to report (UNDP 2012). Police may also commit acts of sexual violence against sex workers in exchange for not arresting them, including forced and coercive sex (UNAIDS 2009; UNDP 2012). These tactics force sex work underground, displacing sex workers to unsafe areas as a means of avoiding police harassment, where they are at higher risk for client physical and sexual violence, further away from safer sex resources, HIV/STI testing, treatment, and care services (UNDP 2012). Sex workers may be inhibited from carrying condoms due to fear of police confiscation and harassment or as evidence of sex work (UNDP 2012). Sex workers may avoid HIV-related prevention, treatment, and care in criminalized

settings because of fear of disclosure of sex work. In a legalized environment, sex workers and business owners face substantial regulations and licensing not applied to other businesses (e.g., mandatory HIV/STI testing, requiring sex workers to carry permits). Mandatory HIV/STI testing of sex workers is a human rights violation and results in avoidance of care and increased HIV risk.

In a decriminalized sex work environment, sex work is regulated by the same laws that regulate other businesses (e.g., tax, employment laws, occupational health, and safety standards) (UNDP 2012). A number of international bodies, including the Global Commission on HIV and the Law, United Nations Development Programme, United Nations Programme on HIV/AIDS, and the World Health Organization, have called for the removal of criminal sanctions targeting sex workers and clients as a critical step in reducing HIV risk to sex workers, and decriminalization is therefore an important component of comprehensive HIV prevention for sex workers on a structural level (Shannon and Csete 2010; UNDP 2012). Instead, international bodies promote a public health and human rights approach, including decriminalization, addressing police harassment and violence, prohibiting mandatory HIV testing of sex workers, and providing safe spaces where sex workers can work without fear of police harassment and arrest (UNDP 2012). Emerging research from New Zealand suggests that decriminalization has had positive impacts on sex work, including reduced violence and stigmatization.

- **Violence prevention in HIV programming**
Sex workers experience high rates of occupational violence (e.g., within the context of sex work) from a variety of perpetrators, including clients, police and managers, and exploitative business owners, as well as violence by intimate or other nonpaying partners (Deering et al. 2014), which has increasingly been linked to increased HIV risk (Shannon et al. 2012). Sexual violence can increase risk for HIV/STIs through the potential damage to

vaginal tracts, facilitating transmission of infection, and the reduced likelihood of condoms being used during acts of sexual violence. Men who commit violent acts against women may themselves be more likely to have higher-risk behavior and be living with HIV/STIs (Dunkle et al. 2006). Fear or the threat of violence by clients has been linked to being pressured into not using condoms or reduced ability to insist on condom use with clients (Shannon et al. 2012). Coercive sex, rough sex, and a history of experiencing violence and sexual assault have been associated with reduced condom use and condom breakages (Shannon et al. 2012).

Despite sex workers' high risk for violence and the link between violence and HIV, there are only a few examples of HIV prevention interventions that have incorporated anti-violence strategies (Shannon et al. 2012). One of the largest-scale HIV prevention interventions that has included antiviolence strategies is Avahan, which has addressed occupational violence against sex workers from police and clients using a comprehensive approach, including state-wide training to police officers, legal literacy training for sex workers, increased mobilization and collectivization of sex workers, crisis response teams, and legal representation for sex workers (Beattie et al. 2010). Sex workers identified the inclusion of antiviolence programming in HIV prevention with Avahan as a critical priority. Evidence suggests that Avahan has been associated with a reduction in the proportion of sex workers reporting sexual violence in follow-up surveys compared to at baseline (Beattie et al. 2010).

- **Safe sex work environments and HIV prevention**

Sex work environments influence sex workers' vulnerability to HIV, and this relationship is context specific. In criminalized settings, soliciting for clients in street or public places often isolates sex workers from other workers, forcing them to work alone and to take clients to hidden outdoor places to provide services, including clients' cars, streets, alleys, and parks, in order to avoid police (Shannon and

Csete 2010). This practice can place sex workers at higher risk for violence by clients and result in sex workers having reduced agency in terms of clients' condom use and negotiations relating to transactions (e.g., amount charged) (Shannon and Csete 2010). Working in more visible settings results in sex workers or their clients being more likely to be harassed by police, displaced to more remote or isolated areas, and less able to access safer sex resources, as well as HIV prevention. In contrast, working indoors (e.g., in homes, motels, brothels) can afford some protection from violence and increased access to HIV prevention. In some settings, however, exploitative brothel owners and operators (e.g., pimps) can increase sex workers' HIV vulnerability by making decisions about condom use with clients, allowing violence by clients and controlling HIV prevention (Shannon and Csete 2010). In settings where sex work is legalized or regulated, sex workers may be able to work indoors but can be subject to human right abuses such as mandatory HIV/STI testing and forced registration with governments, practices which act as barriers to HIV prevention (Shannon and Csete 2010). This can concentrate HIV vulnerability, forcing some sex workers to work outside the legally regulated areas and making the practice of sex work even more dangerous.

Addressing the lack of safe spaces for sex workers to solicit for clients and provide services is an integral component of comprehensive HIV prevention for sex workers. Decriminalization of sex work can have a dramatic impact on improving the safety of sex work environments and reducing sex workers' vulnerability to HIV (Shannon and Csete 2010). In decriminalized environments where sex workers are allowed to organize and collectivize, sex workers have more control over their work environments, which can be structured to meet the health and safety needs of sex workers. Even in settings where sex work is criminalized, safe sex work spaces have been developed collaboratively between sex workers and local organizations and have

highlighted the crucial importance of such spaces in reducing HIV vulnerability. For example, in Canada, unsanctioned indoor sex work environments in low-barrier, supportive housing options for women promoted enhanced control within transactions with clients, including enabling condom use and reducing violent encounters (Krusi et al. 2012). In the Dominican Republic and Nevada, USA, brothels with supportive management policies and physical security measures were shown to promote condom negotiation with clients (Kerrigan et al. 2006). Safer-environment programs (e.g., mobile outreach) can modify sex work environments to improve safety of sex workers and increase access to condoms and connections with health services.

- **Sex work collectivization and destigmatization**

In most settings, criminalization of sex work can obstruct sex workers from supporting one another through formal or informal collectivization processes, isolating sex workers from one another and limiting their involvement in HIV prevention. Perhaps the best-known HIV prevention model that focused on sex work collectivization is the *Sonagachi Project* (“Sonagachi”), a community- and sex worker-led intervention implemented in India in 1992. Sonagachi, highlighted as a United Nations Program on HIV/AIDS/World Health Organization “best practice,” placed emphasis on reconceptualizing sex work risks as occupational hazards, focusing on community empowerment, collectivization, and engagement of sex workers to reduce HIV risk, and evidence similarly suggests that this intervention has been successful in reducing HIV risk to sex workers (Jana et al. 2004).

Sonagachi (and other programs that followed) also placed importance on including sex workers as key stakeholders in all aspects of project design, as well as addressing stigma and discrimination and its negative impacts on HIV risk as part of its community development and health promotion approach (Jana et al. 2004). Stigmatizing and discriminatory

attitudes toward sex work, along with laws criminalizing sex work and punitive sanctions against sex work, increase sex workers’ vulnerability to HIV through reduced use and access of HIV prevention (UNAIDS 2009). Male sex workers and sex workers who do not identify as a traditionally recognized gender or sexual identity can face intensified stigma and discrimination from police and community members (UNAIDS 2009). Sex workers living with HIV experience even more intensified stigma, inhibiting them from accessing HIV treatment (UNAIDS 2009). Reducing stigmatization and discrimination by health service providers, law enforcement officers, and community members is increasingly shown to be an integral part of HIV prevention among sex workers. Sex worker-led structural HIV preventions that focus on individual and collective empowerment developed for/by sex workers (e.g., education, literacy, training, self-esteem support, activism, organizing to protest rights abuses) as well as changing community attitudes toward sex work, including those surrounding safer sex practices within sex work, have contributed toward reducing gender inequalities and decreased HIV risk and HIV/STI prevalence among sex workers. Avahan has included elements to increase public awareness of sex work, as well as police sensitization training and educating sex workers on their legal rights, which are suggested to be important in reducing HIV risk to sex workers (Beattie et al. 2010). Structural interventions that are not implemented with substantial sex worker involvement (e.g., government sponsored 100% condom use campaign as in Thailand and Brazil) have been shown to have mixed effects by reducing HIV vulnerability among some populations while pushing the most marginalized sex workers underground and away from HIV prevention, treatment, and care supports.

- **Economic empowerment**

Most sex workers sell sex to meet economic needs; however, this can range from sex workers in poverty to higher-end sex workers

who engage in sex work for increased social stature, mobility, and economic opportunities. In some settings where credit or financial support outside marriage, employment, and education opportunities for women are limited, sex work may be one of the few economic options for sex workers to support themselves (UNAIDS 2009). The financial insecurity associated with sex work, particularly within criminalized settings, can place sex workers at higher risk for HIV (UNAIDS 2009). Sex workers often have to make difficult decisions regarding their health and safety in the context of economic insecurity. For example, sex workers may feel pressured to agree to sex without a condom or exchange higher-risk sex services (e.g., anal sex) in exchange for a higher fee. Such situations may be exacerbated for sex workers who use drugs or among sex workers who may be forced to charge less for sexual services (e.g., older sex workers in some settings due to competition with younger workers). Sex workers are furthermore prevented from accessing benefits and financial services available to the general population, such as bank accounts, savings schemes, loans and legal forms of credit, insurance, pensions, and other employment benefits, inhibiting sex workers from managing their own finances and planning for the future (UNAIDS 2009). Sex workers living with HIV experience heightened economic insecurity (UNAIDS 2009).

A number of examples exist of successful microcredit and microfinance programs that provide economic opportunities for women and girls and people living with HIV. Within these programs, economic empowerment can reduce stigma, enhance social inclusion, and provide alternate economic options. However, few programs have been specifically designed for sex workers. Many of these types of programs that do exist for sex workers have been criticized for placing heavy emphasis on exiting sex work without providing viable economic alternatives for sex workers (UNAIDS 2009). These “rehabilitation” programs often assume that sex workers *want* to leave sex

work, which is not always the case, with such programs more often reflecting stigmatizing and discriminatory attitudes and policies with hidden agendas to rid society of sex work. Unsuccessful programs can further stigmatize sex workers and leave them in debt and in worse financial situations than prior to the program (UNAIDS 2009). Nevertheless, economic empowerment programs can play an important role in HIV prevention for sex workers, and such programs have shown promise for reducing sex workers’ vulnerability to HIV (e.g., Brazil, where sex work is decriminalized; India and Kenya, where sex work is criminalized) (UNAIDS 2009). These programs address gender-based inequalities that limit women’s economic options and promote gender-based equality within homes and work environments, as well as in social, legal, and political environments. Recognizing sex work as an occupation within decriminalized environments would allow for sex workers to access the same occupational and financial rights as other workers and reduce HIV risk.

- **Substance use programs**

Sex workers who use illegal substances may experience increased HIV-related vulnerability within overlapping sex work and drug use HIV risk environments (Rhodes et al. 2005). In the context of drug and alcohol use, sex workers may experience barriers to HIV prevention including dopesickness, withdrawal, and the immediate need to use drugs, factors that can prevent sex workers from assessing and screening dangerous clients and negotiating safety within potentially high-risk situations (Shannon et al. 2008). Drug or needle sharing with clients or other partners, which has been associated with gender-based power imbalances favoring the male partner, may facilitate increased risk of violence, HIV, or other blood-borne infection transmission (Strathdee et al. 2011). Dual stigmatization of sex work and drug use inhibits sex workers from accessing drug-related HIV prevention, including harm-reduction resources. Drug use is criminalized in most settings and increases harms through enforcement-based policing

approaches toward drug use that increase violence on a community level (Werb et al. 2011), as well as microlevel displacement of drug users to unsafe drug use spaces (e.g., shooting galleries, drug dealing, scoring and distributing drugs).

Addressing substance use can be an important component of comprehensive HIV prevention for sex workers who use drugs. As with HIV prevention that aims to prevent the transmission of HIV through sexual routes, substance use programs have included biomedical, behavioral, and structural components, with growing research supporting the need for comprehensive programs that include all components. Harm-reduction programs including methadone maintenance therapy and needle and syringe programs have been integrated in many settings. Safer-environment interventions (e.g., mobile outreach) along with inclusion of peers in HIV prevention to drug-using sex workers can be highly effective. Drug treatment modalities, including opiate substitution therapies, have had success in increasing economic empowerment within other populations and should be tailored to meet the needs of sex workers.

Future Research and Evaluation of HIV Prevention in Sex Work

Future research on HIV prevention in sex work should include a focus on better understanding of structural factors and their relationship to HIV risk and prevention among sex workers and their clients, as well as the complexities of HIV risk and prevention among sex workers. To help support a strong evidence base to inform HIV programmers and policy makers, improving the evaluation of HIV prevention in sex work should be a priority. The evaluation of HIV prevention programs and interventions remains challenging. Conventional methods (e.g., randomized control trials of communities) are often unethical and/or impractical to implement, particularly in vulnerable populations including sex workers (Boily et al. 2007; Piot 2010). In order to better understand the impact

of HIV prevention, a formal multipronged evaluation framework is necessary, as has been developed for large-scale HIV prevention programs (e.g., *Avahan*) (Boily et al. 2007). Support for community-based organizations to implement and evaluate, in partnership with research institutions, existing interventions remains critical. New evaluation strategies should be developed to understand the impact of modifying complex and interrelated factors that exist on multiple levels of influence and on HIV risk and prevention, including those on a macrostructural (e.g., policy reforms, collectivization of sex workers) and microlevel (e.g., gender-based power dynamics that influence condom use by men).

Conclusion

While there have been some positive examples of comprehensive HIV prevention acknowledging the importance of structural change in reducing sex workers' vulnerability to HIV alongside behavioral and biomedical components of HIV programming and interventions, much more work needs to be done in terms of addressing upstream factors that shape sex workers' risk environments for HIV. Furthermore, while behavioral or biomedical interventions may be deemed successful in some contexts, rigorous evaluation of the potential negative effects is needed (e.g., potential further stigmatization and criminalization, institutional barriers accessing to care for sex workers). To achieve effective community engagement and empowerment and successfully engage sex workers in HIV prevention, it is necessary for sex workers to be involved in the design, research, implementation, monitoring, and evaluation of policies and programs that affect them. New strategies should be developed to reach hidden populations of clients, with increased research scaled up among clients. Accordingly, clients should be involved in the design of HIV prevention *for* clients. Governments and policy makers should make use of the growing evidence base of peer-reviewed research, as well as community knowledge and expertise, to guide decisions surrounding sex work policy as

HIV prevention. Alongside global calls by sex workers, sex worker allies and advocates and researchers to decriminalize sex work to improve sex workers' health and safety (UNAIDS 2009; UNDP 2012), decriminalization of sex work on a global scale, should be considered critical to facilitate effective HIV prevention among sex workers.

Violence against sex workers, which is highly exacerbated within criminalized settings, should be recognized as a key determinant of increased vulnerability for HIV among sex workers, with antiviolence programming incorporated as part of HIV prevention. To reduce vulnerability, structural HIV prevention should include components addressing economic empowerment, destigmatization, empowerment, and collectivization. Supportive environments for sex workers need to be developed, including safe work spaces for sex workers. Partnerships with sex workers and organizations that work with sex workers need to be strengthened, with support available for sex workers who both wish to exit and remain in sex work. Emphasis must be placed on ensuring that all sex workers have universal access to safe, confidential, and voluntary access to HIV prevention, treatment, care, and support.

A growing movement advocates for shifting the focus of HIV prevention away from sex workers and, rather, acknowledging how sex work environments can shape or constrain risk for sex workers and clients (Shannon et al. 2015). HIV prevention would therefore focus on supporting sex work to be a safer occupation instead of placing responsibility on sex workers themselves. Comprehensive HIV prevention must address multiple key factors in combination, with both short- and long-term commitments, and urgently be scaled up to reduce further harms to sex workers.

SIV Infection in Mandrills

Pierre Roques

Service d'Immunovirologie, Institute of Emerging Disease and Innovative Therapy, Commissariat à l'Énergie Atomique, Fontenay-aux-Roses, France

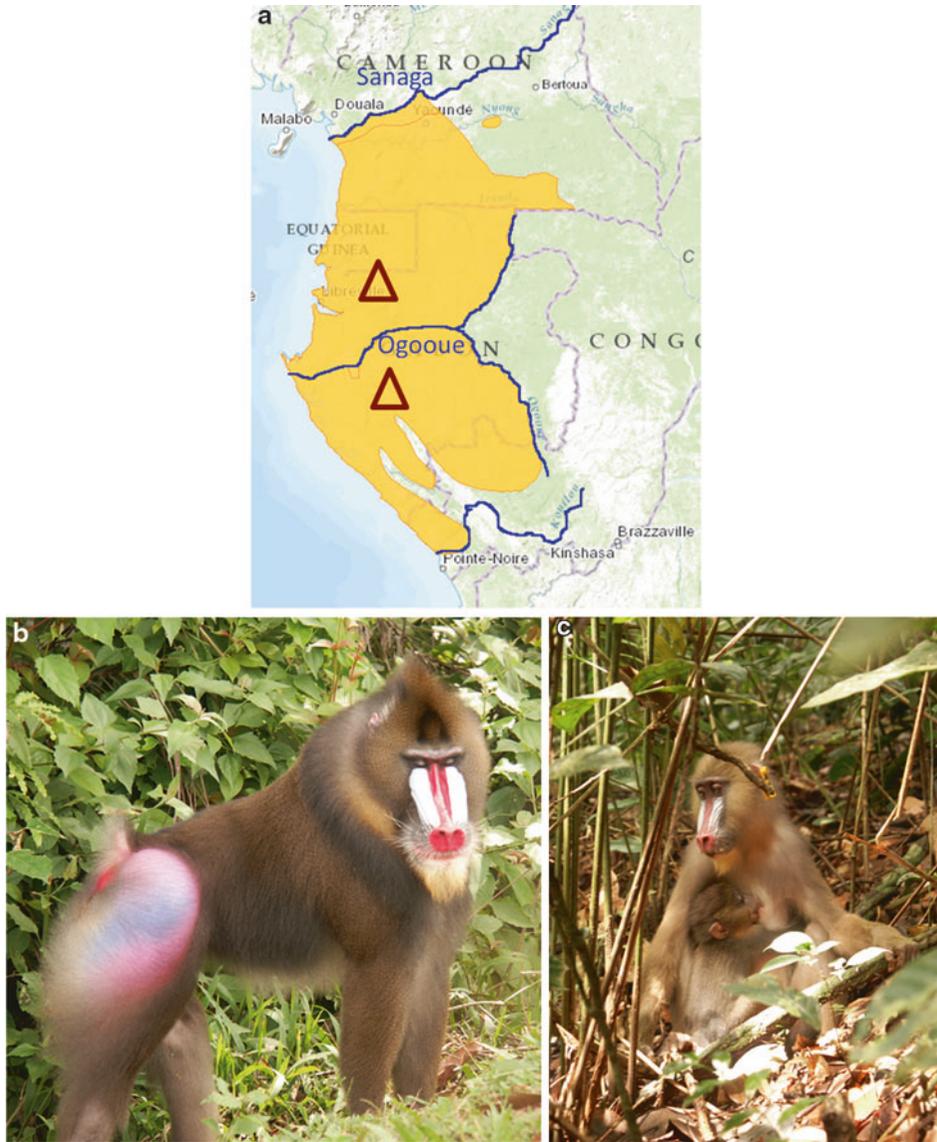

UMR-E1 Université Paris Sud-XI, Orsay, France
Retrovirology Department, CIRMF, Franceville, Gabon Year 2001-2004

Definition

Thousands of years ago, the first simian immunodeficiency virus (SIV) infections occurred in wild African papionine species, specifically among the African mandrills (*Mandrillus sphinx*, Linnaeus 1758). In contrast to human immunodeficiency virus (HIV) infections, the SIV infection among mandrill populations (SIVmnd) is considered to be nonpathogenic and occurs without clinical symptoms of immune deficiency. Similar to HIV, SIVmnd targets activated CD4 T lymphocytes and leads to high viral loads in the peripheral blood, but the infection is not associated with inflammation and is characterized by low antiviral immune responses. Mandrill SIV infection is thus used as a nonpathogenic model to understand the pathogenesis of AIDS and host protection mechanisms.

Introduction

African mandrills (*Mandrillus sphinx*) have distinct physical characteristics. Their large size and colorful face (Fig. 1) make them recognizable

SIV Infection in Mandrills, Fig. 1 (a) Map of the area inhabited by mandrills in West Central Africa, with the main River limits in blue. Highlands are depicted by *open triangles*: north of Ogooué River, Mont de Cristal, south of

Ogooué River, Massif du Chaillu. (b) Male mandrill. (c) Female and her offspring within the semi-free enclosure in CIRMF (©P. Roques 2004)

among all the African monkey populations. While the mandrills are considered iconic for all African monkeys, they only inhabit a small area in Western Central Africa. Their habitat spans from the Kouilou River in the Republic of Congo and the south of Gabon to the Sanaga River in Cameroon. Mandrills occupy a coastal forest habitat with their eastern limit defined by the Ivindo and

Ogooué Rivers in Gabon (map Fig. 1a); however some literature suggests their range may extend further east. Mandrills are prevalent in their endemic area and are hunted for meat by locals. As such, their populations have decreased in size over the past three decades. Since 1986, mandrills have been deemed “vulnerable” by the International Union for Conservation of Nature (IUCN

2008), in addition to their classification within Annex 1 of the Convention on International Trade in Endangered Species (CITES).

Since the early 1980s, the Centre International de Recherche Medicale de Franceville (CIRMF), Gabon, has housed a unique semi-free colony of mandrills. The first isolated strain of SIVmnd (designated GB1 in 1988) was obtained from a wild-born mandrill female, identified as F17, kept in the semi-free enclosure at CIRMF since 1983 (Tsujimoto et al. 1988). SIVmnd GB1 was identified and sequenced (Tsujimoto et al. 1989) after the first identification of SIVs from African green monkeys in 1986 (Kanki et al. 1985), at a time when SIV was also isolated from sooty mangabeys living in captivity in the USA (see “► SIV Infection of African Green monkeys” and “► Nonpathogenic SIV Infection of Sooty Mangabeys”). Within the CIRMF enclosure, the infected mandrills seemed perfectly healthy. No further exploration was done in the following 10 years. At this time, the colony had grown from 15 wild born animals to more than 200 mandrills, and these animals represent the best source of information about the natural history of SIV infection in this genus. Indeed, many scientific collaborations have chosen these animals to examine the course of SIV infection and have compared their data to natural SIV infections in other species and in accidental cross-species HIV/SIV infections involving humans and macaques. Herein, we review virology, immunology, and physiopathology data on SIV infection in mandrills obtained during the last 20 years.

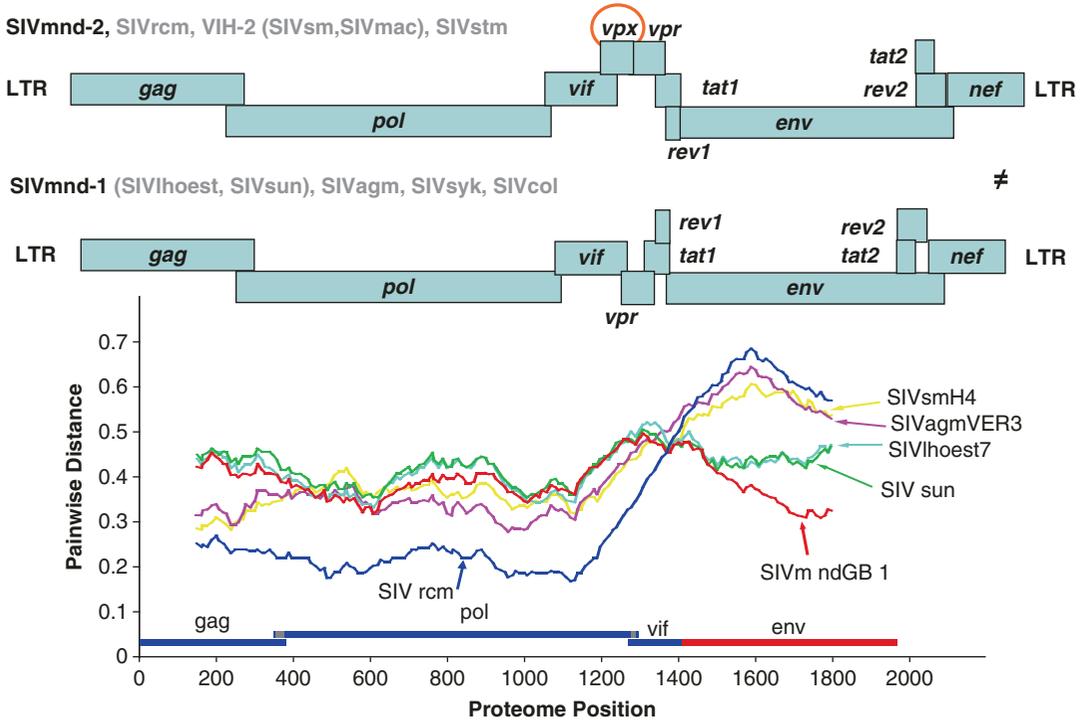

Discovery, Natural History, and Physiopathology of SIVmnd

The GB1 SIVmnd strain was the only representative of the SIVmnd lineage until two *Cercopithecus* viruses, one from L’Hoest’s monkey (*Cercopithecus l’hoesti l’hoesti*, Sclater 1899) and another from the recently discovered sun-tailed monkeys (*Cercopithecus l’hoesti solatus*, Harrison 1988), were shown to cluster in the same lineage (Beer et al. 1999; Hirsch et al. 1999). Sun-tailed monkeys are considered

to be a descendent of the l’hoesti monkey superfamily, which today is restricted to a forest area in Gabon (Forêt des Abeilles). The SIVmnd GB1 genome has the same organization as that of the *Cercopithecus* SIVs but does not match that of the papionine SIVs. Because the habitats of mandrills and sun-tailed monkeys overlap in Gabon, it has been suggested that the SIVmnd GB1 jumped across species barriers, starting in sun-tailed monkeys and moving to mandrills. The lineage was subsequently renamed the L’Hoest lineage (Hirsch et al. 1999). SIVmnd GB1-related viruses were present in up to 60% of tested wild adult mandrills, indicating that the virus is capable of spreading efficiently between animals of this species.

Within the CIRMF colony, western-blot and PCR detection results clearly defined two separate groups of monkeys. In one group containing five male mandrills, viruses were detected using anti-SIV p27 monoclonal antibodies and anti-HIV-1 polyclonal assays. In a second group containing F17 and four of her offspring, the Gag antigen of SIVmnd is detectable only with the HIV-1 polyclonal assay. Pol gene sequences from these animals were strikingly different. These results, together with experiments demonstrating that both viruses are present in wild animals and can spread within the CIRMF’s colony without causing disease, led to defining two distinct viruses: SIVmnd-1 and SIVmnd-2 (Souquiere et al. 2001).

The *env* region of SIVmnd-2 is phylogenetically similar to that of SIVmnd-1; however, the *gag pol* gene resembles that of SIVrcm, which is the SIV derived from the red-capped mangabey (*Cercocebus torquatus torquatus*, Kerr 1792) (Fig. 2). Various groups, including CIRMF researchers, screened drills (*Mandrillus leucophaeus*, Cuvier 1802), the closest living relative of mandrills, and found that wild drills were infected with a species-specific virus SIVdrl closely related to SIVmnd-2. Furthermore, some *Mandrillus sphinx* individuals living in captivity were found to be infected with “SIVdrl” variants. These observations led to the new hypothesis that SIVdrl, SIVmnd-2, and SIVrcm are different strains which may have evolved from an ancestral SIVrcm-like virus.

SIV Infection in Mandrills, Fig. 2 (a) Genomic structure of SIV mandrill type 1 and type 2 (SIVmnd-1; SIVmnd-2). Diversity plot comparing SIVmndM14 (the SIVmnd-2

representative) to SIVmndGB1 (the SIVmnd-1 representative), SIVrcm, SIVsun, SIVlhoest, SIVsm, and SIVagm. Derived from Souquiere et al. (2001)

Thus, under the current classification, the SIVmnd-1 of the SIVlhoest lineage is deemed a “Cercopithecidae-like” SIV. Despite its recombinant structure, SIVmnd-2 is considered more closely related to Papionini viruses, SIVdrl, and SIVrcm.

Screening of human populations also identified a case of probable infection with an SIVmnd (Souquiere et al. 2001). However, this remains a very rare event as no case has been reported since 2003. Human SIVmnd infection is probably an epidemiological dead end, similar to HIV-2 groups D and E (see “► Transmission HIV-2: Origin, Epidemiology, and Phenotype”), although these viruses were previously observed to replicate easily in human peripheral blood mononuclear cells (PBMCs) in vitro (Hu et al. 2003).

SIVmnds Are Ancient Viruses Coevolving with Their Host

Studies of the mandrill cytochrome b gene suggest mandrill populations cluster in two mitochondrial

haplotypes (Telfer et al. 2003), which appear to be associated with a distinct geographical origin. The Ogooué River in Gabon, which divides the mandrill’s range, separates mandrill populations in Cameroon and northern Gabon from those in southern Gabon (Fig. 1). This geographic clustering is concordant with that of known SIVmnd species as well as with the distribution of other viruses, such as the mandrill-associated simian T lymphoma virus (STLVs) and the simian foamy virus (SFV) of which distinct strains circulate north and south of the Ogooué River. Therefore, mandrill phylogenetic groups and viruses may have followed similar evolutionary trajectories.

Both genetic and climatic data suggested a separation of two distinct mandrill populations during a dry period, eight hundred thousand years ago, at a time when forest cover retreated to the highlands of the Mont de Cristal (north of Ogooué River) and of the Massif du Chaillu

SIV Infection in

Mandrills, Fig. 3

Map depicting the superposition of natural habitats of mandrills (orange), drills (dashed dark gray), red-capped mangabeys (*Torquatus* west of brown line), and sun-tailed monkeys (*Sol. bright red*)

(south of Ogooué River). These two highlands are found south of the Sanaga River. This river is the frontier which separates the mandrill and drill, which began evolving into distinct populations for an even longer period of time. A drill subspecies (*Mandrillus leucophaeus poensis*, Zukowsky 1922) inhabits Bioko Island, which separated from the African mainland more than 10,000 years ago. Despite this geographical separation, both drill subspecies still have SIVmnd-2/SIVdrl virus. Thus SIVdrl has evolved within its current host for more than 10,000 years (Worobey et al. 2010). Finally, drill and mandrill species share this virus, which is also closely related to the SIV found in the commensal papionine, the

red-capped mangabey. The red-capped mangabey lives in coastal wet forests and shares similar feeding habits as the mandrills and drills. This suggests these locations and behaviors play an important role in spreading infection between the two species (Map Fig. 3). To support this hypothesis, it was recently shown that groups of drills and red-capped mangabeys may compete when feeding (Astaras et al. 2011), suggesting this close proximity could spread the virus. However, the hypothesis that the ancestral virus SIVmnd-2/drl existed before the speciation of drill and mandrill cannot be ruled out.

In parallel, SIVmnd-1 is found only in mandrills and has a mosaic structure that may be the

result of recombination with multiple SIVs from the *l'hoesti solatus* group found south of the Sanaga River. The rearrangement of SIVmnd-1 likely occurred in more recent ancient history than the introduction of SIVmnd-2 in mandrills, and species jump of SIVsun like viruses may have occurred sometime after the separation of the two mandrill haplotypes.

SIVmnd Infections Are Not Associated with an Immunodeficiency in Mandrills

No pathology has been associated with SIVmnd infection (type 1 or type 2) either in the wild or in the semi-free colony in CIRMF, with one exception. The most recent biological data on the founder female F17, collected after 20 years of SIVmnd carrier status, showed a very low level of CD4 T lymphocytes, a high viral load, and increased immune inflammation when corrected for her age (Pandrea et al. 2001). Because of the difficulty in following wild mandrills, it is very challenging to determine whether this is a common feature among mandrill populations. Nevertheless, there is a very low probability of SIVmnd-associated disease among wild and semi-free colonies. Despite the numerous zoo mandrills which are natural carriers of SIVmnds, only very few reports cite animals with diseases suggestive of AIDS in elderly animals [two in (Pandrea et al. 2001) and one in Zoller et al. (2012)].

Mother to Infant Transmission or Horizontal Transmission?

SIV prevalence was assessed to be as high as 60% in wild mandrill groups via serology and PCR testing. Detailed studies of prevalence compared to age, as has been done with African green monkeys (see “► [SIV Infection of African Green Monkeys](#)”), are lacking; however a cumulatively increasing SIV seroprevalence is expected as transmission occurs horizontally through sexual contact and physical contact during fights over dominance among males (but not in females). This may affect a large number of animals, as mandrill social groups, such as those in Lope National Park, Gabon, may consist of 30–600 or more animals depending on the season (Kate Abernethy, CIRMF annual report).

One of the more surprising observations in the semi-free colony was the finding of SIVmnd-1 infection in young offspring of the F17 female (Souquiere et al. 2001). Vertical transmission (from mother to infant) was suggested as the cause, but routine annual sampling could not determine the time of infection. Experimental infection of a group of females after delivery and during lactation resulted in very low transmission to the offspring, despite continuously detectable viral load in the female breast milk. Offspring infection was detected only after 6 months of age when the experimentally SIV-infected mothers and infants were housed together in a larger enclosure. None of the animals showed clinical symptoms of infection, whether they were housed in pairs or in social groups. The young mandrills gained body mass and built relationships with their peers that were comparable to the animals in the semi-free ranging groups (Pandrea et al. 2008). In another trial, pregnant mandrills were infected with SIVmnd-1 during their last trimester and vertical transmission (as shown by a high viral blood load at birth) occurred in one out of four infants. Thus, even if rare, vertical transmission of the SIVmnd-1 may occur. There is no data for mother-to-infant transmission of SIVmnd-2 as only males were positive at the beginning of the CIRMF colony history.

The possibility that susceptibility to SIVmnd-1 infection may vary with genetic background was also proposed by studies of the CIRMF colony, but the potential mechanisms involved have yet to be investigated (Fouchet et al. 2012). The diversity of the mandrill population in the colony and their mating behaviors must be accounted for when trying to elicit such a relationship (Charpentier et al. 2005; Setchell et al. 2013).

Molecular Description of the Virus: In Vivo and In Vitro Variation

Molecular analysis of the SIVmnd-1 and SIVmnd-2 viruses highlights the diversity among different SIVs (Fig. 2). There are several differences between these two SIVmnds. The main three are (i) their phylogeny (SIVmnd-1

and SIVmnd-2 belong to different SIV phylogenetic lineages inferred from various genomic regions); (ii) their genomic structures (SIVmnd-1 lacks the *vpx* gene, whereas it is present in SIVmnd-2) (Fig. 2); and (iii) their antigenic properties (SIVmnd-1 and SIVmnd-2 behave differently in commercial EIA and p24 antigen assays).

Thus, two different genera of SIVs can infect mandrills. This is similar to HIV infection encountered in humans, who are susceptible to infection by two lentiviral types, HIV-1 and HIV-2, which have different origins, different genomic structures, and different antigenic properties. The two types of SIVmnd that naturally infect *M. sphinx* can be considered as a model for studying the complexity of HIV evolution and their interaction within humans.

The viral protein Vif of a species-specific SIV is involved in breaking the innate immune response against SIV infection via its interaction with the host factor APOBEC3G. Vif protein is able to interact with exogenous APOBEC and thus is involved in the species barrier break. SIVmnd-1 Vif and SIVrcm Vif were tested by trans-complementation of HIV lacking *vif*. It was expected that only Vif from SIV/HIV viruses found in humans (SIVsm, SIVcpz in addition to HIV-1/2) may complement HIV in vitro to aid in human cell infection. SIVrcm Vif (which is closely related to SIVmnd-2), but not SIVmnd-1 Vif, was found to occasionally complement HIV. Surprisingly, SIVmnd-1 is still capable of replication in HUT78 that expresses both APOBEC3G and APOBEC3F (Gaddis et al. 2004). Thus, the species barrier is not limited to cellular restriction, and species-specific modulation of Vif function is quite complex.

Interestingly, phylogenetic analysis of the *vpx* and *vpr* genes of SIVmnd-2 from similar strains isolated from drills showed that they form a monophyletic cluster that groups with *vpr* from SIVagm (Hu et al. 2003). Unfortunately, there are no studies of the role of Vpr within these viruses versus its role in HIV. However, Vpx was recently found to antagonize SAMHD1, another species-specific lentiviral restriction factor. One possible explanation could be that the deletion of *vpx* from SIVmnd-2 would contribute to the evolutionary

gain of a new function of Vif in SIVmnd-1 and hence provide new trans-species infection capacity. SIVcpz evolved in a similar manner, mounting infection in a human that ultimately led to today's HIV (Etienne et al. 2013).

In terms of viral entry receptor and co-receptor usage, prior studies showed that SIVs primarily use the CD4 receptor on lymphocytes for initiating infection. Initially, the SIVmnd-1 strain GB1 was described as using just the chemokine receptor CXCR4 as a viral co-receptor. Subsequent reports demonstrated that SIVmnd-1 isolated from the same animal (F17) (Pandrea et al. 2001) also used CCR5, as did all the genotype 1 and 2 viruses isolated from other mandrills. In addition SIVmnd-1 and SIVmnd-2 can use other chemokine receptors, such as CXCR6 and GPR15 (also known as Bonzo and Bob, respectively). Similar to HIV, in vitro experimental infection of monocytes shows the use of various co-receptors is driven by SIVmnd envelope protein motifs (Sakai et al. 1992).

Pathophysiology of Experimental and Natural Infection

Pathophysiology of SIVmnd-1 and SIVmnd-2 Infections in Their Natural Host

A pattern consistent with high levels of active viral replication was observed both for SIVmnd-1 and SIVmnd-2 in experimental infection studies (Table 1). A peak in viremia occurs around days 9–11 postinfection (p.i.), and the peak viral load (VL) values range between 10^6 and 10^9 SIV RNA copies/ml of plasma (RNA cp/ml). Immediately following the peak in viremia, the viral load declines rapidly, dropping between 3 and 4 logs. This decrease is observed between days 14 and 28 p.i. This occurs concomitantly with the development of immune responses to the infection, as suggested by the seroconversion of all animals between days 21 and 28 p.i. Starting from day 42 p.i., the set-point values of VL were around 10^5 RNA cp/ml and were remarkably stable up to 2 years later (Table 1). Interestingly there was no variation in the evolution within the animals, regardless of the quantity of virus injected.

SIV Infection in Mandrills, Table 1 Summary of the available immuno-virological data for SIVmnd infection in mandrills and rhesus macaques. Data for SIVagm infection in African green monkeys (AGM) are shown as a reference for nonpathogenic infection.

	Viral load				Immune markers	
	Mandrills	AGM	Macaque + SIVmnd1, 2	Mandrills	AGM	Macaque + SIVmnd-1, 2
	VL peak between d7 and d10 postinfection with 10^7 to 10^9 vRNA/ml plasma					
Acute phase (or primary infection)	10^7-10^8 DNA cp/ 10^6 PBMC	10^4-10^5 DNA cp/ 10^6 PBMC	10^5-10^6 DNA cp/ 10^6 LN cells	Depletion of lymphocyte CD4+ subset according to time of VL peak, inflammation		
	High viral load in LN + PBMC	Low viral load in LN + PBMC	High viral load in LN + PBMC	CD4, CD8 activation, sharp but transient depletion of lymphocytes (4 + 8) in blood (nt in gut)		
	$5 \times 10^5-5 \times 10^6$ DNA cp/ 10^6 LN cells	10^3-10^5 DNA cp/ 10^6 LN cells	$5 \times 10^3-10^5$ DNA cp/ 10^6 LN cells	CD4, CD8 activation, strong but transient depletion of CD4 in blood and small depletion in gut		
Early chronic phase (<1 year)	Plasma vRNA: 10^2-10^7 cp/ml	Around one log below than	Plasma vRNA: 10^2-10^4 cp/ml	Return to normal value in all tissues		
	10^5 DNA cp/ 10^6 PBMC	mandrills – no difference with chronic long term below	Lower DNA SIV-mnd-1 versus-mnd-2 (10^3 cp/PBMC) (10^5 cp/PBMC)	Low (20%) but persistent depletion in macaque infected either by SIVmnd-1 or SIVmnd-2		
	Medium VL (10^4-10^5) in plasma and LN		10^3-10^6 DNA cp/ 10^6 LN cells	Decrease of CD4 but associated with loss of CD4 expression with age; double CD4-/CD8- lymphocytes compensates this defect		
Chronic phase (>2-3 years)	Plasma vRNA: $5 \times 10^4-10^7$ cp/ml	Plasma vRNA: 10^4-10^6 cp/ml	Plasma vRNA: 10^4-10^6 cp/ml	Slight decrease of CD4 + memory after >5 years of infection		
	Trend -2 PVL >-1 PVL			CD4 decrease with age		
	Medium viral load (10^4-10^5) in PBMC and lymph nodes	10^2-10^3 DNA cp/ 10^6 PBMC	Rebound of peripheral viral load	No increase of sCD14 (normal gut barrier)		
		10^2-10^3 DNA cp/ 10^6 LN cells	10^3-10^4 DNA cp/ 10^6 LN cells			

Despite this very active viral replication, there is an absence of primary infection syndrome with all variations of SIV_{mnd} in experimentally infected mandrills. No fever was observed during the first month. After a one-year follow-up, none of the animals had lost weight, nor was there an increase in the size of their lymph nodes (LNs). No opportunistic infections (Onanga et al. 2002, 2006) could be detected, even after 3 years.

Within the semi-free colony at CIRMF, the follow-up of SIV in the “naturally” infected mandrills was performed once or twice a year (sometimes over a larger timespan) in accordance with Animal Health control protocols. In this group the viral load in the animals varied from 10^5 to 5×10^6 regardless of the estimated time of infection (between 1 and 15 years, mean 5 years) (Pandrea et al. 2003; Greenwood et al. 2014).

When animals were inoculated with a high viral dose, T cell populations after the peak of viral replication (day 14 p.i.) were on average 35% lower than those at baseline before infection. CD4+ T cell numbers were then rapidly restored and returned to baseline values by day 60 p.i. All CD4+ T cell subsets were somewhat depleted during acute infection; however, a significant depletion (defined as a cell count more than 80% below baseline, $p = 0.0005$) occurred only in CD4+ effector memory T cells (CD28–) at the peak of viral replication. Restoration of peripheral effector memory CD4 T cells occurred rapidly within 2 months, and normal counts were reached 3 months postinfection. No significant changes were observed for CD8+ T lymphocytes and for B lymphocytes (CD20+ cells). During the acute phase, immune activation of both CD4 and CD8 lymphocytes was observed as a transient increase in Ki67+ and high HLA-DR+ cell counts. However, similar to lymphocyte depletion, the activation level returned to normal values less than 1 month after the highest recorded viral load (Onanga et al. 2002, 2006). Various mechanisms, which are shared with AGM/SIV_{agm} and Mangabey/SIV_{sm} infection, are suspected to be involved in the observed moderate acute infection. These include low counts of CD4+ CCR5+ cells (Pandrea et al. 2008) and Nef inhibition of CD3+ cell activation.

To conclude the experimental infection studies performed in STLV_{neg} animals, close monitoring of infected mandrills over a 3-year period did not reveal any significant modification to lymphocyte subsets nor to peripheral viral load. Additionally, immunodeficiency was never observed in the animals.

Due to the semi-free enclosure in CIRMF, chronically infected animals can be explored while considering the complexity of the “natural life.” This means that external factors have to be evaluated, such as the large age dispersion, the gender distribution (ratio of males to females), the possibility of multiple infections within an individual mandrill, and lastly the amount of stress associated with social relationships or breeding periods. Two studies carried out with animals from the semi-free enclosure showed the numbers of naïve lymphocytes (either CD4+ T, CD8+ T or B cells) are inversely correlated with age and lymphocyte numbers decline faster in male mandrills than in females (Sumpter et al. 2005; Greenwood et al. 2014). Greenwood et al. (2014) used a large number of animals to show that the absolute number of CD4+ T cells was inversely correlated with the first positive time point for SIV infection using a linear model that included age as a covariate. They also showed that viral load in females (with STLV and age as covariates) was significantly higher than in male mandrills and suggested that the breeding season may be associated with high peripheral VL in females. After more than 5 years of SIV infection, the number of CD4+ memory cells was lower than baseline, whereas these cells were not affected in non-infected animals despite a large distribution of their values (Greenwood et al. 2014). Nonetheless, as observed in the colony for many years, there was no difference in the prevalence of other diseases between infected animals and non-infected animals. Although the gut barrier appeared to be intact (as assessed by soluble CD14 concentrations), lymphocyte activation was high (as assessed by Ki-67 and MHC-II levels) in CD8+ cells and MHC-II levels were low in CD4+ cells. During the 3 years of continued observation, the experimentally infected mandrills did not present these same levels of

activation (Onanga et al. 2002, 2006; Souquiere et al. 2009).

Thus, evidence from the long-term monitoring of infected mandrills suggests that while the virus is not fully controlled, it is unable to induce immunodeficiency within the normal lifespan of a mandrill (approximately 15 and 20 years for males and females, respectively).

SIVmnd Superinfection Within Mandrills and Cross-Species Transmission to Nonhuman Primates

Further investigation of the natural course of SIV infection is necessary to elucidate the mechanisms of control and the potential differences between SIVmnd-1 and SIVmnd-2. Mandrills are the only primates infected *in natura* with two very different retroviruses that harbor different supplemental genes, like HIV-1 and HIV-2 among humans (see “► [Update on HIV-1 and HIV-2 Dual Infection](#)”). To date, only two major questions have been addressed: (1) Could interference between the two viruses explain why only one strain is present in a given animal? This can be tested using simultaneous infection, or superinfection, with both viruses. (2) If there is no difference between the viruses in their natural hosts, could experimental infection of non-African macaques reveal any differences?

The apparent mutually exclusive nature of viral infection was tested using coinfection with both viruses. Superinfection of SIVmnd-1- or SIVmnd-2-positive animals (stabilized at 10^5 RNA copies/ml) with the missing viral counterpart showed that infection with both viruses is possible. The initial peak in peripheral viral load of the new injected virus was not observed; however, the two viruses (at least during the first year) reached a steady state of replication identical to that of single infection (i.e., around 10^5 RNA copies/ml) without any significant modification to the immune status. There was no evidence of recombination between the two strains. After 3 years, the SIVmnd-1 VL decreased, whereas SIVmnd-2 VL remained high. Despite this demonstration of superinfection in an experimental setting, it has never been observed in the wild. In the CIRMF colony, superinfection was reported once, despite the co-circulation of the two viruses

(as assessed by an annual follow-up) (Souquiere et al. 2012). These observations are useful for the understanding of the properties of SIV infection in a natural environment and deserve further investigation. In particular, it would be interesting to investigate whether recombination occurs between SIVmnd-1 and SIVmnd-2. In humans, recombination between HIV-1 and HIV-2 has not been demonstrated in coinfecting patients, leading to much discussion about this possible scenario.

Cross-species transmission of SIVmnd-1 or SIVmnd-2 to the rhesus macaque (*Macaca mulatta*) results in two distinct manifestations of infection: SIVmnd-2-infected rhesus macaques maintained normal numbers of CD4+ T cells during a 2 year follow-up period (Table 1). However, these cells were significantly depleted in SIVmnd-1-infected rhesus macaques in the presence of high amounts of T cell activation, suggesting that SIVmnd-1 is more pathogenic than SIVmnd-2 (Souquiere et al. 2009). Both the number of activated T cells and the amount of antibodies in SIVmnd-infected rhesus macaques were higher than in SIVmnd-infected mandrills. In addition, SIVmnd-infected rhesus macaques had higher concentrations of proinflammatory cytokines, with the most significant differences observed for IFN- γ .

Overall, studies of cross-species transmission suggest that *Cercopithecus*-specific SIVs are associated with low pathogenicity in rhesus macaques. Viral competition experiments involving superinfection show that SIVmnd-2 is better than SIVmnd-1 at mounting persistently higher levels of viral replication in mandrills. SIVmnd-1 adaptation to its relatively “new” mandrill host is probably the best explanation for the relatively high pathogenicity of this virus in rhesus macaques, as illustrated by persistent infection and CD4+ T cell depletion.

Levels of T cell activation and plasma IFN- γ secretion were identical for both types of SIVmnd in rhesus macaques. This is surprising given the different pathogenic outcomes of the two infections. However, SIVmnd-2 may progress toward AIDS in infected rhesus macaques after a longer incubation period, ultimately rendering both viruses highly pathogenic. Alternatively, the pathogenicity of these two viruses may differ because of different mechanisms of CD4+ T cell depletion

during SIVmnd-1 and SIVmnd-2 infections. Particular clones of the SIVmnd-1 strain GB1 (from which the virus strains used in experimental infection in CIRMF were derived) are CXCR4-tropic SIVs and probably promote CD4⁺ T cell depletion at extra-intestinal mucosal sites. In contrast, pure CCR5-tropic SIVs, such as SIVmnd-2, may promote intestinal depletion of effector memory CD4⁺ T cells, as described previously for SIVsmm strains (see “► [Nonpathogenic SIV Infection of Sooty Mangabeys](#)”).

The difference in pathogenic potential for rhesus macaques between SIVmnd-2, which induced persistent infection (Takehisa et al. 2001; Souquiere et al. 2009), and SIVrcm, which is controlled in these animals, may also appear somewhat surprising in the context of the close phylogenetic relationship between these two viruses. However, this difference could also be associated with the fact that these viruses use different co-receptors, specifically CCR2b in the case of SIVrcm (Beer et al. 2001) and CCR5 in the case of SIVmnd-2 (Hu et al. 2003). This difference may have given the ancestor of SIVmnd-2 an evolutionary advantage when making the species jump.

Conclusion

The relatively high propensity for successful cross-species transmission of the SIVmnd viruses suggests that host-species barriers can be overcome relatively easily through recombination and adaptation in cross-species-transmitted SIVs. Mandrills and SIVmnd infections should be considered as a system to explore the various mechanisms involved in trans-species transmission and as a model to predict the risk associated with human-primate contact.

For example, some strains of other retroviruses, such as STLVs/HTLVs or foamy viruses, have been found in both humans and mandrills but with a geographical separation between the north and south of the Ogooué River. Host restriction factors are poorly understood, but examination of viral mutations may provide some clues in clarifying the connections between cross-species transmission and immune response adaptation.

The semi-free enclosure in CIRMF allows for close observation. Taking into account the protected status of the mandrills as well as their natural behavior, these enclosures provide a unique opportunity to study the natural history of the SIVmnd/nonpathogenic infection of SIVmnd/mandrill. Current findings also suggest the importance of following SIV-positive animals not only in nature but also in captive animals living on continents where mandrills have been imported and breeding for years.

Experimental infection of AGM or sooty mangabey has been more extensively investigated than in mandrills. Nonetheless, the overall results of the SIV/mandrill studies in connection with other nonpathogenic SIV infection reveal tolerance to the viral infection. Decreased cell-related and antibody-related immune responses are cumulatively a sign of viral tolerance. However, the mechanisms of this tolerance may stem from the virus, the host, or a combination of both.

This review is dedicated to Prof. François Simon who gave me the opportunity to work within CIRMF in Gabon, Prof. Françoise Barré-Sinoussi who encouraged me to go back to Africa, and the late Prof. Dominique Dormont, my mentor in the HIV/AIDS field. Thanks to Michaela Müller for her sharp mind, friendly comments, and ideas and to Jo Setshell and Beatrice Jacquelin for their corrections and questions.

Definition

Human and simian immunodeficiency virus (HIV and SIV) are both *Lentiviridae*, a subgroup of the *Retroviridae*, which are characterized by the presence of regulatory genes in addition to the *gag*, *pol*,

and *env* genes. At least 12 independent cases of SIV transmission from chimpanzees, gorillas, or sooty mangabeys (SMs) to humans have been documented. HIV-1M, the epidemic strain of HIV, was likely introduced into the human population via an SIV-infected chimpanzee around the beginning of the twentieth century. Sooty mangabey SIV (SIVsmm) gave rise to both HIV-2, which is largely restricted to West Africa, and SIVmac (Munch and Kirchhoff 2012). In contrast to natural hosts, Asian macaques are not infected with SIVmac in the wild.

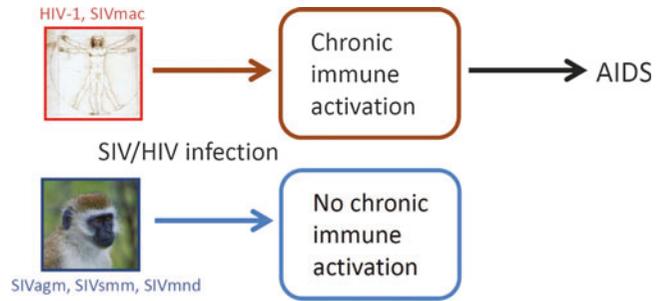

Over 40 African nonhuman primate species are infected with species-specific SIVs. Infection has been extensively studied in only four of these species: African green monkeys (AGMs), sooty mangabeys, mandrills, and chimpanzees. The first three have a nonpathogenic outcome of infection and the last shows an attenuated disease profile. Other species, such as L'Hoest's and Sykes' monkeys, have not been sufficiently studied to state outcome of infection. In this chapter, the term natural hosts will be used to describe AGMs, SMs, and mandrills as in these species a lack of SIV pathogenesis has been demonstrated (► [SIV Infection of Mandrills](#) and ► [SIV Infection of Sooty Mangabeys](#)). AGMs represent the largest reservoir of SIV in the wild, given their seroprevalence rates (mean of approximately 45%) and their wide distribution throughout sub-Saharan Africa (Fig. 1). Comparison of SIV infection in AGMs to HIV infection in humans and SIVmac infection in macaques can give insights into AIDS pathogenesis (Fig. 2) (Diop et al. 2002; Liovat et al. 2009).

AGM Classification

AGMs live throughout sub-Saharan Africa, with the exception of tropical forests and deserts. Four AGM subspecies have been described: vervet (*Chlorocebus pygerythrus*), sabaues (*Chlorocebus sabaues*), grivet (*Chlorocebus aethiops*), and tantalus (*Chlorocebus tantalus*). Vervets inhabit East and South Africa, sabaues West Africa, grivets East Africa, and tantalus Central Africa (Fig. 1). More AGM subspecies are currently being identified by next-generation

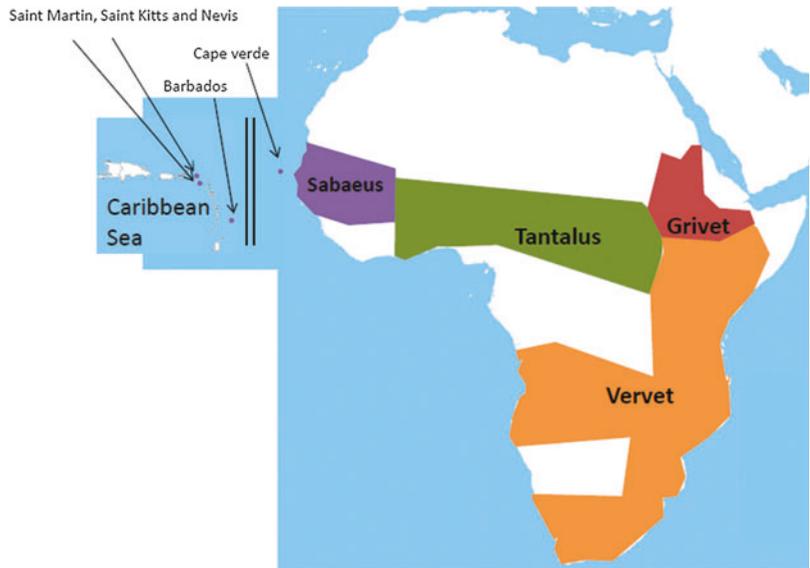

SIV Infection of African Green Monkeys,

SIV Infection of African Green Monkeys,

Fig. 2 Pathogenic and nonpathogenic infection of humans and nonhuman primates. During acute infection, African green monkeys rapidly resolve inflammation and immune activation. The absence of chronic immune activation leads to an asymptomatic chronic infection

sequencing studies. AGMs found in the Caribbean belong mostly to the sabaeus subspecies and are descendants of animals introduced during the slave trade in the seventeenth and eighteenth centuries. In contrast to AGMs in Africa, AGMs that live in the Caribbean are SIV negative. A likely explanation for this is that the transferred animals were pets, which are usually captured as infants. Such young AGMs are generally negative for SIV (Jacquelin et al. 2012).

Seroprevalence, Modes of SIVagm Transmission and Cross-Species Infection

The mean level of SIV infection in wild AGMs is approximately 40–50%. In adults,

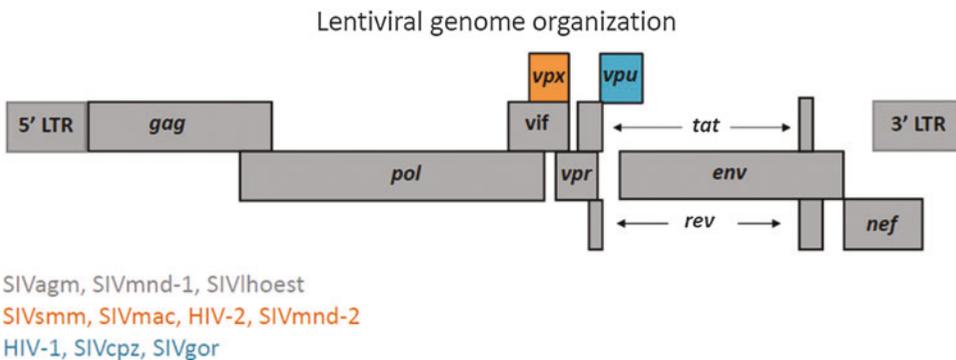

seroprevalence rates of up to 60–90% have been found, with females infected at a higher rate than males. In contrast to HIV infection in humans, mother-to-child transmission is rare in AGMs. Correspondingly, neonate animals are rarely infected, and juvenile animals are infected at an estimated rate of 10–20%. After sexual maturation, seroprevalence increases quickly, indicating that the main mode of SIVagm transmission could be sexual. However, SIV can also be transmitted through biting. SIV infection does not affect AGM lifespan. *In natura*, cases have been described of patas monkeys and baboons infected by SIVagm. Such cross-species infection in the wild may occur through either sexual contacts between sympatric species, biting, or hunting of smaller animals by larger species (Jacquelin et al. 2012).

SIVagm Phylogeny and Gene Function

The four recognized AGM subspecies all carry their own species-specific SIVs: SIVagm.gri in grivet, SIVagm.sab in sabaeus, SIVagm.tan in tanzania, and SIVagm.ver in vervet. The four SIVagm subtypes genotypically cluster by host rather than by geographical distribution. For instance, SIVagm.tan viruses from Uganda and the Central African Republic cluster together, while SIVagm.ver and SIVagm.gri strains that were both isolated in Ethiopia do not. This might be explained by the circulation of SIVagm in the AGM population since before the AGM subspecies diverged. The four SIVagm subtypes display up to 30% differences in the *pol* gene, a similar diversity as observed between distinct HIV-1 groups. SIVagm.sab is a mosaic virus, clustering for most of its genome with the other SIVagms, except for a region in the long terminal repeat (LTR), as well as the 3' *gag* and 5' *pol* region, in which it clusters with the SIVsmm lineage. This is the first example of a recombination event between two distinct types of SIV. It led to a recombinant virus, which outcompeted the native SIVagm.sab strain (Munch and Kirchhoff 2012).

The lentiviral genome is approximately ten kilobase pairs long and contains eight or nine genes encoding fifteen different proteins. All SIVs/HIVs have the virulence genes *vif*, *rev*, *tat*, *vpr*, and *nef* in addition to *gag*, *pol*, and *env*. Three

classes of SIVs are further categorized based on genomic organization: (1) SIVs/HIV-2 that have the additional gene *vpx* (e.g., SIVsmm and SIVmac), (2) SIVs/HIV-1 with the additional gene *vpu* (e.g., SIVcpz), and (3) SIVs without either of these genes (e.g., SIVagm) (Fig. 3) (Munch and Kirchhoff 2012). The absence of the *vpx* and *vpu* genes in SIVagm viruses is at least partially compensated for by additional functions of the *vpr* gene in this lineage. The *vpr* gene is closely related to the *vpx* gene and might share some of its functions, such as the degradation of SAM domain and HD domain-containing protein 1 (SAMHD1), a restriction factor found in both humans and nonhuman primates. Also, the SIVagm *vpr* gene has been shown to counteract the restriction factor tetherin, a function performed by *vpu* in HIV-1 (Munch and Kirchhoff 2012). SIVagm *vpr* can cause cell cycle arrest and apoptosis and is required for import of the pre-integration complex into the nucleus. SIVagm *vif* can increase infection of AGMs peripheral blood mononuclear cells (PBMCs) but not human PBMCs. SIVagm *vif* counteracts the restriction factor apolipoprotein B mRNA editing enzyme, catalytic polypeptide-like (APOBEC) in vivo, similar to HIV-1 *vif*. Nef is another virulence factor in SIVagm, with delta *nef* viruses replicating with lower viral loads than wild-type viruses (Muller and Barre-Sinoussi 2003). The *nef* gene in SIVagm, but not in HIV-1 or other SIVs of

SIV Infection of African Green Monkeys, Fig. 3 Three classes of SIV based on genome organization. The first class of lentiviruses comprises among other SIVsmm, SIVmac, and HIV-2 and is defined by the

presence of the viral protein x (*vpx*). The second class, containing HIV-1, is characterized by the viral gene u (*vpu*). The third class, to which the SIVagms belong, has neither of these genes

the *vpu*-containing group, can downregulate CD3 and CD28 on infected cells. This downregulation has been suggested to account for the lower levels of immune activation seen in SIV-infected natural hosts (Munch and Kirchhoff 2012). The *tat* and *vpr* proteins of SIVagm can transactivate the viral long terminal repeat (LTR), albeit to a lower level than HIV-1. In absence of *tat*, the SIVagm LTR shows a greater basal promoter ability than HIV-1 or SIVmac, possibly due to the absence of negative regulators in the SIVagm LTR (Muller and Barre-Sinoussi 2003).

Pathogenic Potential of SIVagm Infection

Rare examples of AIDS exist in natural hosts. In 1992, a case was described of a 12-year-old AGM that was coinfecting with SIV and STLV-1 that developed a severe enlargement of peripheral lymph nodes, diarrhea, and loss of appetite leading to cachexia (Pandrea et al. 2009).

Furthermore, experimental infection of pig-tailed macaques with SIVagm strains SIVagm.sab92018 and SIVagm.ver90, but not SIVagm.ver155, leads to AIDS in the infected animals. In contrast, SIVagm infection of patas monkeys and baboons is nonpathogenic (Hirsch et al. 1995; Jacquelin et al. 2012). Rhesus macaques that are infected with SIVagm control viral replication. These observations demonstrate that a virus-host interplay dictates the outcome of SIV infection, rather than an absence of pathogenic potential of SIVagm (Jacquelin et al. 2012).

Natural Course of SIVagm Infection

Most information on SIVagm infection has been obtained by studying both experimentally and naturally infected AGMs. The majority of studies have been carried out using the vervet and sabaues subspecies infected with SIVagm.ver and SIVagm.sab, respectively. Both intravenous and intrarectal infections lead to a similar infection course, recapitulating all parameters seen in the chronic phase of naturally infected AGMs (Liovat et al. 2009).

AGM peripheral blood CD4⁺ T cells are transiently depleted during acute SIV infection, with higher baseline CD4⁺ T cell levels correlating with a stronger depletion. The CD4⁺ T cell level in the blood of AGMs is dependent on the age of the animal. Levels in young adult AGMs vary between 800 and 2,900 cells/ μ L (with a median of 1,400 cells/ μ L) and decline by approximately 50 cells/ μ L per year in both infected and uninfected animals. In elder, uninfected animals, the levels of CD4⁺ T cells can fall below 200 cells/ μ L of blood, in the absence of any symptoms of AIDS (Jacquelin et al. 2012). During SIVagm infection, the depletion of AGM CD4⁺ T in the gut is as rapid and dramatic as in SIVmac infection. However, these cells partially rebound in AGMs in the chronic phase of infection (Table 1) (Liovat et al. 2009).

In acute SIVagm infection in AGMs, viremia reaches peak levels with RNA copy numbers between 2×10^4 and 10^9 RNA copies/mL. This is in the same order of magnitude as found for SIVmac infection in macaques and HIV-1 in humans. After the acute phase, viremia decreases several logs to a steady state. While the set-point viremia level between individual AGMs varies, the viral load remains stable over time. This is in contrast to HIV-1 and SIVmac infection where the viral load increases in late-stage infection (Diop et al. 2000). Most strikingly, the viremia in the chronic phase remains high, as high as in macaques progressing toward AIDS. Natural hosts resemble in that aspect a rare group of HIV-infected individuals who display elevated viremia but do not, or only slowly, progress to AIDS, called viremic non-progressors (► [Viremic Non Progressors](#)).

Similarities Between SIVagm and HIV-1/SIVmac Infections

High Mutation Rate

A hallmark of HIV is the high mutation rate throughout infection. Mutations are introduced by both an error-prone reverse transcriptase and recombination events in superinfected cells. This ability to mutate, coupled with a high tolerance for mutations by the virus, is conserved between

SIV Infection of African Green Monkeys, Table 1 Similarities and differences between SIVagm infection and pathogenic HIV-1/SIVmac infections. The table indicates the presence (+) or absence (–) in

pathogenic infection (middle column) and SIVagm infection (right column) of the characteristics described in the left column

Characteristic of SIV/HIV infections	Pathogenic infections (macaque or human)	AGM infection
Virus characteristics

Depletion of peripheral CD4+ T cells	+	–
Infection leads to AIDS	+	–

SIVagm and HIV. This shows that the lack of SIVagm-associated pathogenicity is not due to an inability to escape the immune system (Muller and Barre-Sinoussi 2003).

Inefficient Antiviral Adaptive Immune Responses

Antiviral antibodies are elicited with complete seroconversion occurring about a month after SIVagm infection, as for SIVmac infection in

macaques. For unknown reasons, AGMs and other natural hosts rarely have antibodies against p27. AGMs have low levels of IgG broadly neutralizing antibodies, similar to what is observed in humans. Furthermore, SIV-infected AGMs generate functional SIVagm-specific T cells, at a similar or lower frequency than SIVmac-infected macaques (Jacquelin et al. 2012). Simultaneous depletion of CD8+ and CD20+ cells in chronically infected AGMs increases viral loads,

without leading to depletion of CD4⁺ T cells (Schmitz et al. 2009). This shows that (1) the adaptive immune response partially controls viral load, as in humans, and (2) the absence of AIDS is not due to low levels of viral replication.

Cell Tropism

Like HIV and SIVmac, SIVagm infects CD4⁺ T cells and is cytopathic for infected cells (Broussard et al. 2001). Infection of these cells corresponds with the usage of CD4 as the primary receptor. The coreceptor usage of SIVagm is slightly different from HIV-1 but similar to SIVmac. All SIVs can use CCR5 to infect, they generally do not use CXCR4, and use additional coreceptors as good as, or even better than, CCR5 (Liovat et al. 2009). SIVagm preferably uses Bonzo as alternative coreceptor, while SIVmac and SIVsmm preferentially use Bob. For *in vitro* infection, activation of CD4⁺ T cells is required. *In vivo*, the bulk of SIVagm replication is sustained by short-lived, activated CD4⁺ T cells (Liovat et al. 2009). However, macrophage-tropic SIVagm strains have been isolated from both monocyte-derived macrophages and cerebrospinal fluid macrophages (Broussard et al. 2001). *In situ* hybridization has been used to detect SIVagm-infected alveolar macrophages. In contrast, immunohistochemistry of the gut did not reveal any infected macrophages. Similarly, human intestinal macrophages are poorly infected *in vivo*, as they downregulate CD4 and CCR5 upon migration to the gut. Whether other cell types, such as dendritic cells, are infected in SIVagm infection is currently unclear (Apetrei et al. 2007; Jacquelin et al. 2012).

Tissue Tropism

In acute SIVagm infection, high viral loads are found in the lung, lymph nodes, gut, and in many other lymphoid tissues. Approximately 70% of all CD4⁺ T cells in the body are located in the gut, often displaying an activated phenotype (Jacquelin et al. 2012). They are thus preferential target cells for HIV/SIV, and between 30% and 60% of memory CD4⁺ T cells are infected during the peak of SIVmac infection. Infected cells in the gut can be found in both Peyer's patches and in the

lamina propria in all primate lentiviral infections (Muller and Barre-Sinoussi 2003; Liovat et al. 2009). In the chronic phase, the level of SIVagm RNA and DNA decreases in tissues such as the lung, thymus, and brain. The majority of virus is located in the gut during chronic SIVagm infection.

Viral Capture by Dendritic Cells

Dendritic cells of humans, macaques, and AGMs all have the ability to capture HIV/SIV via cell surface molecules, among them lectin receptors such as DC-SIGN. After HIV/SIV capture, dendritic cells can transfer virions to CD4⁺ T cells, leading to efficient replication in activated CD4⁺ T cells, a process called trans-infection. This process has been suggested to be involved in the acquisition of SIVmac during mucosal transmission. Moreover, viral capture might contribute to dissemination of the virus to lymph nodes (Sodora et al. 2009; Jacquelin et al. 2012). Thus, SIVagm has the same abilities for rapid viral dissemination as SIVmac.

Recapitulating, SIVagm infection in AGMs shows many similarities to HIV infection in humans and SIVmac in macaques including (a) rapid viral mutation; (b) high viremia; (c) partial control of viral replication after acute infection; (d) preferential replication in activated CD4⁺ T cells and the bulk of viral replication is sustained by activated, short-lived cells; (e) cytopathicity of the virus; (f) DC-SIGN-mediated dendritic cell capture and transfer of virus; (g) broad dissemination to all lymphoid tissues in acute infection with persistently high replication in the gut; and (i) dramatic loss of intestinal CD4⁺ T cells in the acute phase (Table 1) (Chahroudi et al. 2012; Jacquelin et al. 2012).

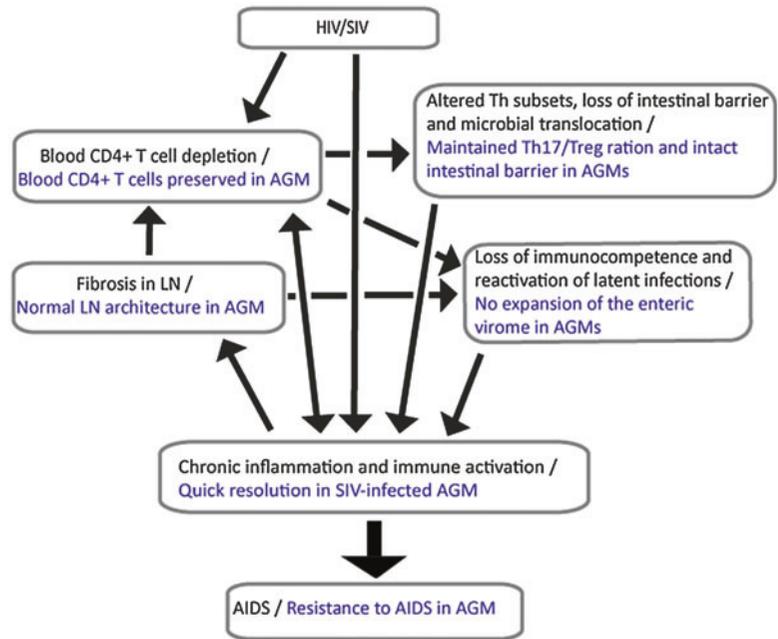

Differences Between SIVagm and HIV-1/SIVmac Infections

Absence of Chronic Immune Activation

The major differences between SIV infections in natural hosts, such as AGMs, and pathogenic SIV/HIV infections are the absence of chronic

SIV Infection of African Green Monkeys,

Fig. 4 Events suggested to contribute to chronic immune activation in HIV-infected individuals and the potential mechanisms by which AGMs avoid this. Upper lines of text, depicted in *black*, display the mechanisms contributing to chronic inflammation in pathogenic SIV/HIV infection. Observations made for AGMs are depicted in *blue*. LN lymph nodes, *Th* Thelper, *Treg* Regulatory T cell

immune activation (IA) and the preservation of peripheral CD4⁺ T cells in natural hosts. During the acute phase of infection in AGMs, proliferation of CD8⁺ T and CD4⁺ T cells increases in the blood, yet levels return to baseline during chronic infection. Lymph nodes display only a moderate peak of CD8⁺ T cell proliferation, and no symptoms of acute viral infection, such as fever or lymphadenopathy, are observed. This is in contrast to humans infected with HIV or macaques infected with SIV that have a sustained increase in CD8⁺ T and CD4⁺ T cell proliferation. The difference in IA between asymptomatic and pathogenic HIV/SIV infections reinforced the notion that IA is the driving force behind the depletion of CD4⁺ T cells. Indeed, the level of CD8⁺ T cell activation before seroconversion is a strong, independent predictive marker of time to progression to AIDS in HIV infection. Even in patients with undetectable viral loads (patients under treatment or viral controllers), the percentage of activated CD8⁺ T cells is still higher than in HIV-negative individuals. This increased IA associates with the loss of CD4⁺ T cells more strongly than viremia (Hunt 2012).

There are multiple proposed contributors to chronic IA in HIV and SIVmac infection:

(1) viral proteins, (2) disruption of the lymph node architecture and function, (3) homeostatic proliferation, (4) intestinal barrier disruption and subsequent microbial translocation, (5) (subclinical) viral reactivation, and (6) chronic inflammation. Figure 4 lists suggested differences from pathogenic infections that could allow SIVagm-infected AGMs to resolve IA and sustain an asymptomatic chronic SIV infection (Jacquelin et al. 2012).

Resolution of Inflammation

AGMs do not show chronic inflammation during SIVagm infection, indicated by the absence of high expression levels of inflammatory markers (e.g., TNF α), monocyte activation markers (e.g., soluble CD14), coagulation markers (e.g., D-dimer), and interferon-stimulated genes (e.g., IP10) (Jacquelin et al. 2012). The reasons for the absence of chronic inflammation in SIV-infected AGMs are still unknown. AGM plasmacytoid dendritic cells (pDCs) readily sense SIV (Diop et al. 2008). Indeed, in acute SIVagm infection, cytokines such as IFN α , IFN γ , and IP10 are strongly upregulated, indicating a robust innate immune response. This corresponds to the recruitment of activated plasmacytoid dendritic cells

(pDCs) and myeloid dendritic cells (mDCs) to the lymph nodes. However, cytokines such as TNF α and IL-18 are not upregulated, or upregulated to a lesser extent, in AGMs than in macaques during acute SIV infection. Before the end of acute SIV_{agm} infection, all inflammatory markers return to baseline levels in AGMs. This shows the remarkable capacity of AGMs to resolve inflammation despite ongoing viral replication (Kornfeld et al. 2005; Jacquelin et al. 2012).

Upon HIV-1 or SIV_{mac} infection, an inflammatory response is rapidly elicited in humans and macaques, respectively. This response is characterized by high levels of IFN α , IFN γ , and IP10 as for AGMs. However, markers as TNF α and IL18 are more strongly upregulated in pathogenic infection than in SIV_{agm} infection (► [Inflammatory Cytokines](#) and ► [Immunopathogenesis of SIV_{mac} Infection in Macaques](#)). Furthermore, chronic HIV-1 and SIV_{mac} infection are characterized by elevated levels of markers for inflammation, monocyte activation, and coagulation. While IFN α and IFN γ are not detectable in the asymptomatic part of chronic infection, many interferon-stimulated genes are still elevated compared to preinfection (Jacquelin et al. 2012). The relevance of chronic inflammation has been established recently when chronic inflammation was shown to be stronger associated with mortality than T cell activation in HIV infection (Hunt 2012).

Low Viral Load in Lymph Nodes in the Chronic Phase of SIV_{agm} Infection

While high viral levels are found in lymph nodes of acutely infected AGMs, the amount of SIV-infected cells there declines during chronic infection (Diop et al. 2000; Chahroudi et al. 2012). A similar infection profile has been observed in the lymph nodes of SMs. In natural hosts, SIV is confined to the T cell zones and does not infiltrate the germinal centers. There is also no trapping of SIV_{agm} by follicular dendritic cells. In contrast, in pathogenic SIV_{mac} infection, viral replication takes place in the T cell zone during acute infection but then predominantly shifts to the germinal centers. The majority of SIV_{mac} in lymph nodes can be found in follicular T helper

cells (T_{fh}) or trapped by follicular dendritic cells in germinal centers. Concomitantly, there is an expansion of T_{fh} cells, increase of germinal center size, and infiltration of CD8⁺ T cells into the germinal centers. These alterations could have an impact on the B cell maturation process, leading to incorrectly matured B cells in pathogenic HIV-1/SIV_{mac} infections.

In SMs, it has been demonstrated that T_{fh} cells are not infected, which is likely also true for AGMs, as there is no viral replication in the germinal centers of AGMs. Low levels of T cell infection in lymph nodes correlate with maintenance of the lymph node architecture in AGMs. SIV_{agm}-infected AGMs also do not have infiltration of CD8⁺ T cells into the germinal centers of their lymph nodes (Diop et al. 2000). In contrast to AGMs, the lymph nodes of humans and macaques become fibrotic during HIV-1/SIV_{mac} infection. This fibrosis has been linked to the production of TGF β in macaques. TGF β is not produced by AGMs chronically infected with SIV, further protecting the lymph node integrity of these animals. The disruption of the lymph node architecture in humans and macaques could impact B and T cell education, leading to an impaired immune capacity after infection. This would hinder adaptive immune responses to pathogens, lead to the reactivation of persistent infections, and drive chronic IA (Chahroudi et al. 2012; Jacquelin et al. 2012).

Low Levels of SIV Infection in Central Memory T Cells in AGMs

In natural hosts, central memory CD4⁺ T cells are infected at lower levels than in macaques. This correlates with a lower level of CCR5 expression on these cells. Furthermore, in AGMs, upon activation of CD4⁺ T cells, the expression of the *CD4* gene is downregulated. This leads to a population of double-negative memory T cells, which do not express CD4 or CD8, but preserve a helper function similar to CD4⁺ T cells (Jacquelin et al. 2012). A relative resistance to infection by central memory cells might contribute to the lower lymph node viral load in AGMs and SMs as a large proportion of these long-lived cells are found in the lymph nodes.

Central memory CD4⁺ T cells are pivotal for immunity as they provide immunological memory, so a preservation of these long-lived cells might contribute to the immunocompetent state maintained in SIV-infected natural hosts in contrast to HIV and SIVmac infections (Chahroudi et al. 2012; Paiardini and Muller-Trutwin 2013). A similar lower contribution of central memory CD4⁺ T cells to the viral reservoir has been observed in some HIV controllers and in posttreatment controllers (► [Posttreatment Controllers](#)).

A loss of central memory CD4⁺ T such as observed in HIV infection can contribute to the reactivation of normally latent viruses, such as *Cytomegalovirus*. These reactivated viruses can further contribute to the IA observed in HIV-1/SIVmac infections. A study on the enteric virome in AGMs and macaques has shown that there is no such viral expansion in AGMs (Handley et al. 2012). Avoiding the (subclinical) reactivation of latent viruses could help the prevention of chronic IA in these animals.

Low Proviral Loads in AGMs

While AGMs and macaques have similar blood SIV RNA viral loads, they differ in proviral load. The proviral load of AGM PBMC in the chronic phase ranges from 1 to 10³ SIV DNA copies per 10⁶ PBMCs, approximately tenfold lower than what is observed in HIV-infected individuals. Furthermore, AGMs display lower infectious titer of PBMC (Muller and Barre-Sinoussi 2003). The reasons for this relatively high viral RNA/DNA ratio and its implications for pathogenesis are still unclear.

Absence of Bystander Apoptosis of CD4⁺ T Cells

Most of the CD4⁺ T cells that undergo apoptosis during pathogenic SIV/HIV infections are uninfected, a process called bystander apoptosis. In AGMs there is no bystander apoptosis of CD4⁺ T cells during SIV infection, while the level of CD8⁺ T cells undergoing bystander apoptosis is slightly increased compared to preinfection. This bystander apoptosis has been linked to chronic IA

and inflammation via several hypotheses: (1) interferon alpha can induce expression of proapoptotic molecules on the surface of CD4⁺ and CD8⁺ T cells. One such molecule, TRAIL, was found to be upregulated in the CD4⁺ cells of lymph nodes of macaques, but not AGMs. (2) IL-18, which can induce caspase-1-mediated apoptosis, is downregulated in AGMs compared to macaque (Jacquelin et al. 2012). (3) NKp44L is upregulated on uninfected, activated CD4⁺ T cells in macaques, which could lead to NK-mediated killing of these cells. Homeostatic proliferation in response to loss of CD4⁺ T cells by bystander apoptosis has been proposed in turn to contribute to the chronic IA in pathogenic SIV/HIV infection. This proliferation can lead to immune exhaustion, diminishing the efficiency of antiviral immune responses (► [HIV-Associated Immune Exhaustion](#)). As AGMs lack bystander apoptosis, homeostatic proliferation is only required to replace the cells killed by SIV. This is a minor percentage compared to macaque where also the apoptotic, uninfected cells need to be replaced (Jacquelin et al. 2012).

Microbial Translocation

AGMs show a preservation of the Th17/regulatory T cell (Treg) ratio during infection, while Th17 cells are preferentially depleted in pathogenic SIV infections. Th17 cells are known to secrete interleukin 22 (IL-22), a cytokine required for the homeostasis of epithelial cells. The preferential Th17 cell loss in macaque is associated with the loss of the epithelial barrier integrity and a circulation of products derived from gut microbiota in the blood (► [Microbial Translocation](#)). Bacterial products, such as lipopolysaccharides (LPS), can activate monocytes and macrophages and thus contribute to the chronic IA observed in pathogenic infection (► [Macrophages in HIV Immunopathogenesis](#)) (Hunt 2012). In contrast, in SIV-infected AGMs, the intestinal barrier remains intact and there is no microbial translocation. This has been proposed to contribute to the absence of inflammation and IA in chronically SIV-infected AGMs. Indeed, administration of LPS to AGMs leads to elevated CD8⁺ T cell

activation levels, demonstrating the importance of microbial translocation (Chahroudi et al. 2012; Jacquelin et al. 2012).

Conclusions

SIVagm infection of its natural host, AGMs, has served as a useful model to gain insight into the causes of AIDS in HIV infection. In particular, studying nonpathogenic SIV infection has contributed to acknowledging the importance of immune activation in the progression to AIDS. SIVagm infection in its natural host is asymptomatic despite rapid viral mutation and high levels of viral RNA in the blood and intestine. Remarkably, AGM lymph nodes are infected with lower levels of virus in the chronic phase of infection, and the lymph node architecture is maintained. Less infection of central memory CD4+ T cells and follicular helper T cells as well as a lack of viral trapping in the germinal centers is thought to underlie this. AGMs are capable to resolve acute inflammation and chronic immune activation is absent. Studying this model may yield further insights into HIV pathogenesis, contributing to identify the precise mechanisms of HIV-1/SIVmac-induced immune activation.

SIVmac Infection of Macaques, Immunopathogenesis of

Birgit Koriath-Schmitz and Jörn E. Schmitz
Center for Virology and Vaccine Research, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, USA

Definition

The simian immunodeficiency virus of macaques (SIVmac) induces an AIDS-like disease in rhesus macaque monkeys with similar symptoms and immunological consequences seen in HIV-infected humans. SIVmac was discovered in rhesus macaques that were accidentally infected in captivity with SIV of sooty mangabey monkeys (SIVsmm). Unlike rhesus macaques that are not naturally exposed to SIV, sooty mangabeys show a high prevalence of SIVsmm infection in the wilderness without developing overt signs of disease. The SIVmac virus was named for rhesus macaques within which it was discovered rather than for its original source. SIVmac lifelong persistently replicates within the macaques' immune system that continuously tries to counterattack this virus infection and thereby induces a chronic immune activation. Thus, macaques develop SIV-related immunopathological symptoms while the inadequate immune responses fail to eradicate the virus. The SIVmac-infected rhesus macaque is an outstanding nonhuman primate (NHP) animal model to investigate virus-host interactions, intricate viral pathogenesis, and progressive immunopathological host responses. This animal model is the premier model for preclinical exploration of HIV vaccine candidates and treatment interventions aimed to prevent infection and/or control of viremia.

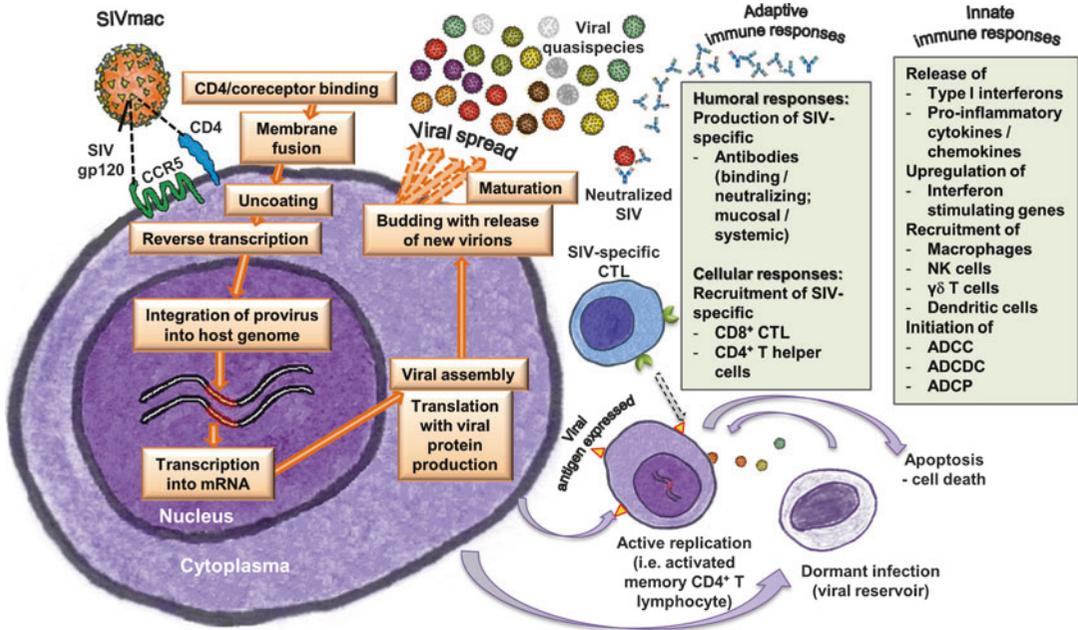

Overview

Rhesus macaques were first exposed to SIV when they were cohoused in primate center corrals in the United States with sooty mangabeys that were,

unsuspectingly, naturally infected with SIVsmm. Traces of the first detected SIVmac strain go back to a colony housed at the Caribbean Regional Primate Research Center (CRPRC) in Puerto Rico in the 1960s–1970s (Gardner 2003; Pancino et al. 2011). Apparently healthy rhesus macaques carrying SIVmac without symptoms were then imported in the 1970s to the New England Primate Research Center (NEPRC) that did not house any sooty mangabeys. These SIVmac-infected rhesus macaques built the seeds for further spread among cohoused rhesus macaques (horizontal transmission) and their offspring (vertical transmission) (Gardner 2003; Pancino et al. 2011). An increased incidence of opportunistic infections and lymphomas in rhesus macaques consistent with simian acquired immunosuppressive disease syndrome (simian AIDS) prompted medical investigations in search for a potential infectious causative agent that ultimately led to the discovery of SIVmac at the NEPRC in 1985. At that time, HIV was used to be called human T-lymphotropic virus III (HTLV-III). Therefore, the newly discovered virus was originally named simian T-lymphotropic virus III (STLV-III) of macaques and later renamed SIV (Daniel et al. 1985; Kannagi et al. 1985; Gardner 2003).

As SIVmac infection in rhesus macaques derived from SIVsmm in sooty mangabeys, human HIV-2 infection groups A through G similarly originated from cross-species transmission of SIVsmm by proximate human contact to sooty mangabeys in West Africa. In the HIV-2 endemic areas of West Africa, an exposure risk to SIVsmm exists through blood contact with infected bushmeat or pet sooty mangabeys. A comparable crossing of a species barrier happened by the spread of SIV in chimpanzees (SIVcpz) to humans that is considered the origin of HIV-1. In contrast to endemically SIV-infected African NHP species (e.g., sooty mangabeys, African green monkeys), Asian NHP (e.g., rhesus macaques) are not naturally infected with SIV (Gardner 2003; Pancino et al. 2011).

SIVmac is phylogenetically closely related to HIV-1 but even more closely to HIV-2. Large parts of the genomic structure and sequence are shared between SIVmac, SIVsmm, and HIV-2.

SIVmac Infection of Macaques, Immunopathogenesis of, Fig. 1 Virus-host interactions between SIV and macaque. Binding of SIV Env gp120 to CD4 and cytokine coreceptor on the surface of the host cell lets the envelope of the SIVmac virion fuse with the cell membrane of the macaque CD4(+) cell, enabling a single virus to enter the cell. Upon uncoating of viral material into the host cytoplasm, the SIV RNA template is reverse-transcribed in an error-prone process into cDNA, allowing mutations to occur. After entering the host cell nucleus, viral DNA is integrated into the host genome as provirus enabling viral replication. Newly assembled SIV virions bud off the host cell, mature, and spread SIV infection. Innate immune

responses immediately attempt to counteract infection, before adaptive cellular and humoral immune mechanisms respond specifically, but mostly inefficiently, as viral quasi-species or escape mutants recurrently evade immune responses that lag behind in adapting to the viral evolution. As SIV-specific CTL, MHC class dependent, recognize viral antigen-expressing activated CD4(+) T cells and kill infected cells, they play a pivotal role in the control of SIV replication, especially during acute infection. Selective pressure causes the virus to develop CTL escape mutants. Likewise, SIV-specific antibodies that are rarely broadly neutralizing fail to eliminate the virus. The ongoing chronic viral replication results in a continuous T-cell loss (Not to scale)

The viral structural genes *gag*, *pol*, and *env*, the essential regulatory genes *rev* and *tat*, and additional accessory regulatory genes (including *nef*, *vpr*, and *vif*) that do not occur in other retroviruses are characteristic for primate lentiviruses (Coffin et al. 1997; Pancino et al. 2011; King et al. 2012). SIVmac and HIV-2 differ from HIV-1 by the presence of the nonstructural *vpx* instead of a *vpu* gene and by more than 50% sequence deviation (King et al. 2012).

Viral Determinants of SIVmac Infection

To enter a host cell, the SIVmac virion surface glycoproteins, especially areas of the Env protein,

have to interact with specific cell surface receptors of the CD4(+) T cells. To facilitate entry of an SIVmac virion, the susceptible recipient cell needs to express both a CD4 protein and a chemokine receptor on its cell membrane (Coffin et al. 1997; King et al. 2012) (Fig. 1). C-C chemokine receptor type 5 (CCR5) and alternatively C-X-C chemokine receptor type 4 (CXCR4) are predominantly used as coreceptors or second/fusion receptors by SIVmac strains. Low expression of the coreceptor or its blockage decreases viral entry (Pancino et al. 2011; King et al. 2012).

After the SIVmac envelope trimeric glycoprotein gp120 binds to CD4 and the coreceptor, the envelope of the SIVmac virus fuses with the cell plasma membrane allowing it to enter the cell.

Subsequently, the virus is uncoated and releases its genetic material including ribonucleic acid (RNA) and the enzyme reverse transcriptase into the CD4(+) host cell. With the help of this enzyme, SIVmac RNA is transcribed in the host cell cytoplasm into complementary deoxyribonucleic acid (cDNA) (Coffin et al. 1997; King et al. 2012). As typical for retroviruses, the genetic information is transferred “backwards” (or in Latin *retro*) from RNA to DNA (King et al. 2012).

After the integration of the retroviral DNA into the host chromosomal DNA as provirus, the host cell is enabled to produce new copies of SIVmac with tropism for CD4(+) cells (Coffin et al. 1997). During the reverse transcription, a high rate of genetic recombination and variation takes place. Consequently, an abundance of genetically diverse viral copies or virions develop so that viral quasi-species are formed differing from each other in their functional properties such as virulence and protein expression (Coffin et al. 1997). The newly assembled SIVmac virions are released from the host cell by a process called budding that uses the host plasma membrane for the capsid assembly of the virion (Coffin et al. 1997; King et al. 2012).

Various SIVmac strains with different properties such as virulence, attenuation, coreceptor usage, or neutralization resistance are used in biomedical and translational research. Some of the strains consist of cloned viruses, while others are swarms with genetic variabilities. There are pathogenic differences between viruses propagated *in vitro* by culturing in suitable human or nonhuman primate cells and passaged *in vivo* in NHP. Serial passage in rhesus macaques can increase the pathogenicity of SIVmac. Accordingly, virus with low pathogenicity from clinically healthy monkeys resulted via serial passage at the NEPRC in highly pathogenic SIVmac251 (a swarm generated after four viral passages in rhesus macaques) and SIVmac239 (a clone produced after seven viral passages) (Voevodin and Marx 2009). Another pathogenic clone derived from SIVmac251 is SIVmac32H (Voevodin and Marx 2009). Less pathogenic, highly attenuated clones such as SIVmac142 are infrequently used. Similar to the SIVmac lineage discovery at the

NEPRC, another lineage called SIVb670/H4/H9 group was isolated after unintended transmission of the virus from sooty mangabeys to rhesus macaques in a leprosy-related experiment at the Tulane National Primate Research Center (TNPRC) (Voevodin and Marx 2009). This group of viruses includes SIVsmE660 that is moderately sensitive to neutralization, in contrast to the highly neutralization-resistant SIVmac239 clone (Voevodin and Marx 2009; Pancino et al. 2011; Sui et al. 2013).

An example of an attenuated SIVmac is SIV delta *nef* (SIV Δ *nef*), which lacks the accessory gene *nef* and shows a significantly reduced pathogenicity in rhesus macaques. SIV Δ *nef*-infected adult rhesus macaques are usually able to control infection, have low viral loads, and typically do not progress to simian AIDS, comparable to human HIV-1 long-term non-progressors who control HIV-1 infection without progressing to AIDS (Coffin et al. 1997). However, SIV Δ *nef* is by far more pathogenic in infant rhesus macaques within which infection regularly results in simian AIDS (Coffin et al. 1997).

In order to study clinically relevant HIV-1 gp120 envelope responses in rhesus macaques, simian/human immunodeficiency virus (SHIV) strains have been molecular-biologically engineered. SHIV is a chimera consisting of an SIV backbone with an HIV envelope insert. Since primate lentiviruses are species specific and HIV-1 does not cause infection in macaques, challenges with SHIV in rhesus macaques allow investigating HIV vaccines in the animal model while addressing HIV clade variances as well as antigenic differences between SIV and HIV (Abee et al. 2012).

Routes of SIVmac Transmission

Intravenous inoculation of SIVmac was the classical route for challenge studies in rhesus macaques resulting in a very predictable course of infection in 100% of inoculated animals. However, the probability of transmission of HIV to humans is much lower since most of the infections occur via mucosal route. Therefore, infection

studies in NHP, in particular vaccine challenge studies, have been adapted to mucosal challenge studies, a more relevant clinical setting. Mucosal administration of cell-free or also cell-associated virus commonly utilizes genital such as vaginal or penile (foreskin or urethra), rectal (or gastrointestinal), or oral routes. Transmission of cell-free virus across the intact mucosal epithelial cell layer may occur by transcytosis of the virus particles. This process is possibly enhanced via the neonatal Fc receptor (FcRn) that can transport immunoglobulin G (IgG) across epithelial cells from an acidic pH at the luminal surface to release at a more neutral pH (Gupta et al. 2013). In addition, mononuclear cells such as dendritic cells are considered to facilitate transport of virus through the mucosal tissues toward activated T cells (Voevodin and Marx 2009). Examples of cell-mediated virus are challenges with SIV-infected peripheral blood mononuclear cells (PBMC), infected isolated cells, or semen from infected monkeys. Typically much higher virus doses are necessary for atraumatic mucosal administration than for intravenous challenges because, in contrast to blood, mucous membranes provide protective antimicrobial epithelial barriers that impede viral penetration. As HIV has a low per-sexual-contact transmission rate and only a single or few variants get transmitted (so-called transmitted founder viruses), repeated challenges with low SIV doses are most suitable to test vaccine efficacy (Friedman et al. 2006; Voevodin and Marx 2009; Shaw and Hunter 2012; Sui et al. 2013).

To increase susceptibility to SIV transmission by vaginal route, hormonal treatment with progesterone or progestin can be used to thin the vaginal epithelium and reduce the barrier. In contrast, estrogen thickens the epithelium and hence fortifies the barrier (Voevodin and Marx 2009; Sui et al. 2013). However, hormonal treatment also has immunomodulatory effects. High progesterone level (occurring in the luteal or premenstrual phase of the hormonal cycle in female macaques and humans, during pregnancy, or during progesterone therapy) is associated with a decrease in IgG and IgA production and secretion in cervical and vaginal mucosa and a decrease of cytotoxic

T lymphocytes (CTL) in the female genital tract (Hel et al. 2010). Thinning of the vaginal stratified epithelium decreases the barrier and might facilitate the access of SIV to CD4(+) lymphocytes, macrophages, and Langerhans cells. The latter cells may play a role in transporting membrane-associated SIV to suitable CD4(+) target cells (Hel et al. 2010).

An oral transmission occurs mainly when an infant acquires an SIVmac infection by drinking breast milk from its mother (Voevodin and Marx 2009; Abee et al. 2012). Apart from infection via nursing, the offspring can also acquire SIVmac by blood contact during delivery or less frequently through the placenta. In contrast to transmission within the species (e.g., by sexual contact), the emergence of SIVmac infections in rhesus macaques and HIV-2 in humans highlights the risk of cross-species transmissions with the possibility of genetic diversity by recombination (Gardner 2003; Abee et al. 2012).

Primate Host Determinants and Virus-Host Interactions

Higher viral loads of pathogenic SIVmac during acute infection often result in more rapid progression to simian AIDS. In contrast, infection with less pathogenic viruses may cause a delayed and less severe disease development. Certain host factors including major histocompatibility complex (MHC) genes are associated with an enhanced CD8(+) T-cell-specific control of SIVmac viremia. Rhesus macaques of Indian origin expressing the MHC class I allele *Mamu A*01* are typically less susceptible to SIV infection than macaques lacking these genes who progress more quickly to symptomatic disease. Distinct other MHC-I alleles such as *Mamu B*08* and *B*17* also have some protective effects against SIVmac infection (Pancino et al. 2011; Sui et al. 2013). Some macaques suppress infection over many years to lifelong, so-called elite long-term non-progressors, and are of interest as study models for human HIV-1 controllers (Abee et al. 2012).

The particular monkey species and virus origin also matter for pathogenicity and course of

disease. Indian rhesus macaques infected with commonly used pathogenic SIV variants (e.g., SIVmac251 or SIVmac239 that originated from Indian rhesus macaques) often progress faster to clinical symptoms than Chinese rhesus macaques. The latter frequently have lower SIVmac viral loads with a more attenuated disease course than rhesus macaques of Indian origin. However, viral loads increase in Chinese rhesus macaques when the challenge virus was grown in Chinese rhesus macaques (Sui et al. 2013). This observation of a species-specific adaptation of the virus is also true for SIV infection in natural hosts: While the SIV infection does not lead to pathogenicity, the SIV strain endemically present in vervet African green monkeys results in a higher viremia than experimental infection of sabaeus African green monkeys. Similarly, sabaeus African green monkeys experience a higher viremia than vervet African green monkeys that are experimentally infected with sabaeus SIV (Pancino et al. 2011).

CCR5-tropic SIVmac strains encounter difficulties recognizing CXCR4 host receptors; the reverse applies to CXCR4-tropic viruses. Alternative coreceptors include chemokines such as CCR (C-C motif receptor)1, CCR2b, CCR3, CCR8, and CXCR6 (or STRL33/Bonzo) or various G-protein coupled receptors, e.g., GPR1, GPR15/Bob, and ChemR23 (chemoattractant receptor 23) (Pancino et al. 2011).

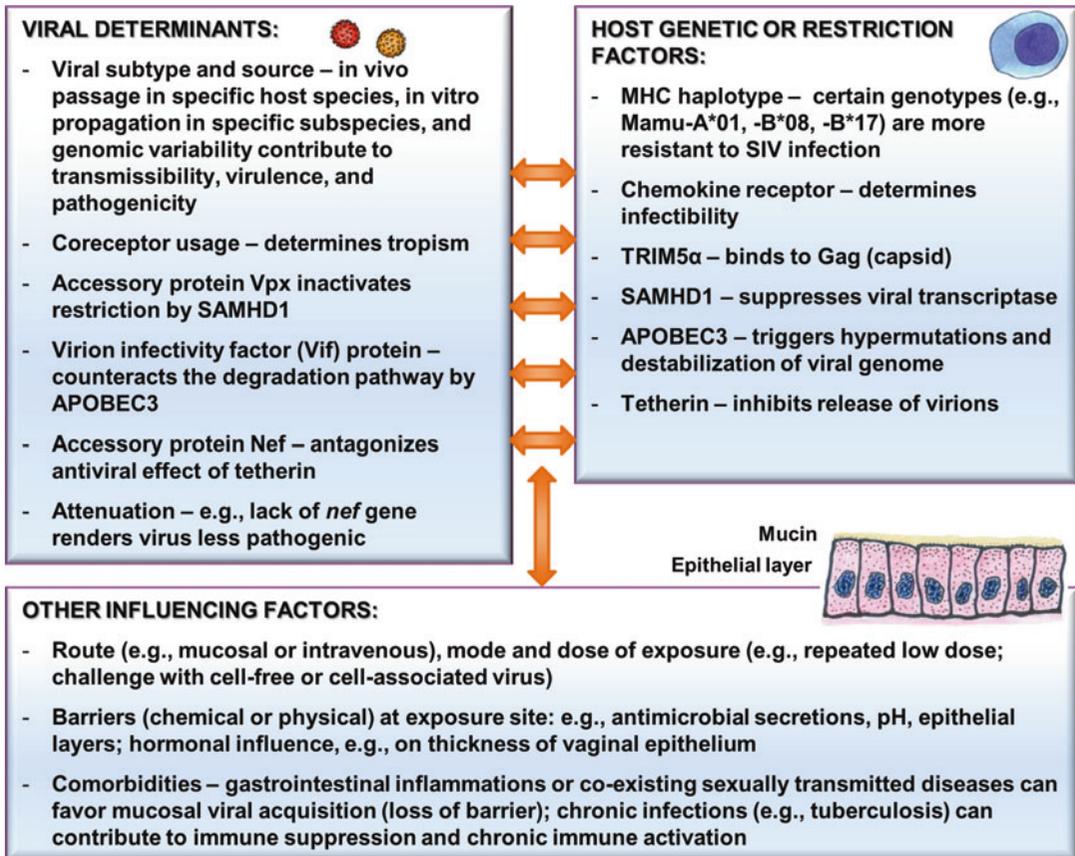

As part of the intrinsic cellular immunity, primate cells express various restriction factors that need to be overcome by SIVmac in order to enable productive infection (Fig. 2). The tripartite interaction motif 5 (TRIM5 α) with or without the insertion of cyclophilin A (CypA) pseudogene exhibits virus isolate-specific capsid-binding activities in rhesus macaques that interrupt uncoating events necessary for reverse transcription (Bieniasz 2004; Pancino et al. 2011; Sui et al. 2013). While sterile- α -motif-and-histidine-aspartic-domain-containing protein-1 (SAMHD1) acts limiting on viral replication by suppressing viral transcriptase activity, the lentiviral accessory protein Vpx (viral protein X) inactivates the restriction by SAMHD1. The cellular cytidine deaminase apolipoprotein

B mRNA-editing catalytic polypeptide-like 3 (APOBEC3) triggers a degradation pathway resulting in hypermutations and destabilization of the viral genome that counteracts the virion infectivity factor (Vif) protein so that SIV/HIV virions deleted of *vif* (SIV/HIV Δ *vif*) have reduced infectivity. The transmembrane protein tetherin has an inhibitive effect on the release of viral particles. While the antiviral activity of tetherin is antagonized by the accessory protein Vpu in HIV infection, Nef has an equivalent function in SIVmac (Pancino et al. 2011). Taken together, the restriction factors have an immunomodulatory suppressive effect on SIV infection, but they are incapable of controlling viral replication.

Innate Immune Responses

The host defense by innate immune responses consisting of physical and chemical barriers at portals of entry (e.g., antimicrobial mucin produced by epithelial cells in the distal colon), cellular components (e.g., neutrophils, macrophages, natural killer (NK) cells), and noncellular components (e.g., cytokines, complement system, other mediators of inflammation) act immediately as the first line of defense against an exposure to SIVmac and do not require prior exposure to SIVmac, but they act unspecifically against any foreign substance or antigen.

Unspecific innate immune responses to pathogenic SIVmac exposure in rhesus macaques include an increased secretion of type I interferons (IFN α and β) and induction of proinflammatory cytokines and chemokines by plasmacytoid dendritic cells, e.g., tumor necrosis factor alpha (TNF α), IL-6, C-C motif ligand 5 (CCL5/RANTES – regulated on activation, normal T cell expressed and secreted), macrophage inflammatory protein (MIP)-1 α or CCL3, MIP-1 β or CCL4, and C-X-C motif chemokine 10 (CXCL10); upregulation of interferon stimulating genes, viral defense by macrophages, NK cells, and gamma delta ($\gamma\delta$) T cells; production of host defense peptides or defensins; and several others (Coffin et al. 1997; Friedman et al. 2006; Bosinger et al. 2011; Pancino et al. 2011). To

SIVmac Infection of Macaques, Immunopathogenesis of, Fig. 2 Interaction between viral determinants of SIV and host genetic or restriction factors. “Viral determinants” influencing virulence, pathogenicity, and transmissibility of SIV are countered by “host genetic

or restriction factors.” Apart from major involvement by the host’s acquired and/or innate immune system (not shown in figure), the interplay between these determinants and additional “other influencing factors” affect viral acquisition, viral control, and/or disease progression

determine the level of immune activation, increased plasma levels of neopterin and beta globulin can serve as biomarkers (Pancino et al. 2011).

NK cells that express various inhibitory or activating killer cell immunoglobulin-like receptors (KIR) on their surface eliminate infected targets either directly by cytotoxicity or indirectly via antigen-dependent cellular cytotoxicity (ADCC) (Pancino et al. 2011). The relative activity of NK cells is dependent on the expression profile of particular KIR molecules (Hellmann et al. 2013). ADCC-inducing non-neutralizing antibodies that occur early after acute infection have been attributed a potential protective role in SIV/HIV infection by possibly delaying

progression to AIDS/simian AIDS (Ackerman et al. 2012). The role of antibody-dependent cellular phagocytosis (ADCP) in SIV/HIV infection, an immune mechanism by which non-neutralizing antibodies recruit phagocytes including monocytes, macrophages, and neutrophils to antibody-opsionized (or antibody marked for phagocytosis) viral particles, still remains unclear (Ackerman et al. 2012). Antibody-dependent complement-dependent cytotoxicity (ADCC), an immune function by which antibody-opsionized viral particles and other antigenic materials are directed through the complement cascade with subsequent lysis, may contribute to some control of viral replication during early SIV infection (Ackerman et al. 2012).

Adaptive Immune Responses

Following acquisition, SIVmac massively replicates in rhesus macaques with peak viral levels between 10^5 and 10^9 RNA copies/ml plasma typically detected after 2 weeks of infection (Pancino et al. 2011). The viral peak coincides with a massive CD4(+) T lymphocyte loss in peripheral blood. For decades, the enhanced programmed cell death of CD4(+) T cells in SIV/HIV infection was attributed to apoptosis. However, caspase-3-mediated apoptosis has been shown to only induce the death of the small fraction (~5%) of activated and productively infected CD4(+) T cells, whereas the remaining vast majority of quiescent CD4(+) bystander cells die by caspase-1-mediated pyroptosis, an extremely inflammatory form of programmed cell death in which the dying cells release large quantities of pro-inflammatory cytokines like interleukin 1 β (IL-1 β) that attract even more cells to die and spur inflammation (Doitsh et al. 2014).

Immediately after the SIVmac peak, the plasma viral load typically sharply decreases by a few log steps (Pancino et al. 2011). This decrease of viremia is temporally associated with a robust rise of CD8(+)CTL. The importance of the cellular immune responses in partial viral containment was demonstrated by experimental depletion of CD8(+) T lymphocytes by antibodies in the primary infection: SIVmac-challenged rhesus macaques are incapable of controlling viremia and undergo a rapid progress to simian AIDS when CD8(+) T-cell responses are inhibited (Schmitz et al. 1999; Friedman et al. 2006; Pancino et al. 2011).

By the third week, the number of circulating CD4(+) T lymphocytes recovers slightly, but is eventually followed by a gradual progressive decline, especially of the memory pool, throughout the course of infection. While the first SIV-antibodies can usually be detected by 2 weeks following infection, seroconversion is completed by a month after exposure, marking the end of primary infection (Pancino et al. 2011). Within the first 10 weeks after SIVmac infection, viremia reaches a plateau or set-point level (Pancino et al. 2011; Abee

et al. 2012). Early on, virus is systemically spread from the initial local site of acquisition to various lymphoid tissues where the virus gets persistently replicated. Alternatively, SIVmac virions can remain dormant inside suitable host cells over longer periods of time by establishing hidden viral reservoirs in latently infected long-lived T memory cells; hence protected from counterattacks by the host immune system, SIVmac evades immune recognition by the host (Picker et al. 2012). While only a fraction of the virions circulates in the peripheral blood, easily accessible for virologic assays, the vast majority of viral particles is produced and stored in lymphoid tissues including the gut that contains the majority of activated memory CD4(+) T cells in the body. In contrast to nonpathogenic SIV infection in African NHP that restore an initial CD4(+) T-cell loss after primary infection, chronic pathogenic SIVmac infection of Asian NHP is characterized by a progradient loss of the CD4(+) T-cell memory population. As the disease progresses, CD4(+)/CCR5(+) T lymphocytes get destroyed and are not sufficiently restored contributing to an immunologic impairment that permits microbial translocation in the gut and inflammation (Pancino et al. 2011; Estes 2013). While the destruction predominantly affects the later-staged CD4(+)/CCR5(+)effector memory T cells, less differentiated CD4(+) central memory T-cell precursors that are capable of producing new effector memory T cells are initially largely spared from loss due to limited co-expression of CCR5. The regeneration of the CD4(+) effector memory cell pool, the major target cells of SIV infection, guarantees viral replication for prolonged time periods. However, due to the hyperimmune activation, with the onset of simian AIDS, the entire CD4(+) memory cell pool gets basically depleted (Picker et al. 2012).

Depletion of the host's CD4(+) T helper lymphocytes further diminishes the host immune control. Since retroviruses utilize error-prone reverse transcriptase for their replication, SIVmac virions show huge mutation rates, replacing the original SIV transmitted founder virus(es) by swarms of escape variants. Thus, the NHP's cellular and humoral immune system is confronted with a

staggering number of viral mutants. Genomically and functionally diverse mutants obtain selective advantage because they are not recognized by the host immune system. The huge level of viral sequence diversity makes it an overwhelming and impossible task for CTL to detect virally infected cells. Moreover, the envelope glycoprotein Env of SIVmac undergoes extensive conformational changes due to errors in the reverse transcription and resulting mutations of proviral DNA. Although B lymphocytes are initially hyperactivated and generate large amounts of SIV-specific antibodies, they have little effect on the magnitude of the primary viremia. As the viral variants continuously select for new variants that are not easily neutralized or deactivated by anti-SIV-specific antibody responses, most antibodies remain inefficient against the next generation of novel viral mutants. Ultimately, the host's adaptive immune responses fail to catch up with the tricks of the intruding virus so that a lifelong viral replication and infection are established (Pancino et al. 2011; Picker et al. 2012; Mascola and Haynes 2013).

Immune Activation in Pathogenic SIVmac Infection

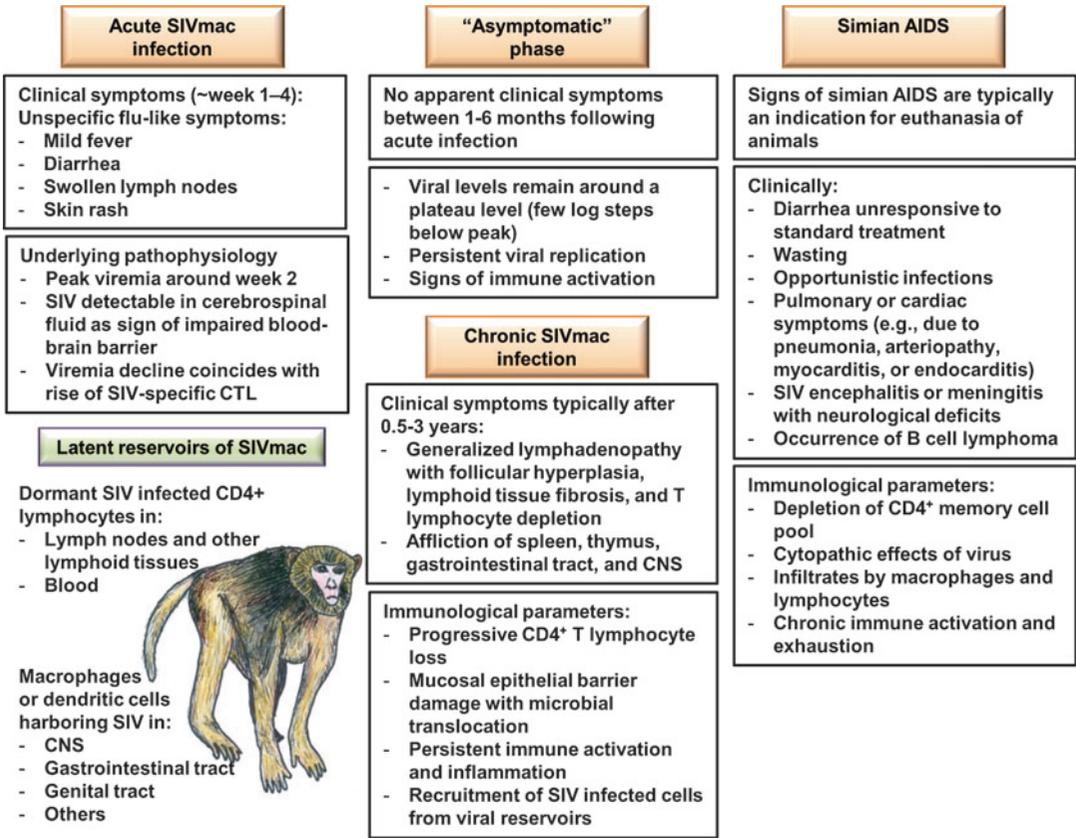

Pathogenic SIVmac infection of Asian NHP causes strong innate immune responses similar to nonpathogenic SIV infection of African NHP. However, SIV-infected African natural hosts present an enhanced immune activation only during acute SIV infection, but this increased immune activation is resolved in the transition to chronic infection. In contrast, chronic hyperimmune activation is a hallmark of pathogenic SIVmac infection. The lack of pathogenicity of SIV infection in African natural hosts is believed to be indicative for specific host adaptations, evolved during extended coevolution of host and virus and not for an effective immune control (Bosinger et al. 2011; Picker et al. 2012). Both adaptive and innate immune responses contribute to keeping the SIVmac virus infection temporally in check, permitting a partial viral containment. However, ultimately these immune responses fail

to eliminate the virus and the vast majority of humans and nonnatural host NHP develop full-blown AIDS.

Clinical Pathological Changes in SIVmac-Infected Rhesus Macaques

Initial clinical symptoms during primary SIVmac infection are unspecific and last from approximately 1–4 weeks (Fig. 3). They can include mild fever, diarrhea, swollen lymph nodes, and malaise. A skin rash with disseminated papules at the trunk, face, and thighs is characterized by a perivascular lymphocytic dermatitis with cytotoxic activity directed against epidermal Langerhans cells. In some macaques, no apparent symptoms occur during the first few weeks following infection. The acute phase of infection is followed by an asymptomatic phase, which can last from months to years until clinical disease becomes apparent (Coffin et al. 1997; Abee et al. 2012).

Clinical signs of simian AIDS typically develop within 1–3 years (compared to 7–10 years in untreated humans), depending on the pathogenicity of the virus, the defense mechanisms of the primate host (i.e., the genetic background), and comorbidities. During the chronic disease stage, various lymph nodes become swollen. In macaques with more prolonged disease course, generalized lymphadenopathy develops with follicular hyperplasia and confluent germinal centers that may be missing in animals with rapid disease progression (Coffin et al. 1997; Friedman et al. 2006). Early after infection, pathogenic SIVmac is detected in the paracortex of lymph nodes, in periarteriolar lymphoid sheaths of the spleen, in medulla of the thymus, to varying degree in the gastrointestinal tract, in the CNS, and in other lymphoid tissues (Letvin et al. 1994). Persistent immune activation leads to chronic inflammation and tissue injury. Attempting to heal the damage, fibroblasts constituting the structural framework of the lymphoid tissue react upon the inflammation by excessive collagen and fibronectin depositions into the extracellular matrix, replacing normal tissue by scar-like

SIVmac Infection of Macaques, Immunopathogenesis of, Fig. 3 Different phases of pathogenic SIV infection. Acute SIV infection is distinguished from chronic pathogenic SIV infection that gradually progresses to simian AIDS. Between the acute and chronic phase, some distinguish an additional "asymptomatic" phase. However, since this phase shows persistent viral

replication and signs of immune activation, the "asymptomatic" phase can also be allotted to the chronic SIV infection. Typical signs and symptoms with underlying pathophysiology are listed. Already starting during acute SIV infection, latent reservoirs of SIV are established that evade immune responses and/or retroviral treatment and contribute to viral persistence

structural elements. Besides providing a supportive infrastructure for lymphocyte populations, fibroblastic reticular cells are crucial for the immunological function by providing lymphocytes with IL-7 (Estes 2013). As naive T cells depend on IL-7 for survival, lymphoid tissue fibrosis causes lymphocytic depletion through programmed cell death, especially of naive CD4(+) T lymphocytes. Since fibroblastic reticular cells require lymphotoxin-beta (LT-β) produced by T lymphocytes for proliferation, the reciprocal dependency of T lymphocytes and fibroblastic reticular cell network perpetually intensifies the progressive fibrosis and CD4(+) T lymphocyte depletion, causing not only

progressive remodeling of the lymphoid architecture but also loss of function (Estes 2013).

A hallmark for pathogenic SIVmac infection is a CD4(+) T lymphocyte loss with a decline of the absolute and relative numbers of CD4(+) T cells and a decreased CD4(+)/CD8(+) T-cell ratio (Letvin et al. 1994; Friedman et al. 2006; Voevodin and Marx 2009; Estes 2013). SIVmac infection is associated with gastrointestinal mucosal epithelial barrier damage that leads to microbial translocation contributing to persistent immune activation and inflammation (Bosinger et al. 2011; Pancino et al. 2011; Estes 2013). Hence, lipopolysaccharide (LPS) produced by bacteria leaking through the gut are elevated in

the plasma and can be used as biomarkers for microbial translocation. Due to the gut barrier damage, chronically SIVmac-infected animals frequently develop persistent diarrhea, occasionally bloody, that is unresponsive to standard treatment and results in dehydration of the monkey. Moribund macaques develop wasting with massive weight loss so that eventually only minimal fat reserves remain, and hip bones and ribs become prominent (Voevodin and Marx 2009; Abee et al. 2012).

Due to its suppression of the immune system, SIVmac triggers opportunistic infections such as generalized cytomegalovirus infection, cryptosporidiosis, *Pneumocystis carinii* pneumonia, candidiasis, atypical tuberculosis by mycobacterium avium, and other, often unusual, infectious diseases (Abee et al. 2012). Furthermore, recent investigations have shown that SIV-infected rhesus macaques suffer from a large number of different gastrointestinal virus infections that contribute to the pathogenicity of the SIV infection (Handley et al. 2012).

Increased cytokine production and elevated numbers of proinflammatory Th17 cells, a lineage of CD4(+) T helper cells producing IL-17 for antimicrobial immune defense at mucosal barriers, as well as SIVmac-infected macrophages in the lung may also cause disorders of the lungs, heart, and blood vessels (Pancino et al. 2011). Chronically SIVmac-infected macaques occasionally develop granulomatous multinucleated giant cell pneumonia, pulmonary arteriopathy that may be associated with thrombosis of vessels and can lead to infarction of lung parenchyma. Pulmonary symptoms clinically manifest as difficulties in breathing or heavy breathing through the open mouth. Cardiac symptoms can occur as a result of an SIV-induced myocarditis and cardiomyopathy. Arteriopathies are caused by infiltrates of moderate numbers of macrophages and lymphocytes causing proliferation of the intimal and medial layer of blood vessels. Similar lesions combined with inflammations develop in other organ systems such as the kidney, pancreas, genital tract, and others causing a multitude of symptoms depending on the organs affected (Coffin et al. 1997; Voevodin and Marx 2009; Abee et al. 2012).

Chronic inflammation and immune activation by SIVmac may also cause disease of the eyes. Ocular pathology in rhesus macaques, e.g., demonstrating as granulomatous lesions of the retina, can be utilized as animal model for retinal pathology in HIV patients (Abee et al. 2012).

SIVmac can be detected in the macaque brain as early as 3 days following primary infection and consistently during peak viremia in perivascular cuffs, the meninges, and the choroid plexus that enables virus detection in cerebrospinal fluid (Williams and Burdo 2012). After crossing the blood-brain barrier, the virus cannot be efficiently reached by many drugs used for antiretroviral therapy and has the ability to hide out for prolonged periods, unrecognized by the immune system, contributing to viral persistence. Thus, the central nervous system (CNS) is regarded as potential latent viral reservoir for proviral DNA (Dang et al. 2012). Following an asymptomatic phase, typically about 25% of SIVmac251-infected rhesus macaques develop SIV encephalitis (SIVE) or meningitis after 1–3 years (Dang et al. 2012; Williams and Burdo 2012). SIVE occurs at a similar rate like CNS manifestations in HIV-1 infected patients without antiretroviral treatment, although neurological symptoms usually progress faster in macaques than in humans. After experimental persistent CD8(+) T-cell depletion of macaques with depleting antibodies, the SIVE risk increases to over 75% with rapid disease progression (Strickland et al. 2012). SIVE is characterized by multinucleated giant cells without inclusion bodies and accumulations of lymphocytes and macrophages perivascular (i.e., around blood vessels) in the CNS. As a marker for cell proliferation and indicator for enhanced immune stimulation in SIVE, increased expression of Ki-67(+) by CD4(+) and CD8(+) memory T lymphocytes is correlated to SIV viral loads in cerebrospinal fluid, but not necessarily SIV plasma viral levels (Dang et al. 2012). Progressive neurological signs manifest as various clinical symptoms, e.g., head tilt, balance difficulties, psychomotoric dysfunction (with overall reduced activities), ataxia (with lack of coordinated muscle movement), or tremor (Dang et al. 2012).

Analogous to HIV-infected human individuals who carry an increased risk of developing non-Hodgkin lymphoma (NHL) or Kaposi's sarcoma (especially in patients without antiretroviral treatment), SIV-infected macaques have a higher likelihood to develop neoplasms, particularly B cell-derived NHL (Voevodin and Marx 2009). While human NHL in HIV patients has been associated with Epstein-Barr virus (EBV), NHP SIV-related B cell lymphomas occur in the presence of rhesus lymphocryptovirus (the macaque equivalent of EBV), and primate rhadinovirus is the correspondent to the human rhadinovirus Kaposi's sarcoma-associated herpesvirus (Abee et al. 2012). SIV is not oncogenic and therefore does not directly cause formation of neoplasms. However, the induced immunosuppression enhances the chance for malignancies (Coffin et al. 1997).

HIV Vaccines

In the most ideal scenario, a successful HIV vaccine would provide sterile protection by completely blocking the virus infection. A similar beneficial vaccine effect may be observed if the vaccine could turn a virus infection into an abortive infection that would permit a local temporal infection without systemic dissemination. If infection could not be prevented, an HIV vaccine should at least slow disease progression. Broadly neutralizing antibodies are the most promising mode of action to provide sterile protection. However, due to a large number of issues, the induction of these kinds of antibodies by an HIV vaccine has been notoriously difficult. Cellular immune responses can only attack the virus once it starts to propagate in vivo and, therefore, at best restrict virus replication at the level of an abortive infection. However, it is commonly accepted that an effective HIV vaccine should induce multiple layers of protection utilizing antibodies and cellular immune responses.

As an effective HIV-1 vaccine still remains elusive, the SIV-macaque animal model serves as a valuable tool to investigate correlates of protection and to evaluate novel treatment modalities and

preclinical HIV vaccine candidates. Vaccination of rhesus macaques with live-attenuated SIV, generated by deletion of the *nef* gene from replication-competent SIVmac239 (SIVmac Δ *nef*), has proven to be the most efficient means of protection against challenge with wild-type pathogenic SIVmac (Coffin et al. 1997). However, due to considerable safety concerns, the live-attenuated HIV vaccine concept could not be advanced into humans: In some vaccinated macaques, the *nef* deletion gets restored due to high retroviral mutation rates and recombination tendencies. The resulting wild-type revertants constitute a major safety concern. Moreover, some SIVmac Δ *nef*-infected infant macaques developed symptoms of simian AIDS so that live-attenuated HIV vaccines based on replication-competent HIV-1 are not suitable as human vaccine (Coffin et al. 1997).

HIV vaccine candidates in recent preclinical trials in macaques have included recombinant viral vectors engineered to express SIV/HIV genes, proteins, synthetic peptides, and recombinant DNA. Various combinations of prime-boost strategies have been applied (Sui et al. 2013). Viral vectors tested in rhesus macaques have been based on poxviruses, adenovirus, vesicular stomatitis virus, cytomegalovirus (CMV), and others, either replication incompetent or replication competent. Frequently inserted genes include *gag*, *env*, and others, but there has not been conclusive agreement which gene inserts are necessary to achieve protection or which genes might even enhance pathogenicity (Sui et al. 2013). Although several HIV vaccine candidates have stimulated enhanced cellular or humoral immune responses, the majority have failed to permanently diminish viral replication and functional viral escape, especially when challenged with heterologous or more neutralization-resistant SIV or SHIV strains.

A number of HIV vaccine trials based on eliciting cellular immune responses were able to slow disease progression or even delay acquisition of infection. However so far, HIV vaccines based on the elicitation of cellular immune responses were not successful in humans and in some cases may have even increased the likelihood of infection. A promising new vaccine concept has recently emerged with the generation of

an SIV protein-expressing replication-competent rhesus CMV vaccine. This approach has elicited robust and durable effector memory CD8(+) T cell capable to effectively control SIV replication in about 50% of the animals (Picker et al. 2012; Sui et al. 2013).

Some of the most promising vaccine candidates build on top of the discovery of very potent neutralizing antibodies either by providing a passive immunization (Barouch et al. 2013) or generation of these types of antibodies via an adenovirus-associated viral vector (Balazs et al. 2012). Moreover, the observation that the protection provided by the first successful AIDS vaccine (Thai Phase III clinical trial RV144) in humans was likely mediated by antibody responses has invigorated the entire field (Rerks-Ngarm et al. 2009; Haynes et al. 2012). A large number of vaccine trials are ongoing that focus on eliciting humoral immune responses against the four most important antibody targets to inhibit viral entry ((1) V3 region of HIV gp120, (2) V1/V2 region of HIV gp120, (3) CD4 binding site on HIV gp120, and (4) membrane-proximal region of HIV gp41).

Conclusions

The SIVmac/rhesus macaque model is an elegant preclinical model to study the immunopathogenesis of HIV infection in NHP. Investigation of viral determinants of SIVmac and their interactions in the NHP host system provides insight into the transmission of SIV, the early steps of infection that cannot be feasibly studied in humans, consecutive viral spread, establishment of viral reservoirs, immune defense mechanisms, and viral evasion from the host immune system. Thorough understanding of the immunopathogenesis of the SIV infection is crucial for the development of treatment modalities and the generation of a successful prophylactic HIV vaccine.

SLX4 Complex and HIV Replication

Christelle Brégnard, Jessica Guerra and Nadine Laguette

Institute of Human Genetics, Molecular Basis of Cancer-Related Inflammation Laboratory, CNRS UPR1142, Montpellier, France

Definition

SLX4, also known as BTBD12 or FANCP, is a Fanconi anemia (FA) complementation group protein. Mutations in *SLX4*, or any of the additional 18 FA genes, lead to FA, which is a rare, autosomal recessive, genetic disorder. Clinical features of FA patients include congenital physical anomaly, elevated cancer susceptibility, and

SLX4 Complex and HIV Replication, Fig. 1 Schematic representation of SLX4 scaffold protein and binding partners. SLX4 domains are presented with their binding

partners. Broad interaction domains are indicated by a thick black line

evolution toward aplastic anemia. FA is the most frequent inherited bone marrow failure syndrome. Collectively, FA proteins compose the FA DNA repair pathway that is involved in the repair of double strand breaks by homologous recombination (HR). SLX4 plays important roles in the final steps of HR by facilitating the resolutions of four-way DNA structures called Holliday junctions (HJ). Indeed, SLX4 is a molecular scaffold to which several proteins with nucleic acid binding and processing activity are recruited, forming the SLX4 complex (SLX4com). Additional reported functions of SLX4com include nucleolytic resolution of HJs, telomere maintenance, facilitation of the HIV life cycle, and regulation of spontaneous and HIV-induced innate immune responses.

Introduction

SLX4 is involved in the repair of stalled/collapsed replication forks and DNA interstrand cross-links (ICL) by HR. HR allows accurate repair of DNA lesions by using the sister chromatid as a template and leads to the formation of HJ that must be removed prior to chromosome segregation. The SLX4com is also involved in telomere maintenance through prevention of telomere damage and in negative regulation of pro-inflammatory responses in patient-derived cells, indicating that the FA pathway may also regulate the production of pro-inflammatory cytokines (for review (Kim 2014; Bregnard et al. 2014)). Biallelic inactivating mutations in *SLX4* lead to FA. In

this inherited syndrome, cells are susceptible to chromosomal instability and present hypersensitivity to DNA cross-linking agents, such as mitomycin C (MMC). FA patients are predisposed to various cancers, including leukemia, breast cancer, and head and neck squamous cell carcinoma. Another major clinical feature shared by FA patients is evolution toward aplastic anemia. The reason for bone marrow defects in FA most likely resides in combined molecular features of FA. Indeed, elevated production of pro-inflammatory cytokines, together with DNA repair defects, contributes to compromise bone marrow progenitors of FA patients laying the ground for aplastic anemia.

SLX4 is an 1834 amino acid protein that possesses a BTB/POZ structural domain, at position 638-788. BTB/POZ structural domains promote homomeric or heteromeric dimerization of proteins. SLX4 interacts with several proteins, including proteins involved in nucleic acid processing or binding (Fig. 1). This includes interaction with (i) structure-specific endonuclease modules. ERCC4^{XPB}-ERCC1 (5' endonuclease) interacts with the MUS312-ME19 interaction-like region (MLR) of SLX4, while MUS81-EME1 (3' endonuclease) interacts with its SAF-A/B, Acinus and PIAS (SAP) domain whereas SLX1 (5' endonuclease) with the SLX1 binding domain (SBD). Interaction of SLX4 with these structure-specific endonucleases is key to its role in the resolution of HJs. In addition, SLX4, via its N-terminal region, also interacts with (ii) the MSH2-MSH3 complex involved in DNA mismatch repair and (iii) the SLX4IP^{C200R}

protein of yet-to-be defined function, while its C-terminal region allows interaction with (iv) the PLK1 cell cycle-dependent regulatory kinase sheltering complex and with (v) the TRF2-TRF2IP components of the telomere sheltering complex. The latter interaction is important for SLX4-dependent telomere maintenance (Kim 2014). Interaction with PLK1 has important regulatory roles with regard to SLX4-associated endonuclease activities by ensuring activation of MUS81-EME1 through EME1 hyperphosphorylation.

SLX4 also contains a tandem of ubiquitin-binding motifs (UBZ – Fig. 1), which are essential for its role in the repair of DNA lesions. A cluster of three SUMO-interacting motifs (SIMs) at positions 1088-1091, 1151-1155, and 1194-1194 of SLX4 has been identified to promote SLX4 function in DNA repair processes. Finally, SLX4 and/or SLX4com appears to possess intrinsic SUMO-ligase activity, through binding to the SUMO-loaded SUMO E2 conjugating enzyme UBC9. SLX4-associated SUMO-ligase activity targets at least SLX4 and ERCC4 within the SLX4 complex. SLX4 SUMOylation would contribute to targeting SLX4 to DNA lesions (Gibbs-Seymour and Mailand 2015).

SLX4 and the Fanconi Anemia DNA Repair Pathway

The FA DNA repair pathway functions essentially during the S phase of the cell cycle when sister chromatids are present, allowing repair by HR. Repair of ICLs and collapsed/damaged replication forks by the FA pathway is initiated by recognition of lesions by the FA anchor complex based on FANCM that binds chromatin at damage sites. This triggers the recruitment of the core E3-ligase complex comprised of FANCA, FANCB, FANCC, FANCE, FANCF, FANCG and FANCL where FANCL bears the RING (Really Interesting New Gene) domain that confers E3-ligase activity. The FA core complex monoubiquitinates FANCD2–FANCI, providing the signal for downstream activation of effectors

of the pathway. Among the latter are SLX4, FANCO^{ERCC4}, and additional DNA repair proteins (FANCF^{BRIP}, FANCN^{PALB2}, FANCD1^{BRCA2}, and FANCO^{RAD51C}).

In somatic cells, the favored pathway to remove HJ relies on Bloom (BLM)-related helicases that promote “dissolution” rather than “resolution.” Resolution is a process that may promote sister chromatid exchanges, thus leading to potential cancer-predisposing loss of heterozygosity. For this reason, it is broadly accepted that HJ resolution pathways mostly act as a backup mechanism in cases – absence of BLM or overload of the dissolution pathway – where dissolution does not suffice. Resolution of HJ is mediated by two major pathways in eukaryotic cells: resolvase activity resulting from (i) interaction of SLX1 and MUS81-EME1 with SLX4 or (ii) mediated by GEN1 (for review (Sarbjana and West 2014)). Resolution of HJ by the SLX4com has been shown to occur in a sequential way, by a coordinated mechanism with SLX1 catalyzing the initial rate-limiting incision into an intact HJ and MUS81 cleaving the nicked HJ. Activation of SLX4-associated MUS81-EME1 is cell cycle dependent and is mostly confined to the Gap 2 (G2) phase of the cell cycle and early mitosis (M) after synthesis of bulk DNA (during the S phase) has been completed. This prevents inappropriate processing of healthy replication forks during S phase and subsequent replication stress. Temporal regulation of MUS81-EME1 is achieved in mammalian cells through hyperphosphorylation of EME1 by PLK1.

Although ERCC4-ERCC1 have been shown to interact with SLX4 and to harbor 3' endonuclease activity, the role played by this endonuclease module in HJ resolution remains unclear. Importantly, this structure-specific endonuclease module has been shown to play crucial roles in nucleotide excision repair and to be involved in telomere maintenance through interaction with TRF2. Whether this involves SLX4com-engaged ERCC4-ERCC1 remains to be explored, particularly in the light of SLX4com binding to telomeres.

HIV Vpr and DNA Repair Pathways During HIV Infection

The HIV life cycle interferes with pathways involved in DNA repair, in particular through the Vpr accessory protein. Vpr is a virally encoded 14 kDa protein that exerts many molecular functions resulting in a major cellular phenotype: cell cycle arrest at the G2/M boundary of the cell cycle.

Cell Cycle in the Absence of Vpr

The cell cycle of mammalian cells is divided in four phases: (i) the Gap 1 (G1) phase that corresponds to the interval between M and (ii) the S phase, and (iii) the G2 phase, which precedes the (iv) M phase – where segregation of chromosomes occurs. In healthy cells, the transition through the different phases of the cell cycle is controlled by cyclin-dependent kinases (CDK) and cyclin (CCN) complexes. Cell cycle checkpoints serve as control mechanisms at each of these steps to ensure that the genetic material is correctly transmitted to daughter cells. Halting the cell cycle at these transition steps provides an opportunity to repair lesions or, if the extent of incurred damage is too high, leads the cell to apoptosis.

The G2/M transition is controlled by CDK1:CCNB1. During G2, CDK1:CCNB1 is activated through phosphorylation of CCNB1 by CDK1 and PLK1. This leads to nuclear sequestration of CDK1:CCNB1. Full activation of CDK1:CCNB1 requires dephosphorylation by CDC25C. Once the G2/M boundary is crossed, the complex is inactivated by ubiquitination of CCNB1 by the anaphase-promoting complex (APC). When genotoxic stress is incurred, entry into M can be prevented through inactivation of CDC25C (Stark and Taylor 2006). This response is regulated through a signaling cascade that involves detection of DNA lesions by the key DNA damage response regulators ataxia-telangiectasia-mutated kinase (ATM), ATM and Rad3-related kinase (ATR), and DNA-dependent protein kinase (DNA-PK) and downstream activation of CHK1 or CHK2.

These phosphorylate CDC25C. Consequently, the CDK1:CCNB1 complex remains inactive and the cell cycle stops at the G2/M transition.

Vpr and the G2/M Boundary

Expression of the HIV-1 Vpr accessory protein activates ATR, ATM, CHK1, and CHK2 kinases, causing inactivation of CDK1:CCNB1. In agreement, treatment of Vpr-expressing cells with caffeine, which inhibits ATR and ATM, relieves the Vpr-mediated cell cycle block. Several mechanisms have been proposed to explain checkpoint activation in the presence of Vpr.

Mobilization onto subregions of the chromatin of DNA repair proteins, such as breast cancer susceptibility protein 1 (BRCA1) and γ H2ax proteins, has been reported following expression of Vpr, forming foci that are downstream activation hallmarks of the ATM/ATR pathway. Indeed, factors involved in the repair of broken DNA are recruited to these foci. However, it remains unclear whether Vpr expression leads to genomic lesions. Furthermore, the link between genomic lesions and cell cycle arrest in this context is not established.

Interaction of Vpr with several cellular proteins has been reported, but the only direct partners are VPRBP and SLX4. Vpr interacts with the C-terminus of VPRBP. The interaction of Vpr with the VPRBP-DDB1-CUL4 E3-ligase complex is required, but not sufficient, for G2/M arrest. Vpr can directly bind the carboxy-terminal region of SLX4. Vpr induces the recruitment of VPRBP and kinase-active PLK1 to SLX4. This leads to VPRBP-dependent ubiquitination of MUS81 and hyperphosphorylation of EME1 (Laguet et al. 2014). Thus, SLX4-associated MUS81-EME1 is activated outside of the physiological time frame, i.e., during the S phase. Consequently, Vpr-induced activation of SLX4-bound MUS81-EME1 results in cleavage of healthy replication forks, which leads to replication stress and to G2/M cell cycle arrest. Thus, as supported by previous work (Li et al. 2010), Vpr causes cell cycle arrest through a S phase-dependent mechanism.

SLX4 has also been identified as an ATR substrate, and in yeast, phosphorylation of Eme1 requires Rad53^{ATR} activation (Dehe et al. 2013). Thus, aberrant processing of stalled replication forks by Vpr-activated SLX4-associated MUS81-EME1 would cause replication stress, ATR-CHK1 pathway activation, resulting in inhibition of CDC25C. This signaling cascade ultimately leads to inability of CDC25C to activate CCNB1:CDK1 and thus results in G2/M arrest (Bregnard et al. 2014) (Fig. 2).

Vpr and Genomic Instability

MUS81-EME1 are important for the removal of ultrafine DNA bridges (UFBs) that arise from regions of the genome that replicate at a slower rate, such as centromeres and common fragile sites. UFBs are formed during the S phase and can be visualized after chromosome condensation in mitotic cells as bridges between sister chromatids that must be processed to allow chromosome segregation. Absence of MUS81-EME1 leads to accumulation of unprocessed UFBs and subsequent chromosomal instability and mitotic catastrophe. In the absence of Vpr, accumulation of UFBs is usually translated into cell cycle arrest at the G1/S transition.

Vpr targets MUS81 for ubiquitination by VPRBP, leading to decreased levels of MUS81. Since Vpr expression leads to accumulation of UFBs, it is likely that decreased MUS81 levels in Vpr-expressing cells may be sufficient to impair UFB processing prior to M. However, Vpr-associated replication stress that prevents completion of G2 likely impedes mitotic catastrophe that would otherwise occur. In addition, steric hindrance imposed by UFBs by linking sister chromatids may also contribute to the extent of G2/M arrest witnessed in Vpr-expressing cells (for review (Bregnard et al. 2014)) (Fig. 2).

SLX4 and HIV Escape from Innate Immune Sensing

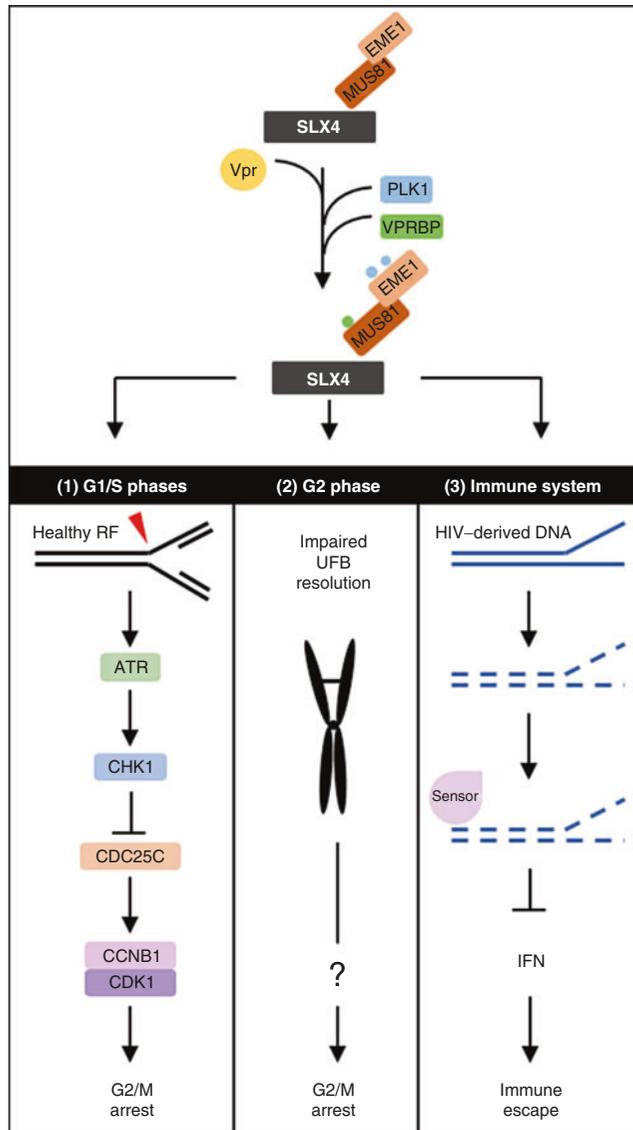

HIV Escape from Innate Immune Recognition

Efficient HIV replication in target cells relies on both the availability of cellular dependency

factors and the ability to escape cellular blocks. One of the most critical steps of HIV life cycle is the delivery of virus-derived nucleic acids in the host cell. This obligate step of the viral life cycle is targeted by several cellular factors, including cellular sensors that are specialized in the recognition of noncanonical nucleic acid species. These sensors belong to the pattern recognition receptors (PRRs) that recognize pathogen-associated molecular patterns (PAMPs) to trigger a signaling cascade that leads to production of pro-inflammatory cytokines, including antiviral interferon (IFN).

PRRs are capable of recognizing a broad range of substrates, including nucleic acids. HIV-derived nucleic acid species include the ssRNA genome and the intermediates generated during the course of its reverse transcription into dsDNA, including DNA/RNA hybrids and DNA flap structures. These intermediates may be recognized by several cellular sensors. Indeed, viral RNA is detected by TLR7 in endosomes and activates IFN production (Beignon et al. 2005). IFI16 has been identified as involved in the detection of nonself, virus-derived DNA in the cytoplasm of lymphoid quiescent CD4 T cells (Monroe et al. 2014). Another cytosolic sensor was also identified to be a specific sensor of HIV and other retroviruses, the cyclic guanosine monophosphate-adenosine monophosphate (cGAMP) synthase (cGAS), which recognizes viral DNA (Gao et al. 2013). These sensors are the first factors to trigger IFN production and thus establish an antiviral response to infections.

HIV-1 has developed different mechanisms to escape the innate immune response and establish productive infection. To prevent recognition of reverse-transcription intermediates, viral genomes are protected within the capsid core. If decapsidation is correctly orchestrated, fully reverse-transcribed viral genomes are delivered into the nucleus and integrated into the host cell genome. Otherwise, reverse-transcription intermediates may be released in the host cell cytoplasm where they can be detected by innate immune sensors and have adverse effects on the viral life cycle. In this scenario, several mechanisms coexist to prevent innate immune signaling

SLX4 Complex and HIV Replication, Fig. 2 Consequences of premature SLX4 activation by Vpr. Vpr expression leads to the recruitment of PLK1 and VPRBP on SLX4. PLK1 phosphorylates EME1 while the VPRBP E3-ligase complex ubiquitinates MUS81 leading to premature activation of the SLX4com. (1) Premature activation of SLX4com leads to the processing of healthy replication forks (RF) and to ATR activation. CHK1 is activated and inhibits CDC25C by phosphorylation. Thus, CKNB1/CDK1 is inhibited, leading to cell cycle

arrest at the G2/M transition. (2) UFBs formed during S phase cannot be removed during G2 because of premature degradation of MUS81-EME1 complex after VPRBP-dependent ubiquitination. This could contribute to G2/M arrest after HIV infection. (3) SLX4com binds to HIV DNA. SLX4com cleaves dsDNA, which is no longer recognized by a cytoplasmic immune sensor resulting in the block of interferon (IFN) production. This likely contributes to the immune escape of HIV

resulting from exposure of HIV-derived nucleic acid species. These mechanisms include either a direct action on the IFN signaling cascade (inhibition of IFN synthesis, IFN receptor decoy

and inhibition of IFN signaling, or degradation of abortive HIV-derived nucleic acid species, through cellular exonucleases (ribonuclease H2 (RNaseH2) and three-prime repair exonuclease 1

(TREX-1)) or the SLX4com (Laguette et al. 2014).

SLX4 in HIV Escape from Innate Immune Sensing

Infection with an HIV-1 molecular clone harboring a deletion of the Vpr open reading frame causes an increase of IFN production as compared to infection with wild-type HIV-1 (Doehle et al. 2009; Laguette et al. 2014; Okumura et al. 2008). This HIV-induced IFN production is increased following SLX4com subunit (SLX4, VPRBP, and MUS81) knockdown, indicating that the SLX4 complex is required for inhibition of HIV-dependent pro-inflammatory cytokine production (Laguette et al. 2014). *SLX4* or *MUS81* deficiency leads to activation of pro-inflammatory pathways, resulting in the establishment of an antiviral state through upregulation of IFN-stimulated genes rendering the cells unable to support efficient HIV replication. Furthermore, the SLX4com binds HIV-1-derived reverse-transcribed DNA only in the presence of Vpr, and in the absence of SLX4, there is an increase of HIV DNA accumulation in infected cells. This suggests that the SLX4com is required to degrade excess HIV-derived nucleic acids susceptible of triggering innate immune responses, a process for which the MUS81-EME1 endonuclease module appears to be required. Of note, Vpr also compromises the establishment of adaptive immune responses. Vpr-mediated impairment of innate immune recognition may contribute to this process (Fig. 2).

Conclusion

The SLX4 protein, through recruitment of structure-specific endonucleases, is an actor of DNA repair. The HIV-1 Vpr protein takes advantage of SLX4com-associated endonuclease activities, inducing the processing of viral reverse-transcription intermediates that, if present in excess in the cytoplasm, would activate immune responses. In addition, SLX4 also recruits MSH2-MSH3 and TRF2-TRF2IP. The latter is known to account for the protective role played by SLX4 at

telomeres. This function may therefore be altered in the presence of Vpr. This is of particular importance in the light of telomeric damage inducing pro-inflammatory signaling. In addition, the contribution of SLX4 activation to additional Vpr-associated functions remains to be explored. Indeed, Vpr contributes to fidelity of reverse transcription and to the nuclear transport of the pre-integration complex and promotes the trans-activation of LTR promoter and induction of apoptosis. It is clear that HIV-1 exploits the cellular environment to establish a productive and effective infection. The SLX4 complex is an example of how the virus uses a component of the cellular machinery, usually involved in the DNA repair pathway to favor its life cycle.

South, Southeast, and East Asia-Specific Characteristics of HIV/AIDS Epidemic

Chen Zhang
Vanderbilt Institute of Global Health, Vanderbilt University School of Medicine, Nashville, TN, USA

Definition

An estimated five million people are living with HIV/AIDS (PLHIV) in Asia as of early 2015. While the characteristics of the HIV epidemic in Asia vary from country to country, there are four major transmission routes, including commercial sex work, unprotected sex with commercial sex workers, needle sharing among persons who inject drugs (PWID), and unprotected sex among men who have sex with men (MSM) (AVERT 2015).

Overview

Compared to Africa, the Americas, and Europe, the HIV epidemic in Asian countries started a decade later. In the early to mid-1980s, while other parts of the world began to tackle the severe HIV epidemic, Asian prevalence rates were exceedingly low, though this changed quickly in the early 1990s. Although the overall HIV prevalence is still much lower compared to countries in southern Africa, Asia's huge population makes the absolute number of PLHIV large.

With declining rates of transmission among PWID due to expanded needle/syringe exchange and, in some venues, drug treatment opportunities, unprotected sex is the major route of transmission, notably linked to sex work and male-to-male sex. It is estimated that from 0.5% to 15% of men buy sex from commercial sex workers in any given year (WHO/UNAIDS/UNICEF 2011). These clients of sex workers can then transmit the HIV that they contracted from sex workers to their low-risk partners (e.g., wives, girlfriends). An increasingly prominent subgroup accounts for the rapid increasing epidemic in many Asian nations, namely, those MSM who do not use condoms often and have multiple partners. More than their Western peers, Asian MSM are more likely to hide their sexual preferences due to the cultural norms and prevalent homophobia. They may get married and have offspring to carry their family names and satisfy family expectations. Thus, MSM can act as a “bridging population,” transmitting HIV both among MSM and also to a broader population (van Griensven and de Lind van Wijngaarden 2010; Wirtz et al. 2013). The second route of transmission is through sharing needles among PWID. Having declined in frequency in nations that have had an aggressive prevention intervention response, such as China, India, Indonesia, Malaysia, Thailand, and Vietnam, HIV transmission continues in nations that have not yet fully embraced prevention on a mass scale, including Burma, Pakistan, and some central Asian nations that are still within the Russian sphere of influence. (Russia is hostile to needle and syringe exchange and, as a consequence, has one of the world's worst HIV epidemics related to

injection drug use [IDU].) In addition, the overlap between IDU and commercial sex makes epidemic dynamics complex. PWID may sell sex to support their drug use habit, or they may turn to drug use after their sex work is initiated (Tucker et al. 2011; UNAIDS 2013).

Region-Specific Characteristics

East Asia (Table 1)

East Asia encompasses a population of over 1.7 billion, including China and Taiwan, Japan, North and South Korea, and Mongolia, among others. Although the HIV prevalence in East Asia is relatively low (<0.1% in the age group between 15 and 49) compared to other regions in the world, the large size of population means that there are hundreds of thousands of PLHIV needing care. Sexual transmission has surpassed IDU as the dominant route of HIV spread. Although heterosexual transmission is most often reported, male homosexual contact is increasing rapidly since 2000, posing a challenge for HIV prevention in East Asia that is reminiscent of challenges in Europe and the Americas.

China, the country with largest population size, has an estimated 437,000 PLHIV (NHFPC 2014). Heterosexual transmission is the dominant route which accounts for 52% of newly infected HIV from 2013 surveillance statistics. An estimated 4–10 million of female sex workers (FSW) work either part- or full time in China. While they have been blamed as a main source of HIV infection, their historic prevalence rates have typically been very low, with the exception of women who are also injection drugs. An estimated 6% of Chinese men have had sex with FSW. The large absolute number of commercial sex consumers combined with low condom use can result in men who are a bridging population, acquiring HIV from high-risk FSW to low-risk intimate partners of the FSW clients (Qian et al. 2005). Since male-to-male sexual contact accounted for 13.7% of HIV infections in 2012, an increase from 2.5% in 2006, this is an increasing proportion of cases. MSM, too, can serve as bridges when they are bisexual with contacts with

low-risk women or with FSW. The traditionally dominant role of HIV transmission among PWID has kept decreasing since 2000 as a result of effects by the Chinese government, community-based organizations, and support from the international community (AVERT 2015; NHFPC 2014; Wu et al. 2015, 2013). A unique and massive outbreak of HIV among former plasma donors in central China was caused by illegal and unhygienic blood donation practices where pooled red blood cells were reinfused post-donation to reduce anemia among donors. This was halted by legal and police action by the mid-1990s, but not until hundreds of thousands of rural farmers and family members were infected (Qian et al. 2006).

Japan is an island nation in East Asia and one of ten most populous nations in the world. By 2011, only 11,146 HIV-positive patients and 5,158 AIDS patients had been reported. The number of new HIV infections reached a record high in 2010 with a total of 1075 new cases of PLHIV. MSM have accounted for more than half of PLHIV in Japan since 2006. Meanwhile, the style of drug use has switched from Japanese to Western style in the past a few years, and PWID accounted for 0.3–0.4% of HIV infections in 2011. About one third of HIV cases were identified among unregistered migrant workers in Japan (AVERT 2015). Despite high numbers of FSW in Japan, HIV has been kept to very low levels by near-universal condom use.

Mongolia is a landlocked country border with Russia to the north and China to the south, east, and west with a total population of 2.8 million in east Central Asia. HIV prevalence is very low in Mongolia with only 62 HIV cases having been reported by the year of 2009. About 80% of cases were among MSM practicing condomless anal intercourse. Bisexual men serve as a bridging population to wives, girlfriends, and/or FSW. Although the HIV prevalence among FSW is relatively low compared to MSM, high rates of sexually transmitted infections suggest potential for further spread of HIV (Munkhbaatar et al. 2014; Parcesepe et al. 2015; Hagan and Dulmaa 2007; Schwebke et al. 1998). In addition, due to poverty and limited employment opportunities, a

South, Southeast, and East Asia-Specific Characteristics of HIV/AIDS Epidemic, Table 1 Characteristics of HIV epidemic in East Asia

Countries	Epidemics				Risk populations				
	# of PLWHA in 2014	Prevalence (0.046–0.070%)	Categorization	Characteristics of the epidemic	Sex workers	MSM	Drug users	Mom to children	Other risk populations
China	437,000	0.058% (0.046–0.070%)	Low-prevalence country	Heterosexual transmission surpassing other routes becomes the dominant transmission route; the number of PLHIV keeps increasing but new infections have been retained at a low level (2012 UNAIDS report)	52% of newly infected HIV is attributable to heterosexual transmission. An estimate of 4–10 million FSW actively work in China	Homosexual contact accounted for 13.7% of HIV infection, compared to 2.5% in 2006	HIV prevalence is 6.4% among this population in 2012, and it keeps decreasing	1.1% of HIV infection was through the mother-to-child transmission in 2011. 75% of HIV-positive pregnant women received ART to prevent MTCT	Former plasma donors: account for 10% of HIV infection in 2005
Japan	11,146 in 2011	<0.1%	Low prevalence	Homosexual transmission is the dominant route, which accounted for more than half of the HIV infection	Sex industry gets increased although it is illegal	In cumulative number, homosexual transmission accounted for 63% of the 11,146 HIV-positive patients and 40% of 5,158 AIDS patients as of December 30, 2011	IDU accounted for 0.3–0.4% of HIV infection in 2011. The pattern of drug use has been changed from Japanese style to Western style (Wada 2013)		Unregistered migrant workers accounted for 1/3 of all cases in 2004. HIV tainted-blood scandal among hemophiliac patients in late 1980s
Mongolia	150 reported case in 2013		Very low prevalence	Early stage with only 5 cases registered during 1992–2005, 20 registered during 2005–2006. With only 150 cases reported as of December 31, 2013		7.5% among MSM in a cross-sectional study conducted in 2012, compared with 6.9% in 2009; more than 80% of cases of HIV were attributable to MSM			
South Korea	10,425 cases by 2013		Low prevalence	Men infection was outnumbered 14 times higher than women, and sex transmission is the major route					

significant proportion (14% in 2005, 5% in 2007) of young women (15–24 years) had reported having sex for money or gifts. Few were self-identified as FSW. With the opening of foreign travel opportunities, an increasing number of Mongolian women have migrated for work as FSW in either China or Russia in the 2000s (AVERT 2015).

South Korea: Since the first HIV case was reported in 1985, a total of 10,425 cases had been reported through 2013 with a high male-to-female ratio of 14.0. Condomless sex, particularly among MSM, is the principal route of transmission. Due to strong stigma and discrimination against HIV and homosexuality, HIV prevention and treatment has been challenging (AVERT 2015).

South Asia (Table 2)

The HIV epidemic in South Asia has been driven by PWID and sex work, though the roles of migrant men and MSM are also substantial. The relative importance of different subpopulations and transmission routes vary by country and even within regions of a country significantly. Poor public health hygiene (e.g., rampant use of therapeutic injections), the often low status of women, the large transvestite/transgender community (*hijras*), and men who migrate for work and often frequent female or male sex workers, MSM, and focal IDU drive the complex South Asian epidemic. Coinfection of HIV and other infectious diseases (e.g., hepatitis C virus [HCV] and tuberculosis [TB]) complicates the treatment regimens and care for patients. India plays an important role in South Asia due to the prevalence of vulnerable populations, a diverse set of epidemic drivers, high HIV prevalence in the urban south, and proximity to many contiguous nations. Heroin from opium is readily available, given the magnitude of poppy farming in Afghanistan. To make drug use more affordable and psychoactive, many PWID choose injection, and needle sharing is common. In addition, migrants include truck drivers, seasonal workers, refugees, and displaced people; all can bridge HIV from high- to low-risk populations within and across countries in this region (AVERT 2015).

Afghanistan is a landlocked country located in Central Asia and South Asia. It is one of the most impoverished countries in the world and has experienced over three decades of war. It is estimated that 4,300 Afghans were living with HIV by the year 2012, mainly PWID. As one of the major opium-producing countries, an estimated one million people aged between 15 and 64 are opioid users. With the reduction of availability of heroin potent enough to be smoked, drug users are more likely to turn to a more cost-effective option— injection. The use of non-sterile shared needles, syringes, and equipment (i.e., other drug paraphernalia) can lead to a rapid HIV transmission among PWID in needle/syringe sharing networks. In addition to PWID, there are a large number of refugees and displaced people in this country; survival sex work and sexual violence is common. Afghanistan's high level of illiteracy and other urgent health priorities (e.g., maternal and infant mortality, other infectious diseases) have contributed to a lack of focus on HIV prevention. Hence, HIV prevalence doubled in the 6 years since 2006 due to the combination of prevalent drug use and unsafe paid sex in the context of low HIV knowledge, lack of HIV testing, and promiscuous use of contaminated needles/syringes (AVERT 2015; UNAIDS 2013).

Bangladesh ranked as the world's eighth most populous country with 169 million people in 2015. The HIV epidemic is concentrated in high-risk populations including PWID, sex workers, MSM, and international returned migrant workers (Alam et al. 2013; Shariful Islam et al. 2015; Urmi et al. 2015). Needle sharing practices are very common among PWID, and approximately 10% of PWID have ever had paid sex with a small proportion of them use condom consistently. For international returned migrant workers, more than half identified HIV cases came from this group and their spouses. In addition, other factors contributing to Bangladesh's HIV/AIDS vulnerability include cross-border interaction with high-prevalence regions like Burma in India and low HIV knowledge among general population, which played an important role of HIV epidemic in this country. Furthermore, an epidemic with different HIV strains may emerge among FSW working in

South, Southeast, and East Asia-Specific Characteristics of HIV/AIDS Epidemic, Table 2 Characteristics of HIV epidemic in South Asia

Countries	Epidemics		Risk populations					Other risk populations
	# of PLHIV	Prevalence	Categorization	Characteristics of the epidemic	Sex workers	MSM	Drug users	
Afghanistan	4,300 [1,600–14,000]	<0.1% [$<0.1\%$ – $<0.1\%$]	Concentrated epidemic among IDUs	HIV prevalence has doubled since 2006. Mainly dominated among IDU	Drug use with unsafe sex made the epidemic even worse		A dramatic increase over the last 4 years	
Bangladesh	9,500 [4,100–97,000]	<0.1%	Low prevalence	focus on MSM, IDU and FSW as well as migrant workers			1.4% to 4.9% in 2005–2006; needle sharing is common practice; 10% IDU buying sex with only less than 10% using condoms	It was estimated that 67% of identified HIV-positive cases in the country were returnee migrant workers and their spouses
India	2,100,000	0.3% in 2013	It is predicted that India will be experiencing “generalized” epidemic	Most affected groups included injecting drug users, sex workers, truck drivers, migrant workers, and men who have sex with men	# of SW is 868,000 with 2.7% HIV prevalence	427,000 MSM with 4.4% of HIV prevalence; MSM had sexual relationship with females in the past 3 m	177,000 IDU with 7.1% of HIV prevalence which has been stabilized since 2007	In 2013–2014, 9.7 million pregnant women accessed HIV testing against a target of 13.2 million – coverage of 74%

(continued)

South, Southeast, and East Asia-Specific Characteristics of HIV/AIDS Epidemic, Table 2 (continued)

Countries	Risk populations											
	Epidemics		Characteristics of the epidemic			Sex workers	MSM	Drug users	Mom to children	Other risk populations		
Nepal	# of PLHIV	Prevalence	Categorization	Characteristics of the epidemic			Sex workers	MSM	Drug users	Mom to children	Other risk populations	
	50,200 in 2011	0.3% [0.2-0.4%]	HIV epidemic Nepal is highly heterogeneous and concentrated among most at-risk population including FSW, IDU, MSM and migrants	HIV in Nepal is extremely heterogeneous; unprotected sex is the main drive, followed by IDU, and MSM			24,649-28,359 FSW with 1.7% of HIV;	They are between 65,864 and 82,330 male sex workers, transgendered and their clients (MTC) in Nepal 2011.	An estimate of 30,155 and 33,742 IDU with 939 were PLHIV in 2011		Nationally, clients of FSWs have account for 4.4% of total estimated HIV infections. Nearly 8% HIV positive among migrants returning from Mumbai.	
Pakistan	97,000(46,000-210,000)	0.10%	Pakistan has a concentrated epidemic among injection drug users in most cities and among male sex workers in a few cities				HIV among female sex workers has remained negligible; the overall HIV prevalence among MSWs remains low at 3.1% (95%CI: 2.8,3.4)		HIV prevalence of 21% among IDUs in 2011		Unsafe injections account for 62% of Hepatitis B, 84% of Hepatitis C, and 3% of new HIV cases	

towns bordering India. Meanwhile, Bangladesh has a high burden of tuberculosis, and the coinfections complicate treatment regime and care for both diseases. All these factors make Bangladesh as the only country in South Asia where new infections keep rising (AVERT 2015; UNAIDS 2013).

Nepal is a landlocked country with a population of 27 million. There were an estimated 50,200 people living with HIV as of 2011, and more than half of them were unaware of their serostatus. The HIV epidemic in Nepal is highly heterogeneous and concentrated in vulnerable populations including FSW, PWID, MSM, and migrants. Nepal estimated that the number of PWID was around 33,000 by 2011. Injecting pharmaceutical drugs and poly-drug use are common. In addition, IDU is linked to commercial sex. HIV prevalence among FSW is about 1.7%. Many women from Nepal are recruited or are trafficked to Mumbai and elsewhere in India to work in brothels. Up to 50% of Nepalese sex workers working in brothels of Mumbai have been estimated to be HIV positive. In order to achieve economic survival, 1.5–2 million people work as internal or external migrants for seasonal and long-term labor. The removal of traditional structure of households promotes unsafe sexual practice including multiple sexual partners and engagement in commercial sex. As of 2011, male labor migrants comprised of 27% of HIV-infected persons in Nepal. Around 4.4% of HIV cases are among clients of sex workers, and 14.4% are MSM. Only 24% PLHIV were deemed eligible to receive ART by the end of 2011, and Nepal's HIV prevention program coverage is limited (AVERT 2015; UNAIDS 2013).

India is the world's second most populous country with over 1.2 billion people. In 2013, the Indian government estimated that 2.4 million Indians were living with HIV. HIV prevalence in India varies geographically, and the main risk groups include FSW, MSM, PWID, transgender/transvestite *hijras*, migrants (particularly those in the south and northeast), and long-distance truck drivers. It is estimated that 836,000 FSW have a prevalence of 2.7%. Government estimates of 427,000 MSM living in India are surely underestimates, and needs are great for both prevention and care (Patel et al. 2012; Thomas et al. 2011).

Due to prevalent stigma and discrimination, many MSM hide their sexual orientation through marriage or sexual relationships with women. An estimated 42% of MSM were married, and 50% have reported sexual relations with a woman in the past 3 months; half reported condom use in their last sexual encounter. Hijras (transgender women and/or transvestite men) often sell sex and represent a subgroup of high risk for HIV and bridging infection to their clients. The HIV prevalence stabilized among PWID and is now falling. An estimated 7.1% of 177,000 PWID in India are HIV infected. While needle/syringe exchange programs have been expanded with good results, opiate substitution therapy is not widely available (Reid et al. 2014). An HIV prevalence of 1% is estimated among 7.2 million migrant workers and 2.6% among long-distance truck drivers. Migrants also act as bridging populations between risk groups and general population (AVERT 2015; UNAIDS 2013).

Pakistan has an estimated population of 192 million in 2015, with an estimated 97,000 PLHIV. Early cases were among returning migrant workers who acquired infection in the Gulf emirates or elsewhere (Shah et al. 1999). The epidemic is concentrated among PWID, but also MSM, *hijras*, FSW, and prisoners (often PWID). The social norms of a conservative Muslim society oppose nonmarital sex, and efforts to prevent HIV are limited, with only modest risk reduction programs targeting MSM, *hijras*, and FSW (Thompson et al. 2013; Kazi et al. 2010; Siddiqui et al. 2011). With IDU as common in urban areas, the epidemic among PWID exploded in 2002 such that over 30% infection rates are seen in major urban areas and incidence rates are among the world's highest among PWID (Samo et al. 2013). Given low literacy rates, high levels of poverty, and prevalent risk behaviors among PWID and sex workers, the further spread of HIV is inevitable unless improved interventions are implemented (AVERT 2015; UNAIDS 2013; Abdullah and Shaikh 2015).

Southeast Asia (Table 3)

The epidemic in Southeast Asia is mainly driven by sexual transmission and IDU. Some countries,

South, Southeast, and East Asia-Specific Characteristics of HIV/AIDS Epidemic, Table 3 Characteristics of HIV epidemic in Southeast Asia

Countries	Risk populations								
	Epidemics	Prevalence	Categorization	Characteristics of the epidemic	Sex workers	MSM	Drug users	Mother to child	Other risk populations
Cambodia	# of PLHIV 76,000 [59,000–120,000]	0.8% [0.5–1.5%] for aged 18–49	Decreased HIV epidemic	Heterosexual transmission driven	15% infected with HIV	Low rate of condom use among MSM		About one- third of new infections occurred through MTCT	Sexual partners and clients of sex workers
Indonesia	610,000 [390,000–940,000] by 2012	Generalized epidemic with 2.4% HIV prevalence in general population ages 15–49	Rapidly increase	Fastest-growing epidemic in Asia. 59% of HIV infections is attributable to IDU, 41% due to heterosexual transmission	Extensive sex industry	High-risk behaviors: 5.2% among MSM (2007 survey)	36% of IDU were HIV infected in 2012		Sexual partners and clients of sex workers
Laos	6,230 reported cases of HIV by the end of 2013	0.29% among 15–49 years old in 2013	Low prevalence	Unsafe sexual activity is the primary mode of transmission	1.00%	3.10%	1.50%		Clients of FSW was estimated as 98,660 in 2010
Malaysia	86,000 [66,000–120,000]	0.4% [0.3–0.6%] for 15–49 years	Concentrated among males	The epidemic concentrated injecting drug users (IDUs), female sex workers and the transgender population. In 2013,	60,000 sex workers comprising of 40,000 female sex workers (FSW) and 20,000 transgender (TG)	There were 2,406 (2.5%) out of 94,841 cumulative number of HIV reported cases among this category	It is estimated that there are about 170,000 IDU in the country	Children and young people ≤19 years made up 3.5% (120) of 3,479 new reported HIV cases, out of which 65 (54%) were <13 years (vertical)	Transgendered: approximately HIV prevalence of 9.7% among them by a 2009 survey
Burma	220,000	0.6% [0.5–0.7%]	one of the highest prevalence countries in HIV in Asia	key risk groups disproportionately are affected by HIV infection (FSW, clients of SW, MSM, IDU)	11.2% (9.2–13.6%); about 60,000 (40,000–80,000) active fsw	22.3% (18.2–26.4%); ≈1.5% of male population is MSM (224,000) in 2008. Syphilis 14.1% among MSM in 2008	34.6% (31.6–37.7%). An estimate of 75,000 (60,000–90,000) are PWID		clients of FSW was estimated as 880,000 in 2007 (5.6% of general population); about 2.5% among military

Philippines	10,514 HIV positive cases in 2013; 15,000 [11,000–23,000] in 2012	<0.1%	Low prevalence	over 90% from sexual contact: from 2007 there has been a shift in the predominant trend of sexual transmission from heterosexual contact (20%) to males having sex with other males (80%)	Low prevalence of condom use	HIV infection increased rapidly among MSM, doubled since 2005	Composed of 4% of PLHIV; high prevalence of needle sharing practice	< 1% cases; Only 5% of HIV-positive pregnant women have received anti-retrovirals to prevent mother-to-child transmission
Singapore	4374	<0.1%	Low prevalence	Predominantly males infected with a M to F ratio of 10:1	0.00%	3.14% in 2013	Very low	
Thailand	490,000	1.20%	Thailand has the highest prevalence of HIV in Asia	An example of a country where a strong national commitment to tackling the HIV and AIDS epidemic has paid off; with an admirable history of HIV prevention efforts	1.8% of brothel-based FSW are HIV positive	Increases in HIV prevalence among MSM is particularly marked in Bangkok, where HIV prevalence among this group has risen from 17.3% in 2003 to 31.3% in 2009;	Among IDU, 22% were infected with HIV	ART has been offered to 90% of infected pregnant women, which significantly reduced the MTC transmission
Vietnam	280,000	0.47%	Concentrated epidemic	Vietnam's epidemic is still in a concentrated phase; Of the 0.47% prevalence, within which 5,670 are children – it indicates the trend moving from high risk to general population	Female sex workers (FSW) are the second highest infected risk population with national rates slightly increasing from 9% in 2007 to 9.3% in 2012	national prevalence for MSM will remain 2% in the 2007–2012 period	IDU accounts for 65% of PLHIV, and the HIV prevalence among male IDU is estimated to be 23.1%	It is reported that more than 1% of pregnant women in some provinces are found HIV positive

notably Thailand, have shown significant improvement as the result of strong government commitment toward HIV prevention. Other nations like Vietnam face concentrated epidemics that are not well controlled in defined subgroups. As with the South Asia, coinfections with HCV, TB, and malaria present major regional challenges (AVERT 2015; UNAIDS 2012).

Cambodia is a country with an estimated population of 15.9 million in 2015 located in the southern Indochina Peninsula. The HIV epidemic is primarily driven by the heterosexual route and the nation experienced high incidence in the 1990s, particularly among FSW. Cambodia has had an aggressive nationwide scale-up HIV prevention campaigns including “100% condom use” among high-risk populations, such as FSW. HIV prevalence decreased from 1.2% in 2003 to 0.6% in 2011, thought to be linked to successes in their prevention efforts. However, the low levels of condom use among MSM as well as continuing mother-to-child transmission underscores the ongoing challenges (Vun et al. 2014). Male clients of FSW have played a bridging role high-risk sex workers to their low-risk wives or girlfriends (AVERT 2015).

Indonesia: Ranking as the fourth most populous country in Asia, Indonesia has an estimated 252 million people. The Indonesian HIV epidemic is understudied, in comparison with other Asian nations (Dokubo et al. 2013). Nevertheless, data suggest that the HIV epidemic has been spreading with an estimated 610,000 PLHIV by 2012. The number of PLHIV has risen sharply in recent years among a few vulnerable groups including PWID, FSW and their clients, and MSM/transgender women. Contributing factors may include a highly mobile population, a growing IDU problem, denial of sexual health service to unmarried people, and the challenges created by both economic and natural crises. PLHIV have had suboptimal access (estimated 24%) to ARV treatment, even lower among children with HIV (11%) (AVERT 2015).

Laos is a landlocked country with a total 2014 population of 6.8 million. The HIV epidemic in Laos is about 0.1% with an estimated 6230

PLHIV by 2013. The epidemic is concentrated among PWID, FSW, and MSM. Among PWID, 5% were seropositive in 2005. Although the HIV prevalence is relatively low among FSW, due to their low literacy and disempowered status, these women are highly vulnerable to HIV infection (AVERT 2015). The high TB incidence rates in Laos pose the HIV-TB coinfection challenges, also a concern in the rest of Asia (Vermund and Yamamoto 2007).

Malaysia is a multiethnic and multicultural nation of 28 million persons. The main HIV transmission route is heterosexual, followed by PWID, and homosexual. Men represented 90% of all reported cases in 2002, a male-to-female ratio of 9:1, but the proportion of women is increasing, and in 2014, the ratio was only 4:1. Social factors contributing to the rapid increase among women likely include gender inequities and denial of sexual health services to unmarried young persons (AVERT 2015).

Myanmar (or *Burma*) is experiencing a serious HIV epidemic with an estimated 220,000 PLHIV within a total population of 55 million persons in 2015. With police crackdowns on drug production, many heroin users have switched to injection as a more cost-effective way of using drugs. Only a few locations provide needle change programs. Similarly, opiate substitution therapy using methadone has been initiated in a small number of government locations. In addition to high prevalence among PWID, HIV rates are rising among MSM in Burma, with MSM HIV prevalence of 23.5% in the city of Yangon and 35% in Mandalay. FSW have high HIV infection rates, but recent condom campaigns seem to be having benefits, analogous to successes in Thailand, Cambodia, and China (Swe and Rashid 2013; Aung et al. 2014). Poverty, poor border control, violence against ethnic and religious minorities, migration, and a lack of investment from the government and international sponsors all complicate prevention and HIV care efforts, including access to antiretroviral therapy (AVERT 2015).

Philippines is considered to be part of Southeast Asia, situated in the western Pacific Ocean. A low-HIV prevalence country, Philippines

estimated 10,514 PLHIV in 2013, less than 0.1% HIV prevalence among adults. About 41% of total infections are attributable to male homosexual contact, and MSM have a rising incidence rate, raising the kinds of concerns noted for China. High population mobility within and outside the country, a conservative culture that suppresses sexual health education, high levels of sex work, low condom use rates, and prevalent IDU all contribute to concerns for an expansion of the HIV epidemic (AVERT 2015; UNAIDS 2013).

Singapore serves as a hub of international travel and business but has a low-prevalence of HIV infection. However, there are high numbers of infections found in countries nearby, which makes it plausible that Singapore will experience an increasing epidemic in the coming decades. About 3% of MSM in Singapore were HIV infected from estimates published in 2010 (AVERT 2015; van Griensven and de Lind van Wijngaarden 2010).

Thailand is in the heart of Southeast Asia with a population of 66 million persons. Since the first HIV case was reported in 1984, more than one million people have been infected with HIV by the year 2008 and half had died. The adult prevalence was as high as 1.3% in 2009, and it ranked as the highest prevalence country in Asia. HIV incidence has been substantial among FSW, PWID, and MSM at different stage of the Thai epidemic timeline. Among MSM, HIV prevalence has expanded in recent years to 20% in 2010, and 41% of all HIV infections were attributable to MSM. This population has experienced a substantially rising prevalence over time (van Griensven et al. 2015). On the other hand, the HIV prevalence among transgender persons has been lower than 10% for reasons that are not clear. The HIV prevalence among venue-based FSW was 1.8%, but the prevalence was as high as 19% among freelance sex workers in past years. HIV prevalence among PWID was more than 20%, but has declined. Due to the strong government-operated crackdown on drug trafficking in 2003, drug users have been labeled as “criminals,” making HIV prevention campaigns targeting PWID quite difficult. There are about five million migrant workers

living in Thailand. Due to the language barriers, high mobility, and exploitative working condition, migrant workers have very limited access to health care to HIV/AIDS, which make them vulnerable to HIV infection. About 7.6% of TB patients are coinfecting with HIV. The government of Thailand has had a strong national commitment to curbing the HIV epidemic and its successes with 100% condom campaigns for brothel-based sex work are legend (Hanenberg et al. 1994; Celentano et al. 1998; Nelson et al. 2002). A total of 490,000 PLHIV lived in Thailand in 2012, half of the peak prevalence (AVERT 2015; Wirtz et al. 2013).

Vietnam is the easternmost country on the Indochina Peninsula in Southeast Asia with a population of 90.5 million as of 2014. By 2012, an estimated 280,000 PLHIV accounted for 0.47% of the adult population. The epidemic is concentrated among high-risk groups including PWID (65% of cases), FSW, and MSM (Do et al. 2012; Le et al. 2015b; Pham et al. 2015). Needle sharing and unprotected sex are common among PWID; Vietnamese PWID have been shown to initiate drug use at earlier ages, and their time between non-injecting drug use to IDU has become shorter in recent years (Do et al. 2012). Among FSW and MSM, inconsistent condom use is the norm. The marginalized status of MSM makes them hard to have access to healthcare and HIV testing (AVERT 2015; UNAIDS 2012). Complex interactions between risk groups are seen worldwide, and Vietnam is no exception. Investigators have examined risk among MSM who are sex workers (Colby et al. 2015) and FSW who are PWID (Le et al. 2015a). Coinfections are complex in this tropical nation, including hepatitis, TB, and malaria.

In summary, Asia is an immense region. We have not discussed central Asia, beyond Mongolia, since this is addressed elsewhere, but in the East Asia, South Asia, and Southeast Asian context, the HIV epidemic is wrapped into particular higher-risk populations. High background population sizes and persons who are behaviorally vulnerable to HIV infection contribute to ongoing HIV spread.

Stem Cell Transplantation

Christine Durand¹ and Richard Ambinder²

¹Department of Medicine, Division of Infectious Diseases, Johns Hopkins University School of Medicine, Baltimore, MA, USA

²Department of Oncology, Division of Hematologic Malignancies, Johns Hopkins University School of Medicine, Baltimore, MA, USA

Definition

Stem Cell Transplantation (SCT), also referred to as bone marrow transplantation or hematopoietic stem cell transplantation is a treatment in which hematopoietic stem cells are administered to a patient, usually as treatment for hematologic cancer or bone marrow failure. Prior to infusion of stem cells, patients receive fully myeloablative or reduced-intensity chemotherapy both to reduce tumor burden and to allow engraftment of the stem cells. There are several potential sources of the hematopoietic stem cells in clinical use. In autologous SCT, hematopoietic stem cells are collected from the patient prior to chemotherapy and infused after treatment to rescue the hematopoietic system. In allogeneic SCT, hematopoietic stem cells are donated by a close relative or genetically matched unrelated individual and infused after conditioning chemotherapy. Availability of suitably matched donors remains a major limitation to SCT and new advances now allow for more flexibility in matching human leukocyte antigens (HLA) between donors and recipients. Alternative

stem cell sources include the use of partially-matched relatives, partially-matched unrelated donors, and umbilical cord fetal blood.

Introduction

SCT is the standard treatment for a variety of hematologic malignancies for which human immunodeficiency virus (HIV)-infected patients are at increased risk, including primary-refractory lymphoma, relapsed lymphoma, and aggressive leukemia. Early in the epidemic, HIV infection was considered a contraindication to high-dose chemotherapy and SCT. With effective ► [antiretroviral therapy](#) (ART) the morbidity and mortality of HIV infection have been dramatically reduced. In addition, substantial improvements in SCT have occurred, such as prophylaxis against opportunistic infections and the use of leukocyte growth factors. With these advances, HIV-infected individuals are now being offered curative SCT therapy for treatment of hematologic malignancy. Outcomes of autologous SCT in HIV-infected individuals are now considered similar to the general population. In allogeneic SCT, there are a growing number of successful case reports and series. Close attention to interactions between antiretroviral medications to treat HIV, conditioning chemotherapy administered pre-transplant, and immunosuppressants administered post-transplant is required. Of note, there has been a long-standing interest in the possibility that SCT could lead to the cure of HIV infection.

Hematologic Malignancies Associated with HIV-Infection

Many types of hematologic malignancies are associated with HIV infection and acquired immunodeficiency syndrome (AIDS). Aggressive B cell lymphoma was among the “AIDS-defining” conditions that could lead to a clinical diagnosis of AIDS early in the epidemic, even before the virus had been identified. With the widespread institution of ART, the epidemiology of cancer in the HIV/AIDS population has

changed, but hematologic malignancies remain a major cause of morbidity and mortality (Shiels et al. 2011). In the United States, hematologic cancers still account for more than one third of all cancers diagnosed in individuals with HIV/AIDS (Shiels et al. 2011). In the era of ART, the absolute numbers of AIDS-related malignancies such as non-Hodgkin lymphoma (NHL) have decreased but NHL represents a greater proportion of deaths in individuals with AIDS, as a result of substantial success in reducing infection-related mortality (Shiels et al. 2011).

NHL is the most common hematologic cancer in individuals with AIDS (Shiels et al. 2011). Whereas some types of NHL have almost disappeared with ART, such as ► [primary central nervous system lymphoma](#), and others have substantially decreased, such as ► [diffuse large B cell lymphoma](#), ► [Burkitt lymphoma](#) seems unaffected. Similarly ► [Hodgkin lymphoma](#) (HL) has not decreased and may be on the rise (Shiels et al. 2011). Finally, rates of myeloma and certain types of leukemia, such as acute myelogenous leukemia (AML), are also increased in this population.

Role of AutoSCT in the Treatment of Malignancy in HIV- Infected Individuals

In the early years, aggressive chemotherapy in HIV-infected individuals with lymphoma resulted in an unacceptably high risk of treatment-related death with no clear survival benefit (Gates and Kaplan 2002). These early studies made reduced-dose treatment regimens the standard of care and SCT was not considered in this patient population. After implementation of effective ART in 1997, several studies showed that HIV-infected patients could tolerate standard dose regimens (Gates and Kaplan 2002). These improvements were attributed to ART as well as to the institution of routine prophylaxis against pneumocystis pneumonia and herpes virus reactivation. These successes opened the door to explore high-dose therapy with stem cell rescue in the form of autologous SCT, which was the standard treatment for relapsed or primary-refractory lymphoma in the general population.

Autologous SCT to treat lymphoma in HIV-infected individuals has been instituted at several centers. It has also been studied in small cooperative group trials (Ambinder 2009). In these cohorts, the rate of infectious deaths has not been significantly increased and mortality has primarily been attributed to cancer progression or treatment-related organ toxicities such as veno-occlusive disease (Ambinder 2009). The current consensus is that outcomes of autologous SCT in HIV-infected individuals with relatively well-controlled HIV disease are essentially equivalent to outcomes in the general population. There has also been no clear deleterious impact of autologous SCT on the long-term management of HIV infection in these patients. Amounts of HIV virus in the plasma are not significantly increased and immunologic recovery after autologous SCT also appears to be comparable to the general population (Ambinder 2009).

Role of AlloSCT in the Treatment of Malignancy in HIV-Infected Individuals

The favorable outcomes of autologous SCT in HIV-infected individuals have encouraged consideration of allogeneic SCT in HIV-infected individuals with aggressive hematologic malignancies such as leukemia, and in those who require salvage therapy for unresponsive lymphoma. As in autologous SCT, the use of ART to control HIV disease is critical to outcomes in allogeneic SCT. Early in the AIDS epidemic, survival in HIV-infected patients receiving allogeneic SCT was less than 15% (Gupta et al. 2009; Hütter and Zaia 2011). With effective ART and other advances, survival with allogeneic SCT is now greater than 50% (Gupta et al. 2009; Hütter and Zaia 2011).

In addition to concerns regarding increased mortality, there has been speculation that HIV-infected individuals might be at risk for SCT complications such as graft failure and/or graft-versus-host-disease (GVHD). This potential risk is hypothesized to be a result of underlying immunologic dysfunction caused by HIV, which is thought to persist even with effective ART. For

example, in the solid organ transplant setting, although overall survival and organ/graft survival rates are generally comparable between the HIV-infected and uninfected transplant recipients, higher than expected episodes of organ rejection were observed (Stock et al. 2010). Based on the small studies to date in HIV-infected individuals receiving allogeneic SCT, disproportionate rates of graft failure and/or GVHD have not been observed (Gupta et al. 2009; Hütter and Zaia 2011).

ART during SCT in HIV-Infected Individuals

The extraordinary success of ART in controlling and reversing clinical disease due to HIV infection has allowed for curative SCT therapies to be extended to HIV-infected individuals. At the same time, the complexity of ART combinations necessitates focused approaches related to drug interactions, drug toxicities, and drug interruptions. There are more than 20 approved antiretroviral medications. The major classes of drugs include nucleoside or nucleotide analogue reverse transcriptase inhibitors (NRTIs), nonnucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), integrase inhibitors, a fusion inhibitor, and a CCR5 chemokine receptor antagonist. Unique challenges associated with specific drugs or drug classes exist as well as more general challenges to maintenance of any antiretroviral regimen during SCT.

Overlapping organ toxicities can occur with antiretrovirals and chemotherapeutic agents (Rudek et al. 2011). Zidovudine or AZT is an NRTI and was the first approved antiretroviral drug. Prior to the development of combination drug regimens, AZT monotherapy was used in HIV-infected individuals during SCT (Hütter and Zaia 2011). With the development of less toxic alternatives, AZT is now contraindicated during SCT as it can cause myelosuppression (Rudek et al. 2011). Other overlapping organ toxicities for which monitoring is required during SCT and concurrent ART, include kidney toxicity, which can occur with the NRTI tenofovir, and peripheral

nerve toxicity which occurs with older NRTIs such as stavudine (d4T) and didanosine (ddI) (Rudek et al. 2011).

Drug interactions between ART, antineoplastic agents, and immunosuppressants used to prevent GVHD are another management challenge in SCT for HIV-infected individuals (Rudek et al. 2011). Interactions due to antiretrovirals in the PI class are the most common. In most cases, two PIs are used in combination; one PI is used at a dose designed to inhibit HIV replication and a second PI, ritonavir, is used at a lower dose designed to inhibit the cytochrome P450 enzyme system in order to increase the concentration and therapeutic efficacy of the first PI. This approach is known as “ritonavir-boosting” and is critical to the efficacy of this drug class. Other drugs are now being developed to affect PI boosting in place of ritonavir. The strategy has been extremely effective and ritonavir-boosted PIs are components in certain recommended first-line ART regimens. Many drugs, including chemotherapeutic agents and immunosuppressants are also metabolized by the cytochrome P450 system and in the presence of PIs, serious interactions can occur (Rudek et al. 2011). In some cases, these interactions can be managed with close monitoring of drug levels though concerns remain that the levels of critical cancer drugs or immunosuppressants may be compromised. In other instances – for example, with myeloablative conditioning regimens and/or the use of high-dose cyclophosphamide, interruption of PI-containing regimens is mandatory for at least a few days (Rudek et al. 2011). Another antiretroviral drug implicated in drug interactions during SCT is the NNRTI efavirenz. Efavirenz is an alternative to the use of PIs in the first-line ART regimens but induces, rather than inhibits, the cytochrome P450 enzyme system. During SCT, efavirenz use also requires close monitoring of levels of several critical medications (Rudek et al. 2011).

Mucositis, nausea, and vomiting are common side effects of cancer chemotherapy and may prevent patients from taking any medications by mouth for extended periods of time. Unfortunately, nonoral formulations of ART have not been widely developed (Swindells et al. 2011).

The only non-oral formulations of antiretrovirals that are currently available include intravenous AZT and the fusion inhibitor enfuvirtide (T20) which is administered as a subcutaneous injection (Swindells et al. 2011). AZT is contraindicated during SCT due to bone marrow suppression. T20 is rarely used except as salvage therapy for HIV-infected patients with multidrug resistant virus and can cause painful injection site reactions (Swindells et al. 2011).

With interruption of ART, detectable levels of HIV in the blood typically return within a few weeks. Although rebound viremia can be managed without adverse clinical outcomes in most cases, there have been cases during SCT in which ART interruption and rebound of virus resulted in a febrile syndrome similar to the acute retroviral syndrome described in primary HIV infection (Hütter and Zaia 2011). Interruption can also increase the risk of developing antiretroviral drug resistance particularly when components of the ART regimen have different half-lives. Efavirenz has a half-life of 36–100 h and remains detectable long after levels of other antiretrovirals in a standard regimen have disappeared (Rudek et al. 2011). This discrepancy in rates of drug elimination will result in a period of functional efavirenz monotherapy and a significant risk of developing HIV drug resistance which will compromise the efficacy of future ART. In addition to these clinical implications, avoiding any interruptions in ART may also be important to emerging strategies that propose to use SCT in the pursuit of an HIV cure.

Donor Sources in SCT in HIV-Infected Individuals

Many patients who need allogeneic SCT are unable to find an HLA-matched donor. Approximately 70% of patients do not have an HLA-matched sibling and only half of those patients will find a matched unrelated donor in the national registry. The proportion of individuals who cannot identify a donor is even higher among racial and ethnic minorities, which are also disproportionately affected by HIV infection. Alternative donor sources have been developed and

studied in the general population but have not been investigated in HIV-infected individuals. These newer strategies include the use of partially-matched or haploidentical relatives or cord blood stem cells (Brunstein et al. 2011). In the past, haploidentical SCT was associated with increased mortality due to high rates of GVHD but this has been reduced with the use of high-dose, post-transplantation cyclophosphamide as GVHD prophylaxis (Brunstein et al. 2011). Concerns remain with regard to cord blood transplant as higher rates of nonrelapse mortality have been reported in a recent cooperative group study (Brunstein et al. 2011); however cord blood SCT may also offer unique benefits related to the role of SCT in HIV cure (Petz et al. 2012).

Persistence of HIV in Hematopoietic Cells

HIV preferentially infects activated CD4⁺ T cells, and as part of the retroviral lifecycle, the virus stably integrates into the host cell genome. Activated CD4⁺ T cells only have a lifespan of 1–2 days but a subset of activated CD4⁺ T cells will become resting memory CD4⁺ T cells. Memory CD4⁺ T cells are long-lived cells that are designed to survive for the life of the individual in order to maintain immunologic memory. As a consequence of this process, if an HIV-infected activated CD4⁺ T becomes a resting memory CD4⁺ T cell, HIV will survive indefinitely within that cell (Eisele and Siliciano 2012). Resting memory CD4⁺ T cells are quiescent and do not actively produce virus, but if these cells are reactivated, they can produce HIV and reestablish active infection (Eisele and Siliciano 2012). In all HIV-infected individuals, resting memory CD4⁺ harboring latent HIV can be detected and the frequency of these cells is stable over time despite treatment with ART (Eisele and Siliciano 2012). This reservoir of latently infected resting memory CD4⁺ T cells is the major impediment to viral eradication.

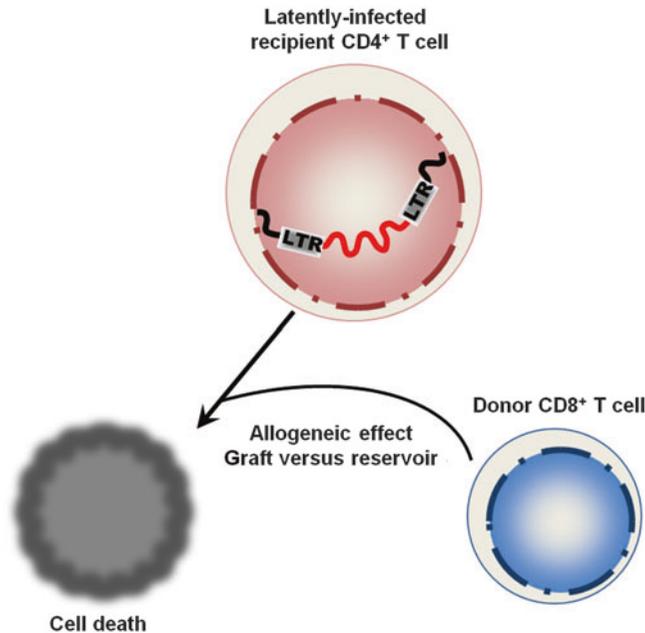

There has been interest in whether hematopoietic progenitor stem cells are directly infected by HIV and whether these cells are an additional

barrier to cure. The majority of studies on this subject in the pre-ART era reported extremely rare detection of HIV in the hematopoietic progenitor/stem cell compartment (McNamara and Collins 2011). The prevailing consensus was that viral detection was due to the presence of CD4⁺ T cells which traffic between the blood and the bone marrow. In the ART era, debate has continued. One study reported evidence of HIV infection in CD34⁺ hematopoietic progenitor cells in patients on ART (McNamara and Collins 2011), but follow-up studies in which CD4⁺ T cells were carefully excluded from samples has not confirmed HIV infection of CD34⁺ cells (Durand et al. 2012a). Thus, consensus remains that latently-infected resting memory CD4⁺ T cells represent the primary obstacle to cure (Eisele and Siliciano 2012).

Role of SCT in HIV Cure

The concept that HIV infection is limited to hematopoietic cells led to efforts in the 1980s to cure AIDS with SCT by replacement of the hematopoietic compartment (Hütter and Zaia 2011). These studies, which occurred prior to the use of effective ART, did not demonstrate success. Decades later, interest in allogeneic SCT as a means to eradicate HIV has been revived. This came to attention with a remarkable report of HIV cure in an HIV-infected patient who was treated for AML with myeloablative chemotherapy and allogeneic SCT (Hütter et al. 2009). The patient was originally known as the Berlin patient, because he received his cancer treatment from a German oncologist, Dr. Gerard Hütter, in Berlin. The patient is now known to the public as Timothy Ray Brown and is a community activist and strong advocate for research efforts focused on an HIV cure.

For treatment of his AML, Brown received myeloablative chemotherapy, total body irradiation, and allogeneic SCT from an “HIV-resistant” donor (Hütter et al. 2009). This unique donor was homozygous for a naturally occurring genetic mutation in one of the cell surface receptors, CCR5. The mutation, known as CCR5Δ32 is a 32-base pair deletion that results in a complete lack of expression of CCR5 on the cell surface.

Stem Cell Transplantation, Fig. 1 Impact of the allogeneic effect on HIV latently-infected cells. The allogeneic effect occurs as a result of donor CD8⁺ lymphocytes which are present within the stem cell transplant product. These donor lymphocytes eliminate host hematopoietic cells. This effect is nonspecific and results in favorable

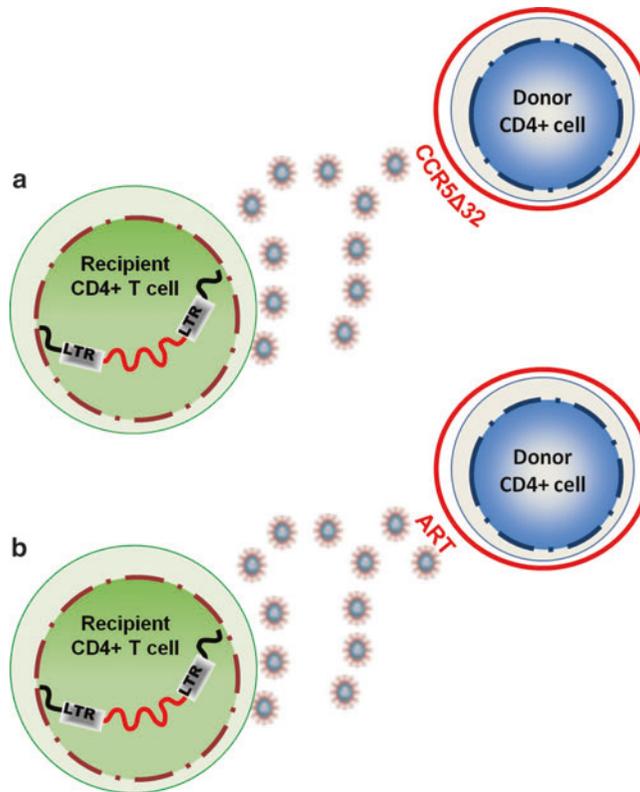

graft-versus-tumor-effects as well as unfavorable graft-versus-host-disease. This allogeneic effect should also eliminate latent HIV infection by killing latently-infected host CD4⁺ T lymphocytes and causing a “graft-versus-viral-reservoir” effect

The majority of HIV variants require binding to the CCR5 receptor to infect cells. These viruses are known as R5-tropic variants. Other strains of HIV use the cell surface receptor, ► **CXCR4** to enter cells, but these X4-tropic variants are rarely transmitted, and typically evolve in late-stage AIDS. Between 5% and 15% of Caucasians of Northern European-descent are CCR5Δ32 heterozygotes and carry one copy of the mutation which does not confer HIV-resistance. Less than 1% of Caucasian individuals homozygotes, and, carrying two copies of the allele, are resistant to HIV-acquisition. Homozygosity for the mutation is even rarer in racial and ethnic minority populations (Petz et al. 2012).

Due to the rarity of this genetic polymorphism, it has been relatively difficult to identify other matched CCR5Δ32 homozygous donors to test this approach. Several strategies have been developed to overcome this challenge (Durand et al. 2012b). First, there are now technologies capable of genetically engineering patient CD4⁺

T cells and/or CD34⁺ hematopoietic progenitor cells to lack CCR5 and CXCR4 (Durand et al. 2012b). This approach has been tested in early phase clinical studies and appears to be safe and well tolerated. A significant impact of this approach on clinical outcomes in patients has not yet been demonstrated. (Durand et al. 2012b). Current challenges of the strategy include optimizing the levels of engraftment and the survival of the genetically modified cells (Durand et al. 2012b). One application of this method that is in preclinical development is a combination of gene therapy tools to mutate CCR5 or CXCR4 in hematopoietic progenitor stem cells from HIV-infected individuals with hematologic malignancies who require autologous SCT (Durand et al. 2012b).

Cord blood SCT may provide another way to overcome the lack of CCR5Δ32 homozygous donors. A program to genetically screen cord blood units for the CCR5Δ32 mutation has been implemented (Petz et al. 2012). This initiative has identified more than 100 CCR5Δ32 homozygous

Stem Cell Transplantation, Fig. 2 (a) HIV-resistant donor cells. The Berlin patient received a SCT from a donor who was homozygous for a naturally occurring 32-base pair deletion in the cell surface receptor CCR5. Homozygosity for this deletion, CCR5 Δ 32, results in a lack of expression of the CCR5, which in addition to CD4 is the co-receptor used by HIV to infect cells. Thus, the transplanted donor hematopoietic system could not be

infected by HIV from the recipient. **(b) Antiretroviral therapy to prevent donor cell infection.** During the process of SCT and the transition from a recipient to donor hematopoietic system, continuous ART may prevent infection of the transplanted cells. If in concert, all host cellular reservoirs of HIV are eliminated by a combination of chemotherapy and the allogeneic effect, this could lead to HIV cure

units, with an ultimate goal of identifying 300 units. Due to less stringent requirements for HLA matching with cord blood SCT, it is predicted that this inventory would translate into a 27% chance of identifying a matched CCR5 Δ 32 homozygous unit for an HIV-infected Caucasian adult who requires SCT (Petz et al. 2012).

The possibility that allogeneic SCT could eradicate HIV infection even without CCR5 Δ 32 donors is also being considered. In the process of allogeneic SCT, donor CD8⁺ T cells in the stem cell product eliminate recipient hematopoietic cells, due to alloreactivity (Fig. 1). This process, known as the allogeneic effect, is

responsible for the graft-versus-tumor-effect as well as GVHD. The transition from a recipient hematopoietic system to a donor hematopoietic system occurs over weeks to months. Once all hematopoietic cells detected in the peripheral blood are donor in origin, the SCT recipient is said to have achieved full donor chimerism. Since all identified HIV reservoirs are in hematopoietic or hematopoietic-derived cells (Eisele and Siliciano 2012), the HIV reservoir in the recipient should disappear once full donor chimerism is complete. The donor cells must be also protected from acquiring HIV during this process for cure to be achieved. In the case of Timothy Ray Brown,

the donor cells were protected by the CCR5Δ32 mutation (Fig. 2a). With allogeneic SCT using standard donors, ART may provide the same protection (Fig. 2b). This latter protective effect might be considered analogous to the ability of ART to prevent HIV acquisition in utero, or after a high-risk needle stick exposure.

Conclusions

SCT is the treatment of choice for several hematologic malignancies which are increased in the HIV-infected population. With continued improvements in HIV therapies and SCT strategies, evidence suggests that SCT can and should be offered to persons living with HIV/AIDS for treatment of cancer. There are special risks to consider in this population related to underlying immunodeficiency as well as the challenges of administering ART, chemotherapy, and immunosuppressants in combination. Prospective trials of autologous SCT have not demonstrated increased mortality or treatment-related complications. Further data is emerging related to the use of allogeneic SCT in this population but there are encouraging reports in the literature. Further investigation in outcomes of SCT using alternative donor sources is needed. Beyond curing malignancy, the prospect of achieving HIV cure with SCT remains an exciting opportunity that promises to bring new insights into the fields of SCT and HIV/AIDS.

Surveillance Case Definition

Mary Lou Lindegren

Department of Pediatrics and the Department of Health Policy, Vanderbilt Institute for Global Health, Nashville, TN, USA

Introduction

Surveillance is the ongoing systematic collection, analysis, and interpretation of data on cases of disease for use in the planning, implementation, and evaluation of public health practice. HIV/AIDS surveillance data are used to monitor the spread of HIV infection, to target HIV prevention and health-care services, and to allocate funding for HIV prevention and care.

AIDS Surveillance

Since the first cases of AIDS were reported in 1981, population-based AIDS surveillance has been used to track the magnitude of the HIV epidemic. State governments are the legal entities responsible for collection of surveillance data on cases of infectious diseases, including AIDS. By the end of 1983, most of the 50 states had enacted laws making AIDS a reportable public health condition (IOM 1986). State and local health departments collect information on AIDS cases from physicians, hospitals, clinics, laboratory reporting, HIV counseling and testing sites, and medical record reviews in a standardized case report form. Before the etiologic agent was identified and diagnostic tests were routinely available, AIDS surveillance focused on monitoring opportunistic illnesses characteristic of severe immunosuppression. The AIDS case definition, reflecting severe morbidity, has been periodically revised to incorporate new understanding of the spectrum of HIV disease, new diagnostics, and changes in medical practice (CDC 1982, 1985, 1986, 1992, 1999).

The reporting of AIDS cases has helped to identify modes of transmission, measure the impact of the epidemic, monitor trends among affected populations, target HIV prevention services, monitor HIV-related outcomes (e.g., death), and allocate resources for HIV treatment and care services (e.g., Ryan White). Understanding AIDS trends and the course of untreated HIV infection allowed the use of back-calculation techniques on AIDS data to reconstruct trends in HIV incidence.

Case Definitions

Following the report of the first cases of AIDS in 1981 (CDC 1981a, b), a case definition of AIDS was published in September 1982 (CDC 1982), and this definition was also adopted worldwide. AIDS was defined as a disease, at least moderately predictive of a defect in cell-mediated immunity (e.g., *Pneumocystis carinii* pneumonia (PCP) and Kaposi's sarcoma (KS)), occurring in a person with no other known cause for immune suppression (CDC 1982). The AIDS indicator diseases met the case definition if the diagnosis was based on reliable methods, such as histology or culture. However, this case definition did not include the full spectrum of AIDS manifestations, which ranged from asymptomatic to non-specific symptoms (e.g., fever, weight loss, generalized, persistent lymphadenopathy) to specific diseases that were insufficiently predictive of cellular immunodeficiency to be included in the AIDS case definition (e.g., tuberculosis (TB), oral candidiasis) and malignancies related to immunodeficiency.

In 1985, the AIDS case definition was revised for the first time, as a result of the discovery of human T-cell lymphotropic virus type II/lymphadenopathy-associated virus (HTLV-III/LAV) (CDC 1985). After HIV was discovered to be the cause of AIDS and highly sensitive and specific HIV antibody tests became available, the spectrum of manifestation of HIV became better defined, and the HIV classification system was developed in 1986 (CDC 1986). By 1986, all 50 states, the District of Columbia, and three US territories had AIDS reporting.

AIDS surveillance case definition was revised again in 1987 to reflect the severe morbidity and spectrum of disease associated with HIV, with inclusion of HIV encephalopathy, HIV wasting syndrome, and a broader range of specific AIDS-indicative diseases for those with laboratory evidence for HIV infection (CDC 1987). As clinicians gained experience with AIDS opportunistic infections (OIs), these conditions were increasingly diagnosed presumptively, up to 10–15% of patients, and no longer met the case definition. To improve the sensitivity and specificity of the AIDS case definition, persons reported with indicator diseases diagnosed presumptively were included if there was laboratory evidence of HIV infection. Exclusions due to other causes of immunodeficiency were eliminated. CDC noted that the effectiveness of the revision would depend on “how extensively HIV antibody tests are used.” Recognizing that pediatric AIDS differed from adults, the pediatric AIDS definition was revised to include multiple or recurrent serious bacterial infections and lymphoid interstitial pneumonia/pulmonary lymphoid hyperplasia as AIDS indicator diseases among children. For children <15 months of age, due to the presence of maternal HIV antibody, laboratory criteria for HIV infection were more stringent.

In 1993, the AIDS case definition for adolescents and adults was expanded to include (1) all HIV-infected persons with severe immunosuppression (a CD4 count of <200 cells/ μ L or a CD4 percentage of <14) and (2) three additional clinical conditions (pulmonary TB, recurrent pneumonia, and invasive cervical cancer), in addition to retaining the 23 clinical conditions in the previous AIDS case definition (CDC 1994). These three conditions, unlike other AIDS OIs, were more common infections, which were recognized to be more severe and frequent among HIV-infected persons with immunosuppression and reflected changes in the epidemiology of HIV infection (e.g., cervical cancer reflected the increasing impact of HIV on women).

In 1993, both the classification system and the AIDS case definition for adults and adolescents were revised to include CD4 as a marker of immunosuppression, to simplify the classification

system, to reflect current standard of medical care that use CD4 to guide both prophylaxis and treatment, and to more accurately categorize HIV-related morbidity. Monitoring of CD4 counts had become of standard of HIV care. Classification of HIV infection and the expanded AIDS surveillance case definition for adults and adolescents were based on both three clinical categories (i.e., A, B, and C) and three categories of CD4 counts (i.e., \geq 500 cells/ μ L, 200–499 cells/ μ L, and <200 cells/ μ L) or CD4 percentages (CDC 1992). Clinical category A included asymptomatic acute or primary HIV infection or persistent generalized lymphadenopathy. Clinical category B includes symptomatic conditions that were not included in clinical categories A or C but are attributed to HIV infection or indicative of a cell-mediated immunity defect or for which the clinical course or management was complicated by HIV infection. Clinical category C included the 23 retained AIDS-defining conditions from the previous AIDS case definition and the three new clinical criteria. Increasing the use of both PCP prophylaxis and treatment had slowed the rate that HIV-infected persons developed AIDS (CDC 1992).

This expansion of the AIDS case definition was made available for both public comment and was discussed at an open meeting in 1992. This increased public interest was related to use of CDC AIDS surveillance definition for defining eligibility of social security benefits. Additionally, at the end of the first decade of AIDS, Congress authorized the funding of outpatient and ambulatory medical and support services for persons with HIV, the Ryan White Comprehensive AIDS resources emergency (CARE) act in August 1990. This included Title I for emergency assistance to metropolitan areas with the highest numbers of reported AIDS cases and Title II which were formula grants to all states that took into account number of reported AIDS cases in most recent years (Bowen et al. 1992; McKinney et al. 1993). Thus, the use of AIDS surveillance data was now expanded to target HIV resources.

The revision to the case definition resulted in a substantial increase in the number of reported cases, most of these met the new case definition

based on severe immunosuppression (CDC 1993). Increased case reporting was greatest among women, racial/ethnic minorities, adolescents, IDUs, and persons infected through heterosexual contact reflecting the changes in the HIV epidemic. Different surveillance methods were used by the states, including laboratory-based reporting of HIV antibody and CD4 counts and using TB and cancer registries to find cases. This increased number of new cases made interpretation of AIDS trends difficult; however, it enabled a representative and complete estimate of the number and distribution of persons with severe HIV-related immunosuppression, facilitating the use of these data to target and evaluate HIV care and treatment programs.

In 1994, the pediatric classification system was revised from the 1987 classification system based on increasing knowledge of the progression of HIV disease in children (CDC 1994). Children were classified into three mutually exclusive categories based on (1) infection status, (2) clinical status, and (3) immunologic status. Diagnosis of HIV infection in children born to HIV-infected mothers was complicated by the presence of maternal anti-HIV IgG antibody which crosses the placenta to the fetus, who are HIV antibody positive at birth, though only 25–30% are infected. In those children who are not infected with HIV, maternal IgG antibody becomes undetectable by 9 months of age and sometimes up to 18 months of age. Thus, HIV IgG antibody tests are not used for HIV diagnosis before 18 months of age. Polymerase chain reaction (PCR) was the most sensitive and specific assay for detecting HIV infection in children born to infected mothers; and positive results on two separate occasions or if the child meets the AIDS case definition defined HIV infection in children <18 months. For those 18 months and older, repeatedly reactive EIA and confirmatory test (Western blot or IFA) were used. Clinical categories were revised to include not symptomatic (N), mildly symptomatic (A), moderately symptomatic (B), and severely symptomatic (C). Immunologic categories included no evidence of suppression, moderate suppression, and severe immunosuppression. CD4+ counts are higher in infants and

young children compared to adults normally and decline over the first few years of life. As a result, children may develop OIs at higher CD4+ counts than adults; thus immune categories were based on age group (<12 months, 1–5 years, 6–12 years).

Impact of Treatment on Surveillance

In the mid-1990s, advances in treatment with combination antiretroviral therapy slowed the progression of HIV disease to AIDS and contributed to first declines in AIDS incidence and mortality (CDC 1997). These advances in treatment decreased the ability of AIDS surveillance data to monitor trends in HIV incidence and to monitor the impact of the epidemic on the health-care system. Antiretroviral treatment of pregnant women and their newborns reduced perinatal HIV transmission and resulted in dramatic declines in the incidence of perinatally acquired AIDS also reducing the usefulness of AIDS data to monitor the impact of new perinatal treatment recommendations.

Therefore, in 1997, the Council of State and Territorial Epidemiologists (CSTE) and CDC recommended that all states and territories conduct HIV case surveillance as an extension of their AIDS surveillance programs (CDC 1997; Council of State and Territorial Epidemiologists, C 1997). In 1999, CDC published guidelines for national HIV case surveillance, including reporting of HIV infection and perinatal HIV exposure to monitor the impact of advances in antiretroviral treatment, implementation of the new HIV treatment and PMTCT guidelines, resources needed for patient care, and the increased need for data on all HIV-infected populations (CDC 1999). At the time of the 1999 recommendations, 24 states and the Virgin Islands had implemented named-based HIV case surveillance in addition to AIDS surveillance; two of these states conducted pediatric surveillance only. Four states and Puerto Rico were reporting cases of HIV infection using a coded identifier.

HIV Surveillance

HIV case surveillance data provide critical information about the current state of the epidemic in

ways that AIDS surveillance data could no longer provide. HIV case surveillance data are more likely to represent new diagnoses and are more useful in assessing the impact of prevention activities. HIV surveillance data can better monitor the extent of the epidemic among youth, where new HIV diagnoses most likely reflect recent infections. States with HIV surveillance have used data on both perinatal HIV-exposed and HIV-infected children to document the decline in perinatal acquired HIV infection and implementation of recommended maternal HIV testing and antiretroviral therapy to prevent perinatal HIV transmission (CDC 1999). By 2007, HIV data were used to calculate funding allocation amounts for Titles I and II, under the Ryan White AIDS program. By April 2008, all 50 states had implemented named-based HIV reporting.

Since the discovery of HIV as the etiologic agent of AIDS and the availability of diagnostic tests to identify HIV infection in 1985, HIV infection reporting was initiated in many states, using the same confidential methods as used for AIDS. Conducting named HIV infection reporting met with great resistance in the community at that time as there was no treatment of HIV infection and there was concern about confidentiality of the information and the potential negative impact on HIV-infected persons such as avoidance in seeking confidential HIV testing and other prevention services. Challenges exist in the interpretation of HIV surveillance relate to the long latency of HIV infection, as characteristics of persons newly diagnosed with HIV infection may represent changes in HIV testing practices and behaviors, rather than changes in incidence. To respond to community concerns, CDC conducted research to assess the impact of named HIV surveillance on person's willingness to seek HIV testing and care, reviewed program practices and legal protections for security and confidentiality of state and local HIV data, and evaluated the performance of coded-identified-based surveillance systems (CDC 1999). Results from an analysis of publicly funded HIV counseling and testing data from six states 12 months before and after HIV reporting found no significant declines in the total number of HIV tests performed in any state (Nakashima

et al. 1998). Other studies, however, documented concerns that name-based reporting of HIV infection was a factor that might deter HIV testing for HIV for some persons with high-risk behaviors and that availability of anonymous testing was associated with higher rates of intention to test. Given these data, CDC strongly supported continued availability of anonymous testing opportunities as part of prevention programs. Based on evaluation of HIV reporting systems using coded identifiers for conducting confidential HIV case reporting, CDC found that confidential name-based HIV/AIDS surveillance systems were most likely to produce quality surveillance data.

Confidentiality and security of HIV surveillance data are of absolute importance. The legal authority to mandate HIV reporting and the methods used for reporting are the responsibility of state governments. HIV surveillance data that are protected by state HIV/AIDS surveillance confidentiality laws and regulations are subject to the same procedures as used for AIDS surveillance. In the 1990s, CDC reviewed state confidentiality laws that protect HIV surveillance data and determined that all states have legal safeguards for the confidentiality of government held health data but that state legal protections varied. To address concerns from the community and to help ensure uniform confidentiality protections, the Georgetown University Law Center developed the *Model State Public Health Privacy Act* (Gostin et al. 2001). The model legislative language protected confidential, identifiable information held by state and local public health departments against unauthorized and inappropriate nonpublic health uses but still allowed public health officials to use surveillance information to accomplish the public health objectives defined by the law. At the federal level, HIV data are protected by federal statutes that prevent release of HIV data for nonpublic health purposes.

As trends in new diagnoses of HIV infection are likely affected by testing practices or behaviors, in 2005, HIV surveillance was expanded in selected surveillance programs to conduct HIV incidence surveillance in conjunction with routine case surveillance to provide a more reliable estimate of newly acquired HIV infections (both

diagnosed and undiagnosed) and to help focus prevention efforts. These programs collect additional data, including testing and antiretroviral use history, and result from additional testing of remnant diagnostic HIV-positive blood specimens. Residual blood specimens are tested for recency using an immunoassay to distinguish between recent and long-standing infections. The resulting data, along with case surveillance data, can be extrapolated to the general population to estimate HIV incidence in the United States (Hall et al. 2008).

HIV surveillance data have been used to more accurately estimate HIV prevalence than AIDS surveillance data alone and have modified existing back-calculation methods (CDC 2011a). The model estimated both overall HIV prevalence and the proportion undiagnosed. More recently, HIV and AIDS surveillance data have been used along with two other surveillance data systems to monitor the continuum of care from HIV diagnosis, linkage and retention in care to receipt of ART, and viral load suppression (CDC 2011b).

Case Definition

In 1999, the revised case definition for HIV infection in adults and children incorporated reporting criteria for HIV infection and AIDS in a single-case definition and new laboratory tests in the laboratory criteria for HIV case reporting (CDC 1999). Four categories of HIV infection for children <18 months were defined: definitively HIV infected, presumptively HIV infected, definitively uninfected with HIV, and presumptively uninfected with HIV. Case definitions were revised to reflect the use of HIV nucleic acid detection tests that can detect HIV infection in almost all infants 1 month of age or older.

In 2008, the adult and adolescent HIV classification system and HIV and AIDS case definition were revised into a single-case definition for HIV infection that includes AIDS and incorporates the HIV infection classification system (CDC 2008). Laboratory-confirmed evidence of HIV infection was required to meet the surveillance case definition for HIV infection, including stage 3 HIV infection (AIDS).

Current HIV/AIDS Surveillance

Monitoring the HIV epidemic in the United States consists of a comprehensive national surveillance system based on standardized methods of data collection. HIV surveillance focuses on key events in the progression of HIV disease, including HIV infection, detected through new HIV diagnoses and, in some areas, is further classified as incident infections. New diagnoses are tracked to identify the degree of immunosuppression and entry into care based on initial CD4 and viral load tests and tracked to determine progression to AIDS and death. To facilitate this, CDC recommends reporting of all HIV-related test results, including CD4+ T-lymphocyte (CD4) results (counts and percentages) and all viral load test results (undetectable and specific values). CD4 and viral load data can be used to identify cases, classify stage of disease at diagnosis, and monitor disease progression. As a result, national HIV/AIDS surveillance data can be used to monitor HIV testing and prevention efforts; determine entry into care; measure viral load suppression, incidence of HIV infection, new diagnoses, AIDS, mortality, and HIV prevalence; and assess unmet health-care needs. However, state reporting laws, regulations, or policies, the level at which results must be reported, vary.

CDC also conducts supplemental surveillance activities, including the Medical Monitoring Project (MMP) and the National HIV Behavioral Surveillance system (NHBS). MMP is a national population-based surveillance system that collects information on clinical outcomes and behaviors of HIV-infected persons receiving care in the United States through abstraction of medical records. Collection of data from interviews with HIV-infected patients provides information on current behaviors that may facilitate HIV transmission; patients' access to, use of, and barriers to HIV-related secondary prevention services, utilization of HIV-related medical services, and adherence to drug regimens (Blair et al. 2014). The NHBS conducts behavioral surveillance among persons at highest risk for HIV infection in the United States. This system involves conducting rotating 12-month cycles of surveillance among the three

groups with the highest HIV burden: men who have sex with men (MSM), injection drug users (IDUs), and heterosexuals at increased risk of HIV infection (CDC 2014a).

Case Definition

The case definition for HIV infection was revised in 2014 (CDC 2014b). The revision addresses new diagnostic multi-test algorithms that do not use Western blot or immunofluorescence HIV antibody assays. This multi-test algorithm consists of a positive (reactive) result from an initial HIV antibody or combination antigen/antibody test and an accompanying or subsequent positive result from a supplemental HIV test different from the initial test. Supplemental HIV tests can now include antibody immunoassays or nucleic acid tests (CDC 2014a). The new definition also includes (1) criteria for differentiating between HIV-1 and HIV-2; (2) recognition of early HIV infection by a negative HIV test within 6 months of HIV diagnosis; (3) revision of criteria for reporting diagnoses without laboratory evidence; (4) simplification of criteria for opportunistic illnesses (OI) indicative of AIDS, eliminating the need to distinguish presumptive from definitive diagnoses of OIs; and (5) consolidation of staging systems for adults, adolescents, and children. A confirmed case can be classified into stage 0 (early HIV infection), to stage 1–3 of HIV infection based on CD4 cell count and stage 3-defining OIs (AIDS). Stage 0 allows monitoring of cases diagnosed within months of their infection when viral loads are high and in their most infectious period when interventions could be most effective to prevent transmission. Staging for children is based on specific age group criteria (<1 year, 1–5 years, ≥6 years). Staging for children aged 6–12 years is treated the same way as in adults and adolescents.

Global HIV/AIDS Surveillance

The World Health Organization (WHO) and the United Nations Program on HIV/AIDS (UNAIDS) oversee global surveillance of HIV. HIV surveillance globally initially relied on

AIDS case surveillance and sentinel studies on HIV prevalence (e.g., antenatal care attendees (ANC)). However, AIDS case reporting was limited in resource-limited settings due to underreporting, delays in reporting, lack of diagnostic testing capacity, and weak health infrastructure. In 2000, WHO/UNAIDS recommended second-generation HIV surveillance strategies which were tailored to the epidemic type in the country. Data sources included HIV and HIV advanced infection or AIDS case reporting but also sentinel surveillance (antenatal care attendees, key populations at higher risk), probability surveys of the general population, STI case reporting and behavioral or biobehavioral surveillance, and immunization clinic surveys for children (WHO 2013). For example, in generalized epidemics, recommended surveillance activities may include HIV or advanced HIV case reporting where case reporting data can be useful for investigating any area where unusually large numbers of cases are reported. However, as with HIV reporting in the United States, to interpret these data correctly, it is critical to understand the underlying pattern of testing, diagnostic capability, and reporting by different facilities. Additionally countries may also conduct general population surveys with behavioral and biological markers, which can provide data on the geographic distribution of HIV prevalence and other risk factors, but these surveys are resource intensive and therefore only conducted every 3–5 years in countries with prevalence over 2% in the general population. ANC sentinel surveillance is the most feasible method to monitor trends in HIV prevalence in the general population and can be used as a proxy for the general population; however the ANC population is young and of course not using condoms.

Case Definitions

WHO developed a clinical AIDS case definition for both adults and children in 1986 for reporting in low- and middle-income countries. This was modified for adults and adolescents to include serological HIV testing and again in 1994 to include the revisions to the 1993 CDC AIDS case definition (WHO 1988, 1994).

With the scale-up of ART, data were needed on persons diagnosed with HIV infection to estimate those in need of care and treatment and assess impact of care interventions. In 2007, WHO recommended reporting of newly diagnosed cases of HIV infection in adults and children and revised the case definitions for HIV infection and AIDS as well as the clinical staging system (WHO 2007). The case definitions for HIV infection were standardized and coordinated with the clinical staging for HIV infection (stages 1 and 2), advanced HIV disease (stage 3), and AIDS (stage 4) and required laboratory confirmation of HIV infection. The clinical staging system was simplified and harmonized the WHO 2002 three-stage pediatric staging system with the WHO 1990 four-stage adult system, including clinical staging and immunologic staging criteria. Although there were some differences between the WHO and CDC definitions and staging systems, the CDC and WHO stages could still be compared (CDC 2008).

Summary

A comprehensive, national HIV/AIDS surveillance system based on standardized methods of data collection continues to provide critical information about the current state of the epidemic both in the United States and, globally, and is critical for HIV prevention, care, and treatment program planning and evaluation (Table 1).

Appendix: 2014 CDC Revised Surveillance Case Definition for HIV Infection (CDC 2014b)

Criteria for a Confirmed Case

Criteria for a confirmed case can be met by either laboratory evidence or clinical evidence. Laboratory evidence is preferred over clinical evidence.

Persons Aged ≥ 18 Months and Children Aged < 18 Months Whose Mothers Were Not Infected

Laboratory Evidence Laboratory criteria require reporting of the date of the specimen

collection for positive test results in multi-test algorithms or stand-alone virologic tests and enough information about the tests to determine that they meet any of the following criteria:

- A multi-test algorithm consisting of
 - A positive (reactive) result from an initial HIV antibody or combination antigen/antibody test
 - An accompanying or subsequent positive result from a supplemental HIV test different from the initial test (CDC 1981b)

The initial HIV antibody or antigen/antibody test and the supplemental HIV test that is used to verify the result from the initial test can be of any type used as an aid to diagnose HIV infection. For surveillance purposes, supplemental tests can include some not approved by the Food and Drug Administration (FDA) for diagnosis (e.g., HIV-1 viral load test, HIV-2 Western blot/immunoblot antibody test, and HIV-2 NAT). However, the initial and supplemental tests must be “orthogonal” (i.e., have different antigenic constituents or use different principles) to minimize the possibility of concurrent nonspecific reactivity. Because the antigenic constituents and test principles are proprietary information that might not be publicly available for some tests, tests will be assumed to be orthogonal if they are of different types. For example:

- One test is a combination antigen/antibody test and the other an antibody-only test.
- One test is an antibody test and the other a NAT.
- One test is a rapid immunoassay (a single-use analytical device that produces results in < 30 min) and the other a conventional immunoassay.
- One test is able to differentiate between HIV-1 and HIV-2 antibodies and the other is not.

Tests also will be assumed to be orthogonal if they are of the same type (e.g., two conventional immunoassays) but made by different manufacturers. The type of HIV antibody test that verifies the initial test might be one formerly used only as

Surveillance Case Definition, Table 1 Changes in the case definition and classification system used for surveillance of HIV/AIDS, CDC, and WHO, over the course of the epidemic, 1981–2014

Year (reference)	Adult/pediatric	Case definition/classification	WHO/CDC	Main change in the case definition
CDC 1981a, b				First cases of Kaposi's sarcoma and PCP in young homosexual men
CDC 1982	All	First AIDS case definition	CDC/WHO	Persons with a disease moderately predictive of a defect in cell-mediated immunity and no known cause for diminished resistance to that disease (e.g., KS, PCP, and serious OI)
CDC 1985	All	Revised AIDS case definition	CDC/WHO	Expanded to add cases with a positive serologic test for human T-cell lymphotropic virus type III/lymphadenopathy-associated virus (HTLV-III/LAV) and with other severe opportunistic infections and chronic lymphoid interstitial pneumonitis for children <13 Excluded cases with negative serologic tests, no other type of HTLV-III/LAV test with positive result, and do not have low number of CD4 counts or low ratio of CD4–CD8 lymphocytes
CDC 1986	All	First HIV classification system	CDC	Definition of HTLV-III/LAV infection: repeatedly reactive screening tests for HTLV-II antibody (e.g., enzyme-linked immunosorbent assay) and antibody identified in supplemental test (e.g., Western blot, immunofluorescence assay); direct identification of virus in host tissue by virus isolation (not widely available) Classification into groups and subclassified based on CD4 counts and types of opportunistic infection Group 1: acute HTLV-III/LAV infection Group 2: asymptomatic HTLV-II/LAV infection Group 3: persistent generalized lymphadenopathy Group 4: other HTLV-III/LAV disease
CDC 1987	All	Revised AIDS case definition	CDC	Inclusion of HIV encephalopathy, HIV wasting syndrome, and a broader range of specific AIDS indicator diseases, inclusion of presumptively diagnosed indicator diseases, and exclusion of cases with other causes of immunodeficiency. Multiple or recurrent serious bacterial infections and LIP are AIDS indicator diseases among children but not adults
CDC 1987	Pediatric	HIV classification system in children <13 years of age	CDC	Definition of HIV infection in children Classification based on clinical symptoms Class P-O perinatally exposed infants with indeterminate HIV status Class P-1; asymptomatic infection; subclassified based on immunologic testing Class P-2: symptomatic infection; subclassified based on types of symptoms
CDC 1993	Adult and adolescent	Revision of the classification system and AIDS case definition	CDC	Expanded to include (1) all HIV-infected persons with severe immunosuppression (a CD4 count of <200 cells/ μ L or a CD4 percentage of <14) and (2) three additional clinical conditions (pulmonary TB, recurrent pneumonia, and invasive cervical cancer)

(continued)

Surveillance Case Definition, Table 1 (continued)

Year (reference)	Adult/pediatric	Case definition/classification	WHO/CDC	Main change in the case definition
CDC 1994	Pediatric	Revised classification system for children <13 years of age	CDC	The pediatric classification system based on increasing knowledge of the progression of HIV disease in children. Children were classified into three mutually exclusive categories based on (1) infection status, (2) clinical status, and (3) immunologic status
CDC 1999	All	Updated HIV case definition and recommendations for national HIV reporting	CDC	Recommend that all states and territories conduct case surveillance for HIV infection as an extension of current AIDs surveillance activities
CDC 2007			WHO	Recommends reporting cases of HIV infection as HIV infection or advanced HIV disease, including AIDS; four clinical stages for disease classification to reflect the WHO ART treatment guidelines: (1) no symptoms, (2) mild symptoms, (3) advanced symptoms, and (4) severe symptoms; and requires laboratory confirmation of HIV infection
CDC 2008	All	Revised surveillance case definitions for HIV infection among adults, adolescents, and children aged <18 months and for HIV infection and AIDS among children aged 18 months to <13 years – United States, 2008	CDC	HIV classification system and the surveillance case definitions of HIV infection and AIDS were revised into a single-case definition for HIV infection that includes AIDS. Laboratory-confirmed evidence of HIV infection is required to meet the surveillance case definition for HIV infection, including stage 3 (AIDS)
CDC 2014	All	Revised surveillance case definition for HIV infection – United States, 2014	CDC	The new definition includes (1) new diagnostic multi-test algorithms that do not use Western blot or immunofluorescence HIV antibody assays; (2) criteria for differentiating between HIV-1 and HIV-2; (3) recognition of early HIV infection; (4) revision of criteria for reporting diagnoses without laboratory evidence; (5) simplification of criteria for opportunistic illnesses (OI) indicative of AIDS, eliminating the need to distinguish presumptive from definitive diagnoses of OIs; and (6) consolidation of staging systems for adults, adolescents, and children

an initial test (e.g., conventional or rapid immunoassay, HIV-1/HIV-2 type-differentiating immunoassay), or it might be one traditionally used as a supplemental test for confirmation (e.g., Western blot, immunofluorescence assay).

- A positive result of a multi-test HIV antibody algorithm from which only the final result was reported, including a single positive result on a

test used only as a supplemental test (e.g., HIV Western blot, immunofluorescence assay) or on a test that might be used as either an initial test or a supplemental test (e.g., HIV-1/HIV-2 type-differentiating rapid antibody immunoassay) when it might reasonably be assumed to have been used as a supplemental test (e.g., because the algorithm customarily used by the reporting laboratory is known).

- A positive result or report of a detectable quantity (i.e., within the established limits of the laboratory test) from any of the following HIV virologic (i.e., nonantibody) tests:
 - Qualitative HIV NAT (DNA or RNA)
 - Quantitative HIV NAT (viral load assay)
 - HIV-1 p24 antigen test
 - HIV isolation (viral culture)
 - HIV nucleotide sequence (genotype)

Clinical (Nonlaboratory) Evidence Clinical criteria for a confirmed case (i.e., a “physician-documented” diagnosis for which the surveillance staff have not found sufficient laboratory evidence described above) are met by the combination of:

- A note in a medical record by a physician or other qualified medical-care provider that states that the patient has HIV infection
- One or both of the following:
 - The laboratory criteria for a case were met based on tests done after the physician’s note was written (validating the note retrospectively).
 - Presumptive evidence of HIV infection (e.g., receipt of HIV antiretroviral therapy or prophylaxis for an opportunistic infection), an otherwise unexplained low CD4+ T-lymphocyte count, or an otherwise unexplained diagnosis of an opportunistic illness.

Children Aged <18 Months Born to Mothers Who Have an Unknown Infection Status or Were Known to Be Infected

Laboratory Evidence A child aged <18 months is categorized for surveillance purposes as HIV infected if all of the following criteria are met:

- Positive results on at least one specimen (not including cord blood) from any of following HIV virologic tests:
 - HIV-1 NAT (DNA or RNA)
 - HIV-1 p24 antigen test, including neutralization assay for a child aged >1 month
 - HIV isolation (viral culture)

- HIV nucleotide sequence (genotype)
- The test date (at least the month and year) is known.

One or both of the following:

- Confirmation of the first positive result by another positive result on one of the above virologic tests from a specimen obtained on a different date
- No subsequent negative result on an HIV antibody test and no subsequent negative result on an HIV NAT before age 18 months

Clinical Evidence

- The same criteria as in section “[Clinical \(Nonlaboratory\) Evidence](#)”
- All three of the following alternative criteria:
 - Evidence of perinatal exposure to HIV infection before age 18 months
 - A mother with documented HIV infection
 - A confirmed positive test for HIV antibody (e.g., a positive initial antibody test or antigen/antibody test, confirmed by a supplemental antibody test) and a mother whose infection status is unknown or undocumented
 - Diagnosis of an opportunistic illness indicative of stage 3
 - No subsequent negative result on an HIV antibody test

Definition for Date of Diagnosis of a Confirmed Case for All Ages

Laboratory Criteria If the diagnosis is based on laboratory evidence, the diagnosis date is defined as the earliest date on which the specimen was obtained for a positive HIV test result.

Clinical Criteria If the diagnosis was based on clinical evidence (“physician documented”) rather than laboratory evidence, the diagnosis date is defined as the date (at least the year) of diagnosis reported in the content of the medical record. If the diagnosis date was not reported in the note, the date when the note was written can be used as a proxy.

Section 2: Criteria for Classifying the HIV Type as HIV-2

All HIV infections in the United States should be assumed to be type 1 (HIV-1) unless laboratory test results are sufficient to classify the infection as type 2 (HIV-2), dual HIV-1 and HIV-2 infections, or undifferentiated HIV infection, as described below. Clinical or epidemiologic evidence might lead to laboratory testing for HIV-2 but is insufficient for classifying the HIV type as HIV-2.

Persons Aged ≥ 18 Months and Children Aged < 18 Months Not Perinatally Exposed

HIV-2 Infection

For HIV-2 infection, one or more of the following laboratory criteria are necessary and sufficient:

- FDA-approved HIV-1/HIV-2 type-differentiating antibody test result positive for HIV-2 and negative for HIV-1
- Positive HIV-2 Western blot (WB) (or immunoblot or line assay) result and negative or indeterminate HIV-1 WB result
- Positive qualitative HIV-2 NAT result
- Detectable quantitative HIV-2 NAT (viral load)
- Laboratory results interpreted as consistent with HIV-2 infection by a laboratory expert experienced in differentiating HIV-2 from HIV-1 if laboratory evidence for HIV-2 is ambiguous

Dual Infection with HIV-1 and HIV-2

The HIV type is classified as “dual” infection (both HIV-1 and HIV-2) if both an HIV-1 NAT and an HIV-2 NAT are positive.

Undifferentiated HIV Type

The HIV type is classified as “undifferentiated” if there is no positive or detectable result from an HIV-1 NAT and a laboratory expert cannot resolve ambiguous evidence for HIV-2, such as:

- HIV-2 WB is positive and HIV-1 WB is HIV positive.
- HIV-1/HIV-2 type-differentiating antibody test result interpretation is “undifferentiated” (positive for both HIV-1 and HIV-2).

Difficulty of Diagnosing HIV-2 Infection in Children Aged < 18 Months Born to Mothers Known to Be HIV Infected or Whose HIV Infection Status Is Unknown

In perinatally exposed children aged < 18 months, antibody tests are not used to diagnose HIV infection because of the expectation that they might be false indicators of infection in the child due to passive transfer of maternal antibody. The HIV-1 NAT routinely used to diagnose HIV-1 infection in children of this age is likely to be negative in an HIV-2-infected child because it is insensitive to HIV-2. A positive HIV-2 NAT result would satisfy the criteria for a case. Otherwise, the diagnosis of HIV-2 infection in a child will need to wait until the child is aged 18 months, when it can be based on antibody test results.

Section 3: Criteria for Uninfected and Indeterminate HIV Infection Status of Perinatally Exposed Children Aged < 18 Months

Uninfected

A child aged < 18 months who was born to an HIV-infected mother or had a positive HIV antibody test result is classified for surveillance purposes as not infected with HIV if all three of the following criteria are met:

- Laboratory criteria for HIV infection are not met (see section “[Laboratory Evidence](#)”).
- No diagnosis of a stage-3-defining opportunistic illness attributed to HIV infection.
- Either laboratory or clinical evidence of the absence of HIV infection as described below.

Laboratory Evidence

Definitively Uninfected

- No positive HIV NAT (RNA or DNA)
- At least one of the following criteria:
 - At least two negative HIV NATs from specimens obtained on different dates, both of which were at age ≥ 1 month and one of which was at age ≥ 4 months

- At least two negative HIV antibody tests from specimens obtained on different dates at age ≥ 6 months

Presumptively Uninfected

- Criteria for definitively uninfected with HIV are not met.
- At least one of the following four laboratory criteria are met:
 - At least two negative NATs from specimens obtained on different dates, both of which were at age ≥ 2 weeks and one of which was at age ≥ 4 weeks.
 - One negative NAT (RNA or DNA) from a specimen obtained at age ≥ 8 weeks.
 - One negative HIV antibody test from a specimen obtained at age ≥ 6 months.
 - If criteria for HIV infection had initially been met by one positive HIV NAT test, then it must have been followed by at least two negative test results from specimens obtained on different dates, one of which is:
 - A NAT test from a specimen obtained at age ≥ 8 weeks
 - An HIV antibody test from a specimen obtained at age ≥ 6 months
- No subsequent positive NAT.

Clinical Evidence

A note in a medical record by a physician or other qualified medical-care provider states that the patient is not infected with HIV.

Indeterminate HIV Infection Status

A child aged < 18 months born to an HIV-infected mother is categorized as having perinatal exposure with an indeterminate HIV infection status if neither the criteria for being HIV infected nor the criteria for being uninfected are met.

Section 4: Criteria for Classifying the Stage of HIV Infection

The stages of HIV infection defined in this document are for surveillance staging of disease and might not be appropriate for patient care, clinical research, or other purposes. A confirmed case that

meets the criteria for diagnosis of HIV infection can be classified in one of the five HIV infection stages (0, 1, 2, 3, or unknown). Stage 0 indicates early HIV infection, inferred from a negative or indeterminate HIV test result within 6 months of a confirmed positive result, and these criteria supersede and are independent of the criteria used for later stages. Stages 1, 2, and 3 are based on the CD4+ T-lymphocyte count. If the CD4+ count is missing or unknown, the CD4+ T-lymphocyte percentage of total lymphocytes can be used to assign the stage. Cases with no information on CD4+ T-lymphocyte count or percentage are classified as stage unknown. If a stage 3-defining opportunistic illness has been diagnosed, then the stage is 3 regardless of CD4 T-lymphocyte test results, unless the criteria described below for stage 0 are met. CD4+ T-lymphocyte counts or percentages at the time of diagnosis allow classification of cases by stage at diagnosis. Subsequent CD4+ T-lymphocyte counts or percentages help monitor disease progression and whether the person is receiving ongoing care.

The stage characterizes the status of HIV disease at a particular point in time. Of primary interest to surveillance is the stage at initial diagnosis, but the stage can change in either direction after diagnosis and might be defined with reference to dates of interest such as the most advanced stage recorded through a particular date. The stages are defined as follows:

2014 Classification of Stage of HIV Infection, CDC

Stage 0 consists of a sequence of discordant test results indicative of early HIV infection in which a negative or indeterminate result was within 180 days of a positive result. The criteria for stage 0 supersede and are independent of the criteria used for other stages.

Stage 0 can be established either:

- Based on testing history (previous negative/indeterminate test results): a negative or indeterminate HIV test (antibody, combination antigen/antibody, or nucleic acid test) result within 180 days before the first confirmed positive HIV test result of any type. The first positive test

Surveillance Case Definition, Table 2 HIV infection stage^a based on age-specific CD4+ T-lymphocyte count or CD4+ T-lymphocyte percentage of total lymphocytes

Stage	Age on date of CD4+ T-lymphocyte test					
	<1 year		1–5 years		≥6 years	
	Cells/ μ L	%	Cells/ μ L	%	Cells/ μ L	%
1	≥1,500	≥34	≥1,000	≥30	≥500	≥26
2	750–1,499	26–33	500–999	22–29	200–499	14–25
3	<750	<26	<500	<22	<200	<14

^aThe stage is based primarily on the CD4+ T-lymphocyte count; the CD4+ T-lymphocyte count takes precedence over the CD4 T-lymphocyte percentage, and the percentage is considered only if the count is missing. There are three situations in which the stage is not based on this table: (1) if the criteria for stage 0 are met, the stage is 0 regardless of criteria for other stages (CD4 T-lymphocyte test results and opportunistic illness diagnoses); (2) if the criteria for stage 0 are not met and a stage 3-defining opportunistic illness has been diagnosed, then the stage is 3 regardless of CD4 T-lymphocyte test results; or (3) if the criteria for stage 0 are not met and information on the above criteria for other stages is missing, then the stage is classified as unknown

result could be any time before the positive supplemental test result that confirms it

- Based on a testing algorithm: a sequence of tests performed as part of a laboratory testing algorithm that demonstrate the presence of HIV-specific viral markers such as p24 antigen or nucleic acid (RNA or DNA) 0–180 days before or after an antibody test that had a negative or indeterminate result. Examples of algorithms that would fulfill this requirement include:
 - A positive initial HIV immunoassay result (e.g., antigen/antibody or antibody only) followed by a negative or indeterminate supplemental antibody test result (e.g., HIV-1/HIV-2 antibody differentiation assay or Western blot) and a positive NAT result. All three tests are usually performed as part of the same testing algorithm, but time might elapse between tests if additional specimens must be obtained for definitive supplemental testing.
 - A negative initial HIV immunoassay result followed by a positive NAT result that might have been done to evaluate the presence of acute HIV infection.

Exception

A confirmed case of HIV infection is not in stage 0 if the negative or indeterminate HIV test used as the criterion for it being a recent infection was preceded >60 days by evidence of HIV infection, such as a confirmed positive HIV test result, a clinical (physician-documented) diagnosis of

HIV infection for which the surveillance staff have not found sufficient laboratory evidence, a CD4+ T-lymphocyte test result indicative of stage 3 (Table 2), or an opportunistic illness indicative of stage 3.

Classifying a case as stage 0 depends on documenting negative HIV antibody test results in the specific situations described above. Negative test results from testing algorithms that have concluded that the person is not infected need not be reported to HIV surveillance programs.

Progression of Stage After Initial Diagnosis in Stage 0

Although the stage at diagnosis does not change, if >180 days have elapsed after the stage was 0 at diagnosis, the stage at the later date is classified as 1, 2, 3, or unknown, depending on CD4+ T-lymphocyte test results (Table 2) or whether an opportunistic illness had been diagnosed >180 days after HIV infection diagnosis. (Table 2)

Stages 1, 2, 3, and Unknown

If the criteria for stage 0 are not met, the stage is classified as 1, 2, 3, or unknown, depending on CD4+ T-lymphocyte test results or whether an opportunistic illness was diagnosed (Table 2). Infection among children aged 6–12 years is staged with the same criteria as infection among adults and adolescents, including opportunistic illnesses indicative of stage 3 (see below) that formerly applied only to adults and adolescents

(i.e., pulmonary tuberculosis, recurrent pneumonia, and cervical cancer). Multiple or recurrent bacterial infections (other than recurrent salmonella septicemia), which formerly applied only to children aged <13 years, now apply only to children aged <6 years. Lymphoid interstitial pneumonia is no longer classified as indicative of stage 3 in children because it is associated with moderate rather than severe immunodeficiency (CDC 1986). The diagnosis of any of the opportunistic illnesses, irrespective of diagnostic method used, will meet the criteria for staging, thereby eliminating the requirement in the 2008 case definition for some of them to be “definitively” diagnosed.

2014 Stage 3-Defining Opportunistic Illnesses in HIV Infection

Bacterial infections, multiple or recurrent ^a
Candidiasis of bronchi, trachea, or lungs
Candidiasis of esophagus
Cervical cancer, invasive ^b
Coccidioidomycosis, disseminated or extrapulmonary
Cryptococcosis, extrapulmonary
Cryptosporidiosis, chronic intestinal (>1 month's duration)
Cytomegalovirus disease (other than the liver, spleen, or nodes, onset at age >1 month)
Cytomegalovirus retinitis (with loss of vision)
Encephalopathy attributed to HIV ^c
Herpes simplex: chronic ulcers (>1 month's duration) or bronchitis, pneumonitis, or esophagitis (onset at age >1 month)
Histoplasmosis, disseminated or extrapulmonary
Isosporiasis, chronic intestinal (>1 month's duration)
Kaposi sarcoma
Lymphoma, Burkitt (or equivalent term)
Lymphoma, immunoblastic (or equivalent term)
Lymphoma, primary, of brain
<i>Mycobacterium avium</i> complex or <i>Mycobacterium kansasii</i> , disseminated or extrapulmonary
<i>Mycobacterium tuberculosis</i> of any site, pulmonary ^b , disseminated, or extrapulmonary
Mycobacterium, other species or unidentified species, disseminated or extrapulmonary
<i>Pneumocystis jirovecii</i> (previously known as “ <i>Pneumocystis carinii</i> ”) pneumonia
Pneumonia, recurrent ^b
Progressive multifocal leukoencephalopathy

(continued)

<i>Salmonella</i> septicemia, recurrent
Toxoplasmosis of brain, onset at age >1 month
Wasting syndrome attributed to HIV ^c

^aOnly among children aged <6 years

^bOnly among adults, adolescents, and children aged ≥6 years

^cSuggested diagnostic criteria for these illnesses, which might be particularly important for HIV encephalopathy and HIV wasting syndrome, are described in the following references:

CDC (1994)

CDC (1992)

Definition

HIV-1 infects CD4+ T cells and completes its replication cycle in approximately 24 h. During this time, infection profoundly perturbs the cellular physiology and makes extensive use of host factors. Cells react to viral invasion by deploying a defense strategy, including general innate immune mediators and specific antiviral factors. At the organism level, the viral-host interaction involves barriers and innate and acquired immunity and results in physiological changes in response to the infectious process. The study of these complex relationships and the tools for large-scale screening of factors involved in cellular and organism responses is part of the field of systems biology.

Systems Biology: Overview

Key elements that define systems biology are (i) the use of high-throughput quantitative measurements (ii) of a model that can be perturbed (iii) in iterative cycles with (iv) integration and modeling of the resulting data. In the context of HIV infection, an ideal systems biology experiment would include a model that dynamically captures the changes and interactions that occur during infection. One of the outcomes is the identification of host factors necessary for successful infection (sometimes referred to as “dependency factors”) or host factors that limit infection (generally referred to as “restriction factors”). A number of technologies are being used to identify these factors (Table 1), although their use does not necessarily represent a complete systems

Systems Biology, Table 1 Large-scale quantitative measurements used in HIV research

Approach	Technology	Materials	Outcomes	References
Transcriptome studies	Microarrays, RNA deep sequencing	Peripheral blood, individual cell populations, cell lines	Description of features of the infectious process that massively modulate the antiviral defense systems, as well as genes involved in the cell cycle and degradation/ proteasome pathway. Elite controllers have CD4 + T-cell transcriptome profiles that are similar to that from individuals receiving effective treatment and, in many cases, undistinguishable from that of the uninfected individuals. Next-generation sequencing offers an unprecedented opportunity to jointly analyze cellular and viral transcriptional activity without prerequisite knowledge of the nature of the transcripts	Rotger et al. 2010 , 2011 ; Lefebvre et al. 2011 ; Schopman et al. 2012 ; Imbeault et al. 2012
miRNA screens	Microarrays	Peripheral blood, individual cell populations	There are technical issues that result in conflicting literature on the role of host miRNAs in HIV infection. miRNAs may potentially target the conserved Nef-3'-LTR region	Sun et al. 2012
Gain-of-function screens	Recombinant DNA, overexpression	Cell lines	One gain-of-function screen used a cDNA library representing 15,000 unique genes in an infectious HIV-1 system. A second screen expressed a collection of over 300 interferon-stimulated genes	Schoggins et al. 2011
siRNA screens	Silencing siRNA, shRNA technologies	Cell lines	Individually, each screen has identified a few hundred candidate genes. However, there is limited overlap across studies except for a small core of proteins that include the mediator complex, a number of key kinases, and components of the NF- κ B complex	Bushman et al. 2009
Proteome analysis	Various mass spectrometry approaches	T-cell lines and primary cells	Analyses of 2,000 to 3,200 proteins by various groups resulted in limited overlap. This may reflect differences in detection and quantification methods, and in the experimental systems	Kramer et al. 2012 ; Navare et al. 2012

Systems Biology, Table 1 (continued)

Approach	Technology	Materials	Outcomes	References
Protein-protein immunoprecipitation	Affinity tagging and purification mass spectrometry	Cell lines	HIV proteins interact with 435 human proteins, of which 11 host factors were reported to inhibit HIV replication	Jager et al. 2012
Evolutionary analysis	Amplification and sequencing of gene orthologs, whole primate genomes	Evolutionary analyses followed by functional analysis	Mainly used in the study of single genes, its use is becoming integral part of large-scale screens. In parallel, sites under positive selection in the viral genome identify escape from host pressure	Snoeck et al. 2011 ; Telenti and Johnson 2012
Genome-wide genetic screens	Genotyping arrays, full exome or genome sequencing	DNA from large patient samples	All genes/proteins identified in the various large-scale approaches can be evaluated for genetic polymorphism in individuals and populations. A number of dataset from genome-wide association studies can be queried for this purpose	Fellay et al. 2010

biology approach as defined above. This chapter describes both the techniques and their application in the field of virology and HIV.

Transcriptome and Proteome Analyses

Among the very first tools of systems biology were technologies that simultaneously measured the expression level of all genes (transcriptome) in a particular cell model or tissue. Such studies generally sought to discover genes and pathways that were differentially expressed after some level of perturbation. In recent years, the analysis of mRNA levels has undergone significant change. Most notably, the techniques have evolved from microarrays to deep sequencing. Microarrays suffered from the limitation of hybridization to a fixed number of probes covering known genes, and in the less than optimal capacity to compare across experiments and laboratories. In contrast, the new generation of analyses using RNA deep sequencing offers absolute counts of all genes expressed – including transcript orientation and sequence and splice variants and alternative RNA species such as lincRNAs, miRNAs, and sRNAs that may also have biologic function of

importance to infectious diseases. Furthermore, there is increasing emphasis on the dynamic process that modulates transcription and on the possibility to investigate specific cellular populations – eventually at the single-cell level.

Microarray transcriptome analysis has been extensively applied to cell lines and more recently to ex-vivo studies of CD4 and CD8 T cells, monocytes, and macrophages from HIV-infected individuals. A recurrent observation is the profound perturbation of the cellular physiology of the infected cell in vitro (Rotger et al. [2010](#)) and of the general signatures of deregulation of the interferon response in vivo. In primate models of pathogenic infection (Rhesus macaque, ► [SIVmac infection of macaques, immunopathogenesis of African green monkey](#), ► [SIV infection of African Green Monkeys](#)) the early interferon response is maintained beyond the seroconversion phase (Bosinger et al. [2009](#); Jacquelin et al. [2009](#)). In contrast, nonpathogenic models of infection (Sooty mangabeys, ► [Non-Pathogenic Infection of Sooty Mangabeys](#)) are characterized by a normalization of the levels of transcription of interferon-stimulated genes after primary infection despite a persistently high level of viral replication. The profile of interferon response in

humans mirrors that of the models of infection in monkeys. Human rapid progressors have persistently high levels of expression of interferon-stimulated genes that increase with increasing levels of viremia (Rotger et al. 2011). The rare HIV-infected individuals that progress very slowly despite high levels of replication have an interferon-stimulated gene expression pattern closer to that of Sooty mangabeys (Rotger et al. 2011). Similarly, elite controllers (individuals maintaining extremely low viral loads in the absence of therapy, ► [Long term non progressors and elite controllers](#)) have been the object of transcriptome analyses. The consistent observation in various cellular subsets is that of minimal transcriptome differences compared to healthy, HIV-negative donors (Rotger et al. 2010; Vigneault et al. 2011). Successful antiretroviral therapy can also normalize transcriptome profile to a substantial degree (Rotger et al. 2010). Importantly, this normalization of cell function may help to alleviate some of the consequences of long-term immune activation resulting in better patient outcomes.

RNA sequencing is progressively applied to the study of HIV infection (Lefebvre et al. 2011; Schopman et al. 2012; Chang et al. 2011). The major benefit of this technique is the apparent unbiased measurement of splice variants and transcripts with non-reference sequence (i.e., variant alleles). The most revealing aspects concerned the analysis of expression of viral sequences in the infected cell that may represent up to 0.7% of all transcripts. Alternative viral RNA splice events, antisense viral transcripts, and numerous small RNAs that correspond to the HIV-1 RNA genome have been identified. The majority of the small viral RNA sequences have a positive polarity and may represent miRNAs; the small portion of viral RNAs of negative polarity is mainly encoded within the 3'-UTR and may represent viral siRNAs – they were shown to potently repress HIV-1 production (Schopman et al. 2012). A number of studies evaluated host miRNA expression differences of CD4 T cells of HIV-1-positive individuals. There is however controversy on the contribution to pathogenesis of selected miRNAs (Sun et al. 2012).

Many studies are hampered by the fact that the study materials are a heterogeneous mix of infected and uninfected cells that may dilute the signal of subtle expression changes in the infected cellular subset. This is particularly an issue in the study of CD4 T cells from peripheral blood of infected individuals. Novel approaches use reporter viruses to allow sorting of the infected cells followed by transcriptome profiling of the infected versus the uninfected cell populations (Imbeault et al. 2012). These have shown that within a population of activated CD4 T cells, HIV-1 has no detectable effect on the transcriptome of bystander cells – at least at the early time points following infection (Imbeault et al. 2012). Improvement in single-cell transcriptome analyses will allow more precise analysis in the future (Tang et al. 2011).

While the transcriptional profiles associated with infection have been extensively studied, the proteome profile has been less well characterized. High-throughput mass spectrometry has been used in the study of T cells infected with HIV to show that the most dynamic changes are observed at the time when intracellular viral production reaches its maximum. More recent studies used the isobaric tag for relative and absolute quantitation (iTRAQ (Navare et al. 2012)) method to reveal early changes in the host proteome affecting the ribosomal proteins and translational machinery, suggesting that HIV might disrupt cellular functions of the infected T cell even before the time of peak intracellular viral protein and virion production. Linking the transcriptomic profile to the proteomic profile is an ongoing process. As expression of specific species of RNA and protein interactions can both modulate viral replications; understanding how these levels of biology interact is a critical next step.

Functional Screens

Technical developments facilitate the large-scale analyses of gene and protein functions and interactions. These generally involve the systematic perturbation of every gene in the genome. The first such series of analyses used gene silencing

through siRNA or shRNA to knock down the expression of each gene individually (Bushman et al. 2009). Although each aimed at determining the full complement of host proteins required for productive HIV replication (albeit in different model systems), the overlap in genes significantly identified as required by the virus for productive infection was limited. Thus, individual screens proved difficult to interpret, probably because of difficulties in standardization, bystander effects on the cell, and false positives and negatives. Although the individual genes identified showed limited overlap, the joint analysis of these data supports evidence of shared pathways that when targeted result in reproducible effect on viral replication (Bushman et al. 2009). These initial screens mainly proposed genes that when silenced brought viral replication down – described as “dependency factors.” More recently, screens aimed at the identification of those genes that when silenced are associated with greater viral replication – so-called candidate restriction factors (Liu et al. 2011). Restriction factors may be more readily identified through gain-of-function screens where a permissive system is rendered nonpermissive by the introduction of a gene or protein product. For example, TRIM5 α was identified by the expression of a DNA library prepared from primary rhesus monkey lung fibroblasts in HeLa cells, rendering them resistant to HIV-1. More recently 380 interferon-stimulated genes were assessed in a large-scale gain-of-function screen (Schoggins et al. 2011). Several effectors were identified with activity against HIV as well as other viruses.

The global landscape of HIV-host protein interactions, as determined by genome-wide screens, has also been reported recently (Jager et al. 2012). Affinity tagging and purification mass spectrometry were used to identify physical interactions of all 18 HIV proteins and polyproteins with host proteins in two different human cell lines. HIV proteins interacted with 435 human proteins, with 40% of the interactions shared by both cell lines. Eleven host proteins were reported to inhibit HIV replication. Similar strategies, using expression of viral open reading frames from viruses other

than HIV, mapped numerous interactions with host factors and revealed different perturbation strategies used by individual viruses and by viral classes (Pichlmair et al. 2012). Certainly, understanding the full landscape of genes that enhance, restrict, or otherwise interact with HIV can lead to the identification of novel targets for intervention.

Evolutionary Genetics

Unique to the host-pathogen relationship is the process of interaction, defense, and escape. At the genetic and genomic level, this translates in specific signals that can be identified by bioinformatic analyses and thereafter tested in functional screens (Telenti and Johnson 2012). The approach using functional evolutionary biology is of particular interest in the study of HIV because of the long association of retroviruses (and lentiviruses) with mammalian genomes. Repeated exogenous viral attacks and episodes of cross-species transmission and successful endogenization contribute a significant load of retroviral material to the host genome. Host-pathogen coevolution resulted in positive selective pressure on genes of innate immunity.

Evolutionary genetics has been used successfully in the study of the TRIM and APOBEC families, as well as in the study of BST2/tetherin and more recently SAMHD1. The virus deploys counteracting factors that are often multifunctional and target host antiviral molecules for proteasomal degradation. In all cases, genetic analyses have used sequences from primate orthologs to identify the domains and specific codons that likely participate in direct interaction with viral products. Experiments then used swaps of domains and site-directed mutagenesis to validate the role of specific sites in the process of host-pathogen interaction.

The field is now moving toward genome-wide assessments of signatures of positive selection and including these measurements as part of the characterization of genes and proteins identified by the genome-wide screens described in previous sections of this entry.

Restriction factors are expected to display features of rapid adaptation, while dependency factors, being part of central cellular processes and not necessarily engaged in direct interaction with the pathogen, are encoded by highly conserved genes.

Systems Vaccinology

High-throughput approaches used in systems biology greatly benefit from study designs where the perturbation is readily controlled. Thus, administration of an immunogen (and adjuvant) to a defined, and in many cases healthy, population can be seen as an optimal setting to apply concepts of systems biology at the organism level. This has been the rationale behind studies on the immunogenicity and signatures of successful vaccination against yellow fever and influenza. This approach has also been identified as promising for the study of vaccines against HIV (Nakaya and Pulendran 2012). Here, the value of systems vaccinology is in the understanding of vaccines that do not have clear correlates of protection or immunogenicity, such as the HIV vaccine tested in the RV144 trial. Understanding cascades of gene/protein expression that are modified in the context of a challenge of a protective vaccine can help to inform design of future studies as these will provide a readout in addition to the more traditional immunological correlates (i.e., antibodies and CTLs).

Currently, this field of research has primarily targeted whole blood or peripheral blood mononuclear cells. This material is widely available; however, the analysis captures both cellular composition and transcript abundance and may not identify a particular cell type of significant function. Additionally, the cellular heterogeneity may mask subtle changes in gene function in important cell types of low abundance. Some advanced bioinformatic tools can deconvolute the signatures as an alternative approach to studying selected cellular subsets. The integration of these approaches into clinical trials may capture enough information to assist rational vaccine design.

Host and Viral Genetics

The wealth of human genetic variation and the ever-increasing accessibility of methods to interrogate the full genome are being used extensively to understand complex traits. Although these techniques are currently being used to study differences in disease outcome after HIV infection (discussed in a separate entry “► [Host Genetics and Genomics](#)”), they exclusively focus on association testing of single variants or single genes (albeit in the genome-wide context). This has proved successful for discovering common variants in large cohorts; however, recent studies demonstrate that the vast majority of human variation is rare which, if tested individually, would require samples of unrealistic size (Keinan and Clark 2012). This situation may be improved by collapsing approaches that combine variation across genes and pathways to enhance power for detection, on the hypothesis that multiple hits in a gene and pathway may result in the same outcome at the population level. In HIV infection, in addition to using canonical biological pathways, analysis could be enhanced by the full understanding of the host systems perturbed by the virus: including dependency factors, restriction factors, and innate immune mediators. These data sets (such as the ones discussed above) could be used to feed back information to genetic studies to perform pathway-wide association analyses as proposed for other complex diseases (Califano et al. 2012).

In the case of the infected patient, the system includes both the host and the pathogen. Although much work has been done on viral sequences to highlight variants that impact viral fitness, this work has mainly focused on selection pressure mediated by HLA genes on viral epitopes. Systematic analysis of the interaction between variant alleles of host genes and viral sequences may be used to uncover other genes that induce selection pressure on the virus, thus identifying novel host/virus interactions. Such evidence exists for alleles of TRIM5 in rhesus macaques that show varying ability to restrict retroviruses (Kirmaier et al. 2010) and has been proposed for KIR in humans (Alter et al. 2011). Such analyses will require the generation of large data sets of

combined host and viral sequences, possibly including time points throughout the course of infection, as well as new analytical methodologies to account for viral and host population structure. As sequence yields and cost and availability of deep sequencing improve, this will become a feasible method by which to study host/virus interactions.

Conclusions

The type of knowledge generated by novel technologies and new conceptual approaches will take some time to mature and deliver. Additionally, the volume of data and the production of statistical and bioinformatics tools that can properly manage and perform integrated analyses are still under development. It is however important to emphasize the interest to compile detailed information on all components and interactions, as no gene acts in isolation from the broader system. Even the most-detailed functional studies of a single protein and single interaction can be facilitated and placed in context by data on the biological setting where such individual events take place.

Among the first series of initiatives to enhance access to such data types have been the creation of repositories and search motors that allow querying of multiple large-scale screens. The Gene Overlapper (<http://microb32.med.upenn.edu/GeneListOverlapper/>) provides output from genome-wide surveys of host-cell genes linked to HIV infection and allows user-configured exploration of overlaps among studies. GPS-Prot (<http://kroganlab-cmp.ucsf.edu/wiki/gpsv103/index.php>) is a tool to display proteins within their landscape of interacting partners. In order to build up a complete network for protein-protein interactions, it is necessary to access multiple databases. GPS-Prot searches publicly available databases and overlays genetic/proteomic profiling data on the physical interaction network. Such initiatives need to be extended to other data types in order to fully realize and harness the power of system-wide information.

As methods mature for acquiring holistic information on genetic variation, gene/protein

expression, and protein-protein interaction, methods to integrate these data to build networks that accurately reflect the complexity of the system will need to be widely accepted. Such analyses will allow for the rational design of experiments to perturb these systems and monitor the resulting changes to detect candidate pathways for drug targeting and intervention. While integration of data may not fulfill all the criteria that define systems biology, it will prove a useful tool for understanding HIV pathogenesis and immunology.

Definition

T follicular helper (TFH) cells are CD4⁺ T helper cells that localize in germinal centers of secondary lymphoid tissues and specialize in supporting B-cell differentiation and maturation, mainly through secretion of IL-21. These cells are phenotypically characterized by constitutive expression of the B-cell follicle homing marker CXCR5, and their developmental program seems to be guided by the transcription factor Bcl6. Increasing data suggest that functional defects of TFH cells during HIV-1 infection contribute to dysregulation of humoral immunity and decreased responsiveness to vaccines in HIV-1-infected persons. In addition, TFH cells seem to be highly susceptible to HIV-1 infection and may play an important role as a cellular reservoir for HIV-1 persistence. Manipulation of TFH cells may be necessary for the induction of HIV-1-specific broadly neutralizing antibodies by preventative vaccine candidates.

This entry provides a summary of the multiple roles of TFH cells in HIV-1 immunopathogenesis.

Introduction

The first line of defense against invading pathogens is the innate immune response. This response is rapid but rather unspecific. If the innate response fails to clear the pathogen, the adaptive or acquired immune response is activated. The adaptive immune response takes more time (days to weeks) to develop but is more specific. The two major arms of adaptive immunity are cellular and humoral responses, which work in synergy to ensure a specific and efficient response to intra- and extracellular pathogens. These responses adapt to the specific antigen on the basis of the hosts' genetic background and differentiate and mature to allow for the maximum affinity and avidity. During the adaptive response, immunological memory is developed which generates a rapid specific response upon reencounter with that same pathogen. The induction of a memory humoral response consisting of B cells capable of secreting highly specific antibodies is dependent upon CD4 T-cell help and specifically a subset of CD4 T cells called T follicular helper (TFH) cells. Understanding differentiation and function of TFH cells is important since most licensed human vaccines function by inducing T-cell-dependent protective antibody responses. This entry will give an overview of TFH cells and

address their functions in initiation and maintenance of potent B-cell responses and how that might be dysregulated in HIV infection.

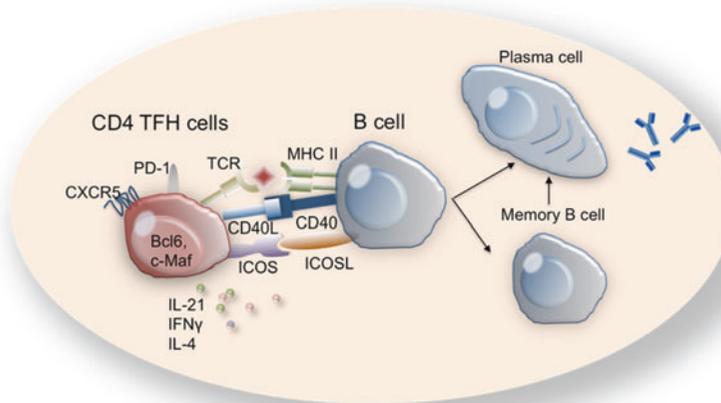

T-Cell-Dependent Induction of B-Cell Responses

The induction of B-cell responses and antibody production occur in secondary lymphoid organs, and with the exception of lipid and polysaccharide antigens, this event is T-cell dependent. During viral infections, dendritic cells take up the antigen and transport it to secondary lymphoid tissues where priming of specific CD4 T cells takes place. These primed CD4 T cells interact with BCR (B-cell receptor)-activated B cells which initially occur at the follicular border (see Fig. 1). Following this initial interaction, B cells can enter distinct pathways, either become extra-follicular, short-lived plasma cells and perifollicular early memory B cells or go through germinal center (GC) reaction to facilitate the establishment of a pool of long-lasting memory B cells. When entering the germinal center

pathway, the B cells undergo (I) somatic hypermutation, which involves random mutations of the B-cell receptor, (II) selection of randomly mutated B cells with the highest affinity for the specific pathogen which ensures specificity of the immune response, and (III) class switching, during which the immunoglobulin undergoes class-switch recombination (CSR). Depending on the extracellular signals induced by the pathogen, activated B cells are able to switch their IgM surface antibodies to IgG, IgA, or IgE, all with different functions adapted to the pathogen. These are all events leading to the generation of high-affinity mature antibody secretion and memory formation. These events are highly dependent on CD4 T-cell help and no formation of GCs can occur in the B-cell follicles without this crosstalk.

Characterization of TFH Cells

The importance of intrafollicular CD4 T-cell help for potent B-cell responses was acknowledged a long time ago, but it was only in the year 2000 that these CD4 T cells started receiving recognition as

T Follicular Helper Cells in HIV Infection, Fig. 1 CD4 TFH cells are critical for the induction of potent B-cell responses. The first interaction between TFH cells and B cells occurs at the follicular border in secondary lymphoid tissue where B cells present a given antigen to these specific T cells and crosstalk between the T cell and activated B cell

occurs through co-stimulatory molecules such as CD40L, ICOS, and cytokines such as IL-21. Stimulated B cells can then enter germinal center reaction where they undergo somatic hypermutation, class switching, selection, and differentiation into antibody secreting plasma cells or memory B cells, events that are all dependent on TFH cells

a separate subset and acquired their name T follicular helper (TFH) cells (Breitfeld et al. 2000; Schaerli et al. 2000). The classification of CD4 T cells into separate lineages is typically based on differential cytokine secretion and expression of various transcription factors shaping their diverse functions. Whereas T-bet and Gata-3 are highly expressed by TH1 and TH2 subsets, respectively, TFH cells express high levels of the transcriptional repressor Bcl6 (Chtanova et al. 2004). In addition to Bcl6, other transcription factors such as B-cell-activating transcription factors (BATF) and musculoaponeurotic fibrosarcoma (MAF) have also more recently been identified for being involved in TFH cell differentiation. Although Bcl6 can be used to define TFH cells, due to their unique localization in B-cell follicles, TFH cells have often been phenotypically characterized by expression of CXCR5 in addition to various other chemokine receptors, inhibitory receptors, and co-stimulatory molecules including high expression of PD-1 and ICOS, but also CXCR4, CD95, SAP, CD154 (CD40L), BTLA, and CD69 (reviewed in Yu and Vinuesa 2010). TFH cells are capable of secreting various cytokines, including typical TH1 (IFN γ , TNF- α), and TH2-like (IL-4) cytokines; however, IL-21 is considered as the cardinal TFH cell cytokine and is used to characterize this distinct T helper cell subpopulation (Chtanova et al. 2004).

TFH Cell Functional Markers

TFH cells provide help to B cells through the expression of multiple surface molecules and cytokine/chemokine secretion. However, the interaction between TFH cells and B cells is not unidirectional. TFH cells provide helper signals to B cells and B cells provide crucial survival signals for TFH cells. The surface molecules expressed on TFH cells are not only involved in direct contact with B cells but also in positioning TFH cells in close proximity to B cells, as it is the case for chemokine receptors such as CXCR5. One of the most important stimuli for B cells comes through CD40-CD40L signaling. Upon stimulation TFH cells can express high levels of CD40L, which

induces B-cell activation, proliferation, and survival when binding to CD40 on B cells. Other molecules involved in the direct contact between TFH cells and B cells are SLAM family receptors. The SLAM receptors are expressed on CD4 T cells and bind SAP expressed on B cells. The interaction between SAP and SLAM receptors prolongs T-cell-B-cell interaction, and their absence results in reduced GC formations. ICOS-ICOSL interaction is also important for GC formation, but so far the benefit has only been proven on the TFH cell side, for which it is important for differentiation and maintenance. In addition to molecules involved in direct contact between the two cell types, cytokines play a crucial role. IL-21 is considered a cardinal cytokine for TFH cells although other CD4 T-cell subsets can secrete it too. IL-21 has several important functions; it is the most potent cytokine for driving plasma cell differentiation and promotes B-cell survival, and like other cytokines such as IL-4 and IFN γ , it drives class switching into certain antibody isotypes (Crotty 2011).

CD4 T Follicular Cell Subsets

As mentioned previously, TFH cells in secondary lymphoid organs are often characterized by high expression of BCL6, CXCR5, PD-1, and ICOS. However, these cells are not a homogenous cell population. Recently, a subset of these T follicular cells expressing FoxP3 has been described. This transcription factor defines T regulatory cells, a CD4 T-cell subset that limit effector T-cell response and maintain peripheral tolerance (Ramiscal and Vinuesa 2013) by modulating the dephosphorylation pathway of ATP (Toth 2013). Mice studies have shown that these T follicular regulatory (TFR) cells localize in the B-cell follicles and can regulate humoral immune responses through repressing TFH cells and GC formation. Studies in HIV-infected individuals indicate significant perturbations of Treg frequency and function depending on the stage of the disease (Schulze zur Wiesch 2011); however, the role of follicular Tregs in HIV-infected lymph nodes remains to be elucidated. Further, emerging data indicate that there are both CXCR3-positive and

CXCR3-negative TFH cells. CXCR3 is expressed on TH1 type of cells, and these cells preferentially secrete IFN γ upon stimulation, whereas CXCR3-negative cells secrete IL-4, a typical TH2 cytokine. It therefore appears that within TFH cells, there is great heterogeneity which is currently investigated.

Peripheral TFH Cells

Owing to their function, TFH cells have mainly been detected in lymphoid organs. However, a subset of peripheral CD4 T cells express CXCR5. The characterization of TFH cells in the periphery will become increasingly important to study the role of TFH cells in human diseases or following vaccinations, since human lymph nodes are challenging to acquire especially with regard to longitudinal studies. Characterization of peripheral TFH (pTFH) cells based on current lymphoid markers has been challenging due to alterations of phenotypic markers on these cells upon memory differentiation and migration out of lymphoid tissue. Individuals deficient in the co-stimulatory molecule ICOS, which have severely reduced GCs and are deficient in CXCR5 expressing CD4 T cells in the periphery, shed light on the potential role of pTFH cells since ICOS is important for survival and maintenance of TFH cells; it is believed that CXCR5-positive CD4 T cells in the periphery stem from TFH cells. CXCR5 expressing CD4 T cells in the periphery express a memory phenotype and are considered peripheral TFH (pTFH) cells. Beyond CXCR5, various markers have been used by different research groups to describe pTFH cells including PD-1, CXCR3, CCR6, and ICOS, and results have been contradictory. It is possible that, depending on the milieu and whether they are recently activated, TFH cells or memory TFH cells have variable B-cell helper capabilities *in vitro* and express various levels of PD-1, CXCR3, and ICOS (Schmitt and Ueno 2013). However, it has to be emphasized that TFH-mediated B-cell maturation and differentiation and the formation of a normal germinal center reaction will primarily depend on the presence of functional intrafollicular TFH cells in secondary lymphoid organs.

Induction of TFH Cells

Naïve CD4 T cells can differentiate into functionally distinct subsets, such as TH1 and TH2 based on the type of APC it interacts with, its TCR avidity for the antigen, and the surrounding cytokine milieu (Tao et al. 1997). These mechanisms are also involved in the differentiation of TFH cells. It has been shown that CD4 T cells with strong TCR affinity preferentially develop into TFH cells *in vivo*. Upon activation of CD4 T cells by dendritic cells, maturation of CD4 T cells into becoming specialized in B-cell help starts with migration to the follicular border. This migration is dependent upon chemotaxis. The pre-TFH cells downregulate the chemokine receptor CCR7, which ligands CCL19 and CCL12 are mainly expressed in the T-cell zone, and instead upregulate CXCR5, which ligand CXCL13 is produced in the B-cell follicles. This shift in chemokine sensitivity is controlled by the transcription factor Bcl6. Without Bcl6 expression, TFH cells do not develop *in vivo*. The role of cytokines for TFH cell development has been demonstrated *in vitro* where TFH cells were generated by CD4 T-cell activation in the presence of IL-6, IL-12, and IL-21. Lack of either IL-6 or IL-21 retains TFH cell frequencies, most likely due to a redundancy between the two cytokines (Eto et al. 2011). High levels of IL-6 are present during viral infections, and increased frequencies of TFH cells during inflammatory conditions have been noted in several autoimmune disorders, in a few cancers, and in chronic viral infections as discussed below.

TFH Cells in Chronic Viral Infections

In 2011, it was first shown in a mouse model for viral infection that virus-specific CD4 T cells preferentially differentiate into TFH cells in lymphoid organs in chronic infection (Fahey et al. 2011). The induction of TFH cell differentiation in this mouse model was driven by the inflammatory cytokine IL-6 which upregulated Bcl6 expression in CD4 T cells. TFH cells were subsequently shown to be expanded in SIV-infected monkeys. These monkeys also showed a substantial increase

in B-cell proliferation and antibody secretion in the lymph node (Hong et al. 2012; (Petrovas et al. 2012). These findings have since then been confirmed in humans. An increase in the relative frequency of TFH cells among CD4 T cells was detected in the lymph nodes of chronic HIV-infected individuals compared to healthy controls (Lindqvist et al. 2012). The accumulation of TFH cells in HIV-infected lymph nodes strongly correlated with the differentiation of germinal center B cells into the plasma cell lineage but not into memory B cells, indicating an important role for TFH cells in the observed skewing of B-cell subsets and subsequent hypergammaglobulinemia in chronic HIV infection (Lindqvist et al. 2012).

Dysregulated TFH Cell- and B-Cell Responses in HIV Infection

One of the hallmarks of HIV infection besides loss of CD4 T cells is defective humoral immune responses with reduced class switching of antibodies, loss of memory B cells, and reduced antibody responses and protection following vaccinations (Moir and Fauci 2009). It was previously believed that the loss of CD4 T cells contributes to dysfunctional B-cell responses in HIV infection, but with recent data showing an expansion of TFH cells in chronic infections, this is now challenged. Under physiological conditions, TFH cells are a limiting factor in the GC, allowing only B cells with high specificity to survive and further differentiate into plasma cells or memory B cells. The GC B-cell selection is a safety checkpoint to prevent the development of autoreactive B-cell clones or less efficient B cells to survive. It is possible that an abnormal expansion of TFH cells in chronic infections leads to loss of that selective pressure on the GC B cells which leads to secretion of high amounts of nonspecific antibodies. A common condition in HIV-infected individuals is called hypergammaglobulinemia, which is manifested as hypersecretion of nonspecific IgG antibodies. It is however not clear how the dysregulation of TFH cells in HIV infection correlates with the loss of neutralizing antibodies. Under physiological conditions, TFH cells expand following infection and start contracting after 5 days, most likely

as a result of antigen clearance (Deenick et al. 2010). However, in chronic viral infection with persistent viremia, the retraction of TFH cells is not observed and the increased frequency could be due to accumulation. In line with this, it was shown that abundant amounts of virions are trapped on the surface of follicular dendritic cells (FDC) and that viral antigens (e.g., p24/gag) are retained on the FDC network despite successful antiretroviral combination therapy (Tenner-Racz et al. 1998; Popovic et al. 2005). Although there is an increase of TFH cells in HIV infection, the crosstalk between TFH cells and B cells is compromised which contributes to dysregulated B-cell responses. Germinal center B cells in HIV-infected individuals express high levels of the inhibitory ligand PD-L1, which reduces TFH cell survival and cytokine secretion through the PD-1 receptor resulting in weakened B-cell help (Cubas et al. 2013). Moreover, alterations in the intrafollicular cytokine milieu are thought to contribute to these changes. The TFH signature cytokine IL-21 plays a pivotal role in mediating a normal germinal center reaction. It has been shown that the addition of exogenous IL-21 could restore B-cell maturation and immunoglobulin secretion in HIV infection *ex vivo* (Cubas et al. 2013). However, the exact mechanisms of disturbed T-cell/B-cell crosstalk in HIV-infected GC remain to be elucidated.

TFH Cells as Viral Reservoirs

Memory CD4 T cells are selectively targeted by HIV, and substantial depletion of these cells occurs throughout AIDS progression. In addition lymphoid organs are the primary sites not only for immune activation but also for viral replication (Tenner-Racz et al. 1998; reviewed in Stellbrink and van Lunzen 2001), making TFH cells with their effector memory phenotype prime targets for HIV. In fact it has been shown that CD4 T cells within germinal centers contain the highest frequency of infected cells and these cells were most efficient in supporting virus replication (Hufert et al. 1997; Perreau et al. 2013). TFH cells have been shown to be preferentially infected even in patients with low viral loads, and replication-competent infectious virions could be readily

recovered indicating the role of TFH cells as potential viral reservoirs (Perreau et al. 2013). The germinal centers are to a large part devoid of CD8 T cells, which may support viral persistence within the TFH cell reservoir. Moreover, activated memory type TFH cells in GC are ideal target cells for de novo infection in the presence of persistent low-level viral replication.

Implications for Vaccine Design

The vast majority of licensed vaccines today imitate immune responses to natural infection and generate long-lived protective antibody responses. However, inducing an immune response against HIV by vaccination resembling natural infection will not be sufficient to provide protection. The knowledge on how to induce potent TFH cell responses and subsequent B-cell and antibody responses by vaccination strategies is scarce. The availability of antigen can regulate the development and function of TFH cells through differential presentation on follicular dendritic cells (FDC) and B cells. The balance between inducing sufficient B-cell help and exacerbated or dysfunctional TFH cell responses needs to be carefully considered and evaluated (Pratama and Vinuesa 2014). The generation of an efficient antibody-based HIV vaccine will require rational design of a combination of antigen, adjuvant (immunomodulator), and delivery system to induce T-cell responses capable of providing optimal B-cell help. Therefore, understanding how to induce and regulate TFH cell responses will be crucial for providing the right B-cell help. Current research thus focuses on the interplay between TFH and B-cell responses in GC, resulting in the formation of high avidity and affinity broadly neutralizing antibodies.

Conclusions

Current studies of TFH cells in chronic HIV infection indicate that TFH cells may have important implications for the dysregulation of B-cell responses in HIV infection. This may be mediated by an abnormal expansion or dysfunction of this highly specialized T helper cell subset or a

combination thereof. The exact mechanisms of perturbations of T-cell-B-cell interactions are not yet fully understood, but recent studies suggest that these alterations are associated with persistence of HIV in the TFH compartment as well as subtle changes in transcription and signaling pathways including dysbalances in the cytokine milieu. A better understanding of the role of TFH cells in health and diseases is crucial to be able to address TFH cell functions as potential therapeutic targets for the induction of proper B-cell responses and against the persistence of HIV infection in this specific cellular reservoir.

Definition

T memory stem cells (T_{SCM}) are a small population of long-lived memory T cells that represent the most undifferentiated stage of all memory T cell subsets. Functionally, T_{SCM} seem to be able to differentiate into all memory T subsets while simultaneously maintaining their own pool size through homeostatic self-renewal. T_{SCM} can persist in the human body for extremely long

periods of time and seem to be responsible for maintaining lifelong cellular immunity to pathogens by generating effector T cells based on demand (Gattinoni et al. 2011; Lugli et al. 2013b). Emerging data suggest that CD4 T_{SCM} can play a major role as a long-term reservoir for HIV persistence despite antiretroviral therapy, and that infection of these cells represents a distinguishing feature of pathogenic SIV infection in nonhuman primates (Buzon et al. 2014b; Cartwright et al. 2014; Klatt et al. 2014). This entry summarizes recent advances in understanding the role of T_{SCM} in HIV/SIV disease pathogenesis.

Introduction

Upon first antigen encounter during an immune response, naive T cells develop into activated effector cells, the majority of which die during the subsequent antimicrobial immune defense process. However, a small proportion of these antigen-experienced cells survives, enters the memory cell pool, and persists long-term to provide antigen-specific immune protection. Such memory cells can be classified according to developmental, maturational, and functional characteristics into central-memory (T_{CM}) and effector-memory (T_{EM}) T cells (Zielinski et al. 2011; Gattinoni et al. 2012; Sallusto et al. 2004; Lanzavecchia and Sallusto 2005). Central-memory T cells represent a long-lasting cell population that express lymphoid tissue homing markers, secrete mostly IL-2 upon TCR stimulation, and can rapidly transition into effector-memory cells upon activation. In contrast, effector-memory T cells are more short-lived, express chemokine receptors and adhesion molecules that allow for extravasation into inflamed tissues, and can rapidly execute effector functions. This classification has led to the assumption of a developmental hierarchy in which central-memory cells represent a more immature version of memory T cells that continuously replenish the effector-memory cell pool in a stem cell-like fashion while preserving their own pool through homeostatic approval (Graef et al. 2014). However, based on a number of experimental and

theoretical considerations, the presence of a defined memory cell population with more pronounced stem cell-like properties has been postulated for many years, and recently, small populations of memory T cells with extraordinary abilities to persist long-term and to repopulate all memory cell populations have been identified in mice, nonhuman primates, and humans (Gattinoni et al. 2009, 2011; Lugli et al. 2013a). These cells, termed “T memory stem cells” (T_{SCM}), were observed both within the CD4 and the CD8 T cell compartment and exhibited a naïve T cell phenotype, except for the surface expression of the memory cell markers CD95 and IL-2R β . Functionally, T_{SCM} were shown to have the greatest proliferative capacity compared to all memory T cell subsets and are characterized by their ability to undergo asymmetric cell divisions that can lead to homeostatic proliferation and self-renewal, as well as to transitional proliferation into more mature central-memory and effector-memory T cell populations. Moreover, when T_{SCM} are serially transplanted in animal models, T_{SCM} can repopulate the full diversity of the memory T cell compartment, such as T_{CM} , T_{EM} , and T_{TD} populations, and efficiently reconstitute cellular immunity in immunocompromised hosts (Gattinoni et al. 2011; Cieri et al. 2013; Lugli et al. 2013a, b). Due to these characteristics, T_{SCM} are likely to persist in the human body for extremely long periods of time and seem to be responsible for maintaining lifelong cellular immunity by generating effector T cells based on demand.

Role of T_{SCM} in Antiviral Immune Defense

Although T_{SCM} represent an immature and quiescent population of memory T cells, they can execute classic lymphocellular effector functions upon stimulation with their cognate antigen. This includes the ability to secrete IFN- γ , IL-2 or TNF- α , and IFN- γ . So far, antigen-specific CD8 T_{SCM} against CMV, flu, tumor antigens, and SIV have been identified (Gattinoni et al. 2011), but it is likely that they contribute to cellular immune

defense against virtually all microbial pathogens that can challenge the host. Virus-specific CD8 T_{SCM} have been studied in most detail in SIV-infected rhesus macaques (Lugli et al. 2013a). These investigations demonstrated that SIV-specific CD8 T_{SCM} cells are generated early after infection and persist throughout the disease process but, in most cases, make only small contributions to a given population of epitope-specific T cells. Interestingly, these studies also revealed that viral mutational escape in CD8 T cell epitopes leads to progressive elimination of central-memory and effector-memory CD8 T cells recognizing the wild-type epitope, indicating that these cell populations require continuous antigenic stimulation to maintain their long-term survival. In contrast, CD8 T_{SCM} specific for the wild-type epitope were continuously detected after viral mutational escape, and their relative contribution within the total population of antigen-specific CD8 T cells disproportionately increased, consistent with prolonged antigen-independent homeostasis of antigen-specific CD8 T_{SCM} (Lugli et al. 2013a). Although the functional role of HIV-specific CD8 T_{SCM} in humans has not yet been explored, a recent correlative study demonstrated that in untreated HIV patients, the frequency of total CD8 T_{SCM} is inversely associated with plasma viral load and with biomarkers of T cell immune activation while being positively correlated to absolute CD4 T cell counts (Ribeiro et al. 2014). If further corroborated in functional studies, CD8 T_{SCM} cells might therefore have an important role for influencing HIV-1 immune defense and natural HIV disease progression.

Susceptibility of CD4 T_{SCM} to HIV-1 Infection

HIV preferentially infects CD4 T cells through the recognition of host cell CD4 molecules and the chemokine receptors CCR5 or CXCR4. However, different CD4 T subpopulations with distinct maturation and activation status differ with regard to their susceptibility to HIV-1 infection *in vitro* (Chomont et al. 2009; Buzon et al. 2014a, b).

Initial investigations on the intrinsic susceptibility of CD4 T_{SCM} cells to HIV-1 indicated that CD4 T_{SCM} are susceptible to *ex vivo* HIV-1 infection, and that HIV-1 mRNA was readily detectable within the CD4 T_{SCM} population in HIV-1 patients who do not receive suppressive antiretroviral therapy, indicating that they are permissive to HIV-1 infection *in vivo* (Buzon et al. 2014b). The susceptibility of CD4 T_{SCM} to R5-tropic infection HIV-1 infection appeared to be similar to CD4 T_{CM} cells, and cytopathic effects associated with HIV-1 infection seemed to be relatively low in CD4 T_{SCM} cells. Interestingly, *ex vivo* infection with a VSV-G-pseudotyped HIV virus that bypasses viral coreceptor-mediated entry processes indicated that among all CD4 T cell subsets, highest levels of viral production were achieved in CD4 T_{SCM} cells (Buzon et al. 2014b), for reasons that are currently unclear. Using an elegant system to discriminate between abortive, latent, or productive infection, recent experiments demonstrated that *ex vivo* infection of CD4 T_{SCM} can result in both productive and latent HIV-1 infection. However, the rate of abortive infection in CD4 T_{SCM} was relatively high in comparison to T_{CM} and T_{EM} cells, possibly due to altered expression or function of the antiviral restriction factor Samhd1 in this cell compartment (Tabler et al. 2014). Of note, expression levels of Trim5a, an HIV restriction factor inhibiting viral uncoating, are significantly reduced in CD4 T_{SCM} compared to alternative CD4 T subsets, which may support their susceptibility to HIV-1 (Buzon et al. 2014b). Collectively, these results suggest that CD4 T_{SCM} are permissive to HIV-1 infection *in vivo* and *in vitro*, highlighting their potential to serve as a putative long-lasting reservoir *in vivo* for HIV infection.

Contribution of T_{SCM} to HIV-1 Long-Term Persistence

The fact that CD4 T_{SCM} are easily infected *in vitro*, harbor HIV RNA *in vivo* in untreated HIV-1 patients, and are long-lived cells might suggest that these cells could serve as an important component of the long-lasting viral reservoir

when active viral replication is effectively suppressed by antiretroviral therapy. In this regard, first studies showed that CD4 T_{SCM} from ART-suppressed HIV-1 patients contain HIV-1 DNA and, importantly, that they have the ability to produce infectious viral particles upon activation (Buzon et al. 2014a, b; Jaafoura et al. 2014). This indicates that these cells can represent a reservoir for replication-competent viral strains in ART-treated subjects. However, due to their low frequency, CD4 T_{SCM} only contribute ~8% to the total viral CD4 T cell reservoir in an average population of ART-treated patients. This contribution seems to critically depend on the duration and timing of antiretroviral treatment initiation: In long-term treated patients who initiated ART early after infection and have a comparatively small total HIV reservoir, CD4 T_{SCM} appeared to make a relatively larger contribution to the total viral reservoir size, as opposed to patients who started treatment during the chronic phase of the infection and had an increased total viral reservoir size (Buzon et al. 2014a, b). Longitudinal studies over more than 10 consecutive years of antiretroviral treatment demonstrated that HIV-1 DNA in CD4 T_{SCM} cells remained stable or only slightly decreased, while decay of HIV-1 DNA in alternative CD4 T cell populations was more pronounced (Buzon et al. 2014b); this led to a disproportionate increase in the contribution of CD4 T_{SCM} to the viral reservoir over time and supports the role of CD4 T_{SCM} as a long-term reservoir for HIV-1 (Buzon et al. 2014b). Moreover, additional studies demonstrated that the half-life of HIV-1 DNA in CD4 T_{SCM} was much longer than in any of the other T cell populations, consistent with CD4 T_{SCM} as a preferential site for viral long-term persistence (Jaafoura et al. 2014). Importantly, phylogenetic studies demonstrated identical HIV-1 sequences in CD4 T_{SCM} collected at the beginning of antiretroviral therapy and several years later; moreover, HIV-1 DNA sequences collected from CD4 T_{SCM} after many years of treatment showed close phylogenetic associations to plasma sequences from early disease. This suggests that viral strains circulating in early infection can persist long-term upon infection of these long-lived memory CD4 T cell subsets (Buzon et al.

2014b). Overall, these studies imply that HIV-1-infected CD4 T_{SCM} serve as a very long-lasting reservoir for HIV-1 in ART-treated patients.

Role of T_{SCM} in SIV and HIV Pathogenesis

Pathogenic SIV infection of rhesus macaques (RM) imitates the disease course of HIV-1-infected untreated humans and leads to progressive loss of CD4 T cells associated with clinical signs of immune deficiency. In contrast, SIV infection of natural hosts for the virus, such as sooty mangabeys (SM), is typically nonpathogenic, despite high levels of virus replication. Several mechanisms have been proposed to explain the nonpathogenic nature of SIV infection in SM, such as a preserved mucosal barrier, reduced expression of the CCR5 SIV coreceptor in the surface of the target CD4 T cells, and downmodulation of the CD4 receptor during the generation of the memory cell population (Chahroudi et al. 2012). In RM, SIV infection is typically associated with high levels of viral replication within the CD4 T_{CM} subset (Paiardini et al. 2011), and a direct link between virus-mediated CD4 T_{CM} killing, CD4 T_{CM} depletion, and the onset of the immunodeficiency has been observed in infected RM (Letvin et al. 2006; Okoye et al. 2007; Brenchley et al. 2012). This represents a striking contrast to SIV-infected SM, where viral infection of T_{CM} seems to be reduced. More recent studies extended these findings by demonstrating even more pronounced differences between SIV infection of CD4 T_{SCM} from SM and RM. While CD4 T_{SCM} from RM are fully susceptible to SIV infection and support high-level SIV replication, SIV infection was in many cases completely undetectable in CD4 T_{SCM} from SM, suggesting the presence of cell-intrinsic restriction mechanisms that protect this particular cell subset against viral infection. These data indicate that the selective resistance of CD4 T_{SCM}, and to a lesser extent of CD4 T_{CM}, to SIV infection represents a distinguishing feature of nonpathogenic SIV infection in natural hosts (Cartwright et al. 2014). Similar observations were recently made in

HIV-1-infected viremic nonprogressors (VNP), an exquisitely rare group of patients who maintain normal CD4 T cell counts for prolonged periods of time in the presence of continuous high-level viral replication and in that sense resemble SIV-infected natural hosts. Interestingly, HIV-1 infection of CD4 T_{SCM} and CD4 T_{CM} from VNP was significantly reduced in comparison to HIV-1 patients with typical disease progression (Klatt et al. 2014). Thus, low levels of SIV and HIV infection within the CD4 T_{SCM} and, to a lesser extent, within the CD4 T_{CM} population seem to be a characteristic feature influencing the disease progression of nonpathogenic SIV and HIV infections. Future studies will be needed to determine possible resistance mechanisms of T_{CM} and T_{SCM} cells to viral infections in SM and viremic nonprogressors.

Conclusions

CD4 T_{SCM} represent a newly discovered T subpopulation that seems to have a key role as a long-lived reservoir for viral persistence despite ART. Future studies will be needed to analyze whether other CD4 T cell populations with stem cell-like functional properties, such as Th17 cells (Kryczek et al. 2011; Muranski et al. 2011), can also serve as a long-lasting viral reservoir for HIV-1 in persons with pharmacologically suppressed viremia. The identification of infected cells with stem cell-like properties as an important component of the viral reservoir may offer novel opportunities for clinical strategies to target the most durable components of the latent viral reservoir. Since stem cell-like transcriptional programs seem to guide long-term maintenance of CD4 T_{SCM}, molecular pathways responsible for stem cell homeostasis may represent attractive targets for reducing HIV-1 persistence in CD4 T_{SCM} in vivo. Moreover, CD4 T cells with stem cell-like properties may represent desirable target cells for creating long-lived populations of CD4 T cells that are resistant to HIV-1 after manipulation of viral coreceptor expression with, e.g., zinc finger nucleases (Kiem et al. 2012).

Talaromyces (Penicillium) marneffeii and HIV

Romanee Chaiwarith¹ and
Khuanchai Supparatpinyo^{1,2}

¹Division of Infectious Diseases, Faculty of Medicine, Chiang Mai University, Chiang Mai, Thailand

²Research Institute for Health Sciences, Chiang Mai University, Chiang Mai, Thailand

Definition

Talaromyces marneffeii, formerly *Penicillium marneffeii*, is a dimorphic fungus. (Samson et al. 2011) *T. marneffeii* infection (TMI) is a common opportunistic infection in HIV-infected patients living in the endemic areas, particularly Southeast Asia, Southern China, and India. However, there have

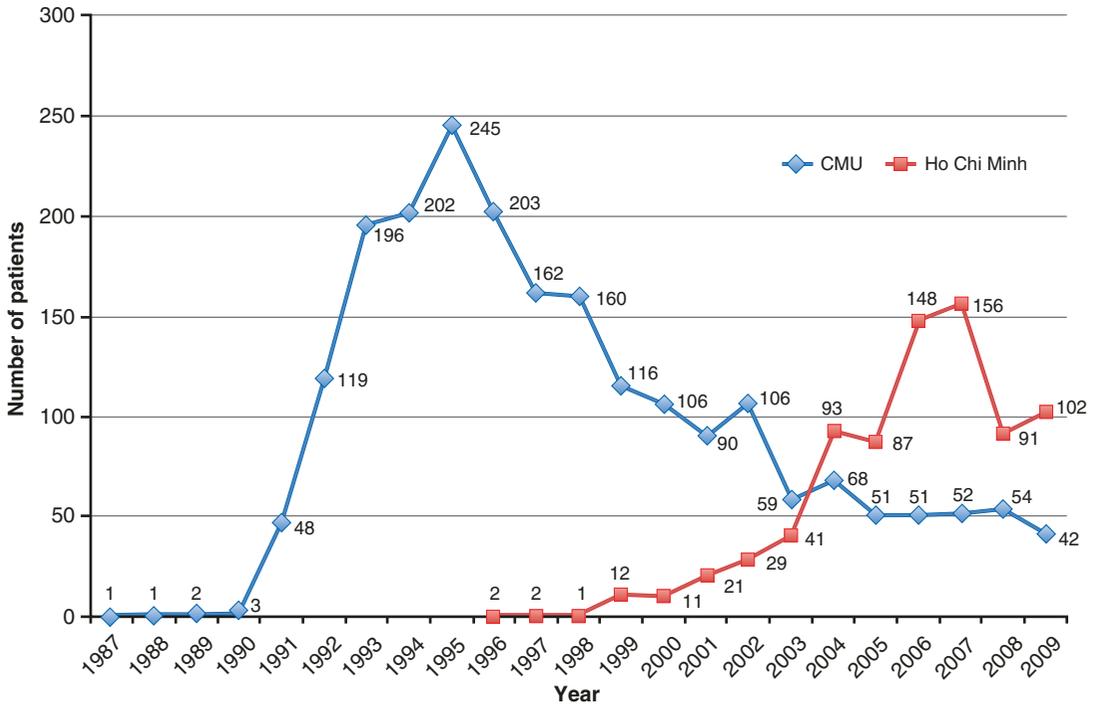

been reports in HIV-infected travelers who have traveled to the endemic areas. (Vanittanakom et al. 2006). The clinical manifestations varied widely from asymptomatic to disseminated infection involving several organs including central nervous system. The epidemiology, clinical manifestations, diagnosis, treatment, and prevention will be described here.

Introduction

T. marneffeii was first isolated in 1956 from the internal organs of bamboo rats (*Rhizomys sinensis*) in Vietnam (Capponi et al. 1956). The first natural human infection was reported in 1973 in an American missionary who had been living in Southeast Asia (DiSalvo et al. 1973). He suffered from non-Hodgkin lymphoma several years after returning to the USA and underwent splenectomy. *T. marneffeii* was isolated from his spleen. Before the HIV/AIDS epidemic, human TMI was uncommon and occurred mostly in immunocompromised patients. The incidence of TMI increases rapidly after HIV/AIDS epidemic hit Southeast Asia in late nineteenth century. The first case of TMI in HIV-infected patients was reported from Thailand in 1988. Since then, there were a number of cases among patients with advanced HIV infection, mostly from Southeast Asia. During 1990s, TMI ranked the third most common opportunistic infection in HIV-infected patients in northern Thailand, following tuberculosis and cryptococcal meningitis (Supparatpinyo et al. 1994). HIV-infected patients who had CD4 cell count < 100 cells/mm³ are at risk of developing TMI (Supparatpinyo et al. 1994). In the era of combination antiretroviral therapy (cART), the incidence of TMI is significantly declined except for those who are unaware of HIV status, unable to access to antiretroviral treatment, or who have suboptimal treatment responses.

Epidemiology

TMI is endemic in Southeast Asia, including but not limited to Thailand, Vietnam, Laos, Myanmar, and Malaysia; Southern China; Taiwan; Hong Kong; and India. The majority of cases were

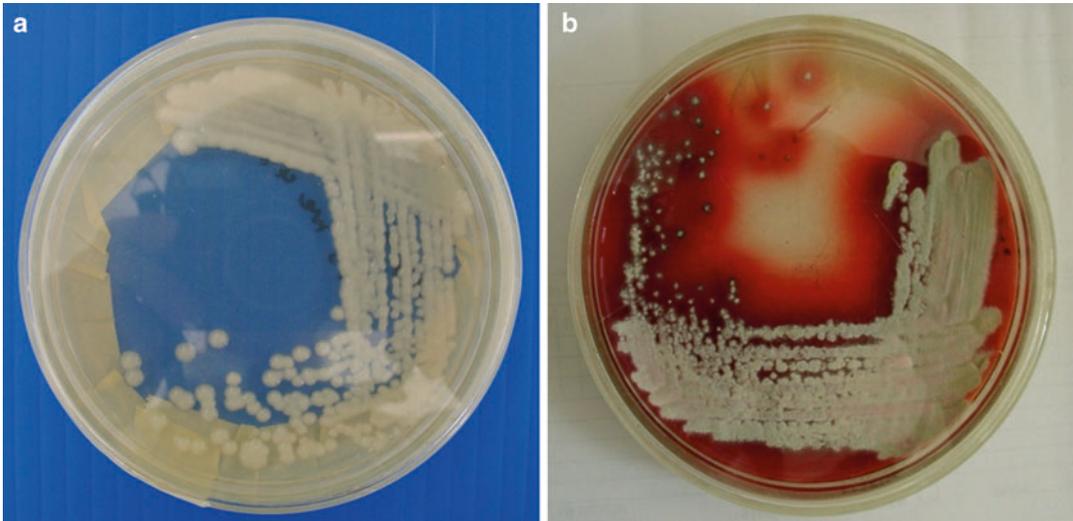

Talaromyces (Penicillium) marneffeii and HIV, Fig. 1 Epidemic curve of patients with *Talaromyces marneffeii* in Thailand and Vietnam

reported from northern Thailand and Vietnam (Supparatpinyo et al. 1994; Le et al. 2011). The increase of patients in these countries corresponds with the spread of HIV transmission into the areas. In northern Thailand, the greatest number of cases was reported during 1990s after the start of HIV/AIDS epidemic in 1984, whereas the number of cases in Vietnam reached its peak in 2007 after the start of HIV/AIDS epidemic in 1996 (Fig. 1) (Supparatpinyo et al. 1994; Le et al. 2011).

Bamboo rat is known to be the natural reservoir of *T. marneffeii* (Deng et al. 1986). A study done in bamboo rat (*Rhizopus* species) in Guangxi showed that *T. marneffeii* can be isolated from 91% of internal organs of *R. pruinosis* and *R. sinensis* (Deng et al. 1986; Li et al. 1989). In Thailand, the prevalence of *T. marneffeii* in internal organs of *R. sumatrensis*, *R. pruinosis*, and *Cannomys badius* were 93%, 75%, and 19%, respectively (Chariyalertsak et al. 1996a). Although *T. marneffeii* can be isolated from this animal, it is still unclear how these animals and humans acquire this fungus. It is believed that bamboo rat may shed

T. marneffeii into the soil and humans acquire the fungus from exposure to contaminated soil or aerosols. A case-control study in northern Thailand comparing 80 HIV-infected patients with TMI and 160 HIV-infected patients without TMI revealed that history of exposure to soil especially during rainy season, but not the exposure or consumption of bamboo rats, was a risk factor of TMI (Chariyalertsak et al. 1997). However, soil sampling from bamboo rat burrows were rarely positive for *T. marneffeii*. The hypothesis of airborne transmission from environmental source has been postulated from a report of undiagnosed HIV-positive physician who contracted *T. marneffeii* while visiting the laboratory culturing *T. marneffeii* on the open bench without direct exposure to the fungus (Hilmarsdottir et al. 1994). The seasonal increase in TMI in rainy season suggests an expansion of environmental reservoirs with favorable growth conditions for the fungus (Le et al. 2011; Chariyalertsak et al. 1996b). A study in Vietnam showed that the number of TMI cases was strongly associated with humidity (Bulterys et al. 2013). Another route of transmission

Talaromyces (*Penicillium*) *marneffe* and HIV, Fig. 2 Characteristics of yeast and mold forms of *Talaromyces marneffe* (a) Yeast colonies (b) Mold colonies

was direct inoculation of *T. marneffe* into the skin, which has been reported in the first human case of TMI, when Segretain accidentally pricked his finger with a needle contaminated with *T. marneffe* (Segretain 1959). The incubation period has not been well defined. A study in Vietnam using the model to estimate the incubation period from the time of exposure to the onset of symptoms estimated that the incubation period was 1 week (95% CI 0, 3 weeks) (Bulterys et al. 2013). However, there was a case report from Australia of an HIV-infected patient who had a 10-year period between probable exposure and clinical onset; this suggested the possibility of a long latency with subsequent reactivation (Jones and See 1992).

Mycology

T. marneffe was named in honor of Hubert Marneffe, the director of Pasteur Institute in Indochina, after its discovery in 1959 (Capponi et al. 1956). It is the only species in this genus that is categorized as dimorphic fungus. At the room temperature, it grows as a mold on Sabouraud dextrose agar, and grows as a yeast on brain-heart infusion (BHI) agar incubation at 37 °C. The analysis of complete genome demonstrates

that *T. marneffe* is closely related to molds than yeasts. The young colonies of *T. marneffe* mycelia have a flat green surface with underlying deep red coloring; aged colonies produce a soluble red pigment that diffuses into the agar. Microscopically, the mycelia show typical structures of *Talaromyces* species, including hyaline septate hyphae and fruiting structures composing of branching metulae and phialides which produce conidia in chains. The demonstration of mold to yeast conversion after incubating at 37 °C is required before concluding that the isolate is *T. marneffe*. The yeast colonies of white to tan color develop in a few days. The yeast cells are round to oval with a central septum (Segretain 1959). Figure 2 shows characteristic of colony of yeast and mold form of *T. marneffe*.

Pathology

Pathology of TMI depends on immune status of the hosts. In immunocompetent host, granulomatous and suppurative reactions are frequently seen (Supparatpinyo et al. 1994; Vanittanakom et al. 2006). The presence of epithelioid granuloma may lead to the diagnosis of tuberculosis which is also common in the same areas. In

immunocompromised host, necrotizing reactions with poor granuloma formation are commonly seen.

Clinical Manifestations

The majority of TMI developed in advanced HIV-infected patients. A study in northern Thailand showed that more than 90% of TMI occurred in patients with CD4+ cell counts of < 100 cells/mm³. Patients with TMI commonly present with systemic symptoms and signs including fever, weight loss, fatigue, and malaise. Skin lesions are present in 70–80% of patients. The lesions are mostly molluscum-like lesions distributing over face, neck, upper extremities, and upper trunk (Fig. 3). Some patients may also present with involvement of one or more organs, e.g., lung, liver, spleen, lymph nodes, bone marrow, and central nervous system. Clinical manifestations of TMI in three large cohorts from northern Thailand, India, and Vietnam are shown in Table 1. Comparing to HIV-uninfected patients, HIV-infected patients were more likely to have fever, umbilicated skin lesions, and splenomegaly (Kawila et al. 2013).

Immune reconstitution inflammatory syndrome (IRIS) after initiation of cART is of concern. Unmasking IRIS diagnosed within 1–3 months after cART initiation has been reported. The

Talaromyces (*Penicillium*) *marneffe*i and HIV, Fig. 3 Skin lesions in patients with *Talaromyces marneffe*i infection

symptoms are not severe in endemic area and mostly present with atypical skin lesions. Instead of umbilicated skin lesion, scaly lesion and erythematous papules and nodules, with or without central necrosis, have been reported (Ho et al. 2010; Saikia et al. 2010). Lymphadenopathy and massive hepatosplenomegaly have been reported in those from nonendemic area traveling to high-risk area (Hall et al. 2013). Up to present, paradoxical IRIS in patients with established TMI have not yet been reported after antiretroviral initiation.

Diagnosis

Definite diagnosis is usually made by isolation of the fungus from clinical specimens. Bone marrow culture gives the highest yield, approaching 100%, followed by skin, lymph nodes, and blood cultures (Table 2). HIV-infected patients were more likely to have fungemia than HIV-uninfected patients (Kawila et al. 2013). The median time to identify *T. marneffe*i from skin and blood cultures was 4 days (IQR 3–5 days) and 5 days (IQR 4–6 days), respectively (Le et al. 2011).

Histopathological diagnosis can also be made on tissue biopsy stained with periodic acid-Schiff (PAS) or Glomormimethenamine silver (GMS) stains. The characteristic yeast-like cells are 3–5 μm in size, round to oval shape, pleomorphic, and frequently contain clear central septum (Drouhet 1993). In contrast, *Histoplasma capsulatum* yeast-like cells are 2–5 μm in size, round to oval, monomorphic, and occasional budding. Granuloma formation may be absent due to poor immune responses.

Presumptive diagnosis could be rapidly made by microscopic examination of Wright-stained clinical specimens showing characteristic yeast-like cells similar to those in histological findings (Fig. 4). In patients with heavy infection, yeast-like cells may be found in peripheral blood smear.

Serological assays to detect antibodies specific to *T. marneffe*i have been studied, e.g., micro-immudiffusion technique using mycelial phase exoantigens, indirect fluorescent antibody test

using antigens from germinating conidia and yeast forms, immunoblot assay using 54- and 50-kDa protein antigens produced during the growth phase of the yeast and mycelial forms, and an enzyme-linked immunosorbent assay (ELISA)-based antibody test using a recombinant *T. marneffeii* mannoprotein (Mp1p). In addition, *T. marneffeii* antigen detections have been developed. Monoclonal antibody used to detect

Aspergillus fumigatus galactomannan was found to cross-react with *T. marneffeii* with lower titer of antigen detection. An enzyme immunoassay for quantifying *T. marneffeii* urinary antigen was developed using fluorescein isothiocyanate-labeled purified rabbit hyperimmune IgG. The diagnostic sensitivity and specificity were higher than 95%. The tests have potential role to monitor treatment response to antifungal therapy.

A monoclonal antibody-based sandwich ELISA was the other method developed for antigen detection in clinical specimens including urine samples. However, studies in larger number of patients are required before making a conclusion of the role of serologic testing (Vanittanakom et al. 2006).

Lastly, the PCR techniques for detection of *T. marneffeii* have been developed in clinical research. The utility in clinical practice needs further studies.

Treatment

In vitro study demonstrated that the MIC of *T. marneffeii* to azoles is low except for fluconazole (Supparatpinyo et al. 1993). The MIC for amphotericin B and flucytosine varied widely. A study in Thailand between 1990 and 1992 among 30 clinical isolates showed the lowest MIC to miconazole, followed by itraconazole (Table 3). The clinical responses were correlated with the in vitro study. However, clinical responses to amphotericin B, which had geometric mean MIC of 0.976, was 80% (Supparatpinyo et al. 1993). The different form of *T. marneffeii* may show different susceptibility to the same agent. In one study, yeast form was more sensitive to fluconazole and itraconazole than mold, while mold form displayed greater susceptibility to amphotericin B and 5-FC (Sekhon et al. 1993). A new azole, voriconazole, has also demonstrated a good activity against *T. marneffeii* in vitro, comparable to itraconazole (Radford et al. 1997). Echinocandins (micafungin and anidurafungin) also has in vitro activity against *T. marneffeii*, (Nakai et al. 2003; Odabasi et al. 2004) and mold form has lower MIC than yeast form (Nakai et al. 2003).

Amphotericin B with or without flucytosine has been used to treat TMI. However, prolonged treatment and high dosage of amphotericin B is associated with kidney injury, electrolyte imbalance, and infusion-related reactions.

The preferred regimen for TMI is amphotericin B 0.6 mg/kg/day intravenously for 2 weeks, followed by oral itraconazole 400 mg/day for 10 weeks (Sirisanthana et al. 1998). The study showed that 72 of 74 patients (97.3%) responded to treatment with negative blood culture at 12th week as well as resolution of fever and disappearance of skin lesions. Among 65 patients whose blood cultures were initially positive, all have cleared fungus from bloodstream at the 2nd week. Liposomal amphotericin B 3–5 mg/kg/day can be used when renal adverse effects are of concern. In patients with mild disease, oral itraconazole 400 mg/day for 8 weeks followed by 200 mg daily is recommended. Oral solution of itraconazole has better bioavailability than the

Talaromyces (Penicillium) marneffei and HIV, Table 3 In vitro susceptibility of *Talaromyces marneffei* isolates

Antifungal agents	Number of Isolates	MIC ($\mu\text{g/ml}$)	
		Geometric mean	Range
Miconazole	29	0.001	<0.002–0.156
Itraconazole	28	0.009	<0.002–0.19
Ketoconazole	29	0.027	<0.002–0.078
Fluconazole	30	7.937	0.313–20.0
Amphotericin B	29	0.976	0.25–4.0
5-Flucytosine	29	0.248	<0.015–0.46

capsule. Voriconazole 6 mg/kg intravenously every 12 h on day 1 and 4 mg/kg every 12 h for at least 3 days followed by oral voriconazole 200 mg twice daily for a maximum of 12 weeks can be used (Supparatpinyo and Schlamm 2007). Oral treatment with voriconazole from day 1 can be used in patients with mild disease.

Prevention

Prevention of exposure is difficult for people living in the endemic area. However, for those with advanced HIV infection living in nonendemic area, avoidance of travel to endemic areas is recommended. Primary prophylaxis for TMI in HIV-infected individuals with CD4+ cell count of <200 cells/mm³ has been studied in Thailand. Oral itraconazole 200 mg/day can prevent the occurrence of systemic fungal infections, i.e., cryptococcosis and TMI (Chariyalertsak et al. 2002). An observational study found that fluconazole 400 mg/week orally was also effective (Chaiwarith et al. 2011). Currently, primary prophylaxis is recommended for HIV-infected individuals who have CD4+ cell count of <100 cells/mm³ and live in endemic areas (Panel on Opportunistic Infections in HIV-Infected Adults and Adolescents 2013). In patients who are receiving cART and have gained the CD4+ cell count to >100 cells/mm³ for at least 6 months, discontinuation of primary prophylaxis may be considered (Chaiwarith et al. 2007). In HIV-infected patients with TMI who do not receive antiretroviral therapy, half of them may develop relapse within 6 months after discontinuation of successful antifungal treatment (Supparatpinyo et al. 1998).

A double-blind, placebo-controlled trial in Thailand demonstrated that oral itraconazole 200 mg daily reduced relapse rate of TMI from 57% to 0% (Supparatpinyo et al. 1998). Currently, all patients should receive secondary prophylaxis with oral itraconazole 200 mg daily. Again, once the patients receive cART and achieve CD4+ cell count of > 100 cells/mm³ for at least 6 months, secondary prophylaxis can be discontinued (Chaiwarith et al. 2007).

Consideration Regarding Antiretroviral Initiation

Currently, there is no strong evidence to recommend optimal timing to start antiretroviral therapy in HIV-infected patients presenting with TMI. However, as mentioned above, TMI occurring after cART initiation was more commonly an unmasking IRIS than a paradoxical IRIS. Therefore, initiation of cART should not be delayed due to a concern of IRIS. Particularly, in patients with CD4+ cell count of < 50 cells/mm³, cART should be started as soon as possible after initiation of antifungal therapy. For those who have CD4+ cell count of >50 cells/mm³, cART may be delayed until 2 weeks after treatment (Panel on Opportunistic Infections in HIV-Infected Adults and Adolescents 2013).

Prognosis

If left untreated, patients with TMI may have poor clinical outcome. In a study in Vietnam among 513 patients with TMI, the case fatality rate was

17% despite amphotericin B or itraconazole treatment (Le et al. 2011). Among 101 deaths, the median time from admission to death was 2 days (IQR 1–5 days). The prognostic factors for poor clinical outcome included intravenous drug users, shorter history of illness, absence of fever or skin lesions, and dyspnea. The presence of skin lesions was the only factor associated with prompt treatment initiation.

Conclusion

T. marneffeii infection is among the most common opportunistic infections in patients with advanced HIV disease. Although the incidence declined in the era of antiretroviral therapy, some HIV-infected individuals who are unaware of their HIV serostatus, unable to access to antiretroviral treatment, or who have suboptimal HIV treatment responses may suffer from *T. marneffeii* infection. Presumptive diagnosis can be easily made by microscopic examination of the clinical specimens. This disseminated infection has poor prognosis if left untreated. Physician awareness to prompt diagnosis and treatment can reduce morbidity and mortality from this infection.

University of California, San Francisco,
San Francisco, CA, USA

Definition

HIV-1 hijacks the cellular transcription machinery by expressing the virally encoded transactivator of transcription (Tat) protein. Tat is a 14- to 16-kDa nuclear/nucleolar protein that serves as an essential adaptor for cellular transcription elongation factors and other transcriptional regulators. This RNA-binding protein recognizes a stem-loop structure called transactivation response element (TAR) in the 5' extremity of initiating viral transcripts. The structural plasticity of Tat enables versatile interactions with host proteins, as well as host and viral RNAs, and forms the basis for Tat's critical role in HIV transcription and pathogenesis. No current drug treatment targets Tat, but recent progress in deciphering the structure and modification status of Tat provides novel impetus for drug development that may help tackle HIV infection and latency at the transcriptional level.

Tat Regulates Its Own Expression

When HIV integrates (► [Integration](#)) into the human genome, the proviral cDNA undergoes chromatinization and becomes subject to cellular RNA polymerase II-mediated transcription (► [Transcription \(Initiation, Regulation, Elongation\)](#)), like a human gene. However, basal HIV transcription is not consistently efficient, as the human RNA polymerase II (pol II) complex pauses shortly after the transcription start site and, in the absence of additional elongation signals, yields only so-called short transcripts that are insufficient to support viral replication (Kao et al. 1987). While human genes depend on activation or differentiation signals to recruit transcription elongation factors, HIV encodes its own specialized viral factor called Tat to overcome this block preventing viral transcript elongation. Tat binds avidly to a cellular protein complex, the positive transcription elongation factor b (P-TEFb) (P-TEFb (Cyclin T1, Cdk9), Cofactors and Transcription) – a factor first discovered to play a fundamental role in HIV transcription but now known to regulate a large number of human genes. P-TEFb, composed of cyclin T proteins (cyclin T1, T2A, and T2b with only cyclin T1 supporting Tat transactivation) and the cyclin-dependent kinase 9 (CDK9), promotes transcriptional elongation not only by enhancing the catalytic rate of the polymerase but also by dissociating negative elongation factors that are physically blocking processive transcription. In this way, Tat exploits this host elongation factor by recruiting it to the TAR element for robust stimulation of viral transcription and the completion of a productive viral replication cycle.

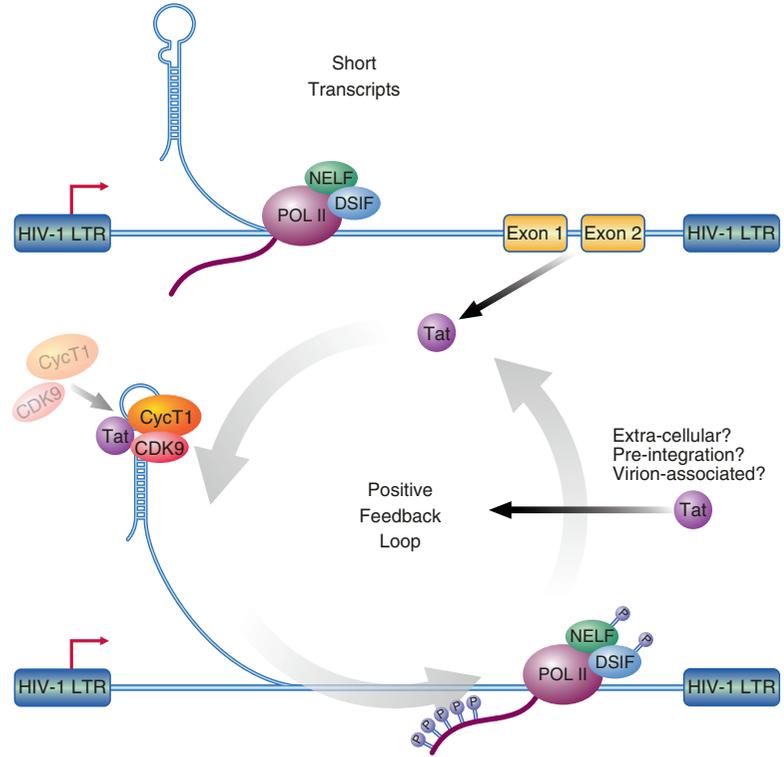

The two phases of HIV-1 transcription have distinct characteristics. The early, Tat-independent phase promotes low-level expression of viral gene products. It is driven by interactions of host transcription factors and *cis*-acting elements located within enhancer and promoter regions in 5' long-terminal repeat (LTR) sequences of the proviral DNA. For example, in the context of activated CD4+ T cells, the preferred target of HIV infection, the cellular transcription factor NF- κ B binds to tandem recognition sites within the HIV promoter

to induce expression of full-length HIV transcripts through Tat-independent recruitment of P-TEFb. However, as this recruitment is transient and less robust than with Tat, this first phase is characterized by a proportionally higher production of short or prematurely terminated transcripts that do not support HIV replication (Fig. 1).

The second Tat-dependent phase promotes high-level viral protein expression. It is driven by adequate levels of the Tat protein generated from full-length viral transcripts produced in the first phase. These transcripts undergo multiple splicing events before being exported to the cytoplasm to produce early viral gene products, such as the viral Nef and Rev (► [HIV-1 Rev Expression and Function](#)) proteins. Importantly, these transcripts also promote production of Tat, which jumpstarts full-length HIV transcript production and fuels persistent expression of Tat in a positive autoregulatory feedback loop (Fig. 1). As a result, the majority of full-length HIV RNA chain assembly, followed by successful viral replication, occurs in the presence of adequate Tat expression and activity. While Tat's role in transcription elongation is well established and the focus of intense studies in the HIV and transcription fields, additional studies point to potential functions of Tat in initiating HIV transcription by recruiting histone-modifying and chromatin-remodeling complexes (► [Histone Acetyl Transferase \(HAT\): CBP/p300, p/CAF, GCN5; and Histone Deacetylase \(HDAC\): YY1](#)) as well as the stimulation of transcription initiation in the absence of TATA-box-binding protein-associated factors (TAFs).

Most models attribute the early expression of Tat to full-length transcript production from integrated proviral DNA as described above, but alternative or complementary models exist. (1) Tat may be expressed before proviral integration from nonintegrated viral DNA, a common feature of HIV and other retroviruses. Tat transcripts have been detected as early as 1-h postinfection in the absence of integration; these may increase the initial pool of Tat proteins fueling early viral transcription. (2) Small amounts of Tat may be incorporated into viral particles and may jumpstart early viral transcription. Support for this model comes from observed defects of Tat-deficient

Tat Expression and Function, Fig. 1 Tat expression is fueled by a positive feedback loop

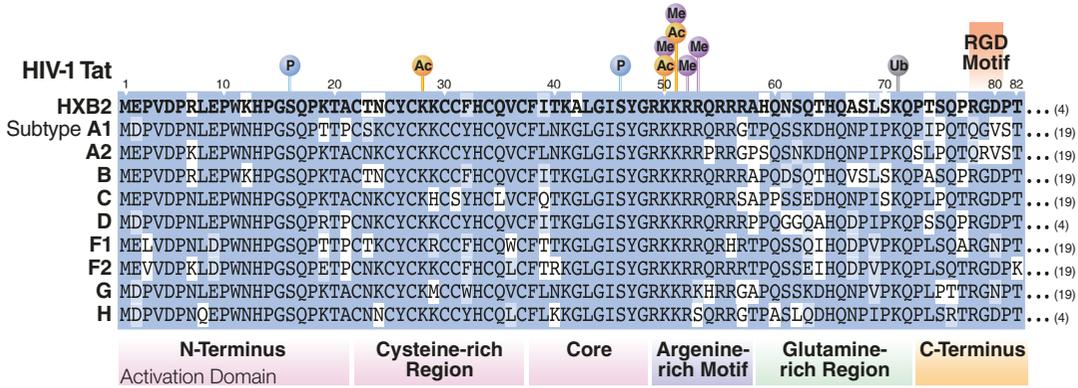

viruses in pre-transcription steps of the viral life cycle, such as reverse transcription (► [Reverse Transcription](#)). Moreover, Tat peptides have been detected by mass spectrometry in highly purified preparations of HIV-1 virions produced by macrophages. However, most studies fail to detect Tat in viral particles. (3) Tat may translocate from neighboring infected cells and activate HIV transcription. Tat contains a protein domain that allows cell membrane penetration, and release of biologically active forms of Tat by infected cells has been reported. While the release and uptake of extracellular Tat has been observed in vitro and may contribute to transcriptional and pathogenic effects of Tat, especially in sanctuaries such as the brain, the quantity and in vivo biological activity of extracellular Tat remain unclear.

Tat Is a Small Versatile Factor with Protein and RNA-Binding Properties

Tat is a small nuclear/nucleolar protein of 72–101 amino acids (aa) that displays a net positive

charge, low hydrophobicity, and low sequence complexity. In the early phases of transcription, a full-length protein (101 aa) is encoded by two *tat* exons and expressed from highly spliced HIV transcripts, whereas later in infection, an additional one-exon form (72 aa) is produced from unspliced transcripts because of a stop codon in the intron after the first *tat* exon. An 86-aa form of Tat is a variant found in the laboratory-adapted strain HXB2 and in subtype D and H Tatts (Fig. 2).

Traditionally, Tat is divided into six conserved regions, based on functional contributions and protein or RNA interactions (Fig. 2). The acidic and proline-rich N-terminus (aa 1–21) is required for LTR transactivation and binds the human transcriptional coactivator and acetyltransferase CREB-binding protein (CBP) (► [Histone Acetyltransferase \(HAT\): CBP/p300, p/CAF, GCN5](#)). The adjacent cysteine-rich region (aa 22–37) features seven clustered cysteine residues, all of which except Cys31 are essential for Tat's transcriptional activity, in a sequence reminiscent to zinc finger motifs common to many human transcription factors. The Tat core (aa 38–48) displays

Tat Expression and Function, Fig. 2 BLOSUM sequence alignment of consensus Tat sequences from HIV-1 group M subtypes A–H, as obtained from

<http://www.hiv.lanl.gov/>. The Tat sequence from the lab-adapted HXB2 isolate is also shown (UniProt ID: P04608)

high sequence conservation among subtypes (Fig. 2) and, with the N-terminus and cysteine-rich region, forms the so-called activation domain (AD, aa 1–48). The Tat AD provides the primary interaction surface for P-TEFb and is essential for the powerful transactivation of the HIV LTR by Tat. In a crystallographic structure of Tat/P-TEFb, the Tat AD extensively interacted with P-TEFb with Tat being almost completely buried into a cleft between the first and second cyclin boxes of cyclin T1 (Tahirov et al 2010). Cyclin T1 is in contact with 88% of the covered Tat surface area; Tat formed more hydrogen bonds with P-TEFb than it did with itself. In addition, the N-terminus of Tat contacted the so-called T loop in CDK9, a part of CDK9 critically regulating its enzymatic activity. These findings support a widely held view that Tat is intrinsically structurally disordered and requires host cofactors for proper folding.

Next to the Tat AD lies the arginine-rich motif (ARM) (aa 49–57), which has general RNA-binding properties and in cooperation with cyclin T1 makes specific contact with TAR RNA. TAR spans positions +1 through +59 of the 5' end of nascent viral transcripts and is thus transcribed irrespective of Tat. TAR spontaneously adopts a stem-loop structure and a three-nucleotide pyrimidine-rich bulge, a unique and invariable secondary structure. Both of these features provide recognition surfaces for the Tat ARM, and cyclin

T1 binds TAR only in complex with Tat. Tat:cyclin T1 binding to TAR is highly cooperative, suggesting that TAR functions to select Tat molecules in complex with P-TEFb. No crystal structure of the HIV Tat ARM in complex with TAR and P-TEFb has been solved so far, but a similar structure of the equine anemia infectious virus (EIAV) Tat protein shows that the retroviral ARM is helical and binds the major groove of the TAR stem-loop (Anand et al. 2008). The N- and C-terminal regions flanking the ARM interact with cyclin T1 to expose the helical ARM for TAR recognition, providing structural basis for cyclin T1 and Tat cooperativity in TAR binding. Importantly, the ARM also serves as a nuclear/nucleolar localization signal and harbors many of the known posttranslational modifications of Tat. Basic residues within the ARM are also essential for the ability of Tat to translocate across intact cell membranes.

The glutamine-rich region of Tat (aa 58–72) is implicated in altering cell fate by inducing T-cell apoptosis, without any specific role in transcription attributed to this region. Similarly, the Tat C-terminus (aa 72–101) has also been implicated in altering T-cell fate and activation. This region is entirely encoded by the second *tat* exon and is thus only present in the full-length form of Tat. Historically, due to extensive studies of the truncated, 86-aa laboratory-strain mutant of Tat, it is likely that the biological activity of the full-length Tat C-terminus is not fully appreciated. The

C-terminus in most strains contains a so-called RGD motif, which can bind surface integrins and, thus, in addition to the ARM, may play a role in the uptake of extracellular Tat.

How Does Tat Deliver Active P-TEFb to Nascent Viral Transcripts?

The tripartite interaction among Tat, P-TEFb, and TAR RNA is at the core of productive HIV transcription (Wei et al. 1998). It is within this trimolecular complex that Tat enacts its leading function – enabling robust elongation of viral transcripts. Owing to the fact that P-TEFb controls transcriptional elongation of many human genes, CDK9 catalytic activity within the cell is tightly regulated. P-TEFb occurs in HeLa cells in roughly equal parts as a small, active complex and as a large, inactive complex, in which CDK9 and cyclin T proteins are sequestered by the small nuclear (sn) RNA 7SK and several accessory proteins termed the 7SK snRNP, which include the CDK9 inhibitors Hexim 1 or Hexim 2, the La-related protein LARP7, and the methylphosphate-capping enzyme MEPCE. CDK9 within this complex is inactive but considered poised for rapid activity after the dissociation of the inhibitory factors. While this mechanism of P-TEFb regulation is well established in tumor cell lines, much less is known about the regulation of P-TEFb activity in non-transformed cells. In resting CD4⁺ T cells, cyclin T1 levels are low due to posttranscriptional regulation via microRNAs (Chiang et al. 2012).

It is mechanistically unclear how Tat delivers active P-TEFb to the site of TAR production. While active P-TEFb associates with the bromodomain-containing protein 4 (BRD4) to activate transcription elongation of cellular genes, BRD4 serves as a cellular competitor of Tat for P-TEFb binding. Tat might extract P-TEFb from its complex with BRD4 to deliver the cyclin T1/CDK9 core complex to the HIV promoter. However, structural similarities between the 7SK snRNP:P-TEFb and the Tat:TAR:P-TEFb complex provide alternative hypotheses. Indeed, a fraction of cellular Tat is found in complex with

7SK snRNA and several snRNP components except Hexim proteins (Sobhian et al. 2010), and the Tat ARM shares remarkable sequence similarity with the RNA-binding domain of Hexim. These findings support a model where Tat dismantles the 7SK snRNP through direct competition with Hexim1 for 7SK snRNA binding. A distinct model proposes that Tat competes with Hexim1 for cyclin T1 binding, as Tat and Hexim1 bind to the same region in cyclin T1 and Tat exerts higher affinity for this site *in vitro*.

Tat may employ one or more of these activation mechanisms with existing or newly forming P-TEFb complexes. Whether inactive P-TEFb complexes engage with chromatin and become locally activated during the transition to productive transcription remains open. Evidence exists that Tat targets the inactive P-TEFb relegated by the 7SK snRNP to the chromatinized provirus, suggesting that Tat liberates P-TEFb at the site of transcription. The synthesis of TAR has a critical role in the ejection of the 7SK snRNP once it is assembled at the viral promoter. In this model, the emergent TAR competitively displaces the 7SK snRNA and snRNP components, thus activating CDK9. The precise role of Tat in this process and the presence of TAR in short transcripts remain open questions. Tat function likely involves a combination of activation mechanisms to adapt HIV transcription to different cellular environments to ensure vigorous high-level HIV transcription.

Tat Binds Cellular Cofactors Other Than P-TEFb

While functional and structural data show that P-TEFb, in conjunction with TAR, is a crucial cofactor for Tat transactivation, several bioinformatic and experimental studies sought to determine the global catalog of human factors that interacts with Tat. Approaches include algorithms designed to extract information from existing literature, large-scale yeast two-hybrid screens, siRNA screens, and tandem affinity purification coupled to mass spectrometry. These studies confirmed reported interaction partners and

revealed novel Tat-interacting factors. The nearly 200 human Tat interaction partners include the ATP-dependent RNA helicase DDX5, the protein deacetylase SIRT1, the protein phosphatase 1G, and the E3 ubiquitin-protein ligase Praja2.

Proteomic approaches identified a novel transcription elongation complex with which Tat associates (He et al. 2010; Sobhian et al. 2010). This so-called super elongation complex (SEC) combines active P-TEFb with another elongation factor PAF1c and several proteins that are known as mixed lineage leukemia fusion partners, including ELL2, AFF4, ENL, and AF9. ELL2 enhances transcriptional elongation by increasing the catalytic rate and preventing the pause by pol II. Several studies reproducibly showed that Tat interacts with the SEC to deliver the elongation complex to the site of viral transcription. In this way, Tat allows for the cooperative activities of P-TEFb, PAF1c, and ELL2 to enhance HIV transcriptional elongation at multiple levels, including both the recruitment and activation of P-TEFb and the assembly and stability of the SEC.

Interestingly, Tat and P-TEFb both have functions beyond elongation and may regulate distinct phases of HIV transcription, such as transcript splicing. The HIV Tat-specific factor 1, necessary for efficient Tat-dependent transcription, was implicated in mRNA splicing through its

interaction with components of the spliceosomal machinery. Similarly, a distinct Tat interaction partner, CA150, affects transcriptional elongation and splicing. P-TEFb itself localizes to nuclear speckles where splicing occurs and interacts with the splicing factor c-Ski-interacting protein, an interaction important for Tat's transcriptional function. These findings and others suggest that Tat regulates HIV transcription at multiple levels.

Posttranslational Modifications Fine-Tune Tat Function

Tat may accommodate interactions with different cofactors in a timely manner through its repertoire of posttranslational modifications. The list of these modifications – clustered mainly in the Tat ARM – is growing (Table 1). Posttranslational modifications add new protein-protein interfaces to Tat and allow for tunable, highly regulated interactions with host cell factors. Certain modifications provide recognition surfaces for specific protein domains, such as bromodomains, which recognize and bind acetyl-lysine residues. Indeed, acetylation of Tat at Lys50 enables interaction of the Tat ARM with the bromodomain of the acetyltransferase PCAF (► [Histone Acetyltransferase \(HAT\): CBP/p300, p/CAF, GCN5](#)), thereby

Tat Expression and Function, Table 1 Tat posttranslational modifications

Modification	Tat residues modified	Enzyme(s) adding	Enzyme(s) removing	Function
Acetylation	K28	PCAF	HDAC6	Enhances interaction among Tat, P-TEFb, and TAR
Acetylation	K50, K51	GCN5, p300	SIRT1	Dissociates TAR from Tat and P-TEFb Generates interaction interface for PCAF bromodomain
Methylation	R52, R53	PRMT6	Unknown	Inhibits formation of Tat:TAR:P-TEFb complex Increases Tat half-life
Methylation	K50, K51	SETDB1	Unknown	Knockdown of SETDB1 enhances Tat-mediated transcription
Methylation	K51	Set7/9	LSD1	Enhances interaction among Tat, P-TEFb, and TAR
Phosphorylation	S62, S68 and T64	PKR	Unknown	Phosphorylation-deficient Tat triple-mutant reduces Tat-mediated transcription
Phosphorylation	S16, S46	Cdk2	Unknown	Phosphorylation-deficient Tat mutant reduces Tat-mediated transcription
Ubiquitination	K71	Hdm2	Unknown	Unclear; does not impact Tat half-life

recruiting the acetyltransferase activity to the site of viral transcription (Mujtaba et al. 2002). In contrast, certain Tat modifications negatively regulate protein-protein and protein-RNA interactions. For example, methylation of Arg52 and Arg53 within the Tat ARM by the protein methyltransferase 6 (PRMT6) interferes with Tat binding to both TAR and P-TEFb.

The functional relevance of some known Tat modifications is unclear. For example, Tat mutants deficient in phosphorylation sites display reduced transactivation capacity, although the mechanism through which phosphorylation enhances transactivation is unknown. Similarly, while Tat is ubiquitinated, and this modification has little effect on the half-life of Tat, the molecular mechanism of how this modification enhances Tat transcriptional activity is not understood.

Is Tat Involved in HIV-1 Latency?

A key role in understanding Tat's involvement in the establishment or maintenance of latency (► [Immunology of Latent HIV Infection](#)) is rooted within the feed-forward mechanism regulating Tat expression (Fig. 1). Viral latency is defined as a state of reversibly nonproductive infection often associated with a transcriptionally silenced integrated provirus in subsets of resting memory CD4⁺ T cells (► [Central Memory CD4⁺ T Cells](#)). These latent reservoirs are found in every infected individual and are widely recognized as premier barriers to eradicating HIV from patients. The persistence of infection requires lifelong treatment with antiretroviral therapy and is associated with shortened life span and numerous HIV-associated comorbidities. While the role of Tat in the establishment, maintenance, and reversal of HIV-1 latency remains under investigation, reports point to levels of Tat expression and activity as central contributors to latency.

In latent cells, HIV LTR activity is expected to be silenced – resulting in a lack of Tat production. Key transcription factors, such as NF-κB and NFAT, are sequestered in the cytoplasm in resting central memory T cells, a critical reservoir for latent HIV infection in patients, and are therefore

unavailable within the nucleus to activate viral transcription. In addition, levels of cyclin T1 are low in resting CD4⁺ T cells, preventing low levels of Tat from effectively transactivating HIV transcription.

Evidence that lack of functional Tat contributes to latency comes from in vitro experiments in which increased intracellular expression of Tat is sufficient to inhibit the establishment of latency and even reactivate most of the latent cell populations tested. Moreover, viruses that were recovered from nonproductively infected CD4⁺ T cells in patients are enriched for Tat variants with attenuated transactivation activity, suggesting that impaired Tat activity contributes to the establishment and/or maintenance of latency. Interestingly, small stochastic fluctuations in Tat gene expression are sufficient to drastically affect the Tat feedback loop and determine whether viral latency or productive infection ensues (Weinberger et al. 2005). Thus, similar to actively infected cells, Tat activity in latent cells auto-regulates its own production or, in this case, the lack of its production; this lack of production contributes critically to the robust silencing of HIV transcription in latency. The precise mechanisms of how Tat function is inactivated in latently infected cells and full-length transcript production is kept low are currently the subject of intense research.

Tat Is an Important Effector of HIV Pathogenesis

In addition to its role in regulating HIV-1 transcription and latency, numerous intracellular and extracellular activities have been attributed to Tat. They include modulating host immune responses, mediating survival and apoptotic processes (► [Lymphocyte Apoptosis](#)), and stimulating cellular growth/proliferation, ultimately ensuring viral persistence and effective viral spread (Table 2). Some of these effects are linked to Tat interaction partners, such as the (NAD⁺)-dependent deacetylase SIRT1. Tat binds avidly to SIRT1 and inhibits SIRT1's catalytic activity, thus preventing the timely deacetylation of

Tat Expression and Function, Table 2 Extra-transcriptional effects of intracellular and extracellular forms of Tat

Functions	Cell-type affected	Mechanisms	Contributions to pathogenesis
Immune activator	T-cells Dendritic cells Monocytes Microglia	Induces expression of pro-inflammatory cytokines: IL-1, IL-6, and TNF- α Increase CCR5, CXCR4, and CD40 expression Binds chemokine receptors: CXCR4, CCR2, and CCR3	Recruits and activates immune cells for propagation of infection
Immune suppressor	T-cells Monocytes	Reduces expression of MHC Class I molecules, IL-2, and NO Induces expression of IL-4 and IL-10 Degrades RON receptor tyrosine kinase	Promotes evasion of immune surveillance
Pro-apoptotic	T-cells Monocytes	Perturbs microtubule dynamics and promotes mitochondria-dependent apoptosis (i.e., Bim) Increases TRAIL, caspase-3, and caspase-8 activity Modulates Fas/FasL system Associates with PTEN and PP2A promoters	Increases susceptibility to infections by weakening immune system
Anti-apoptotic	T-cells Monocytes	Increases Bcl-2 expression Reduces expression of p53	Allows for viral replication Oncogenic
Neurotoxic	Neurons Microglia Astrocytes Endothelial	Alters neuronal calcium flux Activates excitatory amino acid receptors Effects inflammatory and oxidative processes Interferes with Nerve Growth Factor (NGF)	Promotes development of dementia
Growth factor	Kaposi's Sarcoma Endothelial	Stimulates growth of Kaposi's sarcoma cells Activates VEGFR-1, VEGFR-2, and integrins	Oncogenic Angiogenic
Gene regulator	T-cells Monocytes	Activates NF- κ B activity through ROS production, degradation of I κ B- α , interaction with p50-p65 heterodimers, and suppression of SIRT1 deacetylase activity Regulates mRNA capping and splicing Binds and inhibits Dicer function to suppress production of host siRNA	Promotes HIV-1 transcription Enhances pleiotropic cellular effects Subverts cellular defense

downstream SIRT1 targets, such as NF- κ B. As acetylated NF- κ B is transcriptionally more active, this effect of Tat causes increased NF- κ B transcriptional activity and elevated expression of immune activating cytokines that contribute to a state of generalized immune activation (► [Chronic Immune Activation](#)) observed in HIV infection. Increased immune activation is a hallmark of HIV infection directly linked to the progression to AIDS and the unrestricted spread of HIV infection.

Tat also associates with host gene promoters *in vivo*. A genome-wide chromatin immunoprecipitation approach identified ~450 cellular promoters that were occupied by Tat, including the promoters of the phosphatase PTEN and two subunits of the phosphatase PP2A (Kim et al. 2010). This study links Tat with the activation of

phosphoinositide 3-kinase-mediated apoptotic pathways in HIV-infected CD4⁺ T cells, a possible explanation of how Tat contributes to the depletion of CD4⁺ helper T cells (► [CD4+ T Cell Depletion](#)) in patients. Other research has demonstrated the ability of Tat to bind and inhibit the function of the host protein Dicer, an RNase III-like enzyme that processes microRNA (miRNA) and short interfering RNA (siRNA). Because RNA silencing may also serve as a defense mechanism against viral infection, Tat suppression of Dicer's ribonuclease-directed processing activity may allow HIV-1 to more effectively evade cell-based immunity.

The ability of Tat to translocate to neighboring cells theoretically amplifies its pathogenic effect and may be specifically relevant in distinct sanctuaries, such as the central nervous system (CNS).

Before crossing the plasma membrane and accessing the extracellular space, Tat is recruited and inserted into the membrane via its basic ARM in a phosphatidylinositol (4,5) biphosphate-dependent manner. Outside the cell, Tat functions as a promiscuous ligand that binds a number of chemokine and integrin surface receptors on a variety of cell types. The majority of these proposed Tat “receptors” (e.g., lipoprotein receptor-related protein, CXC chemokine receptor type 4 (► [CXCR4, Co-Receptors](#)), and heparin sulfate proteoglycans) are endocytic receptors that may internalize Tat upon binding. In addition, the Tat ARM functions as a protein transduction domain (PTD), a stretch of basic amino acids also found in antennapedia, a *Drosophila* homeodomain transcription factor, and VP22, a herpes simplex virus 1 structural protein, that may allow for spontaneous translocation of Tat across plasma membranes through direct electrostatic interactions with negatively charged phospholipids or through the formation of inverted micelles.

Therapeutic Strategies Surrounding Tat

Because Tat plays essential roles in HIV replication and pathogenesis as well as in protein transduction, it is not surprising that many therapeutic approaches (► [Therapeutic Clinical Trials, Introduction to Evidence and Research](#)) have focused on Tat. These include therapeutic attempts to disrupt Tat transcriptional activity and binding to TAR RNA, a Tat-based vaccine, and the use of Tat peptides as vehicles for cellular delivery of various macromolecules into cells.

A main focus of Tat-based therapy research is small molecules that target the crucial interaction between Tat and TAR RNA, with the promise to halt HIV replication at an early stage. One example is 7-chloro-5-(2-pyrryl)-3H-1,4-benzodiazepine-2(H)-one, which inhibits Tat-dependent transcription in a manner relying on TAR. This compound inhibits replication of HIV-1 and HIV-2. Despite the demonstrated promise for this molecule *in vitro*, a limited therapeutic window and observed toxicity of this drug were issues that preempted its further development. Other examples of

compounds that inhibit the Tat:TAR interface include quinoline derivatives, diphenylfuran derivatives, beta-carboline derivatives, and aminoglycoside-arginine conjugates.

Tat is also considered a promising candidate target for an anti-AIDS vaccine (► [Vaccine Induced Immune Responses; Preventing HIV-1 Transmission Through](#)). Tat is the most conserved HIV protein, thus limiting the risk for the development of resistance. In both primates and humans, cellular and humoral immune responses against Tat are rapid and positively correlated with slower progression to AIDS. Results from recent cross-sectional and longitudinal studies have demonstrated that a Tat vaccine based on the biologically active Tat protein alone is safe and may reduce HIV-1 replication and disease progression.

Since the discovery that the Tat ARM serves as a PTD, research into the use of short peptides mimicking Tat in the cellular uptake of various molecular cargo has dramatically expanded. A key property of these cell-penetrating peptides is that they are cationic and typically enriched in positively charged residues, such as lysines or arginines, as found in the Tat ARM. Peptide fragments encoding tyrosine 47 through arginine 57 of the Tat ARM have been used to transport DNA, proteins, and other materials through the cell membrane and into the cell nucleus. Prominent examples of Tat fusion peptides include a Tat-Bcl-xL fusion to inhibit apoptosis in ischemia, a Tat-p53 fusion to increase the tumor suppressive activity of p53 in tumor cells, and gp91dsTat, which blocks the assembly of the NAD(P)H oxidase complex to alleviate the increase in systolic blood pressure caused by angiotensin II injections. Although the use of Tat peptides holds great promise for gene transfer and drug delivery, current use is limited by a lack of tissue specificity and an incomplete understanding of uptake modes.

Conclusion

Research into Tat biology has been successful in providing an increasing molecular understanding of HIV transcription and latency. Studies of Tat

have fueled important biological discoveries, such as the central role of P-TEFb in transcriptional regulation and the design and usage of Tat-adapted PTDs for the transport of molecular cargo into cells. The “pathogenic” functions of Tat (i.e., in modulating immune activation and cell survival of infected and neighboring cells) have gained molecular shape in part by identifying novel Tat interaction partners. The urgency in better understanding and eliminating viral latency has refocused the field on possible therapeutic interventions targeting HIV transcription. Future pursuits will inevitably need to acknowledge the prominent role of Tat as a central regulator of HIV transcription and address the powerful auto-regulatory feedback loop through which Tat regulates its expression.

T-Cell Homeostasis

Julia Drylewicz, Kiki Tesselaar and José A. M. Borghans
Laboratory of Translational Immunology,
Department of Immunology, University Medical
Center Utrecht, Utrecht, The Netherlands

Definition

During healthy aging, CD4⁺ and CD8⁺ T-cell numbers remain relatively stable, despite a significant decline in thymus output. This T-cell homeostasis is dramatically disturbed during HIV infection, during which naive and memory CD4⁺ and naive CD8⁺ T-cell numbers gradually decline, eventually leading to increased susceptibility to opportunistic infections. In contrast, memory CD8⁺ T-cell numbers are significantly increased in HIV infection. Although the causes of disturbed lymphocyte homeostasis in HIV infection have been subject of much debate, there is a current consensus that the deleterious effects of chronic immune activation play a central role.

During effective combination antiretroviral therapy (cART), CD4⁺ T-cell numbers tend to come back to healthy control levels, albeit very slowly, while memory CD8⁺ T-cell numbers tend to remain elevated for long periods of time. It remains unclear whether active homeostatic mechanisms kick in to reestablish lymphocyte homeostasis or whether the slow reconstitution of the T-cell pools reflects the rate at which lymphocytes are being generated under healthy circumstances.

Pathogenesis

CD4⁺ T-Cell Loss

Acute HIV-1 infection is characterized by a peak of viral load and high levels of immune activation. During this phase, the major part of the memory CD4⁺ T-cell pool in the gut is irreversibly lost (Clayton and Clayton 1997). During the following, chronic stage of infection, CD4⁺ T-cell numbers in the blood gradually decline; both naive and memory CD4⁺ T cells are lost (McCune 2001), while the viral load remains relatively stable. There has been much debate about the exact mechanisms underlying this depletion; factors that have been suggested to be involved vary from direct HIV-induced cytopathicity to immune senescence, thymic impairment, and the deleterious effects of chronic immune activation.

Loss of Virally Infected Cells

In vitro studies in which CD4⁺ T cells were infected in culture with HIV have shown that HIV can directly kill infected cells by inducing apoptosis (Meyaard et al. 1992). As the fraction of productively infected CD4⁺ T cells at any moment in time is low [in the order of 10⁸ out of a total pool of 10¹² CD4⁺ T cells (Clark et al. 1999)], it has been questioned whether HIV-induced cytopathicity by itself could explain the CD4⁺ T-cell loss occurring during HIV infection. In line with this, several studies have shown that the level of in vitro cytopathicity of HIV does not correlate with CD4⁺ T-cell depletion: no difference in CD4⁺ T-cell loss was found between humanized SCID mice infected with non-cytopathic or cytopathic HIV isolates (Mosier et al. 1993), and Simian Immunodeficiency Virus (SIV) isolates that are equally cytopathic to rhesus macaque and sooty mangabey cells in vitro cause CD4⁺ T-cell loss and progression to AIDS in rhesus macaques, while CD4⁺ T-cell numbers in sooty mangabeys are not affected (Silvestri et al. 2003). The CD4⁺ T-cell loss that is characteristic for HIV infection can thus not be explained by the cytopathic effects of productive HIV infection.

Indeed, the number of infected cells in HIV-infected individuals is much smaller than

the number of apoptotic cells, and in fact only a small proportion of productively HIV-infected cells undergo apoptosis (Finkel et al. 1995). T-cell apoptosis in HIV infection is not even restricted to CD4⁺ T cells as the majority of apoptotic T cells express CD8 (Meyaard et al. 1992). The majority of T cells that are lost in HIV infection are thus “bystander” cells, which are not productively infected with HIV themselves. Instead these cells are thought to die as a result of chronic immune activation (see below), or because their refractoriness to HIV infection, leading to the accumulation of incomplete DNA transcripts, triggers an inflammatory form of programmed cell death called pyroptosis (Cooper et al. 2013; Doitsh et al. 2014).

Thymic Involvement: Is There a Lack of CD4⁺ T-Cell Production?

It has been proposed that the gradual loss of CD4⁺ T cells in HIV-infected individuals may not only be due to increased cell death but also to decreased production of new CD4⁺ T cells by the thymus. Experiments in humanized SCID mice (Bonyhadi et al. 1993) and thymic tissue from HIV-1 infected neonates (Rosenzweig et al. 1993) have shown that HIV can infect thymocytes, leading to decreased CD4:CD8 thymocyte ratios, and thymic biopsies from individuals who died of AIDS show signs of severe thymocyte loss (Haynes et al. 1999). It remains unclear, however, to what extent HIV infection of the thymus contributes to the gradual loss of CD4⁺ T cells during asymptomatic infection, especially in adults.

In HIV-infected human adults, T-cell receptor excision circles (TRECs) have been measured to study the in vivo effects of HIV on thymic output (Douek et al. 1998). TRECs are formed through the deletion of the TCR-D locus during gene rearrangement of the TCR α -chain and are not copied during cell division. Therefore, they are produced only upon de novo T-cell formation in the thymus. In HIV-1 infected individuals, the average number of TRECs per T cell (referred to as the average “TREC content”) of naive CD4⁺ and CD8⁺ T cells is significantly lower than in age-matched healthy controls, suggestive of reduced thymic output in HIV-1 infection

(Douek et al. 1998). However, mathematical modeling pointed out that the decreased average TREC content of the naive T-cell population in HIV-infected individuals is much more likely due to the increased rates of T-cell division that are typically observed in HIV-infected individuals than to changes in thymic output (Hazenberg et al. 2000a). In asymptomatic HIV-infected adults, there is thus no evidence that thymic output is reduced.

In the light of the well-known process of thymic involution during aging, one may even wonder how much effect thymic impairment could have on lymphocyte homeostasis in human adults. The contribution of thymic output to the maintenance of the peripheral T-cell pool is a topic of much debate. Recent studies in healthy adults have pointed out that the contribution of thymic output to peripheral naive T-cell maintenance is small (Braber et al. 2012): while an estimated 10% of newly generated naive T cells in adults is generated by the thymus, the other 90% are produced by peripheral naive T-cell division. This suggests that even total abrogation of thymic function by HIV would not lead to significant changes in peripheral T-cell numbers in adults. In fact even in children, in whom thymic function is optimal, peripheral T-cell division contributes significantly to peripheral T-cell homeostasis (Hazenberg et al. 2004). Despite the numerous analogies between the mouse and human immune system, the central contribution of the thymus to the maintenance of the peripheral naive T-cell pool is thus quite specific for mice, and its role in human lymphocyte homeostasis tends to be exaggerated (Braber et al. 2012).

Increased T-Cell Turnover

Quantification of T-cell turnover using deuterium or BrdU labeling has revealed that the rate at which T cells are produced in HIV infection and in SIV-infected macaques by far exceeds that in healthy controls (Mohri et al. 2001; de Boer et al. 2003). The observed negative correlation between CD4⁺ T-cell numbers and their rate of production has raised the idea that the increased CD4⁺ T-cell turnover represents a homeostatic response to the gradual loss of CD4⁺ T cells, leading to

accelerated aging and exhaustion of the regenerative capacity of the immune system, eventually resulting in severe CD4⁺ T-cell depletion (Ho et al. 1995). A proposed mechanism of immune senescence would be telomere erosion through extensive T-cell proliferation. Telomeres – the unique structures at the end of chromosomes consisting of tandem DNA repeats – are known to shorten upon cell division and thereby provide a record of the replicative history of cells. Rather remarkably, in HIV infection CD8⁺ but not CD4⁺ T-cell telomere lengths are reduced, suggesting that – if anything – the CD8⁺ and not the CD4⁺ T-cell pool becomes exhausted (Wolthers et al. 1996).

Increased rates of T-cell production have long been thought to contribute to T-cell homeostasis and to help sustain clinical latency in HIV-infected individuals. Studies in humans and monkeys strongly suggest, however, that increased T-cell proliferation in HIV infection does not reflect a homeostatic response to the loss of CD4⁺ T cells. It turned out that division of CD4⁺ T cells in HIV-infected patients declines dramatically and rapidly after the start of combination antiretroviral therapy (cART), long before CD4⁺ T-cell counts in the blood have normalized (Hazenberg et al. 2000b). The majority of T cells proliferating in untreated HIV infection thus seem to respond to the virus, which decreases rapidly upon the start of cART, rather than to the lack of CD4⁺ T cells (Lempicki et al. 2000).

These findings have put the correlation between low CD4⁺ T-cell numbers and high levels of T-cell proliferation in a different light and have suggested that high levels of immune activation and the resulting T-cell proliferation may even contribute to CD4⁺ T-cell depletion. Indeed, immune activation turned out to be one of the strongest prognostic markers for HIV disease progression, even stronger than, and independent of, HIV viral load (Giorgi et al. 1999; Hazenberg et al. 2003). Interestingly, even levels of immune activation *before* seroconversion are predictive for disease progression. In a study among homosexual men, low CD4⁺ T-cell counts and high CD70 expression by CD4⁺ T cells before HIV seroconversion were associated with fast disease

progression upon HIV infection (Hazenberg et al. 2003). Taken together, these studies have emphasized the deleterious effects of chronic immune activation and the resulting high levels of T-cell proliferation in HIV infection.

Lessons from Nonhuman Primates

Studies in nonhuman primates have further substantiated the central role of immune activation in HIV pathogenesis and have shown that in the absence of chronic immune activation, irrespective of viral load, HIV infection does not lead to AIDS. In SIV-infected sooty mangabeys, who remain healthy despite high SIV load, T-cell turnover rates are normal (Chakrabarti et al. 2000), while in pathogenic SIV infection in rhesus macaques, high levels of immune activation are associated with progression to AIDS. Absence of disease progression in sooty mangabeys cannot be explained by low viral loads, strong cytotoxic T-cell or neutralizing antibody responses, or reduced cytopathicity of SIV for sooty mangabey CD4⁺ T cells, while in rhesus macaques, progressive CD4⁺ T-cell decline and AIDS develop despite strong and ongoing immune responses to SIV (Silvestri et al. 2003). Since the dynamics of virus and virus-infected CD4⁺ T cells in these animal models of SIV infection are also comparable, excessive indirect activation-induced bystander killing of T cells in rhesus macaques seems to be the major pathological difference (Rey-Cuille et al. 1998; Chakrabarti et al. 2000; Silvestri et al. 2003). Viral replication is thus required in HIV pathogenesis but is insufficient to cause disease. It is the immune activation that is induced by the virus that is driving the eventual CD4⁺ T-cell loss and disease progression.

The Cycle Between T-Cell Activation and Death

The major cause of chronic immune activation in HIV-1 infection is currently topic of intense investigation (Miedema et al. 2013). Levels of bacterial products such as LPS in the circulation appear to be increased in HIV-infected individuals, as a consequence of the rapid and drastic loss of CD4⁺ T cells from the gut, leading to translocation of bacterial products and thereby to chronic

activation of the immune system (Brenchley et al. 2006). HIV has also been shown to trigger immune cells more directly, through activation of the innate immune system via Toll-like receptors (TLR) 7 and 8, which recognize single-stranded HIV RNA (Meier et al. 2007). The consequence of this chronic immune activation may in part be the natural process of apoptosis of activated T cells. Indeed, some situations of chronic immune activation independent of HIV infection show that chronic immune activation by itself can induce T-cell loss. In transgenic mice that constitutively express CD70 on the cell surface of B lymphocytes, antigen-activated T cells are continuously co-stimulated via interaction with CD27 on the T-cell surface. Such mice develop a phenotype reminiscent of HIV infection, in that their peripheral T-cell pool becomes progressively depleted, eventually leading to death by opportunistic infections (Tesselaar et al. 2003). Similarly, in healthy Ethiopians increased levels of immune activation, probably caused by common parasitic infections, are related to low CD4⁺ T-cell counts, low percentages of CD4⁺ and CD8⁺ naive T cells, and decreased TREC contents, all characteristics reminiscent of HIV infection. More recently, it has been shown that abortive HIV infection of CD4⁺ T cells can lead to caspase-1 mediated pyroptosis, an inflammatory form of programmed cell death (Doitsh et al. 2014). Since pyroptotic cell death leads to the release of cytoplasmic contents and pro-inflammatory cytokines, this may drive a vicious circle between cell death and immune activation.

CD8⁺ T-Cell Changes

The effects of HIV on immune homeostasis are not confined to CD4⁺ T cells. In fact also the CD8⁺ T-cell pool undergoes major changes in HIV infection. CD8⁺ T cells typically show increased levels of activation, proliferation, and cell death, just like CD4⁺ T cells, but their numbers are typically markedly increased in HIV-infected individuals. Moreover, telomere shortening and TREC dilution are more pronounced in CD8⁺ T cells than in CD4⁺ T cells. In response to HIV infection, there is a massive peripheral expansion of the effector/memory CD8⁺ T-cell pool, while

naive CD8⁺ T cells start to decline shortly after infection (Roederer et al. 1995). The effector/memory CD8 subset only begins to decline at the AIDS stage (Margolick et al. 1995). The fact that telomeres of CD8⁺ T cells are shortened in HIV infection, while those of CD4⁺ T cells are not, suggests that in contrast to CD4⁺ T cells, CD8⁺ T cells that have divided tend to survive and thereby cause the increased CD8⁺ T-cell numbers that are typical for HIV-infected individuals.

Immune Reconstitution During cART

Although there is little evidence that active homeostatic mechanisms are called into action during untreated HIV infection, cell numbers tend to normalize on effective treatment, albeit very slowly. The reconstitution of the CD4⁺ T-cell population can be divided into two phases. During the first 2–3 months following therapy initiation, the number of CD4⁺ T cells in the blood increases rapidly due to redistribution of memory T cells from the tissues and the lymph nodes to the blood (Pakker et al. 1998). The second phase of reconstitution takes much longer and involves the renewal of the naive T-cell pool. CD4⁺ T-cell numbers typically steadily increase during cART (Hunt et al. 2003a), and under sustained viral suppression and if CD4⁺ T-cell numbers at the start of therapy are not too low, the immune system has the potential to fully recover the CD4⁺ T-cell pool without any signs of accelerated immunological aging within 7 years of cART (Vrisekoop et al. 2008).

On the basis of experiments in mice, it is generally assumed that homeostatic mechanisms are called into action when the lymphocyte pool becomes severely depleted, thereby helping to reestablish lymphocyte homeostasis. Although T-cell proliferation levels clearly decline after initiation of cART, they generally remain higher than in healthy age-matched controls and could in principle reflect homeostatically increased levels of T-cell proliferation due to a long-term lack of CD4⁺ T cells. Increased T-cell proliferation levels during cART are, however, generally related to residual immune activation, which itself is

associated with poor immune reconstitution on cART (Hunt et al. 2003b), again confirming the central deleterious role of immune activation in HIV infection. Alternatively, recovery of thymic output during cART may contribute to the recovery of the CD4⁺ T-cell pool, especially in children. Indeed, thymic tissue in HIV-infected children has been shown to increase with time on cART, eventually reaching levels comparable to age-matched healthy controls (Sandgaard et al. 2014). In HIV-infected adults, thymic size, as measured by chest computed tomography (CT) scans, was found to correlate with CD4⁺ T-cell reconstitution on cART (Teixeira et al. 2001). There is discussion whether thymic output could even reach supranormal levels in lymphopenic circumstances to compensate for the lack of peripheral T cells, a phenomenon known as thymic rebound. Although average naive TREC contents in lymphopenic patients can indeed reach supranormal levels (Douek et al. 2000), it is important to realize that a handful of TREC⁺ T cells that migrate from the thymus into a virtually empty peripheral T-cell pool are expected to cause a rapid increase in the average TREC content of the peripheral naive T-cell pool which may reach supranormal levels even in the absence of thymic rebound (Hazenberg et al. 2002). Although T-cell homeostasis is thus generally reestablished after years of effective cART, up till now there is no evidence that this is due to active homeostatic mechanisms that are called into action to increase the generation of naive or memory T cells.

Conclusion

During HIV infection, T-cell homeostasis of both CD4⁺ and CD8⁺ T cells is dramatically disturbed. Although the cause of the CD4⁺ T-cell loss is not fully understood, it is clear that chronic immune activation plays a central role. Both direct activation of the innate immune system by HIV and bacterial translocation due to the severe loss of CD4⁺ T cells from the gut are thought to be important drivers of immune activation in HIV infection. Death of abortively HIV-infected cells is thought to add to the increased levels of

immune activation, through release of cytoplasmic products and inflammatory signals thereby creating a vicious cycle between chronic activation and cell death. During effective long-term cART, T-cell homeostasis is reestablished, albeit very slowly. It remains unclear whether this normalization reflects the normal slow production of T cells under healthy circumstances or whether the body manages to compensate for the loss of CD4⁺ T cells through increased T-cell production.

Th17 Cells

Colleen S. McGary and Mirko Paiardini
Division of Microbiology and Immunology,
Yerkes National Primate Research Center,
Atlanta, GA, USA

Definition

Th17 cells are a distinct functional CD4+ T cell subset, characterized by their expression of the master transcription factor ROR γ t and secretion of interleukin-17 (IL-17). These cells are found predominantly in the gastrointestinal tract (GI tract) and act there to protect the host against extracellular bacteria and fungi. Th17 cells further contribute to mucosal immunity by promoting the regeneration of gut epithelial cells, the maintenance of tight junctions, and the production of antimicrobial peptides. Th17 cells have also been implicated in driving inflammation during certain autoimmune conditions.

Introduction of CD4+ T Cell Subsets

Naïve CD4+ T cells, upon TCR stimulation and costimulation by antigen-presenting cells (APCs), differentiate into distinct CD4+ helper T cell subsets, characterized by their unique cytokine profiles, transcription factors, and different effector functions. The original paradigm for CD4+ T cell differentiation identified two polarized subsets in both mice and humans: Type 1(Th1) and Type 2(Th2) cells. Th1 cells express the transcription factor T-bet, produce IFN- γ , and are primarily devoted to protection against intracellular pathogens. Th2 cells, which express the transcription factor GATA-3, secrete IL-4, -5, -9, and -13,

and are involved in host protection against parasitic helminthes, but can also be involved in allergic disorders (Abbas et al. 1996; Romagnani 1997). However, this paradigm shifted upon the discovery of additional Th subsets that were able to produce other cytokines and possessed functions distinct from Th1 and Th2 cells.

Th17 cells, a third subset of effector Th cells, were first identified through mouse models of autoimmunity. Originally, self-reactive Th1 responses were proposed to drive disease development in two autoimmune mouse models, experimental autoimmune encephalomyelitis (EAE) and collagen-induced arthritis (CIA), based on the absence of disease development upon neutralizing IL-12p40, a cytokine critical for driving Th1 polarization (Gately et al. 1998). However, following the later discovery that the cytokine IL-23 shares the p40 subunit with IL-12, it was revealed that the development of EAE and CIA was dependent on IL-23, a cytokine that expands IL-17-producing T cells (Cua et al. 2003). Since then, the potent inflammatory properties of Th17 cells have been shown to play a critical role not only in autoimmune pathology but also in antibacterial immunity.

Th17 Phenotype and Function

Th17 cells are a subset of memory CD4⁺ T cells that are enriched in mucosal tissues and preferentially produce IL-17, in addition to IL-21, IL-22, TNF- α , and IL-2. The differentiation of Th17 cells, in humans, requires a combination of cytokines, including IL-6, transforming growth factor- β (TGF- β), IL-21 and IL-1 β , and later IL-23 for their expansion and survival (Paiardini 2010). Their differentiation is further regulated by the expression of the master transcription factor retinoic acid-related orphan receptor (ROR) γ t. In fact, overexpression of RORc, the gene which encodes ROR γ t, in human naïve T cells induces IL-17A and IL-17F production, while concurrently decreasing production of IFN- γ . Phenotypically, Th17 cells are characterized by a myriad of surface markers, none of which exclusively define this effector Th subset alone. Human Th17 cells

express the IL-23 receptor (IL-23R); the chemokine receptors CCR6, CCR4, and CCR2; and the C-type lectin receptor CD161. The enrichment of these chemokine receptors directs the preferential migration of Th17 cells to mucosal tissues, which express chemokines including CCL20 (the ligand for CCR6) during periods of chronic inflammation. Additionally, human Th17 cells have been found to originate from a small population of naïve CD4⁺ CD161⁺ T cells found in the umbilical cord blood and thymus and retain the expression of CD161 upon Th17 lineage commitment (Annunziato et al. 2012).

Th17 cells secrete IL-17, which plays a critical role in the clearance of extracellular bacteria and fungi. IL-17 induces the expression of cytokines (IL-6, GM-CSF, TNF- α), chemokines (CXCL1, CXCL8, CXCL10), and metalloproteinases from epithelial and endothelial cells, which coordinate the recruitment, activation, and migration of neutrophils (Korn et al. 2009). In addition to IL-17, Th17 cells produce several other proinflammatory cytokines, including IL-21, IL-22, TNF- α , and IL-2 (Klatt and Brenchley 2010). IL-21 acts on Th17 cells in an autocrine fashion to amplify Th17 responses, regulates long-term maintenance of functional CD8⁺ T cells, and stimulates the generation of memory B cells and antibody-producing plasma cells. IL-22 is able to drive the production of antimicrobial peptides, such as β -defensins, further supporting the role of this effector cell subset in host defense (Liang et al. 2006). To complement their role in host protection against infections, Th17 cells are also critical in the maintenance of mucosal structural integrity. IL-17 and IL-22 contribute to the integrity of the intestinal barrier by promoting enterocyte proliferation (Kim et al. 2012), inducing the expression of claudins (critical in the formation of intestinal tight junctions) (Kinugasa et al. 2000), and stimulating mucin expression (Sugimoto et al. 2008). These protective roles of Th17 cells have been demonstrated in vivo in several infection models, wherein the absence of IL-17 and other Th17 family cytokines is associated with increased susceptibility to disease and bacterial/fungal burden (Korn et al. 2009). Many of these bacterial species represent those responsible for opportunistic

infections in the setting of HIV/AIDS. However, Th17 cells are not specific for viruses, including HIV, CMV, or influenza, as evidenced by a lack of IL-17 production following stimulation of CD4⁺ T cells with viral antigens (Brenchley et al. 2008).

Role of Th17 Cells in Pathogenic SIV/HIV Infection

HIV and SIV infections are characterized by massive dysregulation of the host immune system. During the acute phase of infection, there is massive depletion of mucosal CD4⁺ T cells. The majority of CD4⁺ T cells infiltrating the mucosa are memory CD4⁺ T cells that express the primary coreceptor for HIV/SIV, CCR5, thus making them preferential targets for viral replication and depletion. It is well established that this robust depletion of mucosal CD4⁺ T cells results in structural and immunological damages of the mucosa. As a result, microbial translocation from the gut into the peripheral blood occurs, which is associated not only with HIV disease progression but also with chronic immune activation (Brenchley et al. 2006). Yet, the loss of mucosal CD4⁺ T cells alone cannot explain these pathogenic phenomena, since SIV natural hosts, such as sooty mangabeys (SMs) and African green monkeys (AGMs), do not progress to AIDS despite a significant depletion of CD4⁺ T cells from mucosal sites (Gordon et al. 2007; Pandrea et al. 2007). Consequently, the regulation of specific CD4⁺ T cell subsets was compared between pathogenic and nonpathogenic SIV/HIV infections to best understand the events responsible for disease progression and chronic immune activation. One critical manifestation of the mucosal disruption that occurred was the preferential loss of Th17 cells during pathogenic SIV and HIV infections.

While an initial description of Th17 cell dynamics during HIV infection found a significant increase in the blood of HIV-infected individuals compared to uninfected, additional studies have generated conflicting results, demonstrating both a maintenance as well as a depletion of Th17 cells from the peripheral blood after infection (Maek-A-Nantawat et al. 2007; Macal et al. 2008; Favre

et al. 2010). However, Th17 cells are enriched in the gastrointestinal tract (GI) compared to the blood, and therefore, subsequent efforts focused on evaluating their maintenance in the mucosa following infection. Th17 cells were found to be depleted throughout the entire GI tract of HIV-infected patients. This Th17 cell loss is specific to mucosal tissues and is not seen in the blood or bronchoalveolar lavage (BAL) of HIV-infected individuals (Brenchley et al. 2008). Consistent with these findings, additional studies have demonstrated that both IL-21-producing and IL-22-producing CD4⁺ T cells are lost from the mucosa during pathogenic SIV infection of RMs (Klatt et al. 2012; Micci et al. 2012). The loss of IL-17-producing lymphocytes is associated with epithelial damage of the colon, suggesting that a preferential loss of Th17 cells likely contributes to microbial translocation in the setting of HIV infection. Moreover, in addition to a loss in Th17 cell number during HIV infection, recent work has demonstrated that mucosal Th17 cells are dramatically less functional in their ability to co-secrete IL-22, IFN- γ , and TNF- α from the earliest stages of HIV infection (Kim et al. 2013).

The mechanisms responsible for the loss of Th17 cells during pathogenic SIV and HIV infections have been extensively explored. Th17 cells express the HIV/SIV coreceptor, CCR5, although its expression appears to be tissue-specific. Blood Th17 cells express low levels of CCR5, while Th17 cells in the mucosa are predominantly CCR5-positive, thus making them highly susceptible targets of HIV/SIV infection (Brenchley et al. 2008). However, despite low CCR5 levels, *in vitro* studies have found that Th17 cells from peripheral blood are highly permissive to HIV infection, compared to Th1 cells, although these findings have been difficult to recapitulate *in vivo* (El Hed et al. 2010; Gosselin et al. 2010; Alvarez et al. 2013). Nevertheless, it is less certain whether this increased susceptibility *in vitro* reflects the mechanism by which mucosal Th17 cells are depleted. For example, no correlation was found between levels of plasma viral load and the frequencies of IL-17-producing lymphocytes in the mucosa of SIV-infected RMs, which suggests that viral replication alone is unlikely to be responsible

for the preferential depletion of Th17 cells from the GI tract (Klatt et al. 2012). Investigations of a potential impact of HIV infection on the proliferative capacity of Th17 cells similarly revealed no differences from Th1 cells, illustrating that Th17 cells are not more susceptible to activation-induced cell death (Brenchley et al. 2008). Th17 cells were also found to express comparable levels of Bcl-2, an antiapoptotic molecule, to Th1 cells. Apart from a direct impact of HIV on Th17 cells, one mechanism that may contribute to the preferential loss of Th17 cells is the loss of CD103⁺ dendritic cells (DCs) from the colon and mesenteric lymph nodes following infection, as was demonstrated in SIV-infected RMs. CD103⁺ DCs have been shown to promote Th17 differentiation of naïve CD4⁺ T cells in vitro, and their levels are positively correlated with levels of Th17 cells in vivo (Klatt et al. 2012). In addition, intestinal IL-21-producing lymphocytes are significantly depleted during chronic SIV infection of RMs, which is associated with the loss of Th17 cells (Micci et al. 2012). This finding suggests that the loss of cytokines that are critical for the generation and maintenance of Th17 cells during SIV/HIV infection may also contribute to the preferential depletion of mucosal Th17 cells. Consistent with this model, the administration of recombinant IL-21 to SIV-infected macaques results in a transient increase in mucosal Th17 cell frequencies (Pallikkuth et al. 2013). Therefore, the depletion of Th17 cells is likely influenced by a dysregulation in the priming environment upon HIV/SIV infection, although additional mechanisms that may contribute to this preferential depletion are continually being explored.

The extent of Th17 cell depletion has been shown to be predictive of chronic immune activation and disease progression in HIV-infected individuals (Favre et al. 2010). Interestingly, this loss of Th17 cells during pathogenic SIV/HIV infection is accompanied by an increase in the frequencies of regulatory T cells (Tregs) (Favre et al. 2009). Th17 and Tregs, two distinct effector CD4⁺ T cell subsets, derive from a common progenitor and share reciprocal maturation pathways based on the cytokine milieu. In contrast to Th17

cells, Tregs generally function to suppress T cell responses. However, the expansion of Tregs during HIV infection is insufficient to dampen chronic immune activation and may instead be accelerating disease progression through the suppression of antiviral T cell responses. In fact, the loss of balance between Th17 cells and Tregs is predictive of generalized T cell activation in acute HIV infection, as measured by the frequency of activated CD8⁺ T cells (Chevalier et al. 2013). The importance of this delicate balance in resisting disease progression is further illustrated by the fact that elite controllers, a group of HIV-infected individuals who spontaneously (without antiretroviral therapy) control plasma viral load at undetectable levels, maintain a ratio of Th17 cells to Tregs similar to that seen in uninfected individuals (Favre et al. 2010). Pre-existing levels of Th17 cells may also predict the severity of HIV/SIV pathogenesis, since it was shown that RMs with larger blood and intestinal Th17 compartments prior to SIV infection had lower peak and set-point viral loads following infection than those starting with smaller compartments (Hartigan-O'Connor et al. 2012).

Despite an unclear understanding of the mechanisms responsible for their loss, it is clear that Th17 cells are preferentially depleted from the mucosal tract during pathogenic HIV/SIV infections of humans and nonhuman primates. The loss of this critical cell subset disrupts mucosal immunity, impacting the integrity of the intestinal epithelium that can then lead to microbial translocation and systemic immune activation. Thus, maintaining Th17 cells represents a key feature for preserving mucosal immunity during HIV/SIV infection.

Th17 Cells in Nonprogressive SIV/HIV Infection

In direct contrast to HIV-infected humans, natural SIV hosts, such as sooty mangabeys (SMs) and African green monkeys (AGMs), generally preserve healthy CD4⁺ T cell levels and avoid generalized immune activation, thus remaining AIDS-free. Studying features which distinguish

the host response to SIV in these natural hosts from those in pathogenic SIV infection of rhesus (RMs) and pigtail (PTMs) macaques has helped elucidate mechanisms of AIDS pathogenesis in humans. As was stated previously, HIV pathogenesis has long been associated with gastrointestinal pathology, characterized by mucosal CD4⁺ T cell loss, structural damage, and microbial translocation. Similarly, SIV infections in natural host SMs and AGMs result in a depletion of mucosal CD4⁺ T cells. However, the lack of microbial translocation in these natural hosts following SIV infection suggested that a loss of CD4⁺ T cells, alone, was not sufficient to trigger the loss of mucosal integrity, microbial translocation, and systemic immune activation present in progressive disease models (Paiardini et al. 2009). Because of the proposed role of Th17 cells at mucosal sites in antibacterial immunity, several groups investigated the frequencies of Th17 cells during SIV infection in natural hosts.

Th17 cells in SMs and AGMs were first found to have a similar phenotype as those found in both RMs and humans, with the majority being memory CD4⁺ T cells expressing IL-23R and CCR6 (Brenchley et al. 2008; Favre et al. 2009). Functionally, these Th17 cells were of a distinct lineage, expressing IL-17, TNF- α , and IL-2, but with minimal production of IFN- γ , IL-4, IL-10, or TGF- β , which validated that these cells were the same as those lost during pathogenic SIV infection. However, examination of the frequencies of Th17 cells in the GI tract of SIV-infected SMs and AGMs revealed that this cell subset was maintained in the mucosa of natural hosts, despite an overall loss of mucosal CD4⁺ T cells. The sampling of additional anatomical sites in AGMs demonstrated that Th17 cells were preserved in the spleen, axillary and iliac lymph nodes, and colon following SIV infection, which was unseen upon pathogenic SIV infection in PTMs. These findings illustrate that the maintenance of Th17 cells in the GI tract of natural hosts for SIV is a feature critical for resisting disease progression; in fact, these findings are consistent with data obtained through investigations of Th17 levels in nonprogressive HIV infections in humans (Brenchley et al. 2008; Favre et al. 2009).

Two groups of HIV-infected individuals have been the center of numerous investigations into the mechanisms of AIDS pathogenesis due to their lack of disease progression and improved clinical outcomes – elite controllers (ECs) and long-term nonprogressors (LTNPs). ECs are able to spontaneously control HIV-1 replication below the clinical level of detection (<50 HIV-1 RNA copies/mL of plasma) without antiretroviral therapy (ART). LTNPs, on the other hand, represent a cohort of individuals who are able to preserve CD4⁺ T cell levels in the absence of ART. While most have low viremia, a rare subpopulation of LTNPs also exhibit high viral loads, similar to the manifestation of SIV in natural host SMs and AGMs. Investigations into the frequencies of Th17 cells after HIV-1 infection in these two cohorts have reached similar conclusions as those found in comparative SIV studies. Elite controllers are able to preserve a ratio of Th17 cells to Tregs at levels seen in uninfected individuals, both in the peripheral blood and the mucosal tract, which is lost in HIV-infected non-controllers (Favre et al. 2010). Furthermore, LTNPs have higher levels of Th17 cells than normal progressors in the blood and are able to preserve levels of Th17 cells in the mucosa that are comparable to those found in uninfected individuals (Cicccone et al. 2011; Salgado et al. 2011).

By maintaining their frequencies of Th17 cells in the mucosal tract, SIV natural hosts and HIV-infected nonprogressors are able to preserve mucosal immunity and avoid pathogenic events, such as microbial translocation and chronic immune activation, even when viral replication is high. Continuing investigations into the mechanisms which allow for the preservation of this critical cell subset in natural hosts, but their loss in pathogenic infection, will be invaluable for better understanding AIDS pathogenesis and designing therapeutic interventions that can promote sustained mucosal immunity.

Th17 Cells During Antiretroviral Therapy

Highly active antiretroviral therapy (HAART) successfully suppresses viral replication in the

majority of HIV-infected individuals and restores circulating CD4⁺ T cell levels to near-normal levels, thus representing a major advancement in the treatment of HIV disease. While HAART initiation has dramatic effects on CD4⁺ T cell restoration in the blood, HAART has been less efficacious in the reconstitution of mucosal CD4⁺ T cells that are lost early in primary HIV infection. Instead, HAART results in a delayed and often incomplete restoration of gut mucosal CD4⁺ T cells (Guadalupe et al. 2006). Nevertheless, numerous groups have demonstrated that restoration of mucosal CD4⁺ T cells is possible with HAART, albeit with varying degrees of reconstitution. This variability in the levels of mucosal CD4⁺ T cell reconstitution has been hypothesized to be an effect of the timing of HAART initiation, with earlier initiation supporting a more complete restoration of mucosal CD4⁺ T cells, although this has not been formally proven.

Even less is known about the ability of HAART to reconstitute levels of Th17 cells in the GI tract of HIV-infected individuals. In a cross-sectional study in which HAART-treated patients had modest to high levels of overall CD4⁺ T cell restoration in the mucosal tract, Th17 cells were found at frequencies similar to, or even greater than, those found in uninfected individuals (Macal et al. 2008). This reconstitution of mucosal CD4⁺ T cells and concomitant accumulation of Th17 cells was found to be associated with increased polyfunctional anti-HIV CD4⁺ and CD8⁺ T cell responses. In another study, HAART was found to not only increase the frequency of mucosal Th17 cells in HIV-infected patients but also to restore the polyfunctionality of this critical cell subset (Kim et al. 2013). However, the recovery of Th17 functionality was only seen after prolonged periods of HAART, suggesting that the length of HAART impacts the degree to which mucosal immunity is restored. Nevertheless, additional studies have found variable and incomplete reconstitution of mucosal Th17 cells despite viral suppression by HAART (Chege et al. 2011). This variability may be related to the degree of overall CD4⁺ T cell restoration. Despite this proposed reconstitution

of Th17 cells, though, the majority of studies have been unable to demonstrate the ability of HAART to fully decrease plasma LPS levels, a common indicator of microbial translocation, to baseline levels reported in healthy individuals.

Collectively, these studies indicate that HAART positively impacts CD4⁺ T cell numbers in the mucosa. Furthermore, HAART is able to specifically restore mucosal Th17 cells in HIV-infected patients following their preferential depletion during acute infection. However, the degree of reconstitution of both total CD4⁺ and Th17 cells varies per individual. Longitudinal studies that examine the kinetics of Th17 levels in the mucosa will be critical to validate these findings, as well as identify the key factors which contribute to the level of mucosal Th17 cell, and overall CD4⁺ T cell, reconstitution.

Conclusion

Th17 cells, a CD4⁺ T cell subset enriched in the GI tract and chiefly involved in antibacterial immunity, are preferentially depleted from the mucosal tract of SIV-infected macaques and HIV-infected humans. The depletion of this critical effector CD4⁺ T cell subset is associated with the loss of intestinal integrity, which may ultimately facilitate microbial translocation and systemic immune activation. The impact of this Th17 cell loss on disease pathogenesis is further underlined by the fact that mucosal Th17 cells are preserved during SIV infection of natural host sooty mangabeys and African green monkeys, two species which are resistant to AIDS pathogenesis. Therefore, therapeutic interventions that aim to maintain and restore Th17 cells, and thus restore mucosal immunity, will be critical in slowing HIV disease progression. HAART has been able to partially restore CD4⁺ T cell levels, including Th17 cells, following long-term viral suppression; however, Th17 cell reconstitution is highly variable and further investigations will be necessary to better understand what factors are needed for full mucosal restoration. While gaps remain regarding the mechanisms of their loss and reconstitution, it is undeniable that Th17 cells are

crucial for the maintenance of mucosal immunity and resisting HIV disease progression.

Definition

T-cell maturation within the thymus is key for naïve T-cell homeostasis as it allows maintaining naïve T-cell pool and diversity, essential parameters for preserved capacity to develop efficient immune responses against invading pathogens. HIV infection deeply alters T-cell homeostasis through diverse mechanisms and especially premature thymic aging and exhaustion. Nevertheless, thymic function is implicated in immune reconstitution in HIV-infected patients under highly active antiretroviral therapy (HAART).

Normal Thymopoiesis

Thymus Architecture

The thymus is a specialized poly-lobular organ of the immune system, localized in the anterior superior mediastinum, on top of the heart and aortic trunks, and beneath the breastbone. It was for a long time considered as an endocrine gland or

Thymic Function, Fig. 1 Anatomic structure and organization of the thymus. Schematic representation of the organization of a thymic lobule (*left panel*) compared to a thymic slice stained for HLA-DR molecule in *brown* (*right panel*). Thymic lobules are separated by trabeculae and can

be divided in two distinct compartments, the cortex, which mostly contains thymocytes and cortical epithelial cells (*cTEC*), and the medulla, which contains thymocytes, dendritic cells, macrophages, and medullary epithelial cells (*mTEC*). The corticomedullary junction is highly irrigated

even as a gland without any function. Its immunologic importance was only discovered in 1961 (Miller 1961). The thymus is very active during fetal life and childhood, producing large amounts of naïve T cell that built the highly diversified T-cell repertoire. Following puberty the thymus starts to involute, thymic epithelium being progressively replaced by adipose tissue while perivascular space is augmented. However, despite this involution, adult thymus still maintains the capacity to sustain T-cell maturation and contains thymocytes at different stage of differentiation, even after 70 years old (Douek et al. 1998).

The thymus is divided in lobules separated by trabeculae. Each lobule comprises two histologically and functionally different regions: (i) a cell-dense outer region that constitutes the cortex and (ii) a lighter inner part that constitutes the medulla. The cortex is mostly composed of thymocytes and cortical epithelial cells (cTECs), whereas the medulla contains thymocytes, medullary epithelial cells (mTECs), macrophages, and dendritic cells (DCs). In between these regions, the corticomedullary junction is a highly irrigated zone. Within the medulla, Hassall's corpuscles are concentric structures composed of reticular epithelial cells. They are involved in the

regulation of medullary DCs through thymic stromal lymphopoietin (TSLP) secretion and in the maturation of regulatory T cells (Treg) (Fig. 1).

T-Cell Maturation

The primary role of the thymus is to sustain thymocyte maturation, leading to the production of fully functional mature naïve T cells. Bone marrow-derived $CD34^+$ thymocyte progenitors enter the perimedullary cortex of the thymus through extravasation from the corticomedullary junction postcapillary venules. This entry is dependent upon P-selectin expression by endothelial cells and is highly regulated by the availability of intrathymic niches (Rossi et al. 2005). These precursors are called triple negative (TN, $CD3^-CD4^-CD8^-$) cells. TN thymocytes mature in the cortex and sequentially acquire CD2, CD5, and CD1a expression. At the TN stage of differentiation, thymocytes extensively proliferate under Notch1 and IL-7 signaling, allowing large amounts of cells to reach subsequent maturation stages. At the end of the TN differentiation stage ($CD34^+CD1a^+CD3^-CD4^-CD8^-$), future $\alpha\beta$ T cells start to acquire T-cell receptor β -chain (TCRB) expression. The TCRB locus, composed of 52 TCRBV segments and 2 TCRBDJ loci,

undergoes rearrangement through V-D-J recombination. This rearrangement is a stochastic mechanism by which non-contiguous V (variable), D (diversity), and J (junction) segments are associated to form a complete and variable TCR sequence. This recombination is driven by RAG enzymes (recombination-activating gene), which recognize specific recombination signal sequences flanking the different segments. Following TCRB rearrangement, cells that express a TCRB chain able to associate with p-T α chain receive survival signals through the CD3 ϵ and CD3 γ chains (β -selection). Unselected cells die by apoptosis.

During this entire step, thymocytes migrate through the thymic cortex to the subcapsular region. This migration is driven by both CCL25, expressed by cortical epithelial cells and macrophages, and CXCL12, expressed by subcapsular fibroblasts (Dutrieux et al. 2014). Thymocytes that survive β -selection express CXCR4 and, by interacting with CXCL12, are retained in the subcapsular region where they become intermediate simple positive cells (ISP, CD3^{low}CD4⁺CD8⁻) and extensively proliferate. This proliferation increases the number of cells expressing an in frame and correctly folded TCRB chain that will further differentiate. It also permits enhancing TCR diversity through α/β pairing (Arstila et al. 1999). Indeed, at early DP stage (CD3⁻CD4⁺CD8⁺), a second wave of RAG expression triggers TCRA chain rearrangement. Thus, ISP cell proliferation allows each selected TCRB chain to pair with a large number of TCRA chains, leading to further increased TCR diversity.

TCRA locus is composed of 70 V α and 61 J α segments which are rearranged using a process similar to TCRB chain. Preceding TCRA chain rearrangement, TCRD locus, which is localized between V α and J α segments on chromosome 14, must be excised. This deletion, as well as all other rearrangements at both TCRA and TCRB loci, leads to the circularization of the excised DNA. Such circular DNA molecules or T-cell receptor excision circles (TRECs) persist in the nucleus as extrachromosomal DNA but are lost upon cell cycling. Of note, several types of TRECs are generated during the entire T-cell

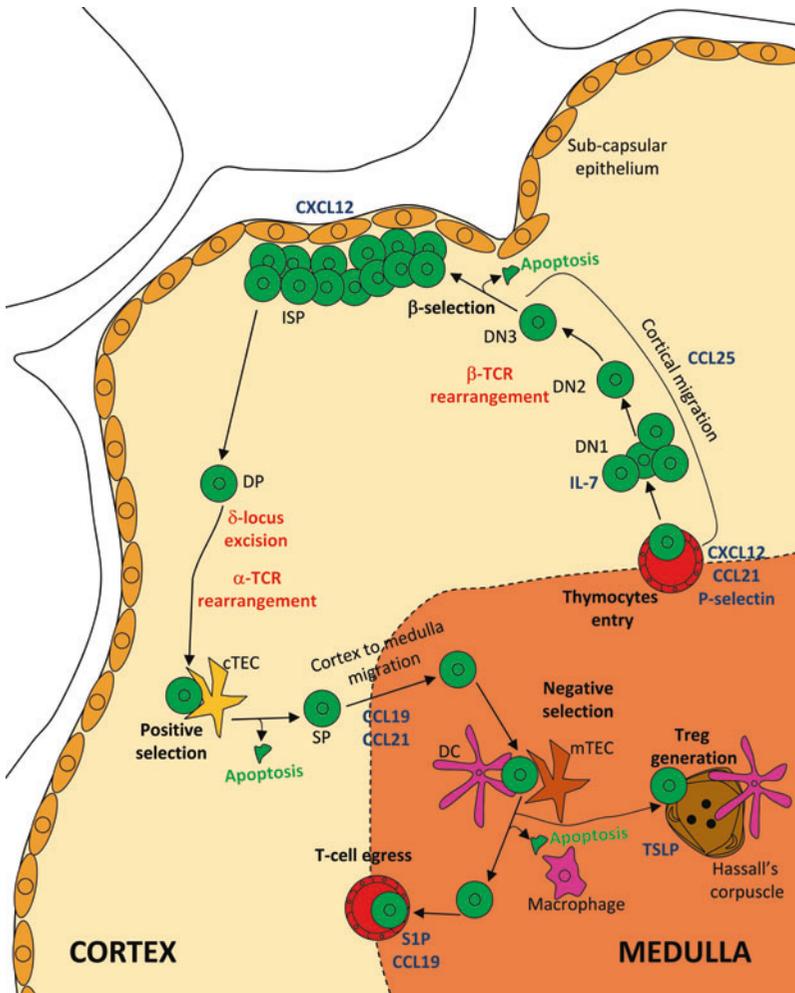

maturation process. The sjTREC (signal joint TREC), byproduct of TCRD locus deletion, is present in the vast majority of cells that exit the thymus (70%); it is thus used as a marker for recent thymic emigrants. Similarly, TCRB and TCRA rearrangements lead to the generation of different TREC molecules (DJ β TRECs, VD β TRECs, and VJ α TRECs). During the TCRA rearrangement process, thymocytes depend upon IL-7 to survive until the positive selection (Guillemard et al. 2001). DP cells expressing a full TCR (CD3⁺CD4⁺CD8⁺TCR⁺) able to interact with class I or class II major histocompatibility complexes (MHC-I and MHC-II) expressed by cTECs downregulate RAG expression and further differentiate into simple positive (SP) cells. Downregulation of CD8 expression allows MHC-II-reacting cells to differentiate into SP4 (CD3⁺CD4⁺CD8⁻). Contrariwise, DP cells that lose signal downmodulate CD4 molecule, reexpress CD8 molecule, and become SP8 cells (CD3⁺CD4⁻CD8⁺). Furthermore, thymocytes recognizing the nonclassical MHC-I CD1d differentiate into NKT cells.

Positively selected SP thymocytes migrate back through the cortex following gradients of CCR7-dependent chemokines (CCL19 and CCL21) (Ueno et al. 2004). In the medulla, they will be subjected to mTECs-driven negative selection. These cells present a variety of self-peptides on their MHC (spermine, prostaglandin, preproinsulin II, etc.) as a consequence of their expression of the transcription factor AIRE (autoimmune regulator) (Anderson and Su 2011). mTEC-reactive SP cells will be eliminated by apoptosis.

Finally, selected CD4 and CD8 mature T-cells expressing CCR7, sphingosine-1-phosphate receptor 1 (S1P1), and CD31 follow CCL19 and sphingosine-1-phosphate (S1P) gradients and exit the thymus through CD31-expressing corticomedullary microvessels. Newly exported cells (recent thymic emigrants – RTE) enter the blood stream and contribute to the diversification of circulating naïve T-cell pool (Fig. 2).

Studying Thymic Function

Thymic function can be measured through measuring the volume and metabolic activity of the

Thymic Function, Fig. 2 The maturation of $\alpha\beta$ T cells within the thymus. Thymocytes (in green) enter in the thymus through corticomedullary junction led by P-selectin. They migrate through the cortex following CCL25 gradient during double negative (DN, $CD3^-CD4^-CD8^-$) maturation. They undergo TCRB rearrangement and β -selection and become intermediate single positive (ISP, $CD3^{low}CD4^+CD8^-$) which are retained in the subcapsular region by CXCL12. ISPs extensively proliferate in this area then become double positive (DP, $CD3^+CD4^+CD8^+$) before acquiring the TCR α -chain. DPs interact with cortical epithelial cells (cTEC) which drive the positive selection. Thymocytes that are able to recognize MHC acquire the simple positive phenotype (SP, $CD3^+CD4^+CD8^-$ or $CD3^+CD4^+CD8^+$). SPs migrate in the medulla through CCR7-dependent chemokines and undergo the negative selection through interaction with medullary epithelial cells (mTEC) and dendritic cells (DC). Autoreactive cells died through apoptosis or are oriented to Hassall's corpuscle to become regulatory T cells (Treg). SPs that survive to negative selection are exported through S1P and CCL19 gradient

DPs interact with cortical epithelial cells (cTEC) which drive the positive selection. gland, quantifying RTEs in the blood, and evaluating thymocyte proliferation.

Computed tomography (CT-scan), associated to positron-emission tomography (PET-scan), allows qualitative in vivo evaluation of the volume and the metabolism of the thymus through measurement of thymic glucose uptake using

a radioactive tracker (^{18}F -fluorodeoxyglucose) (Lelievre et al. 2012).

Since the demonstration that the thymus remains a functional organ in adults, its role in various pathologies has been extensively assessed. Different molecular markers of RTEs have been proposed in the literature. Quantification of the

sjTREC content in blood T-cells is considered as a good surrogate to measurement of thymic function. Indeed, TREC molecules are devoid of replication origin; they are thus not duplicated during mitosis and are diluted down when T-cells proliferate. Accordingly, sjTREC content in blood T-cells marks the presence of cells recently emigrated from the thymus and is informative for evaluating thymic activity (Douek et al. 1998). However, this parameter is also impacted by modifications of naïve T-cell half-life and proliferation. Indeed, in thymectomized patient, sjTREC levels only very slowly decrease as a consequence of increased naïve T-cell survival. In contrast, enhanced RTE proliferation that is often observed in lymphopenic patients leads to the reduction of sjTREC frequencies, leading to erroneous estimate of thymic function.

To circumvent the inaccuracy of sjTREC measurement in estimating thymic function, Dion and colleagues set up an assay aimed at evaluating intrathymic precursor T-cell proliferation. Indeed, as specified above, thymocytes extensively proliferate between TCRB and TCRA rearrangements. This proliferation increases the number of TCRB-expressing cells that reach late DP stage and rearrange TCRA chain, enhancing thymic output. As DJ β TRECs are diluted down during this proliferation, the relative concentration of sjTRECs and DJ β TRECs is dependent upon the extent of thymocyte proliferation. Consequently, their ratio (sj/ β TREC), measured in peripheral blood cells, directly reflects the intrathymic proliferation history of the studied T-cell population and consequently thymic activity (Dion et al. 2007). Thereby, any change in the sj/ β TREC ratio signs modification of precursor T-cell proliferation thus of thymic output.

Finally, several cell surface markers have been proposed to identify RTEs within naïve T-cells. In the CD4 T-cell compartment, naïve T-cells expressing either PTK7 (tyrosine-protein kinase-like 7) or CD31 (platelet endothelial cell adhesion molecule implicated in thymic egress and homing to lymph nodes) present a higher sjTREC content than their negative counterparts (Kimmig et al. 2002; Haines et al. 2009). In contrast, these markers cannot be used in the CD8 compartment.

HIV Infection Affects Thymic Function

With the demonstration of persistent thymic function in adults, the question of its alteration during HIV infection arose. Indeed, naïve T-cell subsets are deeply reduced following infection (Silvestri and Feinberg 2003). However, probably due to increased plasma IL-7 levels that generally characterize HIV-infected patients – even without marked lymphopenia – naïve T-cell homeostatic proliferation does not seem to be significantly impaired following HIV infection. Consequently, naïve T-cell decline in patients could be a consequence of impaired thymic activity and reduced naïve T-cell neo-production.

From the late 1990s, several reports demonstrated that sjTREC content of circulating T-cells (sjTREC/ 10^6 cells) was strongly reduced in chronically HIV-infected patients, suggesting thymic defect (Douek et al. 1998; Poulin and Sekaly 1999). These papers opened a long-lasting debate concerning the reliability of measuring sjTREC frequencies in lymphopenic individuals as their decline in patients' blood could also be a consequence of global increase of T-cell cycling leading to dilution of TREC molecules and/or impaired survival of TREC-containing cells (Hazenberg et al. 2003). However, the observed decline in global sjTREC concentration in the blood (sjTREC/mL) argued against the implication of modified naïve T-cell turnover in the evolution of sjTREC frequencies in HIV-infected patients. This debate was finally solved by the identification of the direct impact that HIV infection has on thymic physiology. Indeed, quantifying sjTREC and DJ β TRECs, Dion and colleagues demonstrated that reduced thymocyte proliferation characterizes HIV-infected patients. Diminished thymocyte proliferation, leading to reduced thymic output, certainly participates to naïve T-cell lymphopenia observed early on following HIV infection (Dion et al. 2004, 2007). Indeed, thymic dysfunction began early on during the first months following infection, suggesting its importance in the establishment of HIV-1 physiopathology, and persists over the chronic phase of the infection. The mechanisms leading to diminished thymocyte proliferation in HIV-infected patients remain

barely studied, but several hypotheses can be envisaged.

On the one hand, even though *in vivo* evidences of thymocyte infection in human remain sparse, it can be supposed that thymus cells constitute a target for HIV due to their expression of CD4, CCR5, and CXCR4. Indeed, ISP, DP, and SP4 thymocytes as well as thymic DCs express both CD4 molecule and HIV coreceptors and are susceptible to HIV infection *in vitro* (Schmitt et al. 2006). Of note, only a small fraction of CD4⁺ thymocytes express CCR5 leading to preferential infection by CXCR4-tropic viruses and suggesting low infection rates during primary infection. However, cytokines expressed in the thymus (IL-2, IL-4, and IL-7) were shown to up regulate coreceptor expression on thymocytes (Pedroza-Martins et al. 1998). Furthermore, thymic epithelial cells (mTECs and cTECs) can also be productively infected *in vitro* suggesting that they could participate to the propagation of the infection within the thymus (Braun et al. 1996). Indeed cellular contacts between thymocytes and TECs are necessary for an intense viral replication in thymocytes (Rothe et al. 1998). In thymocyte, as in circulating T-cells, HIV replication depends upon NF κ B activation, suggesting that proliferating cells are more susceptible to express HIV proteins when infected. Such an expression may lead to specific elimination of proliferating cells, leading to the export of cells presenting with low proliferation history (low sj/ β TREC ratio). However, *in vivo*, infection of the thymus remains strongly limited. Sparse infected cells can be identified in the thymus of acutely SIV-infected rhesus macaques (Dutrieux et al. 2014) as well as *postmortem* on histological thymic tissues from AIDS patients (Pekovic et al. 1987). It is thus unlikely that killing of proliferating infected cells alone can strongly impact on thymic output. Nonetheless, infection of immature T-cells in the thymus may result in the export of infected RTEs that significantly contribute to HIV reservoir (Cameron et al. 2010; Fabre-Mersseman et al. 2011).

On the other hand, HIV infection also triggers modification of thymic physiology leading to the observed reduction of thymocyte proliferation

and the initiation of antiviral innate immune responses. Indeed, infection of fetal thymus in culture stimulates the expression of IFN- α in the supernatant and leads to reduced SP4 production (Sivaraman et al. 2011). Thymic DCs and macrophages (which express CD4) are permissive to CCR5-tropic HIV-1 strains, suggesting that these cells can be infected during the early phases of the infection (Schmitt et al. 2006) and produce IFN- α within the thymus (Bendriiss-Vermare et al. 2001). Lastly, Dutrieux and colleagues recently demonstrated that, in Chinese rhesus macaques, SIV infection stimulates the production of various IFN- α subtypes within the thymus, some of these molecules harboring a strong antiproliferative activity on developing thymocytes (Dutrieux et al. 2014). At the same time, thymic chemokine networks are also altered. While CCL19 and CCL25 expressions are deeply enhanced by day 3 of infection, CXCL12 expression is reduced. Considering the role of these chemokines in triggering either intrathymic cell migrations (CCL19 and CCL25) or cell retaining in the subcapsular area (CXCL12), these modifications are compatible with faster cell trafficking within the thymus (Dutrieux et al. 2014). Interestingly, IFN- α production and modified chemokine networks in the thymus probably have the paradoxical consequence of transiently enhancing thymic output through acceleration of thymocyte differentiation (Dutrieux et al. 2014). Such an increased thymic output was observed following measles infection-induced lymphopenia in both children and rhesus macaques. However, in the long term, IFN- α -dependent inhibition of thymocyte proliferation, leading to reduced numbers of DN cells in the thymus, could affect thymic epithelial cells/thymocytes cross talk and stromal cell survival, leading to thymic exhaustion.

Finally, besides its quantitative consequences on thymopoiesis, HIV infection in the thymus and HIV-induced modifications of thymic physiology could also impact on the quality of thymic production. Indeed, the death of HIV-infected cells within the thymus and expression of HIV proteins by mTECs should lead to the presentation of HIV peptides on MHC molecules, mimicking

self-antigen presentation and triggering the deletion of HIV-specific T-cell clones. Such an immune dysfunction was observed following Gross virus infection of thymic epithelium in mice. Moreover, IFN- α expression in the thymus, known to increase HLA class I expression in the thymus, could also impact on the global affinity of T-cell receptor repertoire, leading to reduced activation following antigen exposure.

Immune Regeneration Under Treatment

Patients achieving sustained virus control under HAART usually reconstitute, at least partly, their CD4 T-cell compartment. During the first months of therapy, most of the increase in circulating T-cell counts occurs in the naïve compartment, suggesting a role of thymopoiesis. Indeed, PET scan analysis of the thymus of HAART-treated patients showed that thymic function is boosted following treatment initiation (Lelievre et al. 2012). Similarly, both sjTREC frequency and sj/ β TREC ratio were significantly enhanced during the first year of therapy, demonstrating the implication of the thymus in the early phase of immune recovery under treatment (Markert et al. 2001; Dion et al. 2004). In contrast, some patients with poor immunological response to antiretroviral therapy barely regain naïve T-cell counts and did not recover normal thymic output (Dion et al. 2007). In these patients, naïve T-cell frequencies strongly correlated with sjTREC frequency and sj/ β TREC ratio, suggesting that increased thymic output plays a major role in immune reconstitution under HAART (Dion et al. 2007). Interestingly, naïve T-cells produced under therapy also present a longer half-life and a diminished sensitivity to apoptosis (Aladdin et al. 2003). However, efficient thymopoiesis is not sustained following T-cell reconstitution. In long-term-treated good immunological responder patients, the sj/ β TREC ratio was similar to that of patients who failed to reconstitute T-cell compartment (Delobel et al. 2006). This suggests that, similarly to FOXN1-deficient patients receiving a thymic graft (Albuquerque et al. 2012), as well as following allogeneic hematopoietic cells transplant

(Castermans et al. 2011), the thymus was able to sustain T-cell production in lymphopenic patients but could not remain active in reconstituted hosts presenting close to normal T-cell homeostasis. Following the initial phase of thymus-dependent immune reconstitution, naïve T-cell counts are mostly maintained through IL-7-driven survival and proliferation.

Finally, even in HAART-treated poor immunological responder patients, thymic function can be boosted through immunotherapeutic intervention. Indeed, in the first IL-7-based clinical trials, both thymic output and circulating naïve CD4⁺ T-cell counts were significantly enhanced in virally controlled poor immunological responders (Sereti et al. 2009; Levy et al. 2012). Similarly, increased thymic function and diversification of T-cell repertoire were observed in IL-7-treated SIV-infected rhesus macaques (Parker et al. 2010).

Conclusion

The thymus is an essential primary lymphoid organ providing the immune system with new naïve T cells in childhood but also in adults. Through continuous production of new T-cells, thymopoiesis ensures maintaining naïve T-cell diversity allowing the development of adequate immune responses to invading pathogens. Viral replication within the thymus can be observed in chronically infected patients as well as from the first days of experimental SIV infection of rhesus macaques. In this model, viral infection in the thymus coincides with major modifications of thymic physiology. While changes in thymic physiology may transiently increase thymic output during acute infection as a consequence of accelerated thymopoiesis, thymic impairment is observed during the chronic phase of the infection. However, the thymus keeps a renewal capacity and, upon antiretroviral or immunostimulating therapy, can functionally regenerate and participate to immune restoration. Indeed, an increased thymic activity is undeniably mandatory for efficient immune reconstitution leading to extended TCR repertoire during antiretroviral treatment.

Definition

T cell immunoglobulin and mucin domain-containing protein 3 (Tim-3) is a member of the T cell/transmembrane, immunoglobulin, and mucin (TIM) gene family of phosphatidylserine-binding proteins (Freeman et al. 2010). It is a type I transmembrane glycoprotein consisting of an N-terminal IgV-like domain and a heavily glycosylated mucin domain, a transmembrane region, and a cytoplasmic tail. Tim-3 plays a role in the regulation of both innate and adaptive immune responses during autoimmunity, cancer, and chronic infections (Han et al. 2013; Zhu et al. 2011). While it has been shown to both negatively and positively regulate innate immune responses, Tim-3 plays a distinct negative regulatory role in regards to T cell responses. During human immunodeficiency virus type 1 (HIV) infection, Tim-3 marks dysfunctional T cells during chronic stages of infection and acts to dampen responses to viral antigen, contributing to the “exhausted” state of the immune system and lack of viral control (Jones et al. 2008).

Introduction

Virus infections are typically controlled by potent T cell responses, particularly a potent CD8+

cytolytic T cell (CTL) response. Viruses, like HIV, that are chronic and persistent are able to evade these potent responses via multiple mechanisms, including epitope mutation and dysregulation of T cell “help” in the case of HIV infection. Virus persistence leads to ongoing CD4⁺ and CD8⁺ T cell activation. Persistent T cell activation in the presence of chronic virus infections, such as observed with HIV, has led to unique phenotype termed “T cell exhaustion.” T cell exhaustion is characterized by the hierarchical loss of effector function, initially with defective proliferation and an enhanced tendency to apoptosis, followed by sequential loss of effector function such as IL-2 and TNF- α production, and then followed by loss of IFN- γ production and cytotoxic ability (Wherry et al. 2003). Efforts to characterize exhausted T cells led to the observation that expression of multiple co-inhibitory molecules, including Programmed-Death 1 (PD-1), Lymphocyte Activation Gene-3 (LAG-3), and Tim-3 (Khaitan and Unutmaz 2011), was a feature of these cells. It is unclear whether T cell exhaustion is a manifestation of a virus evasion strategy or a way for the immune system to limit excessive T cell responses and avoid autoimmunity to cross-reactive self-antigens. This review will focus mainly on the role of Tim-3 in T cell exhaustion in HIV infection.

Tim-3 was originally identified as a marker of IFN- γ secreting CD4⁺ Th1 cells but is also expressed on naïve T cells, CD4⁺ T regulatory cells (Tregs), CD4⁺ Th17 cells, activated CD8⁺ T cells, constitutively on monocytes, activated macrophages, dendritic cells (DCs), and natural killer (NK) cells (Han et al. 2013; Khaitan and Unutmaz 2011). Tim-3 binds to multiple ligands to regulate signaling in cells of both the innate and adaptive immune system, resulting in a complex regulation between the two arms of the immune system. Indeed, multiple studies have described Tim-3 as a negative regulator of immune responses, while others have described Tim-3 as a positive regulator of immune responses (Khaitan and Unutmaz 2011; Ferris et al. 2014). However, these effects appear to be context specific, as Tim-3 appears to play various roles in

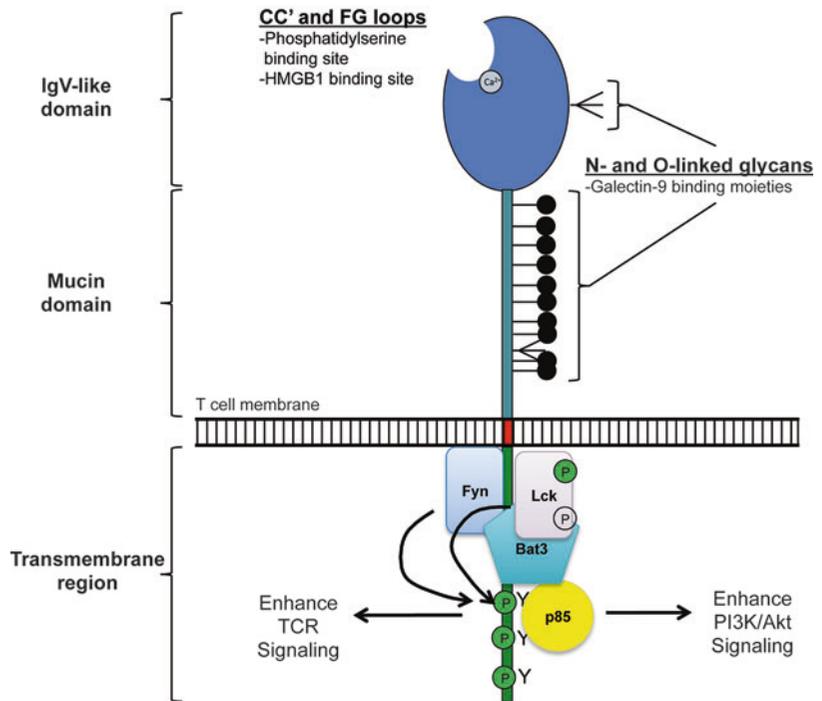

regulating autoimmunity and in immune responses to cancer and acute and chronic infections.

Tim-3 Ligands

Tim-3 binds to multiple ligands, including galectin-9, phosphatidylserine (PS), and high mobility group box 1 (HMGB1) protein (Freeman et al. 2010; Zhu et al. 2005; Chiba et al. 2012). Galectin-9 is a soluble tandem-repeat S-type lectin containing two carbohydrate recognition domains (CRD) joined by a flexible peptide linker. Binding to Tim-3 is mediated via interactions with carbohydrates on the IgV-like and mucin domain of Tim-3 and the galectin-9 CRDs (Fig. 1; Zhu et al. 2005). Galectin-9 does not exclusively bind to Tim-3. Its lectin-binding properties and bivalent nature allow for heterogeneous cross-linking of multiple glycoproteins such as CD45 and CD148 (Clayton et al. 2014). Galectin-9's interaction with Tim-3 results in apoptosis of Th1/Tc1 cells supporting its role as a co-inhibitory molecule (Zhu et al. 2005). However, the signaling cascade responsible for this death induction is still unclear.

PS is a phospholipid, which normally localizes to the inner leaflet of the plasma membrane, but gets “flipped” to the outer leaflet during the early stages of apoptosis, thus acting as an “eat me” signal to mediate clearance of the apoptotic cell via phagocytosis. Like other members of the TIM family, Tim-1 and Tim-4, Tim-3 binds to PS via the unique pocket formed by the calcium-coordinating CC' and FC loops of the IgV-like domain (Freeman et al. 2010) with a rather high affinity (nM range). TIM family molecules insert their IgV-like domains into the opposing membrane to stabilize the interaction with PS. However, molecular modeling suggests that PS binding does not inhibit potential galectin-9 binding, as binding sites for each ligand are on opposite sides of the IgV-like domain (Fig. 1; Freeman et al. 2010). Binding to PS mediates differential function of Tim-3 depending on cell type expressing Tim-3. For example,

Tim-3, Fig. 1 Tim-3 is a type 1 membrane protein of 301 amino acids, belonging to the immunoglobulin superfamily, and contains an IgV-like domain, a mucin-like domain, a transmembrane region, and an intracellular tail. Glycans on surface Tim-3 can bind to galectin-9, and PS and HMGB1 can bind to the region bound by CC' and FG loops of Tim-3. The cytoplasmic tail does not contain recognizable ITIM/ITAM motifs but can be phosphorylated and can bind to a number of upstream signaling proteins

macrophages, DCs, and T cells that express Tim-3 can bind to PS. However, unlike Tim-3 on DCs, which mediates phagocytosis and cross-presentation of apoptotic cells, the effect of PS binding to Tim-3 on T cells is unclear (Nakayama et al. 2009).

Recently, Tim-3 was described as a suppressor of DC-mediated antitumor responses via binding to HMGB1 (Chiba et al. 2012), a nuclear, cytosolic, and extracellular protein with varying functions depending on the cellular or extracellular compartment. This interaction was mapped to the PS-binding calcium-coordinating CC' and FC loops of the IgV-like domain (Fig. 1). When released from necrotic or inflammatory cells, HMGB1 acts as a danger-associated molecular pattern (DAMP) molecule, or alarmin, mediating activation of nucleic acid-sensing systems via pattern recognition receptors (PRRs) and ultimately an inflammatory innate immune response. Tim-3 on DCs binds to extracellular HMGB1 and targets it for degradation, thus suppressing PRR-mediated responses in tumors (Chiba et al. 2012). No work has yet described the whether this

HMGB1-Tim-3 interaction also plays a role in T cell responses.

Tim-3 Signaling

Tim-3 is an important regulator of both innate and adaptive immune responses. Interestingly, despite its role in negatively regulating T cell immune responses, the Tim-3 cytoplasmic tail lacks known signaling motifs, such as the immunoreceptor tyrosine-based inhibition motif (ITIM), for the recruitment of inhibitory factors, such as the phosphatase SHP-1. Common Tim-3 characteristics observed in innate and adaptive immune cell signaling are tyrosine phosphorylation and subsequent binding to Src-family kinases (SFKs). In the innate immune system, engaging Tim-3 on DCs results in tyrosine phosphorylation of its cytoplasmic tail and subsequent activation of the nonreceptor tyrosine kinases Bruton’s tyrosine kinase (Btk) and c-Src. This leads to the release of a soluble inhibitory factor that dampens NF-κB signaling (Maurya et al. 2014). However,

studies have also shown that engagement of Tim-3 can lead to NF- κ B activation (Ferris et al. 2014), whose mechanism is unclear. Likewise, there exists conflicting evidence for Tim-3 signaling in adaptive immune cells. In T cells, initial work showed that Tim-3 plays a role in enhancing T cell receptor (TCR) signaling via recruitment of Fyn, Lck, and p85 (the PI3K adaptor), resulting in enhanced TCR-induced NFAT/AP-1 and NF- κ B signaling as well as Akt/mTOR signaling (Fig. 1; Ferris et al. 2014). Indeed, subsequent studies showed that Tim-3 was recruited to the immunological synapse, further suggesting a role in TCR signaling (Clayton et al. 2014; Rangachari et al. 2012). However, these studies also showed recruitment of receptor phosphatase CD45/CD148 to Tim-3 via galectin-9 to dampen Lck signaling (Clayton et al. 2014) and recruitment of the chaperone Bat3 to dampen Tim-3-induced negative signaling (Rangachari et al. 2012), suggesting that Tim-3 acts to inhibit TCR signaling. However, the exact pathways and downstream targets have still yet to be determined. In addition, it is still unclear which Tim-3 ligand mediates these diverse effects.

Tim-3 and the Innate Immune System

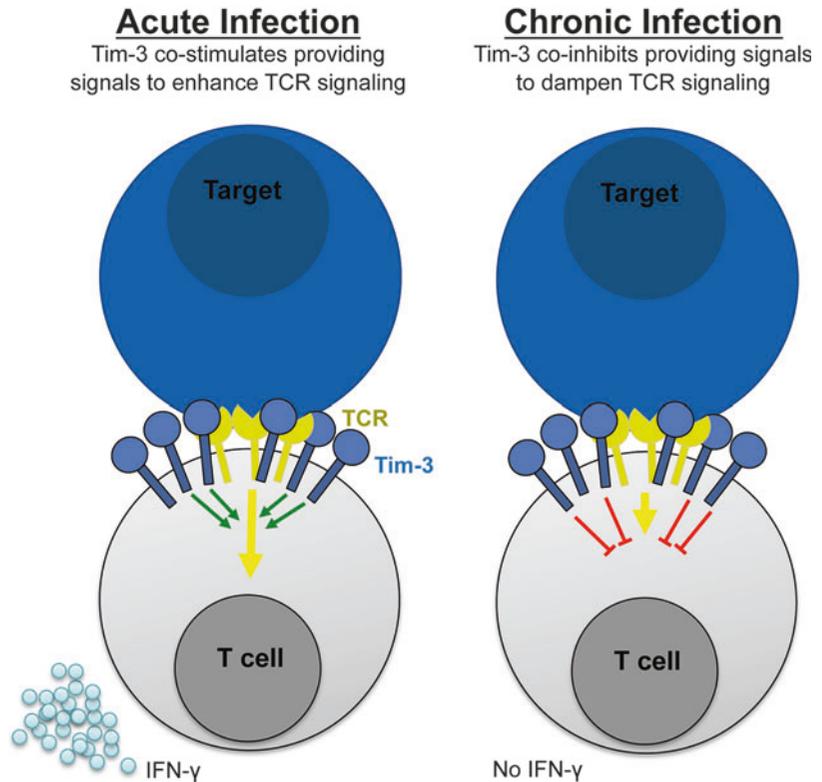

Tim-3 plays an important role in regulating innate immune responses. As mentioned, it is expressed on monocytes, activated macrophages, DCs, and NK cells (Han et al. 2013). On monocytes, it acts to dampen IL-12 on resting monocytes, but after monocyte activation, Tim-3 is downregulated, resulting in expression of pro-inflammatory cytokines. Tim-3 is also upregulated on stimulated macrophages, which suppresses macrophage activation. In addition, it also mediates phagocytosis and cross-presentation of cell debris via its interaction with PS (Nakayama et al. 2009). Depression of the Tim-3 pathway in these cells contributes to the development of autoimmune disease (Nakayama et al. 2009). Expression of Tim-3 on DCs also negatively regulates innate responses. This was shown in the case of tumor-associated DCs with high levels of Tim-3, which bound to the HMGB1 and dampened cellular responses to nucleic acid

(Chiba et al. 2012). In addition, Tim-3 engagement results in release of a soluble negative factor, which dampens NF- κ B signaling (Maurya et al. 2014). The situation is more complicated for NK cells. Activation of NK cells with certain cytokines upregulates the expression of Tim-3, which then marks highly functional, cytotoxic NK cells. However, engagement of Tim-3 suppresses NK cell function. Overall, it appears that Tim-3 expression on innate cells acts a central negative regulator of the innate immune system in terms of cytokine production but favors antigen clearance and cross-presentation.

Tim-3 in the Adaptive Immune System

Tim-3 has been extensively studied in the context of autoimmunity and T cell exhaustion in both cancer and chronic infection. Early work characterizing Tim-3 suggested it acts to dampen Th1 and Th17 responses to self-antigen, as blocking this pathway resulted in development of autoimmune disease (Freeman et al. 2010). Tumor infiltrating lymphocytes (TILs) and virus-specific T cells show characteristics of exhaustion, which include loss of effector function and increased levels of multiple co-inhibitory molecules, including Tim-3 (Ferris et al. 2014). Indeed, expression of Tim-3 correlates with lack of IFN- γ production, and blocking Tim-3 using antagonistic antibodies or soluble Tim-3 has shown to promote rejection of solid tumors in murine mice (Ferris et al. 2014). In some studies, this effect was mediated in part by suppressing Tim-3⁺ Treg responses, which produced high levels of IL-10. In addition, Tim-3 blockade rescued ex vivo function of Tim-3⁺ TILs from patients (Ferris et al. 2014). Thus, Tim-3 can inhibit T cell effector responses via direct and indirect mechanisms. Interestingly, in active tuberculosis (TB) infection, Tim-3 is highly upregulated on T cells, which possess more potent anti-TB responses, and engaging Tim-3 provides a co-stimulatory signal and enhances anti-TB T cell effector responses. Further, Tim-3 is required for effective responses to clear *Listeria monocytogenes* (LM) (Ferris et al. 2014). Thus, Tim-3 plays divergent roles in terms

Tim-3, Fig. 2 Tim-3 appears to show divergent effects on T cells depending on the stage of infection and the balance of co-stimulatory or inhibitory molecules at the surface. During acute infection, Tim-3 may act as a co-stimulator, but during chronic infection, Tim-3 has the opposite effect, in part by bringing in more negative regulators

of controlling T cell responses during acute versus chronic antigen stimulation (Ferris et al. 2014; Fig. 2).

Tim-3 in HIV

During chronic HIV infection, Tim-3 is found highly upregulated on both CD4⁺ and CD8⁺ T cells (Jones et al. 2008). These levels are high in acute/early infection (less than 6 months) and untreated chronic infection (more than 1 year), but not in long-term non-progressors (LTNPs), when compared to healthy controls. These levels positively correlate with viral load, T cell activation (marked by CD38 expression), and negatively with CD4⁺ T cell counts, suggesting Tim-3 expression correlates with HIV disease progression. Recognition of HIV-infected DCs and stimulation via TCR or common γ -chain cytokines mediates this induction of Tim-3 expression (Mujib et al. 2012; Larsson et al. 2013). Highly active antiretroviral therapy (HAART) has

varying effects on Tim-3 expression; however, changes in Tim-3 expression levels correlate with ongoing T cell activation, measured by CD38 expression, further suggesting that chronic immune activation controls Tim-3 expression during HIV infection. Tim-3 expression however is not consistently decreased after HAART when antigen levels drop. As seen with cancer and other chronic infections, Tim-3⁺ T cells fail to respond to stimuli. However, these responses can, in part, be rescued via blockade with either a soluble Tim-3 decoy or antagonistic antibody, suggesting that Tim-3 plays a functional role in T cell exhaustion during HIV infection (Jones et al. 2008). Interestingly, HLA-B*27- and HLA-B*57-restricted HIV-specific CD8⁺ T cells fail to upregulate Tim-3 to levels seen with other MHC-restricted CD8⁺ T cells. In addition, these cells are more functional and correlate with control of HIV infection as is seen in LTNPs (Larsson et al. 2013). Thus, Tim-3 is upregulated on HIV-specific CD8⁺ T cells, which are exhausted. The exact signaling pathways downstream of

Tim-3 that mediate this phenotype are still poorly defined, and much work needs to be accomplished in this regard.

Conclusion

Tim-3 is a receptor found on various cells of the immune system, which acts to dampen excessive inflammatory responses. While this is essential for autoimmune diseases such as multiple sclerosis, it contributes to lack of T cell control of cancer and chronic viral infections, like HIV. This inhibition is mediated, in part, via Tim-3 binding to its ligands galectin-9, PS, or HMGB1, resulting in signaling pathways, which mediate apoptosis, phagocytosis, or inhibition of PRR sensing pathways, respectively. Tim-3 signaling in innate and adaptive immune cells share common characteristics, such as Tim-3 tyrosine phosphorylation and recruitment of SFKs; however, how this results in modulation of cellular responses is still unclear. In addition to Tim-3's inhibitory role, new data suggests that Tim-3 plays a positive role in enhancing T cell responses during acute infections (Fig. 2). It remains to be determined if this is the case for acute HIV infection, which would contrast with its role during chronic HIV infection. Indeed, blocking this pathway using antagonistic antibodies suggests a method to enhance T cell responses during HIV infection, but disease state (acute versus chronic infection) and cell types affected (innate versus adaptive immune cells) are important factors to consider when designing therapeutics to manipulate the Tim-3 pathway. We still lack a complete understanding of downstream signaling pathways of Tim-3 on T cells during acute and chronic infections or in cancer. A fuller understanding of these pathways will guide antibody-based therapies in these diseases so that the correct effect (immune suppression or co-stimulation) can be achieved without unforeseen consequences.

Definition

Toxoplasmosis is the infection caused by *Toxoplasma gondii*, an obligate intracellular protozoan that belongs to the phylum Apicomplexa. In immunocompromised patients, such as AIDS patients with low CD4 cell count, reactivation of latent disease can cause life-threatening encephalitis. The disease usually presents with a focal neurological deficit associated with the formation of multiple *Toxoplasma* abscesses. Treatment requires combination of anti-toxoplasmic drugs and its continuation as suppressive therapy until immune reconstitution occurs.

Biology, Epidemiology, and Transmission

Biology

Toxoplasmosis is an endemic infection of worldwide distribution caused by *Toxoplasma gondii*, an intracellular protozoan of the order Coccidia,

phylum Apicomplexa. *Toxoplasma* can present in three forms in its life cycle: the oocyst, tissue cyst, and tachyzoite.

The infection is acquired orally by ingestion of contaminated food or water oocysts or by ingestion of undercooked meat containing tissue cysts. The infection can also be acquired through the vertical route (mother-to-child transmission). Once inside the body, the cysts and oocysts release tachyzoites, which have the ability to affect intestinal epithelial cells, to invade the mesenteric lymph nodes, and then via the bloodstream to spread to different tissues. Tachyzoites are responsible for the clinical presentation of acute toxoplasmosis; they replicate intracellularly, infesting and destroying cells until the immune system develops the appropriate response. Subsequently, the parasites that survive this immune response encyst in various tissues, including the brain, the retina, skeletal muscle, the myocardium, and occasionally the lungs, where they can stay in a quiescent form for life. Years later, if T cell-mediated immunity is impaired, the cysts in tissues may break releasing tachyzoites, which produce a reactivation of the infection.

Oocysts develop in the cells of the intestinal mucosa of cats, domestic cats, and other wild felines, like the leopard and lions being the definitive host. Cats become infected by ingesting cysts in the raw meat of infected animals or oocysts present in feces eliminated by other felines. After 1–2 weeks, oocyst shedding ceases and rarely restarts. Oocysts must sporulate to become infectious, a process that is favored by heat and humidity, conditions typically found in litter boxes used to deposit cat feces in homes. Sporulated oocysts can remain infectious for more than 1 year.

Tissue cysts can be found in the cells of almost any organ of the host. Maintaining the cysts in a quiescent state and controlling any breakage to avoid the periodical release of tachyzoites is a process mediated by T cells and cytokines. Thus, in individuals previously infected and with T cell impaired immunity, residual cysts are an important source of tachyzoites that may escape immune control. However, cases of retinal involvement can occur in immunocompetent and

immunocompromised individuals, which are presumed to be mediated by additional mechanisms to those described.

Epidemiology and Transmission

The most common route of transmission of *T. gondii* to humans is the eating of raw or undercooked pork or lamb meat. In theory, any animal that ingests infected oocysts or tissue cysts can become infected with toxoplasmosis. If the meat is not cooked above 60 °C or frozen below –20 °C, cysts remain viable (Montoya and Liesenfeld 2004).

The three main forms of transmission to humans of *T. gondii* are:

- Ingestion of oocysts eliminated by cats or eating undercooked meat containing cysts
- Transplacental transmission
- Infection through blood transfusion or organ transplant

Cats living in a strictly domestic environment have little chance of spreading infection. Congenital infection occurs if the mother acquires a toxoplasmic infection during pregnancy (primary infection). However, there have been cases of vertical transmission in HIV-positive women with latent toxoplasmosis after reactivation of the parasite.

Clinical Presentation

Primary infection with *T. gondii* is asymptomatic in most immunocompetent individuals. Up to a third of cases, and more frequently in children, may present an adenitis, a flu-like or a mononucleosis-like syndrome.

Most cases of toxoplasmosis with central nervous system (CNS) involvement associated to AIDS or to other states of severe cellular immunosuppression are the consequences of the reactivation of a previous infection in seropositive individuals. Clinical manifestations depend on where in the CNS the infection is reactivated and the intensity of the local inflammatory response, which can vary according to the CD4⁺ T cell count of the patient.

The clinical description given below is observed in patients with AIDS, who represent the vast majority of cases of cerebral toxoplasmosis. Other patients with cellular immunodeficiency (such as stem cell transplant recipients) have extra-neurological forms, such as lung disease (pneumonitis) or disseminated disease, more often than patients with AIDS, but in the case of brain involvement, the clinical presentation is very similar.

Neurological Disease

About 50% of patients with intracerebral infection present with headaches, confusion, and altered consciousness. The beginning of the disease can be insidious or abrupt. Up to 30% of patients suffer seizures as the initial manifestation, and 50–60% show signs of focal neurological deficiency. High fever with chills, neck stiffness, and other meningeal signs are unusual and should suggest other diagnoses (Miro et al. 2008).

Since cerebral toxoplasmosis is often multifocal, intracerebral masses are very destructive and inflammatory and can develop in any part of the brain, although the cortical-subcortical union of the cerebral hemispheres is the most frequent site. Virtually, any neurological syndrome can develop and produce motor or sensory deficits, among other focal deficits. The brainstem, the basal ganglia, and the cerebellum may also be affected, and patients can present with movement disorders, neuropsychiatric findings, and varying levels of depression in their level of consciousness, including coma.

Hemiparesis is the most common focal deficit, but there may be cranial nerve injuries, focal seizures, aphasia, visual loss, ataxia, dysmetria, tremors, hemiballismus, and other extrapyramidal signs. The involvement of the spinal cord can produce transverse myelitis or conus syndrome. Hydrocephalus, brain hemorrhage, and choroiditis may also occur less frequently (Antinori et al. 2004).

Extra-neurological Disease (Isolated or Concomitant to Cerebral Involvement)

In addition to the CNS, reactivation foci can also be observed in other organs, most frequently the

lungs in form of pneumonitis and the eyes as chorioretinitis, concomitantly or not with brain involvement. Since parasites may form cysts in any organ, and since recurrent parasitemia can occur in association with reactivations, new parasitic implants may occur in other organs, and thus the clinical manifestations of extracerebral toxoplasmosis can be quite diverse. In fact, autopsy studies often show unrecognized multi-organic involvement; up to 50% of patients with no concomitant CNS disease have extracerebral lesions, but these are frequently subclinical (Rabaud et al. 1994).

Ocular Disease

Ocular disease is probably the most common clinical manifestation of extracerebral HIV-associated toxoplasmosis. In 30–60% of chorioretinitis cases, encephalitis is also present. Conversely, relatively few patients with encephalitis present concomitant chorioretinitis. Visual symptoms due to *Toxoplasma* retinitis include loss of visual acuity and myodesopsia. Funduscopic examination reveals areas of yellow-white-colored necrotizing retinitis, sometimes with hemorrhage and vasculitis. Lesions are predominantly unilateral. Fluorescein angiography shows hyperfluorescence from the periphery and progressing toward the center of the lesions. *Toxoplasma* retinitis must be differentiated from retinitis caused by cytomegalovirus, varicella zoster virus, syphilis, and fungi, including *Pneumocystis jirovecii* retinitis.

Pulmonary Disease

Pulmonary manifestations of toxoplasmosis represent up to 35% of extrapulmonary forms. Fever and dyspnea are the most common symptoms, while cough and sputum may be missing. Chest x-rays usually show bilateral diffuse infiltrates in the lungs (similar to *Pneumocystis jirovecii* RX pattern). Multiple nodular infiltrates have been also reported. Typically, there is a massive increase in lactate dehydrogenase (LDH). The diagnosis can be established by examining the bronchoalveolar lavage, which reveals *T. gondii* trophozoites detected by special staining or by molecular biology, i.e., polymerase chain reaction (PCR).

Other Organ Involvement

Along with pneumonitis and chorioretinitis, extracerebral manifestations have been reported in virtually every organ and even sepsis-like clinical presentations in severely immunocompromised patients (generally non-AIDS immunosuppressed patients) with elevated massive LDH increases, to which molecular biology techniques, such as PCR performed in blood, are highly sensitive and specific in establishing a diagnosis.

Central Nervous System Involvement During Acute Toxoplasmic Infection

Although it is much less common, the CNS can be affected during the *Toxoplasma* primary infection. Patients with primary infection and with severe forms of cellular immunosuppression can produce severe visceral manifestations and disseminated infection, including pneumonitis, myositis, myocarditis, orchitis, and encephalitis, manifested in the form of diffuse involvement or intracerebral masses.

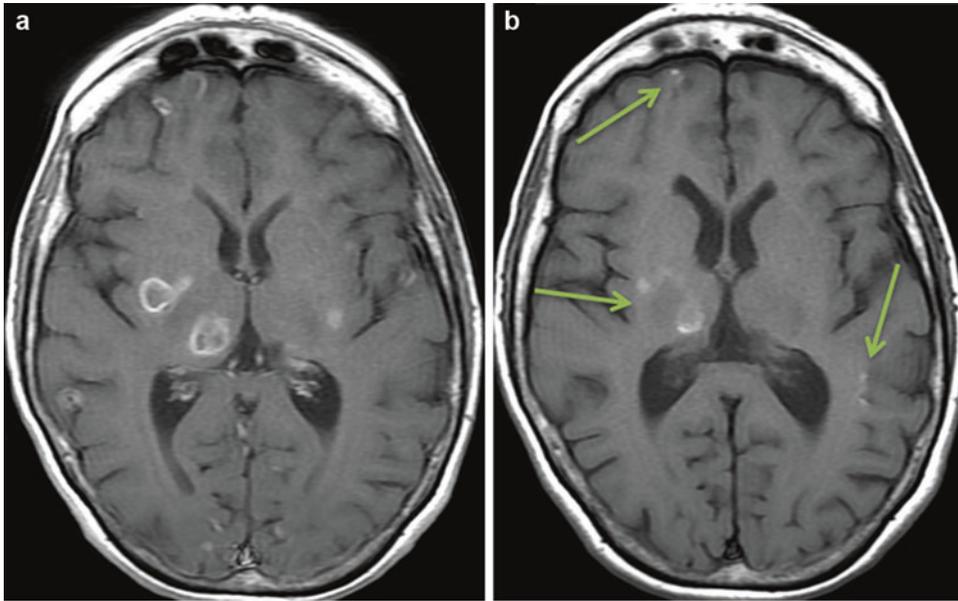

Diagnosis

Clinical Suspicion

Anatomical Neuroimaging (CT/MRI)

When cerebral toxoplasmosis is suspected, neuroimaging must be performed urgently. In most clinical series, 10–43% of patients with toxoplasmic encephalitis have a solitary parenchymal injury, demonstrated by computed tomography (CT); the remaining patients have more than one injury. It is unusual to have a negative CT scan in symptomatic patients (3–10%).

The most typical presentation of cerebral toxoplasmosis is the presence of multiple focal intracerebral lesions (Fig. 1), which are detected more often with magnetic resonance imaging (MRI), as it is more sensitive than CT. With MRI, over 80% of patients are found to have multiple lesions. Therefore, if there is a single lesion on CT, and this is confirmed by MRI, a lymphoma or other causes of focal injury associated with AIDS (as tuberculoma or histoplasmosis) should be ruled out. In cerebral toxoplasmosis, injuries are more often bilateral and

Toxoplasmosis in HIV-Infected Patients, Fig. 1 Toxoplasmosis in a 55-year-old female. Panel (a) Post-contrast axial T1-weighted MRI demonstrating multiple hemorrhagic enhancing lesions (nodular and ring

enhancing) with edema. Panel (b) Non contrast axial T1-weighted MRI taken 4 months later showing marked decrease in the number, size, and edema of lesions with residual calcified images (*green arrows*)

present contrast ring enhancement (80–90% cases) and produce a mass effect and edema. They often develop in the basal ganglia, the thalamus, or the corticomedullary junction of the cerebral hemispheres.

However, no presentation using CT or MRI is considered absolutely diagnostic of cerebral toxoplasmosis. Lymphoma and toxoplasmosis can produce very similar imaging, for example, multifocal disease and contrast reinforcing ring lesions can be seen in up to 40–50% of AIDS patients with primary CNS lymphoma (PCNSL). Hemorrhage before treatment may sometimes be seen in toxoplasmosis, and this finding can help differentiate toxoplasmosis from lymphoma. Furthermore, a “target sign” (an eccentric nodule inside an enhancing ring) is highly suggestive of toxoplasmosis (Smith et al. 2008). Advanced MRI techniques can also help differentiate diagnoses. Lymphoma lesions show reduced diffusion in diffusion-weighted imaging, and MR perfusion shows an elevated relative cerebral blood volume. HMR spectroscopy in lymphoma indicates elevated peaks of choline.

Functional Neuroimaging (SPECT/PET)

In an effort to clarify the noninvasive diagnosis of cerebral toxoplasmosis (which is always presumptive), other imaging techniques have been evaluated, particularly to help to differentiate it from PCNSL. Single-photon emission CT (SPECT) using thallium 201 and positron emission tomography (PET) using marked 2-fluorodeoxyglucose are useful techniques. In both techniques, infections (such as cerebral toxoplasmosis) are observed as cold or hypometabolic lesions, while lymphoma behaves like a hypermetabolic lesion. Both techniques are insensitive to small lesions, less than 8 mm, and, although rare, false positives and false negatives may occur. Although these techniques are useful to diagnose a PCNSL, they are not necessary to confirm toxoplasmosis. If cerebrospinal fluid (CSF) is obtained, these functional imaging techniques can be combined with molecular techniques, such as PCR for toxoplasmosis or the Epstein-Barr virus (EBV), in order to make reliable differential diagnoses between cerebral toxoplasmosis and primary CNS lymphoma (Antinori et al. 1999).

Therapeutic Trial as a Diagnostic Method and Indication to Brain Biopsy

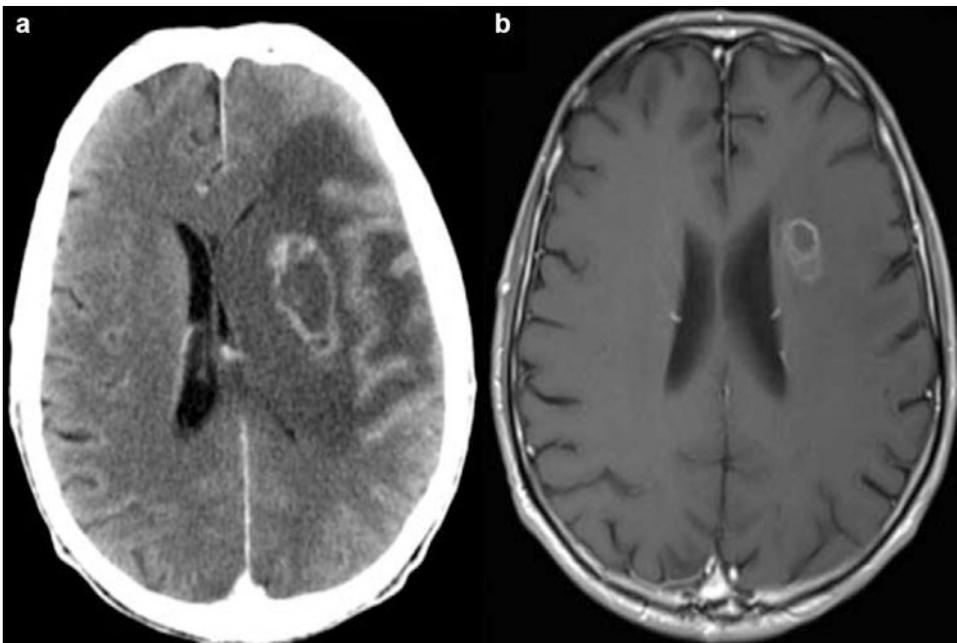

From a practical perspective, however, most of these patients undergo an empirical trial of anti-*Toxoplasma* therapy for 10–14 days. If after this period there is no clinical or radiological improvement, a brain biopsy should be performed. Most patients with cerebral toxoplasmosis (65–90%) respond readily to a treatment of two drugs: pyrimethamine, with either sulfadiazine, or clindamycin, with response rates of over 90% within 2–3 weeks (Fig. 2). Brain biopsy has been transformed over the years into a procedure now only reserved for a limited number of clinical situations, particularly for those patients who do not respond to empirical treatment or who have an alternative diagnosis suggested by imaging or microbiological CSF findings.

Microbiological Diagnosis

The definitive diagnosis of the cause of toxoplasmosis encephalitis is performed by the

demonstration of tachyzoites in the brain tissue (Fig. 3). However, as already mentioned, because of the invasiveness of brain biopsies and the lack of experience in many centers, this option is limited to rare cases in which diagnosis cannot be confirmed by other techniques or in which there has been no response to therapeutic treatment.

Until the advent of molecular biology techniques, the etiologic diagnosis of toxoplasmosis was made almost exclusively by serology. However, if the patient presents severe immunodeficiency, serology may fail or give misleading results, and there have been reports of a lack of *Toxoplasma* IgG response in serum in HIV-positive patients. However, in Western Europe and the United States, undetectable levels of IgG are very rare in determinations performed in reference laboratories. The presence of IgM anti-*Toxoplasma*, however, is difficult to detect in HIV-positive patients; and, since in most cases cerebral toxoplasmosis is caused by reactivations, it has limited value (Marcos et al. 2008).

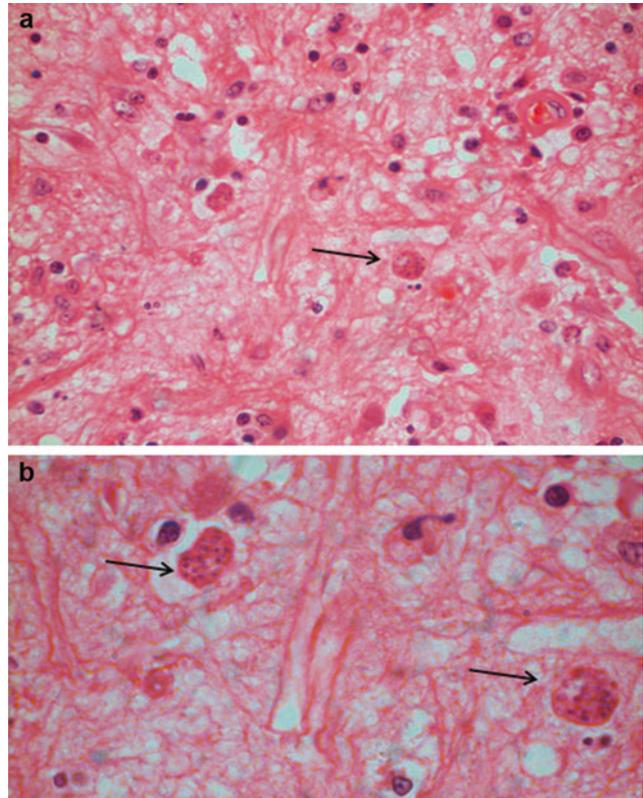

Toxoplasmosis in HIV-Infected Patients, Fig. 2 Cerebral toxoplasmosis. Panel (a) Post-contrast axial CT showing a large deep lesion in the left hemisphere with significant edema, mass effect, and contrast ring enhancement. A second smaller lesion seems to be present

behind the bigger one. Panel (b) Post-contrast axial T1-weighted MRI taken 3 weeks after anti-*Toxoplasma* treatment showing a marked reduction in lesion size, mass effect, and edema

Toxoplasmosis in HIV-Infected Patients,

Fig. 3 *Toxoplasma* encephalitis in humans (AIDS related) – ©LSHTM. Panel (a) Tachycyst of *T. gondii* in brain 100 × (arrows) – hematoxylin and eosin stain. Panel (b) Tachycyst of *T. gondii* (arrows) at bigger magnification – hematoxylin and eosin stain

Anti-*Toxoplasma* IgG detection in CSF is positive in 30–70% of patients with toxoplasmic encephalitis, although this alone does not constitute a diagnosis of brain disease. It does, however, have a high specificity when clinical presentation is also suggestive. Moreover, despite the detection of intrathecal IgG production being very useful, obtaining CSF is not always possible. In many patients with suspected toxoplasmosis, CSF extraction is avoided due to the risk of herniation, and in many centers it is not part of the routine diagnostic procedures for cerebral toxoplasmosis. If it is obtained, CSF frequently does not show any significant alteration, since these lesions are frequently not in contact with the subarachnoid space (Miro and Alvarez-Martinez 2013).

Molecular diagnostic techniques are not exempt from difficulties either. The main problem for the amplification of the toxoplasmic genetic material by PCR techniques is the absence of standardized protocols. Various types of PCR

have been used: conventional PCR, final-time PCR (semi-nested and nested formats), real-time PCR, and PCR followed by oligochromatography. Likewise, several genes have been used as *T. gondii* target amplification. The B1 is the most widely used gene, having 35 copies in the genome, and also the most stable. Other genes used as targets are the P30 gene, a uni-copy gene encoding the major surface antigen; rRNA, encoding the small subunit ribosomal RNA, with 110 copies in the genome; the fragment 529 bp with 300 copies per genome, the genes encoding α -tubulin and β -tubulin; and the DNA repetitive noncoding fragment TGR1E.

In addition to CSF, PCR can be also performed in the bronchoalveolar lavage, the vitreous and aqueous humor, pleural and peritoneal fluid, bone marrow aspirates, peripheral blood, and affected tissues, such as the brain.

Until the development of PCR-based techniques, brain biopsy was the gold standard for

diagnosis confirmation. Currently, the diagnosis is confirmed by PCR from blood or preferably from CSF, preventing the morbidity of intraoperative biopsy. The sensitivity of PCR blood is 16–86%, depending on the type of test used. With CSF, sensitivity is also very variable, from 17% to 100%. For both samples, the sensitivity decreases dramatically if the patient has previously received anti-*Toxoplasma* treatment. Specificity of CSF PCR is higher than 90%. Despite the variable sensitivity, the high specificity and the high positive predictive value of CSF PCR make it a very useful technique in the diagnosis of focal brain lesions in immunosuppressed patients with clinical and radiological suspicion. It must be remembered, however, that a positive PCR for *T. gondii* in the blood does not mean that the intracerebral process has the same etiology. Indeed, multiple opportunistic infections in extremely immunosuppressed AIDS patients are not unusual.

The most common form of extracerebral and extraocular toxoplasmosis in immunocompromised including HIV-infected patients is lung infection. Detection of *T. gondii* by PCR in lung tissue samples or bronchoalveolar lavage has a sensitivity and specificity of 100% in these cases. In the diagnosis of disseminated forms, detection by PCR in blood has a sensitivity and specificity of close to 100%. In ocular toxoplasmosis, DNA detection of the parasite in the aqueous humor is less sensitive than local antibody detection; indeed, PCR has a sensitivity of 18–37%. However, when the diagnosis is made in the vitreous humor, the sensitivity approaches 100%.

Therefore, despite the lack of standardization for molecular diagnostic methods for toxoplasmosis, they should still be considered to supplement or confirm a clinical, radiological, and serological diagnosis in immunocompromised patients as well as to be useful in monitoring the progress of patients with, or at risk of, toxoplasmosis.

Antimicrobial Treatment

Cerebral Toxoplasmosis

Treatment of cerebral toxoplasmosis includes treating the clinically active infection, followed

by maintenance therapy to suppress recurrent disease in patients with CD4⁺ T cell count below 200 cells/mm³. The recommendations for treatment almost always involve drug combination (Table 1).

The standard treatment for toxoplasmosis includes an association of pyrimethamine (loading dose of 100 or 200 mg followed by 75 or 50 mg/day) and sulfadiazine 1,000 mg (<60 kg) or 1,500 mg (>60 kg) every 6 h. In the outpatient setting, the sulfadiazine daily dose can also be given twice daily taking into account the serum half-life of 7–12 h. Intravenous trimethoprim-sulfamethoxazole is a recommended therapy for patients unable to receive oral therapy.

For patients with intolerance to sulfonamides, pyrimethamine plus clindamycin (600 mg four times daily, intravenously or orally) has shown comparable or slightly lower effectiveness in most studies (Katlama et al. 1996). Clindamycin has the advantage of an IV formulation. Clindamycin/pyrimethamine does not prevent *Pneumocystis jirovecii* pneumonia; therefore, a pneumocystis prophylactic regimen must be added. Patients with pneumonitis, chorioretinitis, the involvement of other organs, or a disseminated infection should receive the same treatment. Folinic acid (leucovorin calcium, 10–20 mg/day orally, although this dose can be increased to 50 mg/day or more) must be associated with a regimen containing pyrimethamine to reduce toxicity to bone marrow.

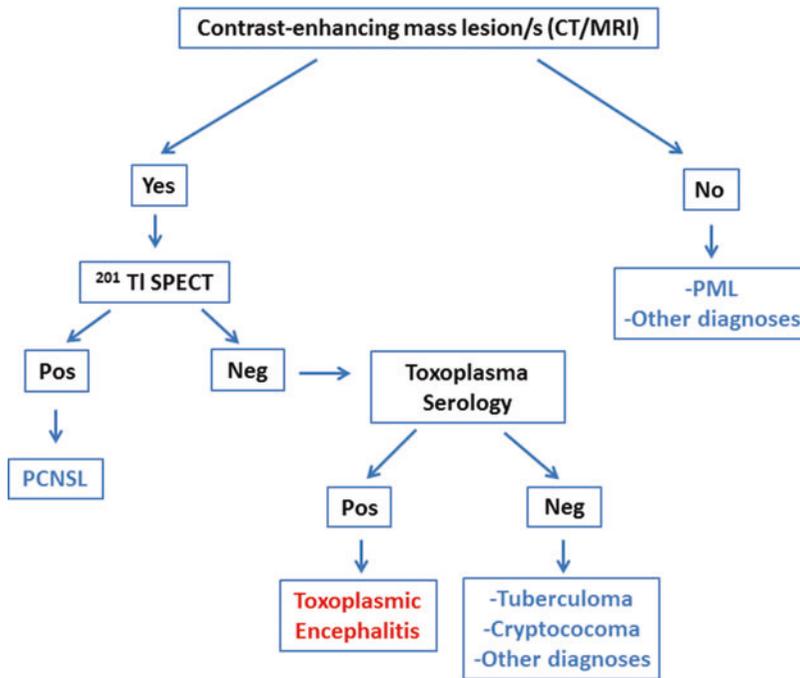

The clinical and radiological response of patients depends on the level of neuronal destruction and the timing of the initiation of therapy and of the immune response, but it should be evident during the first 3 weeks, at least clinically. Resistance of *T. gondii* to drugs used for therapy has not been documented. Most patients with chorioretinitis also respond and show an improvement in visual acuity within 6 weeks. Mortality rates in the acute phase of *Toxoplasma* encephalitis ranged between 5% and 20% in published series. Death usually occurs due to very advanced illness at the time therapy was initiated and is often due to other simultaneous opportunistic diseases. The prognosis for medium and long-term recovery depends on the state of

Toxoplasmosis in HIV-Infected Patients, Table 1 Prophylaxis and treatment of cerebral toxoplasmosis in patients with AIDS^a

Primary prophylaxis			
Indication	Preferred	Alternatives	Suspension/reinitiation
Positive IgG anti- <i>Toxoplasma</i> Ab and CD4 < 100/mcl (US) (AIII) or <200/mcl (Europe) All the regimens recommended for 1ry prophylaxis are effective against <i>P. jirovecii</i> <i>Prevention of exposure</i> Eat cooked enough (or previously frozen at -20 °C) meat, wash fruits and vegetables, and wear gloves if close contact with raw meat or gardening activities (BIII) Wear gloves and apply hygiene measures if close contact with domestic animals (cats) and their droppings Ensure that cats stay at home and avoid eating raw or undercooked meat (BIII)	Co-trimoxazole 1 comp DD (trimethoprim/sulfamethoxazole 160/800 mg) PO/d (AII)	Co-trimoxazole 1 comp DD ×3/sem PO (BIII) Co-trimoxazole 1 comp (trimethoprim/sulfamethoxazole 80/400 mg)/d PO (BIII) Dapsone 50 mg/d VO + pyrimethamine 25 mg + folic acid 25 mg ×2/sem PO (BI) Dapsone 200 mg + pyrimethamine 75 mg + folic acid 25 mg/sem PO (BI) Atovaquone 1,500 mg with/without pyrimethamine 25 mg + folic acid 15 mg/d PO (CIII)	Stop prophylaxis after ≥ 6 months of ART, if CD4 > 200 cel/mcl and VL undetectable during ≥ 3 months (AI) Resume prophylaxis if CD4 < 100–200 cells/mcl (AIII)
Treatment of acute episode			
Disease	Preferred	Alternatives	Comments
Focal abscesses in CNS or retinochoroiditis	Pyrimethamine 200 mg PO (loading dose), followed by: Pyrimethamine 50 mg/d PO + sulfadiazine 1,000 mg/6 h PO (<60 kg) Pyrimethamine 75 mg/d PO + sulfadiazine 1,500 mg/6 h PO (≥60 kg) + folic acid 15 mg/d VO (AI)	Pyrimethamine 50–75 mg/d PO + clindamycin 600 mg/6 h IV o PO + folic acid 15 mg/d PO (AI) Co-trimoxazole (trimethoprim/sulfamethoxazole, -trimethoprim 10 mg/kg/d-) IV o VO (BI) Atovaquone 1,500 mg/12 h PO + pyrimethamine 50–75 mg/d PO (and folic acid 15 mg/d PO) or + sulfadiazine 1,000–1,500 mg/6 h (BII) Pyrimethamine 50–75 mg/d VO + azithromycin 900–1,200 mg/d PO + folic acid 15 mg/d PO (CII)	Minimum duration: 6 weeks (prolong it if growing lesions of incomplete response) (BII) Clindamycin regimens do not protect against <i>Pneumocystis jirovecii</i> ; add specific prophylaxis (AII) If intracranial hypertension, add dexamethasone (BIII) If seizures, add antiepileptic drugs (not as prophylaxis) (AIII)
Suppressive therapy (secondary prophylaxis)			
Indication	Preferred	Alternatives	Suspension/reinitiation
All the patients who have completed the acute phase of therapy	Pyrimethamine 25–50 mg/d PO + sulfadiazine 1,000 mg/6–12 h VO + folic acid 15 mg/d VO (AI)	Pyrimethamine 25–50 mg/d VO + clindamycin 600 mg/8 h VO + folic acid 15 mg/d VO (BI) Co-trimoxazole 1 comp DD/12 h VO (BII) Atovaquone 750–1,500 mg/12 h PO + pyrimethamine 25 mg/d PO (+ folic acid 15 mg/d VO) or + sulfadiazine 1,000 mg/6–12 h (BII) Pyrimethamine 25–50 mg/d PO + azithromycin 500–1,000 mg/d PO + folic acid 15 mg/d PO	Stop if CD4 > 200 cells/mcl and ART > 6 months and viral load undetectable (BI) Resume prophylaxis if CD4 < 200 cel/mcl (AIII)

^aThe level of recommendation (A, B, C and I, II, III) corresponds to the Infectious Diseases Society of America (IDSA) Adapted from Panel on Opportunistic Infections in HIV-Infected Adults and Adolescents, GESIDA and National AIDS Plan Expert Panel (2008), Guidelines of the AIDS Study Group (GESIDA), and National AIDS Plan (2008)

Toxoplasmosis in HIV-Infected Patients, Fig. 4 Neuroimaging work-up plan in AIDS patients with CNS lesions. A cerebrospinal fluid sample should be obtained when possible for viral (*CMV*, *EBV*, *JCV*), parasitic (*T. gondii*), and mycobacterial molecular diagnosis. *CT* computed tomography, *MRI* magnetic resonance image, *201TI SPECT* 201 thallium single-photon emission

computed tomography, *PML* progressive multifocal leukoencephalopathy, *PCNSL* primary central nervous system lymphoma, *CMV* cytomegalovirus, *EBV* Epstein-Barr virus, *JCV* JC virus. 201TI SPECT: useful to differentiate from PCNSL, but not necessary to confirm toxoplasmosis

immunosuppression. Patients with pneumonia or disseminated infection have a poor prognosis, often associated to the base state of immunosuppression.

Treatment of cerebral toxoplasmosis should continue for at least 6 weeks. Most clinicians continue therapy longer if the clinical manifestations do not improve or if lesions on MRI remain stable or do not significantly decrease in size for many weeks. Imaging studies should be repeated within 2 weeks to ensure that toxoplasmosis was the correct and only cause of the injury (Fig. 3). If the lesions have not improved, a biopsy (or a repeat biopsy) should be considered to determine whether more than one process was present. If toxoplasmosis is the only proven diagnostic and neurological symptoms have not improved after 2 weeks, an alternative regimen could be used, but there is no evidence that this strategy may improve the prognosis. Although serial scans

during the following months can demonstrate the complete or nearly complete resolution of the localized and multifocal disease, no repeat studies are required in a patient with clinical improvement receiving standard treatment. The initial diagnosis algorithm in a patient with suspected cerebral toxoplasmosis can be seen in Fig. 4.

Adverse Effects of Treatment and Alternative Regimens

Rashes and other adverse inflammatory reactions to sulfonamides are well recognized in HIV-infected patients. Additionally, patients treated with sulfadiazine can develop crystalluria, hematuria, renal colic, and occasionally some degree of kidney failure. Adequate fluid intake should be guaranteed to minimize tubular crystal formation.

Blood count should be monitored since pyrimethamine is associated with pancytopenia, especially with neutropenia. This effect may be more

pronounced if pyrimethamine is combined with sulfa drugs than with clindamycin.

The main adverse effect of clindamycin is diarrhea. In patients to whom no orally drugs can be given, trimethoprim-sulfamethoxazole has shown comparable activity in some small clinical trials and can be administered intravenously. Some authors consider trimethoprim-sulfamethoxazole as one of the preferred regimens.

Atovaquone is also an antimicrobial with antitoxoplasmic activity and may be associated with both pyrimethamine and sulfadiazine. It can also be used as monotherapy in patients unable to tolerate either of these drugs, but its effectiveness is reduced compared to the previously discussed regimens. Macrolides (azithromycin and clarithromycin) are also active molecules against *Toxoplasma*, but should be used in combination with pyrimethamine.

Adjuvant Use of Corticosteroids and Anticonvulsants

Adjunctive corticosteroids (e.g., dexamethasone) should not be administered routinely but only if a clinical evaluation indicates the need to reduce intracerebral pressure where there is considerable mass effect from focal lesions or when seizures are intractable. Patients receiving corticosteroids must be closely monitored to prevent the development of other opportunistic infections such as cytomegalovirus retinitis, disseminated cryptococcosis, and tuberculosis.

Anticonvulsants should be given to patients with proven seizures but not routinely to all patients with *Toxoplasma* encephalitis. Phenobarbital or phenytoin sodium is not recommended due to potential drug interactions with many antiretroviral drugs. Sodium valproate is preferred. There is no clear evidence of how long they should be continued after an initial convulsive attack. Anticonvulsants should probably be continued for at least the duration of the acute treatment.

Suppressive Therapy (Secondary Prophylaxis) After the Acute Episode

After at least 6 weeks of treatment, with clinical and radiographical response, patients should

maintain treatment for life (secondary prophylaxis or suppressive therapy), unless there is effective immune reconstitution in response to antiretroviral therapy with an increase in CD4⁺ T cells to above 200 cells/ μ l. Maintenance therapy should only be discontinued once CNS lesions show no contrast enhancement on CT/MRI. Without prophylaxis, rates of relapse for *Toxoplasma* encephalitis are 50–80% at 6–12 months in patients without effective immune reconstitution.

For maintenance therapy, most clinicians maintain the oral dosing regimen at a half dosage. Recurrences (10–40%) may occur and, as already mentioned, are due to nonadherence either to drug treatment or to serious immunodeficiency. Drug resistance is thought to be a rare event. In patients who were treated with trimethoprim-sulfamethoxazole, a reduction of the dose to a daily double-dose tablet seems a reasonable alternative to secondary prophylaxis.

Suppressive treatment can be stopped with immune reconstitution and is generally accepted after measurements of CD4 > 200 cells/ μ L in patients whose viral loads of HIV-1 remain undetectable for 3–6 months and who are adherent to treatment. In this situation, discontinuation is considered without risk of recurrence (Miro et al. 2006). The summary of the recommendations of treatment of acute episodes and primary and secondary prophylaxis are shown in the table.

Differential Diagnoses

As previously explained, PCNSL represents the most important diagnosis to exclude. PCNSL presents more frequently as a single lesion, hypermetabolic in SPECT or PET. If a lumbar puncture is not contraindicated, PCR for EBV is frequently positive. Indeed, the association of a single lesion in CT/MRI, a positive PET/SPECT, and a positive PCR for EBV has extremely high specificity and positive predictive value for PCNSL (Fig. 4).

In single lesions, with negative SPECT/PET and negative *T. gondii* IgG serology and no anti-*Toxoplasma* response, alternative diagnoses such as cryptococcoma or tuberculoma should be considered (Fig. 4). Both *Cryptococcus* and *M. tuberculosis* present more frequently as chronic meningitis, but they can produce single or multiple

intracerebral masses, which are normally hypometabolic in functional imaging techniques. PCR for *M. tuberculosis* or capsular Ag for *Cryptococcus* is usually positive in CSF. However, in some cases, confirmation may require the aspiration of material or a biopsy (Skiest 2002).

Other causes of multiple cerebral abscesses, such as a *Nocardia* infection or other bacterial and fungal diseases, may also be considered.

ART Initiation

In AIDS patients with opportunistic diseases, the early initiation of antiretroviral therapy (ART) within 2 weeks of the diagnosis of an opportunistic infection improves prognosis (reduces the risk of clinical progression to new AIDS events and death), with the exception of cryptococcal meningitis and probably of tuberculous meningitis. Therefore, the initiation of ART should not be delayed, although this entails an additional burden given the number of tablets and the risk of interactions. For toxoplasmosis, drug interactions do not represent a major problem, and there is no preferred antiretroviral regimen. Some clinicians prefer an antiretroviral combination with good penetration into the CNS, although it has not been shown that this is associated with a better prognosis. As with most opportunistic infections in patients with AIDS, there is a risk of worsening clinical manifestations when patients improve their immune status, a phenomenon known as immune reconstitution inflammatory syndrome (IRIS). However, it is rarely seen in cerebral toxoplasmosis, even if steroids are not used. Nevertheless, there should be very close monitoring of neurologic outcomes in patients during the first weeks of ART treatment. If IRIS is suspected, other concomitant neurological processes should be excluded. Treating IRIS involves the use of anti-inflammatory drugs such as corticosteroids.

Antimicrobial Treatment of Extracerebral Toxoplasmosis

Data on the outcome of treatment of AIDS patients with toxoplasmosis outside the CNS are limited; available information on the therapy of

ocular and pulmonary involvement indicates that these forms of toxoplasmosis are also responsive to treatment. Therapeutic combinations are the same used for toxoplasmic encephalitis, although duration of therapy is less well established.

Prevention

Primary Prophylaxis

Primary prophylaxis is indicated in patients with a positive serology for *T. gondii* with CD4 < 100 cells/ μ L according to the US guidelines and in patients with CD4 < 200 according to some European experts. In practice, the patients should receive trimethoprim-sulfamethoxazole where CD4 < 200 cells/ μ L to prevent *P. jirovecii* pneumonia, typically a double-dose tablet (160/800 mg) three times a week. This regimen protects very effectively against toxoplasmosis. Pyrimethamine alternative schemes are associated with dapsone, sulfadoxine, or atovaquone or also atovaquone alone (Table 1).

HIV-Infected Patients Seronegative for *T. gondii*

In severely immunocompromised patients who are seronegative for *T. gondii*, primary infection with *T. gondii* should be avoided (by not eating raw meat or poorly washed vegetables).

Conclusions

Cerebral toxoplasmosis continues to be a major problem with high morbidity and mortality in severely immunocompromised HIV-positive patients and, less frequently, in other patients with depressed cellular immunity. The diagnostic approach, treatment, and prognosis have remained relatively unchanged in recent years. Neurological *Toxoplasma* involvement is still prevalent in patients with late diagnosis of HIV infection, so detailed knowledge is essential for specialists in neurology, infectious diseases, clinical microbiology, and internal medicine.

Definition of HIV Transcription

After integration, the HIV provirus serves as a template for the transcription of both viral messengers and genomic RNA by the cellular RNA polymerase II (RNAPII). Proviral transcription is initiated by the viral promoter and is determined by cellular factors and environment. In contrast, HIV-1 transcription elongation is dependent on the viral trans-activator protein Tat in addition to cellular elongation factors. Indeed, HIV-1 gene expression is characterized by an early Tat-independent phase, where the elongation is inefficient, and a late Tat-dependent phase, where the elongation is processive. The regulation of HIV-1 transcription also depends on a number of other elements discussed in this entry.

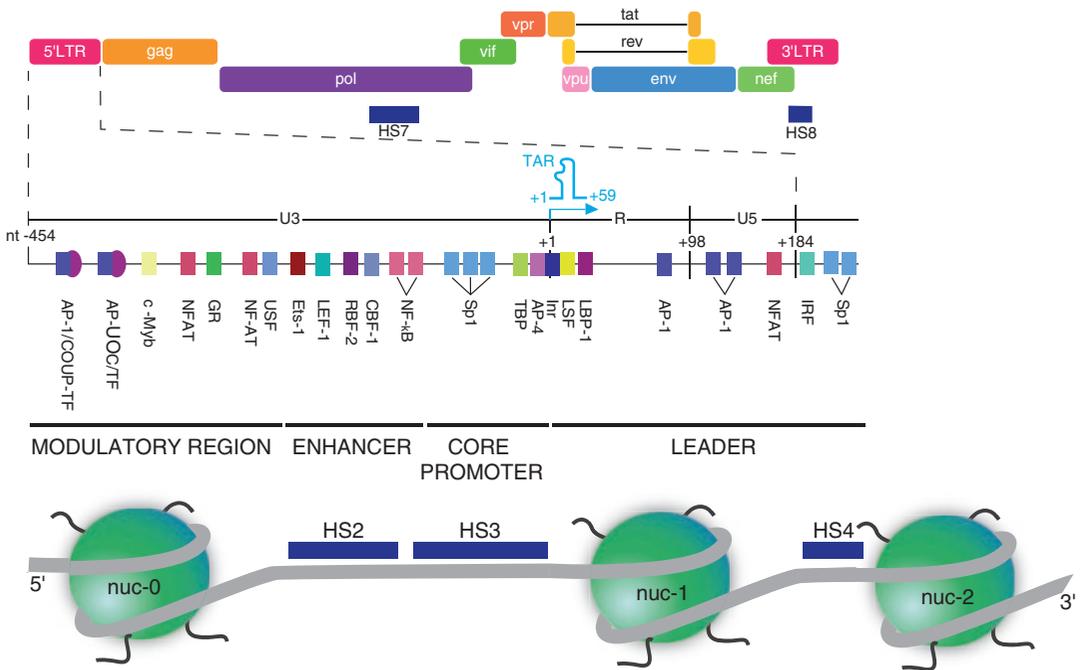

Mechanisms of HIV-1 Transcription

Organization of the HIV-1 Promoter

The main HIV-1 transcriptional *cis*-regulatory elements are located in the viral long terminal repeats (LTRs). These are present at both extremities of the integrated DNA and have been divided in three regions, named U3 (unique in 3'), R (repeated), and U5 (unique in 5') in reference to their respective origin in the viral RNA genome (Fig. 1). Transcription initiates at the U3/R junction in the 5' LTR and transcripts are polyadenylated at the R/U5 junction in the 3' LTR.

The HIV promoter has been extensively characterized *in vitro* and is divided in four functional domains that control basal and activated transcription. Binding sites for several transcription factors (TFs) have been identified in each of these domains using *in vitro* footprinting and gel retardation assays (Fig. 1). From the 5' end to the 3' end, the

four domains are as follows. Firstly, the modulatory region contains two binding sites for the AP-1 and/or the COUP cellular TFs, as well as binding sites for the glucocorticoid receptor (GR), NFAT, and USF/TFE-3. Secondly, the enhancer is composed of a distal region and a proximal region. The distal enhancer region contains DNA-binding sites for the cellular TFs TCF-1/LEF-1 and Ets-1, and the proximal enhancer region contains two binding sites for NF-κB. Thirdly, the core promoter contains three Sp1 binding sites, a TATA box, and an initiator (Inr) element close to the transcription start site. Finally, the leader region contains the inducer of short transcript element and binding sites, for example, UBP-1/LBP-1, AP-1, NFAT, and Sp1. Furthermore, the latter region encodes the transactivating response (TAR) element (nucleotide (nt) 1–59, where nt +1 represent the transcription start site) whose RNA forms a stable stem-loop structure (Fig. 1).

Transcription (Initiation, Regulation, Elongation), Fig. 1 Schematic representation of the HIV-1 5' LTR. The HIV-1 genome is represented at the top of the figure. Major hypersensitive sites (HS, blue boxes) located through the genome and nucleosomal organization of the HIV-1 genome 5' region are indicated. The U3, R, U5, and leader regions are indicated. Nucleotide 1 (nt +1) is the

transcription start site of HIV-1. The four functional regions involved in transcriptional regulation as well as the transcription factor binding sites identified in these regions are shown. See text for details (This figure is adapted from Colin and Van Lint, *Retrovirology* 2009, with permission from BioMed Central)

The HIV-1 pandemic is caused by at least nine subtypes (A, B, C, D, F, G, H, J, and K) from the major (M) group and an increasing number of recombinant forms. The LTR of the HIV-1 genome is one of the most conserved regions among virus isolates and subtypes. This relative conservation indicates that the LTR is subject to strict constraints because it is important for viral gene expression and replication. Although, most HIV-1 isolates have three Sp1 sites and at least two NF- κ B sites, the subtype C promoter contains three canonical NF- κ B motifs. There is considerable variation in the presence of other binding sites, such as AP-1, NFAT, and USF, and some of these differences are subtype specific.

Under basal conditions, two major DNase I-hypersensitive sites (short region of chromatin detected by its super sensitivity to cleavage by DNase I and other various nucleases) are present in the 5' LTR: HS2 (nt -234- > -132) and HS3 (nt -67- > -7), which map to the HIV-1 promoter in the U3 region (Fig. 1). Site HS4 (nt 201- > 265) is located immediately downstream of the 5' LTR in a region overlapping the primer binding site (Fig. 1).

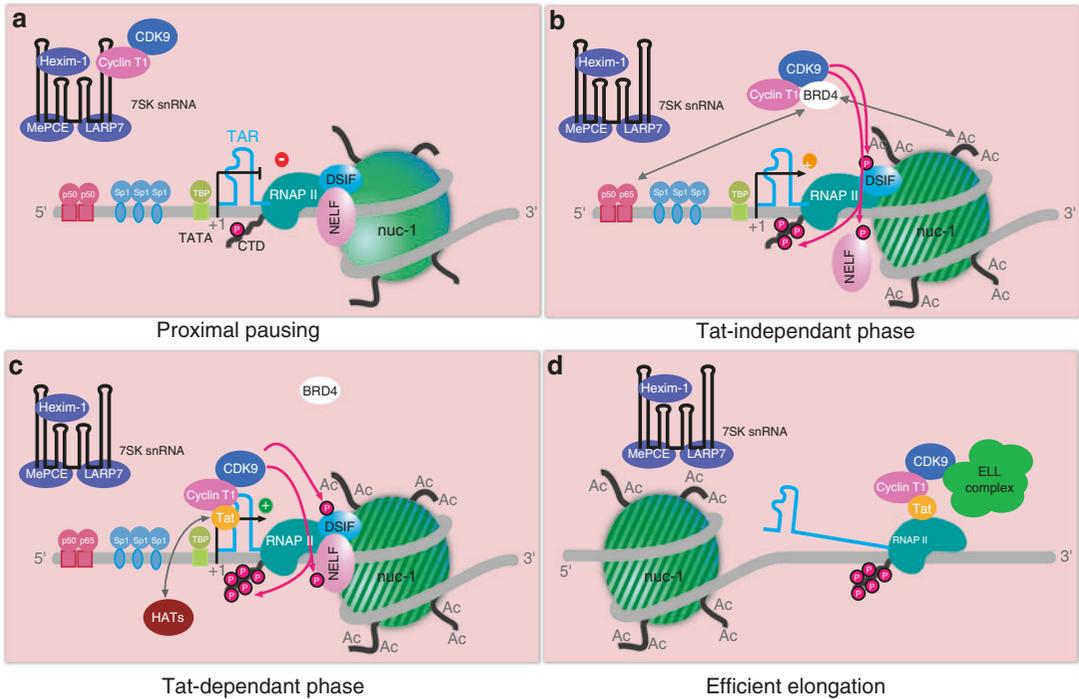

The 3' LTR, containing the polyadenylation signal for viral transcripts, exhibits a pattern of DNase I hypersensitivity that is different from the 5' LTR, with only a single major hypersensitive site (HS8) mapping to nt 8,867- > 9,034 (Fig. 1).

Besides the presence of DNase I-hypersensitive sites in the LTRs, a single major hypersensitive site (named HS7) has been identified in the part of the *pol* gene coding for the integrase (centered on nt 4,035- > 4,311, Fig. 1). Several ubiquitous and cell-specific TFs have been shown to be recruited to the HS7 region (including Oct-1, Sp1/Sp3, PU.1, and AP-1) and to be important for viral infectivity (Colin et al. 2011; Goffin et al. 2005).

Chromatin analyses with micrococcal nuclease (which cuts DNA in nucleosome-free regions and in linker regions separating nucleosomes) and with restriction enzymes have allowed establishing the nucleosomal organization of the 5' LTR. Two nucleosomes (called nuc-0 and nuc-1) are positioned at the viral promoter DNA at precise locations with respect to regulatory

elements (Fig. 1). Nuc-0 is positioned immediately upstream of the modulatory region and nuc-1 immediately downstream of the viral transcription start site. These nucleosomes define two open regions of chromatin corresponding to the modulatory region plus the enhancer/core promoter region (HS2 + 3) and a regulatory domain in the leader region downstream of the transcription start site (HS4) respectively. Interestingly, nucleosomes within the LTR are not deposited according to their thermodynamically most favorable positions (Mahmoudi 2012). Indeed, the comparison between the predicted nucleosome affinity of the HIV LTR sequence (using NuPoP software tool) and the known *in vivo* nucleosome distribution demonstrated a striking reverse correlation. The DNA sequence encompassing the HS2 and HS3 region displayed the highest affinity for nucleosome formation, while the strictly positioned nuc-0 and nuc-1 sequences displayed lower nucleosome propensity. The concerted effect of various TF binding sites in the HS2 and HS3 regions and their relative orientation mediate combinatorial interactions between multiple DNA TFs and cofactor complexes, resulting in a structure thought to be inconsistent with the coexistence of stable nucleosomes. Indeed, the BAF subcomplex of ATP-dependent SWI/SNF chromatin-remodeling complex specially functions to counteract intrinsic histone-DNA sequence preferences at the LTR and to move a preferred nucleosome from HS2 and HS3 regions to position nuc-1 over suboptimal sequences immediately downstream of the transcription start site, explaining that this region is devoid of nucleosome. However, this region still contains a loosely positioned nucleosome, which is evicted upon activation. A genome-wide study revealed that hypersensitive regions to nucleases, which are often assumed to be devoid of nucleosomes, are in fact occupied by histone variants (Mahmoudi 2012).

However, nucleosome positioning is not static and in a growing number of cases, changes in nuclease sensitivity secondary to the disruption of specific nucleosomes have been observed during transcriptional activation. During HIV transcriptional activation, only one change occurs in

Transcription (Initiation, Regulation, Elongation), Fig. 2 Mechanisms of transcriptional activation by the viral protein Tat and the cellular elongation factor P-TEFb. In the absence of Tat (a), transcriptional initiation at the HIV-1 promoter is driven by the recruitment of RNAPII via TBP. However, transcription elongation is impeded as the result of the presence of the nuc-1 nucleosome, the activity of DSIF and NELF, and the sequestration of P-TEFb (composed of cyclin-dependent kinase Cdk9 and Cyclin T1) in an inactive snRNP complex containing 7SK RNA, HEXIM-1, and the RNA-binding proteins MePCE and LARP7. Upon activation (b), P-TEFb is released from its inactive form and is recruited to the HIV-1 promoter through interactions with Brd4 and NF-κB. Once recruited to the HIV-1 promoter, Cdk9

phosphorylates the CTD of RNAPII, DSIF, and NELF, allowing occasional full-length transcripts. Following the synthesis of the first molecules of Tat (c), Tat binds to the TAR RNA and enhances RNAPII processivity by recruiting P-TEFb from its inactive form and by competing with Brd4. This recruitment allows enhanced transcription of the full HIV-1 genome. Transcriptional elongation of the HIV-1 genome (d) is further stimulated because Tat can also recruit, in addition to P-TEFb, other elongation factors (such as ELL2, AFF4, ENL, and AF9), thereby forming the super elongation complex. This larger complex contains notably members of the mixed-lineage leukemia (MLL) family, including ELL2 that stimulate the rate of RNAPII transcriptional elongation. See text for details

this organization: nuc-1 is specifically disrupted (Verdin et al. 1993). In conclusion, nucleosome positioning in the 5' LTR appears to be an intrinsic property of the LTR, as the same positions were observed independently of the different integration sites in cell lines.

Initiation and Elongation of HIV-1 Transcription

As previously described, the HIV-1 5' LTR region contains numerous sites for cellular TFs. These factors help control the rate of RNAPII transcription initiation from the provirus, and their

abundance in different cell types or at different times likely determines whether a provirus is actively transcribed or not. Despite the importance of these factors, HIV-1 transcription is strongly dependent on the viral trans-activator Tat. Therefore, transcription of the HIV-1 provirus is characterized by an early Tat-independent phase and a late Tat-dependent phase (Fig. 2).

During the Tat-independent phase, the HIV-1 promoter is strictly under the control of the local chromatin environment and cellular TFs binding to *cis*-acting elements in the viral promoter region. However, transcription is initiated normally but

elongation is inefficient and results in short abortive transcripts that cannot support viral replication. Indeed, at initiation, the TATA-Binding Protein (TBP) recognizes the TATA box and initiates the recruitment of the TBP-associated factors (TAFs), which assemble into the TFIID complex. Next, additional general TFs associate with RNAPII to form the pre-initiation complex (PIC). The C-terminal domain (CTD) of the largest subunit of the RNAPII is not phosphorylated and binds the Mediator complex. In the absence of Tat, critical TFs, such as NF- κ B and Sp1, are required for the formation of the PIC and the recruitment of TBP and TAFs. Then, TFIIF binds to the promoter and phosphorylates serine 5 of the CTD. This event stimulates promoter clearance and synthesis of the first nucleotides of RNA. However, after synthesis of a short RNA that includes TAR, NELF (negative elongation factor) and DSIF (DRB sensitivity-inducing factor) are directly recruited and induce RNAPII pausing (Fig. 2a). The pausing induced by DSIF and NELF could allow the cleavage/polyadenylation factor Pcf11 to dismantle the elongation complex. In addition to the presence of negative transcription elongation factors (N-TEF), RNA also could contribute to pausing by an RNA interference-independent mechanism. Nuc-1, by its position immediately after the transcription start site, could also impede the progression of RNAPII by accentuating a natural pausing site. In the early phase, cellular TFs, especially NF- κ B, and acetylated histones both via interaction with the bromodomain-containing protein 4 (BRD4) recruit the positive transcription elongation factor b (P-TEFb), composed of cyclin-dependent kinase 9 (Cdk9) and Cyclin T1 (Fig. 2b). P-TEFb is required to overcome early blocks after promoter clearance, thus allowing for elongation of transcription. Once recruited to the transcriptional complex, Cdk9, the catalytic subunit of P-TEFb, phosphorylates serine at position 2 of the CTD and marks the transition from initiation to elongation of transcription (Fig. 2b). Moreover, P-TEFb also phosphorylates NELF and DSIF (Fig. 2b). The phosphorylation of NELF causes its dissociation from TAR and releases paused transcription elongation complexes. Although the unmodified DSIF

inhibits elongation, phosphorylation of Spt5 separates it from the rest of the complex and converts it into a positive elongation factor that stabilizes transcription complexes at terminator sequences.

Despite elongation defect, occasional full-length genomic transcripts are generated, leading to the synthesis of a few Tat molecules. The synthesis of a few molecules of Tat is sufficient to stimulate HIV-1 transcription and causes an increase of the RNAPII processivity that allows the transcription of the entire provirus. The viral trans-activator protein Tat is an atypical transcriptional activator that functions through binding RNA TAR, present at the 5' end of all nascent viral transcripts (Fig. 2c). The binding of Tat to TAR enhances the processivity of transcribing RNAPII complex by recruiting cellular proteins. Indeed, Tat recruits Cyclin T1/Cdk9 either from the inactive complex containing the 7SK snRNA, HEXIM1, the La-related protein 7 (LARP7), and the 7SK-specific methyl-phosphate-capping enzyme (MePCE), by competing with HEXIM for Cyclin T1 binding, or from the active Cyclin T1/Cdk9 complex containing BRD4 present on cellular genes (Fig. 2c; Karn and Stoltzfus 2012; Taube and Peterlin 2013). Cyclin T1 interacts cooperatively with both the N-terminal transactivation domain of Tat (amino acid 1–48) and the loop sequence at the top of the TAR's stem-loop structure. As a consequence, P-TEFb and Tat bind TAR with higher affinity and specificity than Tat alone. Cdk9 then phosphorylates the CTD of the previously bound RNAPII complex. In the presence of Tat, the substrate specificity of Cdk9 is altered, such that the kinase phosphorylates both serine 2 and serine 5 of the CTD instead of serine 2 alone. Moreover, Tat can recruit PCAF, a histone acetyltransferase (HAT), which could play a role in chromatin-remodeling following transcriptional activation. Tat itself is also post-translationally modified (► Tat) by acetylation, for example, in order to promote the recruitment of P-TEFb to the HIV-1 promoter or dissociation of Tat from TAR leading to its subsequent transfer to the elongating RNAPII complex (Fig. 2d). After, the Tat/P-TEFb complex dissociates from the RNAPII complex following transcription initiation and undergoes subsequent cycles of

association/dissociation. Tat deacetylation by Sirtuin 1 (SIRT1), a class III protein deacetylase, allows its dissociation from the RNAPII and PCAF complex and its recycling to initiate a new cycle of transcriptional activation. This function might be important when the amount of Tat is a limiting factor, especially at the early phase of infection. The binding of Tat to TAR also promotes the recruitment of various cellular cofactors to the HIV-1 5' LTR including histone-modifying enzymes, such as the HATs p300 and CBP and chromatin-remodeling complexes, likely reinforcing an acetylated and open chromatin environment. Tat first recruits the PBAF subcomplex of ATP-dependent remodeling complex SWI/SNF via its interaction with BRG-1 and In1 (integrase interactor-1) subunits, allowing the initiation of nuc-1 remodeling (Mahmoudi 2012). Consequently, the optimal activity of Tat is furthermore dictated by its association with different cellular factors while being subject to other post-translational modifications (► [Tat](#)). In this way, Tat increases the production of viral mRNA by ~100-fold and allows the production of a large amount of mRNA in a short time. Tat is also an effective elongation factor because it is able to recruit the “super elongation complex” (SEC) in addition to P-TEFb (Sobhian et al. 2010; Fig. 2d). SEC components of the Tat/P-TEFb complex include ELL1 and its homologue ELL2, AFF1 and its homologue AFF4, ENL, AF9, and the components of the polymerase-associated factor complex. ELL1 and ELL2 are well-characterized transcription elongation factors that stimulate the processivity of RNAPII and act in concert with P-TEFb. In addition to its classically recognized role in the induction of transcriptional elongation and chromatin remodeling, Tat may also influence transcriptional initiation by facilitating the assembly of the pre-initiation complex requiring the Sp1 and NF- κ B binding sites. Increasing evidence suggests that Tat also plays a role in splicing, capping, and polyadenylation processes. Consequently, Tat acts at several levels in HIV-1 transcription (► [Tat](#)).

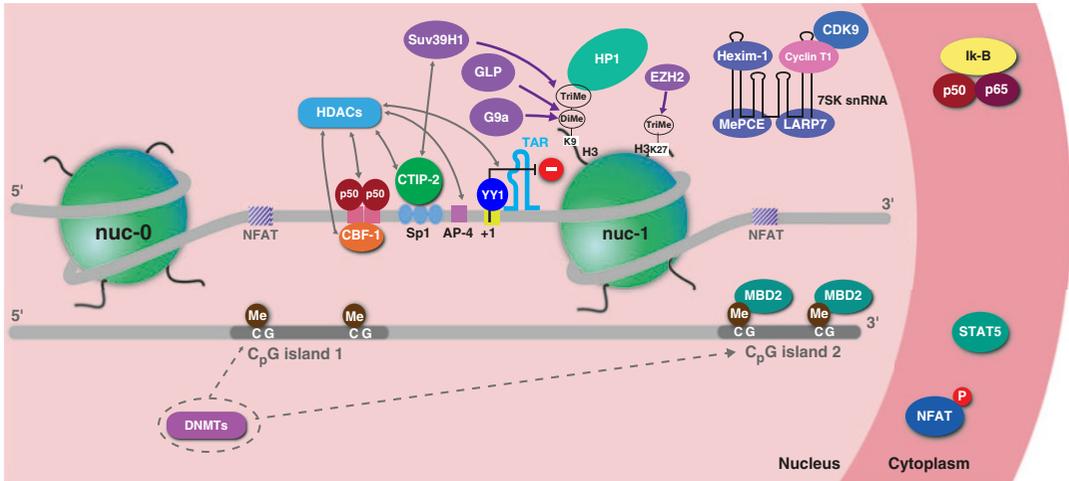

Splicing, capping, and polyadenylation processes occur mostly cotranscriptionally (Karn and Stoltzfus 2012). First, pre-mRNA is capped

at its 5' end by capping enzymes: RNA triphosphatase, RNA guanylyltransferase, and RNA (guanine-N7) methyltransferase. This step is facilitated by RNAPII pausing. The capping reaction is also stimulated by Tat via the TAR-dependent phosphorylation of the CTD by P-TEFb. Further processing of viral pre-miRNA by the host splicing machinery gives rise to a variety of transcripts and consequently, many proteins, due to the alternative splicing. Indeed, nascent transcripts include several 5' splice donor (five), 3' splice acceptor (nine), and branch point sites in order to result in over 40 differently spliced mRNAs. Generated mRNAs are divided into three size classes: (i) unspliced RNA (9 kb) serving as genomic RNA or to produce the Gag and Gag-Pol precursors; (ii) singly spliced (4 kb) RNA encoding Tat exon1, Vif, Vpu-Env, and Vpr; or (iii) fully spliced (2 kb) RNA expressing Tat exon1 + 2, Rev, and Nef (Fig. 1; ► [HIV Life Cycle](#)). Transport of unspliced and partially spliced mRNAs from the nucleus to the cytoplasm is mediated by the viral Rev protein which interacts with the rev responsive element (RRE) in the viral RNA and the cellular export factor Crm1 to connect these viral RNAs to the export machinery (Rev). Before the transport to the cytoplasm, the final step in the processing of the nascent transcript is polyadenylation. The 3' processing and polyadenylation of pre-mRNAs involves recognition of the upstream AAUAAA and downstream GU-rich motifs surrounding the cleavage and poly (A) addition site. For this, host cellular proteins such as the cleavage/polyadenylation specificity factor (CPSF), CstF, CF1m, CF2m, and poly (A) polymerase are required for endonucleolytic cleavage and polyadenylation of viral pre-mRNA. HIV provirus contains two identical LTR and each of them has a poly(A) site. However, the poly (A) site in the 5' LTR has to be ignored for HIV transcription.

HIV-1 Transcriptional Regulation

Transcriptional Regulation

At the level of transcription, the major contributors to transcriptional downregulation are

Transcription (Initiation, Regulation, Elongation), Fig. 3 Mechanisms of HIV-1 transcriptional repression. The main transcription factor binding sites and the nucleosomal organization of the HIV-1 genome 5' region are schematically represented. The transcription start site (nucleotide +1, nt +1) and the nuc-1 nucleosome are indicated. During latency, nuc-1 blocks transcriptional initiation and/or elongation and is maintained hypoacetylated by HDACs recruited to the HIV-1 promoter via several transcription factors or the CTIP2 cofactor. Histone methyltransferases (Suv39H1, G9a, GLP, and EZH2) are also recruited and methylate histone 3 tails on lysines 9 and 27. In addition, the HIV-1 proviral promoter is

hypermethylated by DNMTs in two CpG islands surrounding the transcription start site. Moreover, transcription factors essential for HIV-1 transcription are maintained in an inactive form (in the cytoplasm: sequestration of the active form of the NF-κB (p65/P50 heterodimers) by IκBα, phosphorylated NFAT, and unphosphorylated STAT5; in the nucleus: sequestration of inactive P-TEFb in the nuclear snRNP complex). In this context, several compounds have been proposed for HIV-1 transcriptional reactivation from latency. See text for details (This figure is adapted from Van Lint et al., *Retrovirology* 2013, with permission from BioMed Central)

transcriptional interference, the chromatin environment, lack of key host TFs, and lack of Tat and associated cofactors (Fig. 3).

Transcriptional Interference

HIV-1 integrates into the host genome in a non-random manner (► **Integration**). The finding that latent HIV-1 proviruses integrate in actively transcribed regions may seem paradoxical, considering the establishment of a transcriptionally latent state. Transcriptional interference (TI) has been proposed to explain HIV-1 promoter repression when integrated into introns of highly expressed genes. TI refers to the direct negative impact of one gene on another in *cis* by the following: (i) **Promoter occlusion**: when the provirus integrates in the same transcriptional orientation as the host gene, “read-through” transcription from an upstream promoter displaces key TFs from the HIV-1 promoter and prevents the assembly of the pre-initiation complex on the viral promoter,

thereby hindering HIV-1 transcription. (ii) **Steric hindrance**: provirus integration in the opposite orientation to the host gene may lead to the collision of elongating polymerases from each promoter, resulting in a premature termination of transcription from either the weaker or both promoters. Convergent transcription may also allow for the elongation of both viral DNA strands. The subsequent formation of double-stranded RNAs might lead to RNAi, RNA-directed DNA methylation, or generation of antisense RNAs. (iii) **Enhancer trapping**: this phenomenon can occur when an enhancer of provirus or host gene is placed out of context near the promoter of another gene.

Role of Transcription Factors

Molecular regulation of HIV-1 transcription is a multifaceted process dictated in part by the abundance of cellular TFs that induce or repress HIV-1 promoter activity (Van Lint et al. 2013). HIV-1

promoter activity is also tightly linked to the level of activation of its host cell. It is widely accepted that the lack of inducible key cellular TFs (NF- κ B, NFAT, and STAT5) is one element involved in the initiation and elongation repression of viral transcription in resting CD4⁺ T cells. The presence of host transcription repressors (i.e., DSIF, YY1, CTIP2, c-myc, CBF-1, p50 homodimers) also contributes to HIV-1 silencing.

Firstly, HIV-1 transcription is tightly coupled to the cellular activation status because transcriptional repressors are present under basal conditions, while transcriptional activators, such as NF- κ B and NFAT, are sequestered in the cytoplasm of quiescent T cells but recruited to the nucleus following T-cell activation. Recruitment of HATs by NF- κ B and NFAT proteins promotes chromatin-remodeling of the HIV-1 5' LTR. In contrast, YY1 in cooperation with LSF inhibits transcription.

Secondly, host TFs allow recruitment of chromatin-remodeling enzymes and cooperate in transcriptional regulation (Fig. 3). Indeed, several of these factors, including AP-1, c-Myb, GR, C/EBP, NFAT, E-box binding proteins, Ets-1, TCF-1 α /LEF-1, NF- κ B, Sp1, IRF, and the HIV-1 trans-activator Tat, have been shown to interact with HATs. Several other TFs that bind to the LTR, including unliganded nuclear hormone receptors (such as GR), E-box binding proteins, YY1, Sp1, TCF-1 α /LEF-1, AP-4, and NF- κ B, have been shown to interact with HDACs.

The observed redundancy in transcription activation pathways and the presence of many different transcription binding sites in HIV-1 favor productive viral infection in several cellular environments with large differences in the pool of TFs.

Role of the Chromatin Environment

Evidence has accumulated that the HIV-1 provirus is able to determine its local nucleosomal organization and that chromatin is an integral and dynamic component of the HIV-1 transcriptional regulation. Among these nucleosomes, a single one, nuc-1, is specifically and rapidly disrupted during transcriptional activation (see above). Nuc-1 disruption is independent of DNA replication and also of RNAPII transcription. Nuc-1

itself mediates HIV-1 transcription inhibition either by enhancing sequence-specific pausing or by blocking the binding of a TF. The mechanisms underlying the maintenance of a repressive chromatin state of the HIV-1 provirus and factors implicated in nuc-1 remodeling will be further discussed in association with epigenetic modifications of the HIV-1 promoter (see below). Epigenetic modifications are heritable modifications, which do not involve changes in the DNA sequence itself. They are dynamic, rapidly changing depending on the signaling conditions within the cell, and function sequentially or in combination to form "a code," which is read by effector proteins to produce distinct biological outcomes. These modifications principally include histone posttranslational modifications and DNA methylation.

Chromatin condensation is critical for the regulation of transcription initiation and elongation since it determines the DNA accessibility to regulatory TFs. The chromatin condensation status can be modulated through a variety of mechanisms that can work together: DNA methylation, ATP-dependent chromatin-remodeling events, and histone posttranslational covalent modifications. Indeed, DNA methylation is recognized by methyl-CpG-binding proteins (MBDs) that "read" DNA methylation patterns and allow the recruitment of other chromatin-modifying enzymes. ATP-dependent chromatin-remodeling complexes couple the hydrolysis of ATP to structural changes of the nucleosome. Histone posttranslational modifications, including acetylation, methylation, phosphorylation, sumoylation, ADP-ribosylation, and ubiquitination, are all reversible and mainly localized to the amino-terminal histone tails. These modifications influence gene expression patterns by two different mechanisms: (i) by directly altering chromatin packaging (electrostatic charge modifications or internucleosomal contacts might emphasize or reduce the access of DNA to TFs (such as histone acetylation)) and (ii) by generating interactions with chromatin-associated proteins (such as histone methylation). These modifications function sequentially or act in combination to form the "histone code" and serve as extremely selective

recruitment platforms for specific regulatory proteins that drive different biological processes. The major histone marks involved in HIV-1 repression are detailed below and in Van Lint et al. (2013).

Histone Posttranslational Modifications

Histone Acetylation An acetylation reaction consists in the transfer of an acetyl group from acetyl coenzyme A onto the ϵ -amino group of the lysine residue, resulting in the neutralization of the positive charge on the histone that promotes destabilization of histone-DNA interactions in the nucleosome. The histone acetylation levels are the result of a dynamic equilibrium between competing enzymes: HATs and HDACs. Generally, chromatin deacetylation by HDACs diminishes the accessibility of the nucleosomal DNA to TFs, thereby generating repressive heterochromatin, whereas acetylation by HATs promotes chromatin opening, resulting in increased accessibility of the chromatin to the transcription machinery. Moreover, histone acetylation marks enable the recruitment of bromodomain-containing proteins, such as chromatin-remodeling complexes and some TFs, which in turn regulate gene expression.

To date, numerous studies have demonstrated that HDAC1, HDAC2, HDAC3, and HDAC6 are recruited to the HIV-1 5' LTR (Van Lint et al. 2013). Following activation, cellular HATs, including p300/CBP, PCAF, and Gcn5, are recruited to the promoter. Several TFs have been shown to interact with HDACs and HATs (see above and Fig. 3). By altering histones, recruiting other chromatin-remodeling factors, and modifying the activity of certain TFs, HDACs appear to be critical for the epigenetic repression of HIV-1 transcription. Following the recruitment of HATs and chromatin-remodeling complexes, nuc-1 disruption allows viral transcriptional activation to occur (Van Lint et al. 1996; Verdin et al. 1993).

Histone Methylation Histone methyltransferases (HMTs) catalyze the transfer of one to three methyl groups from the cofactor S-adenosylmethionine to the lysine and arginine residues of histone tails. Histone methylation has

no effect on DNA/histone interactions but serves as a recognition template for effector proteins modifying the chromatin environment. Lysine methylation has been linked to both transcriptional activation and repression, depending on the site of modification. In general, methylation of histone 3 at lysine residue 4 (H3K4) is associated with transcriptional activation, while methylation of H3K9, H3K27, and H4K20 is associated with transcriptional repression.

Histone methylation marks (including H3K9me2, H3K9me3, and H3K27me3) have been shown to be associated with HIV-1 transcriptional silencing (reviewed in Van Lint et al. 2013; Fig. 3). The HMTs Suv39H1, G9a, GLP(-G9a-like protein), and EZH2, which are involved in H3K9me3, H3K9me2, H3K9me2, and H3K27me3, respectively, are recruited to the HIV promoter and are rapidly displaced following proviral reactivation (Fig. 3). In microglial cells, the main central nervous system HIV-1 reservoirs, Suv39H1 is recruited to the HIV-1 promoter via CTIP2, leading to a multi-enzymatic complex including HDAC1/HDAC2. CBF-1 (C-promoter binding factor-1) is responsible for the recruitment of EZH2 and other chromatin-modifying enzymes of the Polycomb complex to the HIV-1 promoter (Van Lint et al. 2013).

The histone demethylase (HDMT, which removes histone methylation with both lysine-site and methyl-state specificity) LSD1 is also recruited to the HIV-1 promoter and associated with both H3K4me3 and H3K9me3 marks. LSD1 functionally cooperates with CTIP2 to repress both viral replication and transcription in microglial cells (Van Lint et al. 2013).

Implication of SWI/SNF Complex

Remodeling of nuc-1 during transcriptional activation required ATP-dependent SWI/SNF chromatin-remodeling complexes (Mahmoudi et al. 2006; Treand et al. 2006). Two biochemically distinct SWI/SNF subcomplexes exist, the BAF and the PBAF complexes. The defining subunit of the BAF complex is BAF250a/ARID1a, and those of the PBAF complex are BAF180, BAF200, and BRD7. The presence of the distinct SWI/SNF subcomplexes BAF and PBAF has

been critical to distinguish between SWI/SNF-mediated LTR repression and Tat-mediated SWI/SNF recruitment. Possible mechanisms of BAF recruitment to the HIV promoter are (i) nuc-1-associated repressive TFs such as ATF3, (ii) LTR-bound TFs such as AP-1 and NFAT, (iii) distinct LTR pattern of histone modifications such as histone acetylation, and (iv) a unique DNA structure within the LTR. BAF is required for LTR repression and maintenance of latency. Upon transcriptional activation, BAF dissociates from the LTR, while the PBAF complex is selectively recruited by acetylated Tat to facilitate LTR transcription. Thus, BAF and PBAF, recruited during the different stages of the HIV-1 life cycle, display opposite functions in regulating LTR activity.

Implication of DNA Methylation

In mammalian cells, DNA methylation occurs as 5-methylcytosine predominantly in the context of CpG dinucleotides and is achieved by the specific recruitment of DNA methyltransferases (DNMTs). DNA methylation in transcriptional regulatory regions is generally associated with gene silencing, either by directly blocking binding of TFs to their recognition sequences or by indirectly preventing TFs from accessing their target sites through attachment of MBDs. These MBDs recruit HDACs and HMTs, thereby resulting in the formation of a closed repressive chromatin structure. During latency, the HIV-1 promoter is hypermethylated at two CpG islands surrounding the HIV-1 transcription start site as demonstrated in the latently infected cell lines (Blazkova et al. 2009; Kauder et al. 2009; Fig. 3). MBD2 and HDAC2 are recruited to the promoter via the second CpG island. Treatment with the demethylating agent 5-aza-2'-deoxycytidine decreases cytosine methylation in the two HIV-1 CpG islands, resulting in the loss of MBD2 and HDAC2 from CpG island 2 of the viral promoter region and in partial transcriptional reactivation (Kauder et al. 2009). However, to date, the DNA methylation status of the HIV-1 promoter in vivo in patient cells is still controversial (Van Lint et al. 2013).

Role of Tat and Its Cofactors

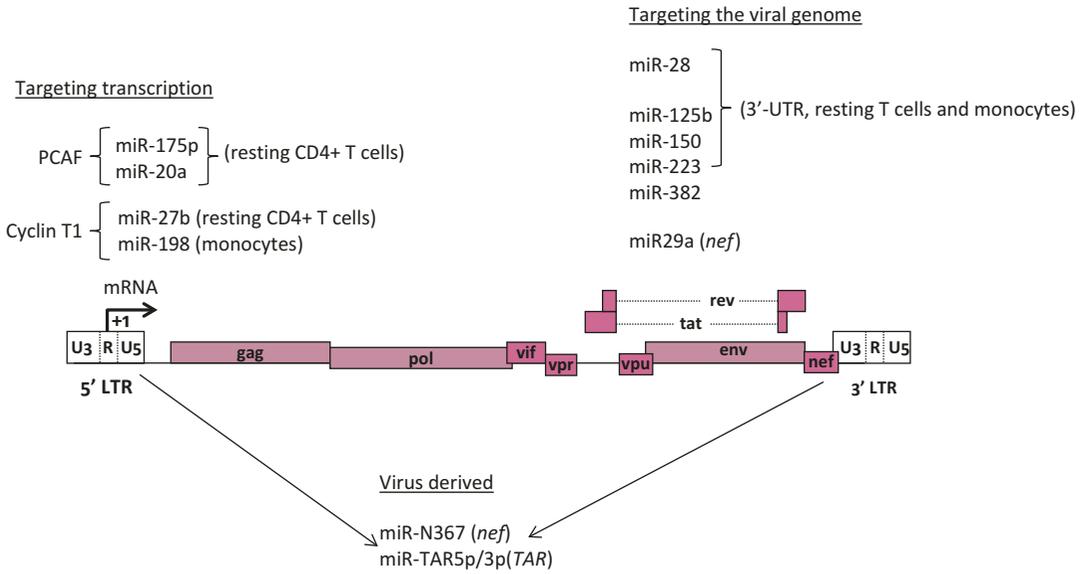

The intricate regulation of Tat function by post-translational modifications and its relationship with P-TEFb and several host cofactors are largely implicated in HIV-1 transcriptional regulation (see above and ► [Tat](#)).

Posttranscriptional Regulation

Considerable attention has focused on the role of chromatin and transcription (co)factors in the control of HIV-1 transcription. However, mechanisms operating at the posttranscriptional level such as inefficient viral mRNA transport or implication of miRNA are also implicated in HIV-1 gene expression.

The generation of infectious retroviral progeny requires the synthesis and export to the cytoplasm of the partially spliced and unspliced genomic RNAs. The viral protein Rev promotes the export of these RNAs (Rev). In resting T cells from HIV-1-infected individuals on cART, both Tat and Rev transcripts are retained in the nucleus. The defect in viral RNA export principally results from insufficient levels of Rev.

MicroRNAs (miRNAs) are short single-stranded noncoding RNAs that act as gene regulators. Primary miRNAs are sequentially processed via the nuclear RNases III Droscha and Dicer to generate mature miRNAs which interact with a complementary sequence in the 3' untranslated region of target mRNAs by partial sequence matching, resulting in degradation of the mRNA and/or translational inhibition. miRNAs can also regulate gene expression at the epigenetic level, by specifically inducing methylation along the promoter region or by directly generating the remodeling of the surrounding chromatin. Upregulation and downregulation of cellular miRNAs induced by HIV-1 infection have been observed in patient cells (Triboulet et al. 2007). Indeed, Tat and possibly Vpr function as RNA silencing suppressors, being able to modulate miRNA expression levels in infected cells. Cellular miRNAs can inhibit HIV-1 gene expression by decreasing the levels of essential cellular cofactors such as PCAF (regulated by miR175p and miR20a) and Cyclin T1 (regulated by miR27b)

Transcription (Initiation, Regulation, Elongation), Fig. 4 Modulation of HIV-1 replication by miRNA. HIV-1 impacts the cellular miRNA pathways in several ways. The figure shows a schematic representation of the HIV-1 provirus with the indicated viral genes and LTRs, including the transcription start site in the 5' LTR. PCAF and Cyclin T1, which are both essential cofactors for viral transcription, are targeted by the indicated miRNAs in

resting T cells and monocytes. A cluster of miRNAs is targeted directly toward the 5' end of the HIV-1 genome, and their inhibition rescues infectious virus from resting T cells. Finally, two sets of miRNA that are derived from the HIV-1 genome are shown. Their location within the LTR (TAR and *nef*) is duplicated (arrows) (From Van Lint et al., *Retrovirology* 2013, with permission from BioMed Central)

and are involved in the susceptibility to HIV-1 infection of different cell types. Alternatively, miRNAs may participate in repressing HIV-1 gene expression by directly targeting HIV-1 mRNAs in resting CD4⁺ T cells. Five cellular miRNAs (miR-28, miR-125b, miR-150, miR-223, and miR-382) recognize the 3' end of HIV-1 mRNAs and are upregulated in resting, but not in activated CD4⁺ T cells. Moreover, the HIV-1 *nef* gene contains a miR-29a-targeted site that interferes with HIV-1 replication. Finally, several HIV-1-derived miRNAs exist and include TAR-derived miRNA-TAR5p/3p and the *nef*-derived miR-N367. TAR-derived miRNAs may target HIV-1 transcription directly. A summary of the principal miRNAs affecting HIV-1 is shown in Fig. 4 and in Van Lint et al. (2013).

Impact of HIV Transcriptional Regulation

HIV-1 transcription repression is crucial for the establishment and maintenance of latency

(Siliciano and Greene 2011; Trono et al. 2010; Van Lint et al. 2013). Elements implicated in HIV-1 transcriptional regulation described above represent potential targets for anti-latency strategies since they can be pharmacologically modulated (reviewed in Van Lint et al. (2013)). Indeed, a major approach to eradicating HIV-1 involves reactivation of HIV viral gene expression in cART patients. Cells harboring induced proviruses could then be lysed by HIV-1-specific cytolytic T lymphocytes (CTL), while new rounds of infection are blocked by cART. HIV-1 reservoirs containing stably integrated, transcriptionally silent but replication-competent proviruses are a permanent source for virus reactivation and could be responsible for the rebound of viremia observed after cART interruption. Persistence of HIV-1 latency certainly represents the major challenge to finding a cure. Indeed, the levels of HIV-1 reservoirs appear as one of the major factors influencing the duration of a “functional cure”

(long-term control of HIV-1 replication and disease progression in the absence of cART) after cART cessation. Indeed, a recent and elegant study described “posttreatment controllers,” patients who durably control HIV-1 after stopping a treatment initiated at primary infection, but, unlike natural controllers, have rather unfavorable HLA genotypes (Saez-Cirion et al. 2013). This study suggests that a low reservoir of latent HIV-1 could be controlled by the patient immune system. Consequently, a decline of the HIV-1 latent reservoir to a level sufficient to permit an efficient control of the infection by the host immune system might allow for interruptions in therapy (“treatment-free windows”) and would represent important progress in AIDS treatment. Reactivation of HIV gene expression in latently infected cells together with an efficient or intensified cART could serve as an adjuvant therapy aimed at eliminating/decreasing the pool of latent viral reservoirs. Several studies have identified individual compounds that are capable of reversing HIV-1 latency. Upregulating cellular transcription to induce HIV-1 gene expression has opened the way of an HIV cure by testing strategies to purge the HIV-1 reservoirs. Several clinical trials have started with HDAC inhibitors (VPA, SAHA, panobinostat, romidepsin), with PKC inducers (bryostatin) and with disulfiram (for a review see Van Lint et al. (2013)). However, results from these clinical trials question the efficiency of these drugs used alone and underly the need to evaluate other classes of HIV-1 inducers and to test combinatory strategies in order to reduce the size of the HIV-1 reservoirs. Indeed, the combined use of two drugs to activate latent HIV could cause a synergistic reactivation of HIV-1 production, i.e., a higher reactivation than the sum of the reactivations produced by each drug individually. In this regard, proof of concepts has been reported for the coadministration of two different types of therapeutically promising HIV-1 inducers together with efficient cART as a therapeutic perspective to decrease the pool of latent HIV-1 reservoirs (Van Lint et al. 2013). Consequently, further understanding of the molecular

mechanisms regulating HIV-1 transcription will identify new targets and should help to develop novel pharmacological therapeutic strategies aimed at eliminating latent HIV-1 infection.

Conclusion

HIV-1 gene expression is a complex process that results from the convergence of multiple mechanisms, including the chromatin environment of the site of HIV-1 integration, transcriptional interference, the chromatin structure of the HIV-1 promoter, the epigenetic control of the HIV-1 promoter, and the varying levels of cellular transcription factors and of the viral trans-activator Tat protein and its associated cofactors. The relative importance of these mechanisms is probably dependent on the physiological state of the cell undergoing infection. Understanding the complexity of the mechanisms involved in HIV-1 transcriptional repression and the numerous links between different control levels has to be continued. They will provide fundamental new insights into the process of HIV-1 transcriptional latency and reactivation from latency and ultimately should contribute to an increased understanding of AIDS pathogenesis. Different forms of latency vary from one patient to the other and even from one cell to the other in single patient. This underlies the importance to test in reactivation strategies the combination of various compounds used simultaneously for targeting HIV-1 transcriptional repression at multiple levels. These combinatory anti-latency strategies could facilitate the escape from latency and the clearance of viral reservoirs. Alternatively, a deeper understanding of the mechanisms regulating HIV-1 transcription could lead to strategies aimed at maintaining the virus latent. In addition to latency, the failure to cure HIV-1 infection is believed to result from T-cell dysfunction stemming from persistent immune activation. Therefore, new therapeutic strategies should also include reversal of immune exhaustion and/or increase of immune clearance to kill the productively infected cells.

Translational Interventions (Intervention Technology Transfer)

Athi Myint-U and Lydia O'Donnell
Education Development Center, Inc., Waltham,
MA, USA

Definition

Translational interventions aim to bridge the gap between prevention science and widespread adoption and diffusion of research-based practices in real-world, uncontrolled community settings. *Intervention technology transfer* is the process that supports the dissemination and implementation of translational interventions, including effective behavioral HIV prevention interventions (EBIs).

Introduction

Advances in prevention science have resulted in the identification of interventions with demonstrated effectiveness or potential to impact behavioral outcomes related to HIV transmission, including reduced sexual risk taking, uptake of

HIV testing, and medication adherence and linkage to clinical care. Yet the availability of proven programs has not guaranteed their dissemination to their intended audiences. Lessons from the field show that innovative prevention strategies are neither naturally diffused nor automatically adopted by program providers. The difficulties of successful technology transfer are not unique to the field of HIV prevention; they reflect the “long and winding road” from research to practice that too often keeps the best prevention from reaching the populations that might benefit most. To address barriers to successful intervention technology transfer, increased attention is being given to understanding intervention technology transfer, which includes the process of *dissemination*, or the “spread of knowledge and intervention materials” to providers and communities, as well as the process of *implementation*, or “the use of strategies to adopt and integrate interventions and to change practice patterns within specific settings” (National Institutes of Health 2012a).

Evidence-based HIV prevention interventions vary in size and scope, as well as the populations they target. Whether they entail modest practice changes, such as the integration of brief motivational counseling for HIV testing and linkage into care, provider-delivered messages to encourage medication adherence, and recruitment of individuals from risk groups to participate in small group sessions, or multicomponent community-level strategies, significant barriers have limited the wide-scale dissemination that is critical for reducing HIV incidence. Even what appear to be relatively simple changes in practice may not be easily adopted or maintained. Common barriers to dissemination and implementation include lack of knowledge, recruitment and retention challenges, staff and resource constraints, lack of interest by or support from agency administrators, and concerns about how to adapt interventions for different target populations (Solomon et al. 2006; Gandelman and Dolcini 2012).

Multiple theoretical perspectives inform scientific understanding of the transfer process and identify key factors that may influence success. Diffusion of an innovation is supported by program designers and early adopters, who can serve

as champions and role models to later users (Rogers 2003). Stages of change theory have been applied to both organizations and individual providers and depict how issues and challenges evolve as a new practice is considered, adopted, implemented, and maintained (Lehman 2002). Operations and systems research identifies key agency inputs and resources that may influence dissemination and implementation success (Sobo et al. 2008). These theoretical perspectives provide a framework for identifying what factors influence intervention technology transfer. Understanding these processes helps identify what types of training, technical assistance, and capacity-building support facilitate dissemination and implementation; it can also identify characteristics of interventions that are most likely to be successful in reaching their intended audiences.

Phases of Intervention Technology Transfer

Intervention technology transfer is commonly divided into distinct phases. From the perspective of changes within agencies (described below), these have been labeled *pre-implementation*, *implementation*, and *maintenance and evolution phase* (Kraft et al. 2000). The Society for Prevention Research has proposed a similar framework scaled to a broader community framework, including Translation stage-setting during pre-adoption phases, Institutional or individual adoption of EBIs, Effective implementation of EBIs, and Sustainability of EBIs, or TIES (Society for Prevention Research 2008). A variety of technology transfer activities are required during all phases for a program to be successfully transferred to real-world settings.

The *pre-implementation phase* focuses on agency identification and selection of an effective behavioral HIV prevention intervention (EBI). Dissemination of knowledge about the benefits, advantages, and characteristics of different interventions is critical at this stage. Providers assess the fit and feasibility of potential interventions by considering their organizational and staff capacity, mission, resources, client characteristics and

needs, and compatibility with existing services. Once they have selected an intervention and have allocated or received resources for its adoption, agencies prepare for implementation by providing staff training, mobilizing support among administrators and providers, and, as necessary, adapting or tailoring the intervention for their local populations.

The *implementation phase* starts with the provider's first use of the intervention with clients. While staff may receive training in the pre-implementation phase, there often is a continued need for assistance on how to best adapt the intervention so that it smoothly integrates into their organizational and programmatic structure. In addition, to inform their own efforts and meet the requirements of funders, providers need to begin collecting data about the implementation process, including documenting numbers and risk profiles of clients reached, how often the intervention was provided, fidelity to the core elements of the EBI, and adaptations made. Monitoring and evaluation is critical for assuring the intervention is being delivered as intended to achieve desired behavioral outcomes, identifying challenges and barriers to reaching the intended audiences, and providing evidence that can support requests for the ongoing resources required for sustainability.

In the *maintenance and evolution phase*, attention turns to how the intervention can be sustained and if it should be altered or replaced. Agencies must put in place strategies for sustaining staff and administrator support, addressing staff turnover and retraining needs, determining ongoing costs and resources, and reviewing evaluation data to see how well the intervention is meeting its objectives. These efforts help determine if and how the prevention intervention can and should be embedded into the organization's routine operations and budget.

Key Components of Intervention Technology Transfer

There are multiple components or activities involved in comprehensive intervention technology transfer. These components include user-

friendly packaging of intervention materials, training, and technical assistance (TA).

User-Friendly Packaging of the Intervention as Replication Kits

An intervention with demonstrated efficacy in a research-controlled setting may not be easily transferrable for a number of reasons. For community-based providers to be able to adopt and implement an intervention with ease, they must not only have adequate training on the intervention but also be supplied with intervention materials that are user friendly and visually appealing. These materials should try to address providers' needs during all three phases of technology transfer (e.g., information about the intervention's objectives for pre-implementation, guidance and tips for implementation, and evaluation measures during maintenance/evolution). In the United States, federally funded initiatives such as Program Archive on Sexuality, Health, and Adolescence (PASHA) and Replicating Effective Programs (REP) have worked with original researchers and program developers to produce program packages or replication kits with materials such as curriculum guides, videos, workbooks, and survey instruments that allow prevention providers to not only easily offer the program to their clients but also to collect information for evaluation purposes (Card et al. 2007; Eke et al. 2006). These materials typically contain information about the program's history and evidence base as well as the materials needed for implementation and easy-to-understand guidelines for use.

Training

Government agencies have played a role in promoting technology transfer through the provision of funding for training and technical assistance programs on effective HIV prevention interventions. In 1999, the Centers for Disease Control and Prevention (CDC) published a Compendium of HIV Prevention Interventions with Evidence of Effectiveness to respond to prevention service providers who requested evidence-based interventions that work. Since then, it has launched the Diffusion of Effective Behavioral Interventions project (DEBI), a national-level strategy to

provide high-quality training and ongoing technical assistance on selected evidence-based HIV/STI/viral hepatitis prevention interventions to state and community HIV/STI program staff.

Because the selection of an EBI is often made by agency administrators and/or is contingent on receipt of funding, attending a training on the intervention is often the first time staff who are responsible for implementing a program learn about a program's objectives and core elements. Quality, standardized training to increase knowledge and skills needed for intervention delivery is a critical component of successful technology transfer. Training activities include the development of formal training curricula, the logistical coordination of training activities, and the delivery of training to two groups of trainees – trainers who will implement training activities (e.g., through a training of trainers) and agency staff. At the agency level, training is usually required for staff who will be implementing the program and often recommended for agency administrators whose support is essential to success and sustainability. Training objectives may focus not only on specific program elements but also general interpersonal skills that program providers need to successfully implement a prevention intervention such as facilitation skills, group management skills, and recruitment skills.

Technical Assistance

While training activities on EBIs often occur over a relatively short period, ranging from 1 to 5 days, literature on intervention technology transfer has demonstrated that after training has been completed, many intervention providers require access to quality technical assistance to support them through the implementation and maintenance and evolution phase (Fuller et al 2007). Surveys of community-based agencies that receive technical assistance suggest that technical assistance (TA) needs are varied and the role of TA providers can change during the different phases of technology transfer. During the pre-implementation phase, for example, agencies may require TA to help staff plan for an intervention and adapt it to fit into agency schedules and existing services. Some providers may need TA

during implementation to overcome specific barriers such as difficulty in recruiting and retaining clients (O'Donnell et al 2000). TA may also be utilized to enhance organizational infrastructure (e.g., fiscal management, strategic planning) that allows the agency to continue to receive funding for program implementation and maintenance.

Online Strategies for Intervention Technology Transfer

Literature on translational interventions has focused primarily on the use of in-person strategies for transference of knowledge and skills, through printed curricular materials and user-friendly packages, face-to-face trainings, in-person or telephone consultations, and site visits. More recently, intervention technology transfer activities have also been offered through the Internet so providers are able to access them through their computers, tablets, or phones. These additional methods include synchronous events, such as webinars and real-time discussion forums, web-based services to link community-based organizations (CBO), and TA requests to TA providers, and asynchronous events, such as interactive, web-based training courses which use video as a means of modeling intervention best practices. Advantages of online methods include decreased costs for travel, increased flexibility for users, and decreased disruption to agency staffing and services. More research is needed on the acceptability and effectiveness of these online strategies for technology transfer.

Fidelity and Adaptation During Intervention Technology Transfer

One of the challenges for translational interventions is maintaining fidelity to the "core," or required, elements of an effective intervention and the need to adapt or tailor the intervention to best fit an agency's circumstances and local needs and its target population. Models of technology transfer highlight the importance of tailoring or customizing delivery of interventions to agency circumstances and ensuring that messages are appropriate for agency target populations without

altering, deleting, or adding to the intervention's core elements. Without sufficient TA and training, HIV prevention providers may unintentionally risk altering intervention effectiveness by modifying interventions in ways that either eliminate or change core elements. Therefore, such guidance needs to be offered proactively before an intervention has been substantially changed and is well into the implementation phase. By working to increase providers' ability to systematically adapt HIV prevention interventions without losing fidelity to the core elements, TA providers and researchers can help ensure their continued use and acceptability in real-world settings.

Translational Research on Implementation in Real-World Settings

While intervention technology transfer activities to successfully embed EBIs into "real-world" settings often follow rigorous randomized control trials (RCTs), fewer HIV/AIDS behavioral health studies have conducted what NIH defines as "Type II translational research" to determine how effective these interventions are when implemented by practitioners and not researchers, with or without intervention technology transfer support (National Institutes of Health 2012b). Some recent studies that have been conducted on the implementation of EBIs by practitioners, however, have shown continued evidence of success and have provided a possible framework for operationalizing criteria to help ensure effectiveness (Neumann et al. 2011; Harshbarger et al. 2012).

Conclusion

Translational interventions seek to provide HIV prevention program providers with the knowledge and skills they need to successfully transfer effective HIV prevention programs to their target populations. Literature on technology transfer shows that to be successful, program providers must have access to user-friendly intervention materials, quality training, and ongoing technical assistance. Effective practitioner-scientist

collaboration is also critical to the success of technology transfer. In addition, supporting technology transfer activities must address a range of issues outside of program implementation, including organizational infrastructure development, adaptation, and evaluation, to help providers overcome common barriers to sustainable implementation.

Definition

This entry focuses on the current knowledge about how HIV-2, the second and more benign form of the human immunodeficiency virus, is transmitted

(“► [HIV-2 Transmission](#)”). First, the origin and geographical distribution of HIV-2 transmission over time will be discussed. Second, the different and most important transmission pathways will be described, and a few well-described transmission chains will also be dissected. Finally, HIV-2 transmission on a cellular level during primary infection and the importance of different HIV-2 phenotypes in transmission and pathogenesis will be discussed.

Origin, Epidemiology, and Subtypes

Current evidence indicates that HIV-2 is the result of several cross-species transmission events and the most likely route of transmission of HIV-2 to humans involves contact with blood of different primates hunted for bushmeat in Africa. Phylogenetic analysis have indicated that HIV-2 is related to SIV from wild sooty mangabeys (SIVsm), and to date eight genetically distinct clades of HIV-2 (“► [Phylogeographic Insights into the Origins and Epidemic History of HIV-2](#)”) have been described (subtypes A–H). However, only subtypes A and B has spread considerably in humans, and groups C–H most likely represent dead-end infections since they only have been detected in one individual, respectively.

The geographic origin of HIV-2 (“► [Phylogeographic Insights into the Origins and Epidemic History of HIV-2](#)”) was initially thought to be Guinea-Bissau where the highest prevalence (ranging from 2% in healthy controls to 64% in commercial sex workers) was recorded in the initial screenings of blood samples obtained between 1985 and 1987 from six West African countries (Kanki et al. 1987). However, the oldest documented HIV-2 cases have been recorded in samples collected in Côte d'Ivoire during 1966, and it has been shown that both group A and B share the most common ancestry with SIV strains collected from communities found in the Tai forest, in western Côte d'Ivoire (Santiago et al. 2005). Furthermore, studies of the timing of the HIV-2 origin have found that group A and B arose within the same time interval, likely during the 1930s and 1940s

(combined interval for group A, 1906–1956; group B, 1907–1961).

Considering that phylogenetic analyses have pointed towards Côte d’Ivoire as the origin of HIV-2 (“► [Phylogeographic Insights into the Origins and Epidemic History of HIV-2](#)”) whereas Guinea-Bissau showed the highest prevalence numbers during the 1980’s, it is possible that the migration of HIV-2 to Guinea-Bissau occurred at a very early stage in the epidemic (Santiago et al. 2005). Transmission in Guinea-Bissau is supposed to have coincided with the prolonged war of liberation against the colonial power Portugal in 1963–1974. HIV-2 has also been recorded in the West African countries (“► [The Epidemiology of HIV-2 Infection in West Africa](#)”) of Cape Verde, Mauritania, Senegal, The Gambia, Guinea, Sierra Leone, Liberia, Ghana, Togo, Benin, Mali, Burkina Faso, Nigeria, Niger, São Tomé and Príncipe, and Cameroon and in patients originating from Equatorial Guinea.

Being the country with the highest HIV-2 prevalence outside West Africa (“► [Epidemiology of HIV-2 Infection in Europe](#)”), Portugal had 1,813 registered individuals with HIV-2 by the end of 2008. As in France (another non-West African country with relatively high HIV-2 prevalence), the majority of these individuals were immigrants of West African origin. From Portugal and France, further spread has occurred to other European countries. Direct immigration from West African countries has likely also occurred, as seen in the United Kingdom and Spain in Europe and the United States and Canada in North America. A Portuguese link has also been seen in HIV-2 transmission with cases in other former Portuguese colonies such as Angola, Mozambique, Brazil, and parts of India (Schim van der Loeff and Aaby 1999). HIV-2 has also been recorded in Japan.

HIV-2 group A (“► [Phylogeographic Insights into the Origins and Epidemic History of HIV-2](#)”) has been the dominant group both in West African countries, including Guinea-Bissau, and subsequently also in countries influenced by Portuguese heritage and other countries outside West Africa. In West Africa, group B has primarily been recorded in Côte d’Ivoire but also in Ghana, Sierra

Leone, and Nigeria. Outside West Africa, group B has been found in France immigrants originating from Côte d’Ivoire and Mali and in Spanish immigrants from Equatorial Guinea.

HIV-2 Transmission Routes

As for HIV-1, HIV-2 can be transmitted both horizontally (e.g., sexually or through contaminated blood) and vertically (e.g., during pregnancy and childbirth or via breast milk) in humans (“► [HIV-2 Transmission](#)”; “HIV-1 Transmission Dynamics”; “► [HIV-1 Sexual Transmission](#)”). However, HIV-2 has consistently been shown to be less transmissible than HIV-1 for all studied transmission pathways (Schim van der Loeff and Aaby 1999). The lower transmission rates for HIV-2 correspond to lower levels of viremia and lower shedding in semen and in the female genital tract. Heterosexual spread was early shown to be substantially lower in HIV-2 compared with HIV-1, estimated at 10–20% of the transmission frequency of HIV-1 (Schim van der Loeff and Aaby 1999). Mother-to-child transmission of HIV-2 (“► [HIV-2 Transmission](#)”; “► [MTCT HIV-1 Transmission Update](#)”) has been demonstrated to be directly linked to maternal viremia, as in HIV-1 infection. Vertical transmission in untreated HIV-2 infection has been recorded at levels between 0% and 4% compared with up to 25% for HIV-1 infection in the same studies (Table 1).

Risk Factors of Transmission

Documented risk factors for HIV-2 transmission are similar to those for HIV-1 including history of or serological proof of sexually transmitted infections including genital ulcer disease, multiple sex partners, and having sex with or being a commercial sex worker. In contrast to HIV-1, where usually a younger population is affected, older age is a risk factor for HIV-2 acquisition. Already in the first community-based survey in Guinea-Bissau in 1987, where an adult HIV-2 prevalence of 8.9% was found, there was an overrepresentation in the

Transmission HIV-2: Origin, Epidemiology, and Phenotype, Table 1 Mother-to-child transmission of HIV-2

Country	Study period	Frequency of HIV-2 transmissions ^a
Côte d'Ivoire	1990–1992	1.2 %, <i>N</i> = 132 (HIV-1: 25 %, <i>N</i> = 138)
Guinea-Bissau	1987–1988	0 %, <i>N</i> = 51
The Gambia	1993–1995	4.0 %, <i>N</i> = 294 (HIV-1: 24 %, <i>N</i> = 144)
Portugal	1999–2005	1.5 %, <i>N</i> = 131 (HIV-1: 3.4 %, <i>N</i> = 1315) ^b
France	1986–2007	0.6 %, <i>N</i> = 531 (HIV-1: 5.2 %, <i>N</i> = 10122) ^c

^a*N* equals the number of children born to HIV-infected mothers in the studies

^b22 % of HIV-1- and 44 % of HIV-2-infected mothers did not access MTCT prevention

^c20 % of HIV-1- and 43 % of HIV-2-infected mothers did not access MTCT prevention

40–65-year-old age group. An overrepresentation especially of older women has suggested that women become more susceptible to HIV-2 at an older age. Later observations also concluded that as part of coinfection with other retroviruses, HIV-2 infection was more common in older women than in men.

Being less transmissible than HIV-1, HIV-2 reached surprisingly high prevalence levels in certain areas of West Africa (“► [The Epidemiology of HIV-2 Infection in West Africa](#)”). It has been hypothesized that a substantial parenteral spread occurred early on in the epidemic, primarily in the 1960s, due to activities such as vaccination and treatment campaigns for trypanosomiasis and tuberculosis as well as ritual acts of female excision (Pepin et al. 2006). Support for this hypothesis is given by the fact that HIV-2 prevalence has been diminishing in several West African countries while at the same time HIV-1 prevalence has been increasing, in particular during the 1990s. The trends of declining HIV-2 prevalence also continued between 2000 and 2010, in spite of HIV-1 prevalence keeping at steady levels. The early expansion of the HIV-2 epidemic has also been hypothesized to coincide with outbreaks of genital ulcer disease, occurring earlier in areas with lower frequency of male circumcision.

Transmission HIV-2: Origin, Epidemiology, and Phenotype, Table 2 Phylogenetically verified HIV-2 transmission chains or clusters

Route	Country	HIV-2 transmissions
MTCT	Portugal	Mother and child
MTCT	Portugal	Mother and two children
Sexual	Denmark	Index case and two partners
Sexual	India	Between a couple
Sexual	South Korea	Transmission cluster (4–6 individuals)
Sexual	Spain	Transmission cluster (4 individuals)

HIV-2 Transmission Chains and Clusters

HIV-2 transmissions have been identified in a number of case and population studies, and some have also been characterized by phylogenetic analysis. This has allowed detailed studies of the genetic relationship between index-recipients viral strains (Table 2).

One study reported evidence of HIV infection in two females in Denmark who had been in sexual contact with an HIV-1 and HIV-2 dual-infected man (Christiansen et al. 1997). Serology from the two female partners indicated that partner one was infected with both HIV-1 and HIV-2, whereas partner two was infected with HIV-2 only. To confirm the serology data, nucleic acid was extracted and amplified from plasma and peripheral blood mononuclear cells (PBMC) of the suspected index case and the two partners. Partner one was positive for both HIV-1 and HIV-2, and female partner two was only positive for HIV-2. Phylogenetic analyses showed that both HIV-1 and HIV-2 sequences of the index case and the two female partners were closely related. The monophyletic clusters retained after analyses with both global and local HIV-2 sequences, strongly suggesting that the index case had transmitted HIV-1 and/or HIV-2 to his female partners.

A Spanish study reported of eight Caucasian men, living in northern Spain, positive by HIV-2 serology and infected during a 5-year period (Cilla et al. 2001). Despite extensive screening, no other HIV-2 infections could be identified in the region. Specimens from four of the eight

infected men were available for PCR and sequence analysis. Sequences were obtained from the HIV-2 *env* and *pol* regions, and phylogenetic analysis showed that sequences of both genome regions from the four patients were highly related. They formed monophyletic clusters in comparison to epidemiologically unlinked HIV-2 reference sequences and also from other Spanish HIV-2 sequences. Epidemiological data could not identify a likely index case; however, sex with other men was the only identified risk factor among the eight patients, suggesting a possible link between them and/or an unknown index case.

Another study identified ten HIV-2-infected individuals in South Korea between 1991 and 2002 (Nam et al. 2006). Among those, nine were residing in the southern part of the country. Phylogenetic analyses using a part of the HIV-2 *env* region indicated that six of the patient samples formed a monophyletic cluster that was distinguishable from other foreign and South Korean sequences. The earliest infected patient (a man) in the cluster reported that he had likely been infected in the Canary Islands, whereas the remaining five (one man and four women) reported that they most likely were infected in South Korea. Among those five, the man had been a co-resident of the earliest infected. The results indicate that the virus of the six patients had a common source, perhaps introduced into South Korea from the Canary Islands followed by local dissemination.

The above studies suggest the existence of several different HIV-2 transmission chains where HIV-2 had been transmitted sexually from a common source. These studies also indicate that HIV-2 infections are spreading in countries where HIV-2 prevalence is low or even not recognized. Because disease progression rate (“► [Natural History and Clinical Features of HIV-2 Infection](#)”) is much slower in the average HIV-2-infected patient compared to those infected with HIV-1, HIV-2 may stay unrecognized in infected individuals for a much longer time compared to HIV-1, resulting in slow and unrecognized spread in some populations, even outside the endemic regions. Although HIV-2 infection is not considered to be

a large global health problem (as HIV-1), HIV-2 is clearly spreading outside its traditional borders.

Primary HIV-2 Infection

The characteristics of virological and immunological markers of an acute infection following either blood-borne, sexual, or vertical HIV-2 transmission between humans are not known due to the paucity of studies reporting results from primary HIV-2 infections. To date, the only well-documented case was a 19-year-old white woman that displayed symptoms of primary HIV infection (Besnier et al. 1990). The woman was negative for HIV-1 but displayed a clear HIV-2-specific serological profile. Her symptoms appeared approximately 3 weeks after infection and disappeared within a few days. However, the knowledge from studies of HIV-1 primary infections (“Modeling Early HIV-1 Infection and Dissemination”) has clearly shown that virological and immunological events taking place during the primary phase of the infection can be associated with rate of disease progression. Thus, it is also likely that the primary phase of an HIV-2 infection differs from that of an HIV-1 infection since the natural disease courses of HIV-1 and HIV-2 infections (“► [Natural History and Clinical Features of HIV-2 Infection](#)”) in general are so distinct.

It is well established that the plasma viral load (“► [HIV-2 Diagnosis and Viral Load Measurements](#)”) set point after an acute HIV-2 infection is significantly lower than that of an HIV-1 infection (de Silva et al. 2008). In fact, the HIV-2 viral load set point is more than ten times lower than for HIV-1. Conceivably, the lower viral load set point of an HIV-2 infection may be the result of differences in acute phase virus replication and/or virus controlling host response. As in HIV-1 infection, the transmission of HIV-2 may occur via the mucosa, even though a major early transmission route is thought to be blood-borne (de Silva et al. 2008). During mucosal transmission (“HIV-1 Transmission Dynamics”), it is known that HIV-1 may target several different cell types, including CD4⁺ T cells, Langerhans cells,

submucosal dendritic cells (DC), and possibly also tissue macrophages. In vitro studies have shown that peripheral blood-derived DCs are less efficiently infected by HIV-2 compared to HIV-1 (Hodges-Mameletzis et al. 2011). However, the susceptibility of Langerhans cells and submucosal DCs to HIV-2 infection and replication is not well established. Acute viremia may also be influenced by intracellular viral restriction factors (“► [Interactions Between HIV-2 and Host Restriction Factors](#)”), including the tripartite motif-containing protein (TRIM)-5 α (“► [TRIM5 Alpha and HIV-2 Infection](#)”). Studies on variations in the HIV-2 p26 capsid that interact with TRIM-5 α have revealed associations with plasma viral load levels (Hodges-Mameletzis et al. 2011).

As for virus controlling immune responses in HIV-2 infection, magnitude of Gag-targeted CD8+ T-cell response (“► [The Cellular Immune Response to HIV-2 Infection](#)”) has been linked to viral control (Hodges-Mameletzis et al. 2011). Broad and potent contemporary autologous neutralizing antibody response (“► [The Antibody Response to HIV-2](#)”), which is common in HIV-2 infection and rare in HIV-1 infection, may also contribute to viral control limiting the primary HIV-2 infection (Hodges-Mameletzis et al. 2011). In addition, better antigen presentation by myeloid cells (“► [Role of Dendritic Cells in HIV-2 Pathogenesis](#)”) has been implied due to the HIV-2-encoded accessory protein Vpx (“► [Molecular Biology of HIV-2](#)”) (Vpx is not present in HIV-1) that counteracts the cellular restriction factor SAM- and HD-domain-containing protein 1 (SAMHD1 [MJ22]) (Hodges-Mameletzis et al. 2011) (“► [Interactions Between HIV-2 and Host Restriction Factors](#)”).

HIV-2, in contrast to HIV-1, can establish infections in Asian macaques and has also been used as a nonhuman primate model for AIDS (“► [Non-human Primate Model - For HIV-1 Transmission](#)”). The natural course of pathogenic HIV-2 infection in macaques appears similar to that of SIVmac macaque infections (Joag 2000). Accordingly, it has been noted that the viremia of acute HIV-2 macaque infections may peak around 2 weeks after infection and can reach up to 10⁸ RNA copies/ml. However, virus replication is

only partially controlled after 4–8 weeks, with a viral set point significantly higher than that observed in humans. Thus, the translation of findings from acute HIV-2 infections in macaques to acute HIV-2 infection in humans has its limitations, possibly due to differences in host genetics, including intracellular restriction factors and immune response.

Coreceptor Use of HIV-2

Early work performed during the 1980s showed that replicative capacity of HIV-2, like HIV-1, correlates with immunodeficiency. Such that syncytia formation (formation of multinuclear cells) in peripheral blood mononuclear cell (PBMC) cultures and the ability to replicate in cell lines frequently characterized viruses obtained from AIDS patients but not viruses obtained from asymptomatic individuals, allowing classification of HIV-2 isolates into rapid/high and slow/low phenotype, respectively (Albert et al. 1989). In fact, the asymptomatic phase of HIV-2 infection rarely yielded virus upon isolation, and the viruses, if obtained, had the slow/low phenotype. Among 24 HIV-2-infected subjects, CD4+ T-cell counts in blood were lowest in AIDS patients compared to asymptomatic or symptomatic but non-AIDS cases. Conversely, it was easier to isolate virus from patients with HIV-2 disease, and the isolated virus had a higher replicative capacity both in PBMC and cell lines than viruses isolated from asymptomatic subjects. This established the link between HIV-2 viral phenotype and clinical progression and suggested that HIV-2 with slow/low phenotype is more likely to be transmitted and/or dominate early in infection. The phenotypic change, if it occurs at all, occurs later in infection. It is known that high HIV-1 viral load in plasma increases the risk of transmission, whereas effective control of viral load by antiretroviral therapy decreases the risk of HIV-1 transmission. The prolonged asymptomatic period in HIV-2 infection with low viral load (“► [HIV-2 Diagnosis and Viral Load Measurements](#)”) and low, if any, replicative capacity of HIV-2 may be linked to the low transmission rate.

Transmission HIV-2: Origin, Epidemiology, and Phenotype, Table 3 Comparison of HIV-1 and HIV-2 coreceptor use

		HIV-1					HIV-2					
Number of coreceptors used		1	1	2	2	3	1	2	2	3	3	5
Tropism		R5	X4	R5X4	R3X4	R3R5X4	R5	R1R5	R3X4	R1R3R5	R1R2bR5	R1R2bR3R5X4
Phenotype	Rapid/high	0	2	1	1	5	1	0	1	1	0	1
	Slow/low	11	0	0	0	0	1	1	0	2	2	1

Phenotype: rapid/high, replication in both PBMC cultures and cell lines; slow/low, replication in PBMC cultures but not in cell lines. X4, CXCR4 use only; R5, CCR5 use only; all other coreceptors CCR1, CCR2b, and CCR3 used in combinations with CXCR4 and/or CCR5. Coreceptor use was tested in human cell lines engineered to express different chemokine receptors

The discovery that HIV-1 uses CD4 and a chemokine receptor, mainly CCR5 and CXCR4 (“► [CXCR4, Coreceptors](#)”; “► [Attachment/Binding](#)”), to enter cells led to the question whether the difference in pathogenic potential of HIV-1 and HIV-2 is reflected by a difference in coreceptor use. Comparison of HIV-1 and HIV-2 coreceptor use revealed that CCR5 use (“Selection of CCR5 Using Viruses Transmission”; “Transmission of HIV-1 CCR5 Phenotypes”), with few exceptions, is a general property of viruses in both groups (Table 3) (Morner et al. 1999). Viruses not using CCR5 used CXCR4 alone or in combination with CCR3. What distinguished HIV-1 and HIV-2 was the ability to use other coreceptors in addition to CCR5. Whereas HIV-1 isolates with slow/low phenotype seem to exclusively use CCR5, the majority of HIV-2 isolates seems to be able to use one or several additional coreceptors. Furthermore, most HIV-1 isolates with a rapid/high phenotype uses CXCR4 alone or in combination with CCR3 and/or CCR5, whereas coreceptor use of HIV-2 isolates with this phenotype does not seem to be as distinct (Morner et al. 1999; Neil et al. 2005). An overview of HIV-2 coreceptor use reported in the literature is presented in Table 4, and in comparison with HIV-1, the use of CXCR5 appears to be unique for HIV-2.

Both HIV-1 and HIV-2 use two receptors for cell entry (“► [Attachment/Binding](#)”; “► [Molecular Biology of HIV-2](#)”). In a first step, binding occurs to CD4 that functions as a “key” to open up the closed viral envelope structure. This will

expose the hidden coreceptor binding site and allow binding of the viral envelope to the coreceptor in a second step. Viruses that can infect cells without first binding to CD4, like some HIV-2 isolates, appear to have a more open envelope conformation than HIV-1, which is with few exceptions CD4 dependent for cell entry. Conceivably, the relative CD4 independence of HIV-2 entry into cells may enable a wider range of coreceptors to be exploited for infection and may even assist in adaptation or switching to new coreceptors *in vivo* (Reeves et al. 1999).

The *in vitro* studies, on which broad coreceptor use of HIV-2 is based, were carried out with human cell lines engineered to express CD4 and chemokine receptors. Expression of receptors on transfected target cells *in vitro* may not reflect expression of receptors on HIV-2 target cells *in vivo*, such that infection of cells *in vivo* may not involve other than CCR5 and CXCR4. In line with this, it has been shown that broad coreceptor use as detected *in vitro* is not associated with the generally slower disease progression caused by HIV-2. Marchant and colleagues observed that both HIV-1 and HIV-2 infected human macrophage cultures, although they differed in the kinetics of replication. After an initial burst of replication, HIV-1 continued to replicate, while HIV-2 seemed to establish latency. It was suggested that this feature of HIV-2 might be responsible for the delayed disease progression.

Alternative receptors have been described for HIV-2 (Neil et al. 2005). D6 (CCR9) is a broad-

Transmission HIV-2: Origin, Epidemiology, and Phenotype, Table 4 Coreceptors used by HIV-2

Coreceptor	Alternative names ^a	Ligand (s)	Cellular distribution ^b
Human chemokine receptors			
CCR1	CD191	CCL3, CCL5, MCP-3	T (effector)
CCR2b	CD192	MCP-1, MCP-2, MCP-3, MCP-4, CCL11	M, T, B

^cUndefined, receptor defined by replication of one HIV-2 isolate in PBMC in the presence of inhibitors to CCR5 and CXCR4 (TAK-779 and AMD3100, respectively)

specificity epithelial chemokine receptor, probably involved in regulating the concentrations of inflammatory chemokines and their endothelial transport. D6 expression is also found in the placenta, on myeloid and lymphoid precursor cell lines, and on macrophages in inflamed tissue, and it has been suggested that it may facilitate transmission and have a role early in infection, perhaps in dissemination of virus infection. For HIV-2, the role of D6 still remains to be clarified.

Conclusion

HIV-2 originates from several cross-species transmission events between wild sooty mangabeys and humans. This likely occurred in or close to Côte d'Ivoire from where HIV-2 has spread mostly within West Africa but also to other parts of the world (in particular to countries with colonial links to West African countries). HIV-2 can be transmitted both vertically and horizontally, and studies of transmission chains have indicated that

HIV-2 can give rise to local spread both among heterosexual couples and men who have sex with men. As in HIV-1 infection, the transmission of HIV-2 may occur via the mucosa, even though the major early transmission route is thought to be blood-borne. Although HIV-2 seems to be more promiscuous in the use of different coreceptors in vitro, most studied HIV-2 isolates favor the use of CCR5 and CXCR4, alone or in combination with CD4, for cellular entry. Finally, despite some efforts, many of the cellular targets and mechanisms involved in transmission and establishment of an HIV-2 infection are not known, and further studies of this virus are clearly needed.

Treatment Failure and Resistance

Mary W. Montgomery and Paul E. Sax
Infectious Diseases Division, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA

Definition

HIV treatment failure can be defined in three different ways. Virologic failure is the inability to suppress the viral load to <200 copies/mL after 24 weeks of therapy or to <50 copies/mL after 48 weeks. Immunologic failure is the inability to attain normal CD4 counts despite viral suppression. Clinical failure is defined as the development of opportunistic infections after at least 3 months of antiretroviral therapy. Clinical failure rarely occurs in patients who are taking their antiretrovirals faithfully and are virologically suppressed. Because the management of immunologic failure is not well defined, virologic failure is the most clinically relevant definition of treatment failure and will be the focus of this chapter.

Development of Virologic Failure

Virologic failure occurs in three main patient groups and the outcomes and management of each of these populations differs. There are patients who fail with no resistance mutations predominantly due to poor adherence, either from never taking their medications or taking them successfully and then abruptly stopping. There are patients who fail with one or two class resistance that is easily salvageable; this is usually due to intermittent adherence. Finally, there are patients who fail with extensive multiclass resistance as a result of being treated sequentially with less potent drugs in the early years of combination ART, generally the period from 1996 to 2001.

Patients with sporadic adherence and treatment-experienced patients with prior

suboptimal therapy are more likely to develop HIV resistance than those who never take medications or abruptly stop them after virologic suppression. When patients intermittently take antivirals, they have subinhibitory drug levels allowing for continued viral replication and the selection of resistance mutations. Treatment-experienced patients with prior virologic failure due to suboptimal regimens are also at risk of selection of additional resistance, as the new regimen may not have sufficiently activated drugs to achieve or maintain virologic suppression. Patients can fall into more than one of these categories, but in general the pattern of adherence and the treatment history determines the degree of drug resistance and the optimal approach to virologic failure.

Work Up of Virologic Failure

Virologic failure is the inability to achieve virologic suppression after initiating treatment or to maintain virologic suppression while on an HIV regimen. The viral load should be <200 copies/mL after 24 weeks of starting therapy or <50 copies/mL by 48 weeks. Virologic rebound is defined as confirmed HIV RNA >200 copies/mL after attaining virologic suppression. When patients are found to have detectable HIV viral RNA on treatment, the first goal is to determine the etiology. The most important thing to assess is adherence and whether they are never, intermittently, or consistently taking their antiretrovirals (ARVs.)

There are many ways to ascertain adherence information. You can ask the patient in a nonjudgmental way about how often they are taking their medications; it is important to ask because often they will not spontaneously admit to treatment noncompliance. You can have them bring in their active pill bottles to assess dispensing dates; even more accurate is to contact their pharmacy to obtain renewal records. You then want to ask about and identify the underlying causes for nonadherence or intermittent adherence (e.g., side effects, insurance issues, pill burden, substance abuse, mental illness). If the patient is consistently

taking their medications you want to review food requirements for their regimen and their medication list, including dietary supplements, all of which could be altering the pharmacokinetics of the ARVs.

The next step is to evaluate for resistance. Resistance testing should be performed on all patients with virologic failure. Ideally it should be ordered while the patient is still taking the failing regimen, as this maximizes the chances of identifying drug resistance. When the selective pressure of HIV therapy is withdrawn, some resistance mutations will no longer be detectable as they are overgrown by wild-type virus. However, even when the patient has stopped antivirals, many resistance mutations will persist – in particular those that do not impair viral fitness, such as the mutations conferring resistance to NNRTIs. As a result, genotype testing is indicated in essentially all patients with virologic failure.

Resistance testing is reliably performed if the viral load is greater than 1000 copies/mL and often is successful between 500 and 1000 copies/mL. If a resistance test is not possible based on viral load <500 copies/mL there are different management approaches. One option would be to increase adherence and recheck the viral load in a short time frame. Another option is to change the regimen based on previous resistance testing or inferred resistance patterns based on the current regimen. A third option that became available recently is to check for “archived” resistance mutations; this advanced diagnostic procedure is more costly than standard genotyping and has not been validated in prospective clinical studies. However, it could provide valuable information in select circumstances.

There are two types of resistance testing: genotypic and phenotypic. Genotype tests report the mutations that are known from both in vitro and clinical samples to cause resistance to particular drugs. Phenotype tests create a recombinant virus from the patient’s blood and test the ability of individual drugs to suppress the growth rate as compared to wild-type virus. Genotype testing is more commonly used as it is cheaper, easily standardized, and has a faster turnaround time; it is also more sensitive for detection of low-levels of

Treatment Failure and Resistance, Table 1 Categories of virologic failure based on resistance pattern

Resistance pattern	Cause of virologic failure	Management
No mutations	Non adherence <i>or</i> Adherence then abrupt stop of medications	Assess for adherence and tolerability Resume regimen unless the cause of poor adherence was drug toxicity; consider treatment simplification if possible
1 or 2 class resistance	Intermittent adherence <i>or</i> Administration/absorption errors (drug-drug interactions, incorrect dosing, dietary effects)	Assess for adherence and inquire about pharmacokinetic factors Change to boosted PI regimen plus either NRTIs or (if no integrase resistance) an integrase inhibitor
Multiclass resistance	Treated previously with suboptimal regimens <i>or</i> History of intermittent adherence to multiple regimens	Review all previous resistance testing Obtain supplemental testing if warranted and not yet available, such as integrase resistance genotype, resistance phenotype, or viral tropism assay Goal is to find regimen with 2–3 active drugs

resistance virus. Phenotype testing is usually reserved for treatment-experienced patients who have complicated resistance patterns, in particular to protease inhibitors.

A standard genotype resistance test checks for mutations to nucleoside reverse transcriptase inhibitors (NRTIs), nonnucleoside reverse transcriptase inhibitors (NNRTIs), and to protease inhibitors (PIs.) Some tests also include resistance assessments for integrase stand transfer inhibitors (INSTIs) but more commonly this requires a separate genotype specifically assessing for integrase-inhibitor resistance.

Mutations are described with letters and numbers. The first letter is code for the wild-type amino acid. The numbers refer to the position of the amino acid and the second letter is code for the new amino acid in the mutant virus. One example is M184V, which denotes a substitution of valine for methionine at position 184. This mutation is selected by lamivudine (3TC) or emtricitabine (FTC). Of note, the resistance mutations and their clinical implications have been determined based on HIV-1 subtype B, which is the predominant strain in the United States, West and Central Europe, Japan, and Australia. There is still ongoing study to determine the effect of the identified resistance mutations in non-B subtypes of HIV.

In assessing virologic failure, it is critical to obtain all of a patient’s prior resistance tests. Some mutations previously detected may no longer be evident if the specific selective pressure exerted by antiretroviral therapy is stopped. However,

these mutations are “archived” and, though no longer detectable, are not completely cleared, and will reemerge rapidly with nonsuppressive treatment.

The next three sections will describe the management of virologic failure in three different patient populations based on their resistance patterns and treatment history. See Table 1 for a summary.

Management of Patients with Virologic Failure and No Resistance

In all patients with new virologic failure, the first step is to assess their adherence. This is optimally done by nonjudgmental questioning and, if necessary, determining the frequency of pharmacy refills. While clinicians’ estimates of patient adherence are notoriously poor, if patients report suboptimal adherence this alone is highly predictive; likewise, irregular refill rates at the pharmacy are strongly predictive of noncompliance.

If it is determined that a patient is not taking medications, the next goal is to figure out why this is the case. Adherence can be affected by a multitude of factors, including but not limited to drug side effects, cost, medication access, housing, food security, patient safety, health literacy, mental illness, and substance abuse. Ideally all involved factors should be addressed with the assistance of a multidisciplinary team including social workers, case managers, pharmacists, and

psychiatrists. If available, the use of community health workers for directly observed therapy can increase adherence in certain patient populations (Chaiyachati et al. 2014).

Although resistance mutations are rare in these nonadherent patients, the testing is still of value since a negative genotype prevents unnecessary switching to potentially more expensive, toxic, or complex regimens. If no resistance mutations are found, then the patient should be started on the simplest and most tolerable regimen, preferably one of the recommended or alternative regimens in the most recent version of the DHHS Guidelines (Panel on Antiretroviral Guidelines for Adults and Adolescents 2015). There are currently four single-pill once daily regimens and one of these would seem the natural choice. However, three of them – elvitegravir/cobicistat/tenofovir/emtricitabine, efavirenz/tenofovir/emtricitabine, or rilpivirine/tenofovir/emtricitabine – have a relatively low barrier to resistance compared with regimens consisting of boosted PIs or dolutegravir. As a result, clinicians must weigh the benefits of simplicity with these treatments with potential consequences of selecting for resistance if the treatments fail. The patterns of resistance with these regimens are described in more detail below.

Regardless of what new regimen is selected, close clinical and laboratory follow-up is recommended. A repeat viral load should be checked 2–4 weeks after restarting treatment, which should demonstrate at least a 1 log or greater HIV RNA decline. Relatively frequent virologic monitoring (for example, every 6–12 weeks) should be done until the HIV RNA is <50 copies/mL.

Management of Patients with Single- or Dual-Class Resistance

Patients develop single- or dual-class resistance most commonly from intermittent adherence to NNRTI or INSTI-based first-line regimens. In rare cases, treatment failure with resistance can also develop from patient errors (i.e., only taking one drug instead of the prescribed three), pharmacy errors (i.e., not dispensing ritonavir with a protease

inhibitor based regimen), or drug-drug interactions (i.e., a patient taking a proton-pump inhibitor with rilpivirine.) The type and frequency of resistance mutations depends on the specific regimen.

Data on patterns of resistance after failure of first-line regimens have been derived both from clinical trials and treatment cohorts; the former give a more precise estimate, as resistance testing has been incorporated into the evaluation of treatment failure for many years. For example, in the 934 study, patients were randomized to receive either TDF/FTC or ZDV/3TC, along with the NNRTI EFV (Gallant et al. 2006). In the TDF/FTC + EFV arm, 12 patients (out of 244 enrolled) with virologic failure underwent genotype testing. Three had no resistance detected, 9 had EFV resistance (mostly K103N), and an additional 2 also had the M184V mutation of FTC and 3TC. Numerous other studies since then of NNRTI-based therapy demonstrate similar results – namely, that a significant proportion of treatment failures will have no resistance and those that do have mutations will show a predominance of NNRTI resistance, sometimes accompanied by M184V. Triple class resistance – meaning inclusion also of the K65R mutation of TDF – is relatively rare.

The pattern of resistance after failure of initial integrase-inhibitor based treatments differs based on the specific agent chosen. For first-line regimens containing raltegravir or elvitegravir, drug resistance occurs in approximately half the patients with virologic failure (Lennox et al. 2009; DeJesus et al. 2012; Sax et al. 2012). Unlike with NNRTI-based first-line regimens, here dual-class resistance usually ensues, with both the M184V mutation of FTC and 3TC and mutations conferring resistance to EVG and RAL. In the three treatment-naïve studies evaluating dolutegravir plus 2 NRTIs, by contrast, no patient with virologic failure assigned to the dolutegravir strategy has developed resistance to this drug (Raffi et al. 2013; Walmsley et al. 2013; Clotet et al. 2014).

Similarly, virologic failure with initial treatment regimens of a boosted PI with 2 NRTIs is rarely associated with genotypic resistance. When such resistance occurs, it is usually limited to

M184V with no detected PI resistance. This property of boosted PI regimens is the primary reason that TDF/FTC with DRV/r is maintained as a recommended regimen in the most recent revision of the DHHS HIV Treatment Guidelines. Specifically, the guidelines state: “For patients who are at high risk for intermittent therapy because of poor adherence or have transmitted NRTI drug resistance, a PI/r-based treatment is preferred given the PIs high genetic barrier to resistance.” (Panel on Antiretroviral Guidelines for Adults and Adolescents 2015)

The optimal management of patients with single- or dual-class resistance can be inferred from the results of the EARNEST and SECOND LINE studies (Boyd et al. 2013; Paton et al. 2014). These two trials enrolled patients who failed initial therapy with 2 NRTIs and an NNRTI, many of whom had resistance to NNRTIs and NRTIs. In the SECOND LINE study, eligible study subjects were randomized to LPV/r plus NRTIs or RAL; in the EARNEST study, to LPV/r plus either NRTIs or RAL, with a third arm of 12 weeks of LPV/r and RAL induction, followed by LPV/r monotherapy. Both studies found that the RAL and the NRTI arms were virologically noninferior, despite extensive resistance sometimes present at baseline (The LPV/r monotherapy strategy was inferior.).

Based on these results, patients with single- or dual-class resistance after failure of an initial NNRTI-based regimen should be treated with a boosted PI plus either NRTIs or an integrase inhibitor. While the studies cited above used LPV/r and RAL, it is reasonable to assume that similar results would be seen with DRV/r as the boosted PI component and DTG as the integrase component.

In patients who develop virologic failure while on boosted PIs, they are unlikely to develop resistance mutations to the PI but might have NRTI resistance. The most common NRTI mutation to develop while on lamivudine or emtricitabine is M184V. This confers high in vitro resistance to these two agents but increases the in vitro-susceptibility to tenofovir, stavudine, and zidovudine. However, studies have demonstrated that lamivudine retains activity and decreases viral fitness when continued even in the setting of the

M184V mutation (Campbell et al. 2005; Castagna et al. 2006). Given this benefit and that M184V also increases tenofovir susceptibility, many clinicians will continue a regimen of tenofovir/emtricitabine in the presence of M184V. So in general for patients who develop virological failure on a boosted PI and NRTI regimen, studies have shown that virologic suppression can be achieved in these patients by keeping the same regimen and increasing adherence (Zheng et al. 2014). If protease inhibitor resistance mutations are found then phenotype testing should be sent.

Management of Patient with Extensive Multiclass Resistance

Some patients were treated with nonsuppressive NRTI-only regimens before more potent combinations were available. Furthermore, as new agents were introduced, they were often added as single active drugs to failing regimens, a practice sometimes referred to as “serial monotherapy.” Despite excellent medication adherence – or, ironically, *because* of excellent adherence – these strategies led to extensive multiclass drug resistance that makes finding a suppressive regimen challenging. Not surprisingly, most of the patients in this category started treatment in the 1990s or earlier. Virologic failure in this patient population requires meticulous attention to current and past resistance testing. Supplemental assessments, including a resistance phenotype (especially in those with complex PI resistance), integrase genotypes, and a viral tropism assay may be required. Once this information is obtained, the goal is to find a regimen that has at least two, and preferably three, fully active drugs.

In the NNRTI category, etravirine often retains viral activity even in those with resistance to the first generation NNRTIs. Genotypic scores are available to help determine if etravirine will still be active based on the NNRTI mutations present (Vingerhoets et al. 2010). Among the protease inhibitors with activity against PI-resistant virus, darunavir is the most potent and well tolerated and has been shown to be active even in the presence of certain protease mutations (Clotet et al. 2007).

In the integrase inhibitor category, dolutegravir retains activity against virus that has become resistant to raltegravir and elvitegravir (Castagna et al. 2014; Eron et al. 2013). Patients can also undergo tropism testing to determine if the CCR5 antagonist maraviroc could be used as a fully active agent.

The above approach generally leads to virologic suppression even in patients with extensive multiclass resistance. In the TRIO study, the combination of raltegravir, etravirine, and darunavir/ritonavir (often with inclusion of NRTIs at the discretion of the investigators) yielded virologic suppression in 90% of study subjects at 24 weeks, a rate comparable to that seen in treatment-naïve patients (Yazdanpanah et al. 2009). A more recent randomized clinical trial demonstrated that in this patient population, inclusion of NRTIs did not improve virologic suppression rates if the background regimen consisted of more than two active drugs by genotypic scoring (Tashima et al. 2015). Eliminating the NRTIs can limit drug toxicities, cost, and decrease the pill burden.

Immunologic Failure in the Setting of Viral Suppression

Immunologic failure is the inability to attain normal CD4 counts despite viral suppression although there is no clear consensus on the CD4 cut off for this definition. Most patients will recover their CD4 counts to >500 cells/mm³ with viral suppression, but some patient's CD4 counts will remain <200 cells/mm³. The key risk factor for immunologic failure is starting HIV therapy with severely depleted CD4 cell counts. These patients have a 2.6 fold greater risk of mortality compared to those with better immunologic recovery (Engsig et al. 2014). Adjunctive therapy with IL-2, while effective at raising the CD4 cell count, does not improve clinical outcomes (Abrams 2009).

Regimens containing zidovudine or the combination of TDF and ddI are known to impair CD4 response. If a patient is receiving these drugs, the regimen should be changed, preferably to one currently recommended in treatment guidelines. In addition, patients should be evaluated for other

conditions that may be associated with low cd4 cell counts, including hepatitis C, cirrhosis, and malignancy. Aside from the examples cited above, modifying treatment in an already virally suppressed regimen does not consistently improve the CD4 count and there is no evidence that it improves clinical outcomes. (DHHS ART)

Conclusions

The most common reason for virologic failure is poor adherence. It is crucial to uncover and then address the obstacles that prevent patients from taking their medications. The next step is to assess for resistance mutations by understanding each patient's treatment history, their resistance history, and patterns of adherence. Treatment decisions can be tailored to each individual based on these data. The goal is to treat each patient with at least two active agents in order to attain virologic suppression, which is possible in the majority of cases.

Treatment of Histoplasmosis, Coccidioidomycosis, and Paracoccidioidomycosis in Patients with HIV Infection

Neil M. Ampel

Department of Medicine, Medical Service (1-111), University of Arizona College of Medicine and the Southern Arizona Veterans Affairs Health Care System (SAVAHCS), Tucson, AZ, USA

Definitions

Endemic mycoses	Fungal infections that occur within specific geographic regions
Immune reconstitution	Improvement in cellular immune function consequent to potent antiretroviral therapy

Prevention of disease	Antimicrobial therapy or other methods to prevent initial infection
Prevention of relapse	Antimicrobial therapy given after clinical disease has resolved

patients who present with an endemic fungal infection at the time of their HIV diagnosis.

Specific recommendations about managing these three fungal diseases are made below. A summary of these recommendations can be seen in Table 1.

Introduction

This chapter will discuss three endemic mycoses, histoplasmosis, coccidioidomycosis, and paracoccidioidomycosis, which have been associated with HIV-related infections. All are dimorphic and reside as molds in the environment, and each occurs in specific geographic regions in the Western Hemisphere, although histoplasmosis can be found worldwide.

As the HIV epidemic spread and involved new geographic regions, endemic fungi became important causes of opportunistic infections. Because they exist in the environment, limiting exposure to these fungi is not easily achieved. While these fungi cause illness among hosts with normal immune function, most infections are sub-clinical and many are self-limited. However, in those with impaired T-lymphocyte responses, clinical infection is both more prevalent and more severe. In those with HIV infection, the severity of illness caused by infection with these fungi is dependent on the degree of cellular immune deficiency of the host and can be estimated by the peripheral blood CD4 lymphocyte concentration.

Because potent antiretroviral therapy increases the CD4 lymphocyte population and results in an improvement of the cellular immune response, effective antiretroviral therapy is the most important tool in preventing and managing clinical disease due to these fungal infections. Improvement in the cellular immune response may be accompanied by inappropriate inflammation, known as the immune response inflammatory syndrome (IRIS). This itself has been associated with significant morbidity and mortality. Fortunately, IRIS appears to be an uncommon complication of the endemic fungi discussed here. Because of this, it appears to be reasonable to start antiretroviral therapy concurrently with antifungal treatment in

Histoplasmosis

Background. Histoplasmosis is due to infection with *Histoplasma capsulatum*. This thermally dimorphic fungus exists as a mold at room temperature and as a yeast within the host. Most cases are due to *H. capsulatum* var. *capsulatum*. Infection is endemic to the Mississippi and Ohio River Valleys of the United States. However, histoplasmosis is seen throughout the world, particularly in Central and South America, Africa, and Asia. Infection occurs by inhalation of fungal microconidia. Because the mold has a propensity to grow in nitrogen-rich environments, exposure to chicken coops, bird nests, caves, and similar areas may increase the risk of infection.

In the immunocompetent host, most infections are asymptomatic or result in a mild pulmonary syndrome. However, in the patient with cellular immunodeficiency due to HIV infection, severe and disseminated infection is common. In an early review of histoplasmosis among patients with AIDS, fever and weight loss were the most common symptoms. Hepatosplenomegaly, splenomegaly, pulmonary infiltrates, skin lesions, and anemia were frequent findings (Wheat et al. 1990). Skin lesions, gastrointestinal ulcers, and lymphadenopathy are also observed. Clinical disease may result from acute infection or from reactivation of a previously quiescent infection as cellular immunodeficiency wanes.

The diagnosis of histoplasmosis can be elusive. The fungus may take weeks to grow from clinical sources. Histopathology may reveal the yeast forms, often within macrophages. Serologic tests are frequently not helpful in disseminated disease. However, urine and serum assays for *Histoplasma* galactomannan antigen have been found to have both diagnostic and prognostic utility in patients with progressive disseminated histoplasmosis.

Treatment of Histoplasmosis, Coccidioidomycosis, and Paracoccidioidomycosis in Patients with HIV Infection, Table 1 Summary recommendations for treatment of histoplasmosis, coccidioidomycosis, and

paracoccidioidomycosis in patients with HIV infection based on disease activity and severity. IV indicates intravenous route; po indicates per oral

Fungal infection	Disease state	Severity	First choice antifungal	Alternatives
Histoplasmosis	Active	Severe	L-AmB ^a IV 3 mg/kg daily	Other lipid formulations of AmB IV 3–5 mg/kg daily; AmBd ^b IV 0.7 mg/kg daily
		Mild-moderate	Itraconazole po 200 mg twice daily	Fluconazole po 400 mg daily ^c
	Relapse prevention		Itraconazole po 200 mg daily	Fluconazole po 200 mg daily ^c
Coccidioidomycosis	Active	Severe	IV AmB, any formulation	Fluconazole IV 400 mg daily
		Mild-moderate	Fluconazole po 400 mg daily	Itraconazole po 200 mg twice to three-times daily ^d
	Relapse prevention		Fluconazole po 400 mg daily	Itraconazole po 200 mg twice daily ^d
Paracoccidioidomycosis	Active	Severe	IV AmB, any formulation	
		Mild-moderate	TMP-SMX ^e po twice daily	Itraconazole po 200 mg daily

^cInferior to itraconazole

^dItraconazole preferred for bone and joint disease

^eTrimethoprim–sulfamethoxazole 160/800 mg

With the advent of potent antiretroviral therapy, the incidence of severe histoplasmosis among patients with HIV infection has declined. However, in resource-limited settings, including areas of Africa and South America, histoplasmosis continues to be an important opportunistic infection.

Treatment of Active Disease. Early studies documented that the deoxycholate formulation of amphotericin B (AmBd) is effective in treating severe histoplasmosis in patients with AIDS (Wheat et al. 1990). However, the renal, hematopoietic, and infusion-related toxicities of AmBd made this regimen problematic. A subsequent randomized, double-blind multicenter study demonstrated that a 2-week course of liposome-formulated amphotericin B (L-AmB) at a dosage of 3 mg/kg daily resulted in superior clinical improvement, lower mortality, and less infusion-related toxicity compared to AmBd at 0.7 mg/kg

daily (Johnson et al. 2002). Other lipid formulations of amphotericin B at a dosage of 3–5 mg/kg daily could also be used.

For patients with mild to moderate disseminated histoplasmosis, an alternative is oral itraconazole. In a nonrandomized, open-label study, 50 of 59 (85%) patients responded to therapy after receiving a 12-week induction course of 200 mg twice daily oral itraconazole with food preceded by a loading dose of 300 mg twice daily for 3 days. Clinical improvement was associated with a drop in the urine and serum *Histoplasma* antigen concentration. The median plasma concentration of itraconazole was 6.1 µg/mL (Wheat et al. 1995). Fluconazole appears to be less effective than itraconazole for the treatment of histoplasmosis. In a nonrandomized, open-label study of 49 patients with mild to moderate disseminated histoplasmosis and AIDS, only 36 (74%) of

patients responded to the initial 12 weeks of induction therapy of 800 mg of daily oral fluconazole (Wheat et al. 1997).

Prevention of Relapse. In the era prior to potent antiretroviral therapy, relapse of histoplasmosis was frequent once induction therapy was completed (Wheat et al. 1990). To prevent this, prolonged courses of antifungals were proposed. McKinsey and colleagues treated seven patients with disseminated histoplasmosis and HIV infection with an induction course of 1000 mg of AmBd followed by 50–80 mg weekly until a cumulative dose of 1000 mg was achieved. Then, 50–80 mg was given every other week indefinitely. Another nine patients received a cumulative induction dose of 2000 mg AmBd followed by 80 mg infusions weekly. Combining both treatment groups, 13 of 14 patients who did not die of other causes remained free of relapse (McKinsey et al. 1989).

Oral itraconazole is an alternative to prevent relapse. In an open-label, nonrandomized trial of 46 patients with mild to moderate histoplasmosis who completed induction therapy, 42 patients received oral itraconazole 200 mg daily. The four other patients received 400 mg daily. Patients were followed for a median of 64 weeks. There were only two relapses, one after 16 weeks and another after 29 weeks of maintenance therapy. The first appeared to be due to medication nonadherence and the second was associated with the addition of rifampin, which likely increased the metabolism of itraconazole (Hecht et al. 1997).

Fluconazole was less effective than itraconazole in preventing relapse. Among 36 patients who responded to 12 weeks of induction therapy with 800 mg of daily fluconazole and were given 200 mg of daily fluconazole for maintenance, 11 (31%) recurred (Wheat et al. 1997). A follow-up study suggested that relapses may be due to lower activity and drug resistance. In 65 subjects, the median minimum inhibitory concentration (MIC) of fluconazole against *H. capsulatum* was significantly lower among the 37 who responded to fluconazole compared to the 28 subjects who did not respond. Moreover, the median MIC for fluconazole among the entire

group was much higher than for itraconazole. Finally, a fourfold increase in MIC of fluconazole occurred over time in isolates from 10 of 17 patients, while the MIC for itraconazole remained unchanged (Wheat et al. 2001).

Discontinuing Therapy After Immune Reconstitution. With effective suppression of HIV replication by potent antiretroviral therapy, cellular immune function improves. This has led to the concept that maintenance antifungal therapy could at some point be discontinued. In a multisite, prospective, observational study, 32 subjects who had received at least 6 months of antiretroviral therapy and 12 months of antifungal therapy for histoplasmosis were studied. All had negative fungal blood cultures, urine and serum *Histoplasma* antigen concentrations <4.1 µg/mL, and a peripheral blood CD4 lymphocyte count >150/µL. After 24 months of follow-up, no instances of relapse were observed.

A recent retrospective study (Myint et al. 2014) of 97 patients with histoplasmosis and HIV infection identified by chart review demonstrates the role of suppression of HIV infection and immune reconstitution on relapse. In this group, antifungal therapy was discontinued by the physician in 38 patients, while it was continued in the other 59. The group continued on antifungal therapy was significantly less adherent to their antiretroviral regimen and had higher HIV RNA concentrations, lower CD4 cell counts, and higher urinary *Histoplasma* urinary antigen concentrations. While none of the patients in the physician-discontinued group had a relapse of histoplasmosis, 29 (36%) of those in the continued group did. The authors conclude that maintenance antifungal therapy for histoplasmosis can be safely discontinued in those who have received at least 1 year of antifungal therapy; had a CD4 cell count $\geq 150/\mu\text{L}$, an HIV RNA <400 copies/mL, and a urinary *Histoplasma* antigen level of <2 ng/mL; and did not have central nervous system histoplasmosis.

Histoplasma Antigen Monitoring. A useful tool for monitoring the clinical response to treatment of disseminated histoplasmosis is the *Histoplasma* galactomannan antigen test. Myint

and coworkers (Myint et al. 2014) found that those with a urinary antigen concentration >2.0 ng/mL after 1 year of treatment had a risk of relapse nearly 13 times that of those with levels below this.

Therapeutic Drug Monitoring and Drug Interactions. The capsule formulation of itraconazole is variably absorbed from the gastrointestinal tract and affected by food, acid, and even grapefruit juice. The oral suspension is more uniformly absorbed in the fasting state. Itraconazole is metabolized principally by the P450 isoenzyme CYP3A4, and its major metabolite is hydroxy-itraconazole, which has equipotent antifungal activity. Because of this, there is variability in metabolism as well as significant drug–drug interactions. Plasma levels <2 $\mu\text{g/mL}$ of itraconazole have been associated with clinical failure in some patients with histoplasmosis (Wheat et al. 1995). Because of this, a random plasma sample should be obtained after 2 weeks of therapy to assure adequate itraconazole concentrations. If the bioassay is used, a level of at least >1 $\mu\text{g/mL}$ should be obtained. If high-pressure liquid chromatography (HPLC) is employed, the sum of itraconazole and hydroxy-itraconazole concentrations should reach this level (Wheat et al. 2007).

Azole antifungals, including itraconazole, both inhibit and are metabolized by the CYP isoenzyme system. Their use may result in bidirectional drug effects. For itraconazole, drugs that induce CYP3A4 may result in subtherapeutic itraconazole levels and treatment failure. This has been observed among patients with HIV infection on efavirenz, a non-nucleoside reverse transcriptase inhibitor (NNRTI). Conversely, HIV-1 protease inhibitors inhibit CYP3A4, and increases in the levels of both itraconazole and protease inhibitors can be expected. Because of this, therapeutic drug monitoring is useful when such drug combinations are used.

Prevention of Disease. It has long been recommended to avoid tasks associated with an increased risk of exposure to the fungus. These include avoiding areas with high concentrations of bird and bat excrement. While reasonable, many infections occur in the absence of such exposures.

For medical prophylaxis, in a double-blind, placebo-controlled trial in several US cities endemic for histoplasmosis, oral itraconazole at 200 mg daily among 295 HIV-infected patients who had a CD4 count $<150/\mu\text{L}$ was associated with a reduction in the number of cases of histoplasmosis from ten to four over a median of 16 months. However, this benefit was only seen in those with CD4 $\leq 100/\mu\text{L}$ and no survival benefit was observed (McKinsey et al. 1999). Moreover, no comment was made regarding the role of potent antiretroviral therapy. Current guidelines recommend prophylaxis only in those living in highly endemic regions (>10 cases per 100 patient-years) and recommend discontinuing when the CD4 count $\geq 150/\mu\text{L}$ (Wheat et al. 2007).

Coccidioidomycosis

Background. Coccidioidomycosis is caused by the dimorphic fungus *Coccidioides*, which is recognized as two genetically distinct species, *C. immitis* and *C. posadasii*. These species are not distinguishable on culture nor by the clinical disease they cause. Coccidioidomycosis is endemic to the San Joaquin Valley of California, the south-central region of Arizona, and northern Mexico. However, it can be acquired in other areas of southern California, certain regions of Nevada, Utah and Texas, as well as areas of Central America and South America, including northeast Brazil and northern Argentina.

Coccidioides spp. exist as molds in the environment. While they reside in the upper 10 cm of the soil, the precise ecological niche is not known. In most cases, inhalation of arthroconidia, small hydrophobic fungal cells, is the cause of infection. In immunocompetent hosts, most infections are asymptomatic. However, in those with cellular immunodeficiencies such as AIDS, severe and disseminated infections are common.

The diagnosis of coccidioidomycosis can be established in several ways. Unlike the other endemic fungi, *Coccidioides* spp. usually grow within 7 days on routine bacteriological media. It can also be seen in biopsy specimens in its unique tissue phase, the spherule. Serologic

tests are very useful in the diagnosis of coccidioidomycosis. In particular, the titer of complement fixation (CF) antibody response is reflective of fungal growth and can be used both for diagnosis and for monitoring response to therapy. Finally, similar to histoplasmosis, a galactomannan antigen test for both urine and serum exists. However, its usefulness appears limited to extrathoracic disseminated disease and has not been studied extensively as a tool to assess response to therapy.

During the late 1980s and early 1990s, coccidioidomycosis emerged as an important opportunistic infection among HIV-infected persons living in the coccidioidal endemic region. In a retrospective study of 77 patients from 1990, a wide range of manifestations were seen, including diffuse pulmonary disease and liver and lymph node involvement. Death occurred in 32 (42%) over a median of 7 months (Fish et al. 1990). In a prospective study of 147 patients followed in a single HIV clinic beginning in 1988, the cumulative risk of developing coccidioidomycosis was nearly 25% over 41 months. Risk factors included a CD4 cell count $<250/\mu\text{L}$ and a previous AIDS diagnosis. Five (38%) of the 13 patients died during the follow-up period. Prior infection did not appear to be a risk, suggesting that most disease was associated with recent infection (Ampel et al. 1993). The incidence of clinically active coccidioidomycosis declined with the advent of potent antiretroviral therapy. A follow-up study in 2010 from the same clinic revealed that 29 (11%) of 257 patients had coccidioidomycosis and the annual incidence was estimated to be only 0.9% (Masannat and Ampel 2010).

Treatment of Disease. Unlike histoplasmosis, there are no placebo-controlled, randomized studies regarding the treatment of coccidioidomycosis in patients with HIV infection. For severe pulmonary and extrathoracic disseminated coccidioidomycosis in the acutely ill patient, amphotericin B is recommended as initial therapy. There are no comparative trials of AmBd and lipid formulations for coccidioidomycosis. Because of this, the formulation used should be based on the risk of renal disease and cost. For initial therapy, AmBd at 0.7 mg/kg daily is recommended,

while 3 mg/kg daily of a lipid preparation is appropriate. Many experts would also start a triazole antifungal at 400 mg daily at the same time. As the patient improves, the amphotericin B preparation can be reduced in frequency and finally discontinued when the patient becomes clinically stable, leaving the patient only on the triazole antifungal.

For less severe disease, initial therapy can be with an oral triazole antifungal at 400 mg daily. For pulmonary disease, most experts would choose fluconazole, given its better absorption and tolerance compared to itraconazole. However, for extrathoracic disease, particularly that involving bones and joints, itraconazole appears to have better activity. There are limited data on the use of posaconazole and voriconazole, but these agents appear appropriate in patients not responding to fluconazole or itraconazole.

Prevention of Relapse. For patients with focal pulmonary disease, treatment with at least 400 mg daily of a triazole antifungal should continue for a minimum of 6 months. For patients with diffuse pulmonary disease and those with extrathoracic dissemination, antifungal therapy is usually much longer and based on clinical and immunological response. There are no data on using lower doses of triazole antifungals to prevent relapse.

Discontinuation of Therapy After Immune Reconstitution. Data indicate that the specific cellular immune response to coccidioidal antigens is maintained when the peripheral blood CD4 cell count is $\geq 250/\mu\text{L}$ (Ampel 1999). Moreover, a prospective study of patients with coccidioidomycosis and HIV infection demonstrated that less severe disease occurs in those with higher CD4 cell counts and lower HIV RNA levels (Masannat and Ampel 2010). Based on this, for those patients on potent antiretroviral therapy with undetectable HIV RNA and CD4 $\geq 250/\mu\text{L}$, the HIV patient with coccidioidomycosis can be managed similarly to the patient without immunodeficiency. For those with focal pulmonary disease, this is usually 6 months of treatment. For extrathoracic disseminated disease, it is longer and is based on the clinical response and the CF titer. Patients with coccidioidal meningitis should receive lifelong therapy.

Prevention of Disease. For those living in the endemic region, it is difficult to avoid exposure to *Coccidioides* spp. Remaining inside during dust storms or similar conditions seems prudent but is unproven. A retrospective study suggested that in highly immunosuppressed patients living in the coccidioidal endemic area, fluconazole resulted in a reduced risk of coccidioidomycosis (Woods et al. 2000). However, the benefit was small. Initiation of potent antiretroviral therapy with its consequent immune reconstitution is the best method to reduce the risk of severe coccidioidomycosis for those living in the endemic region (Masannat and Ampel 2010).

Paracoccidioidomycosis

Background. Caused by the thermally dimorphic *Paracoccidioides brasiliensis*, paracoccidioidomycosis appears to be acquired only in Central and South America and is the most common systemic mycosis seen there. The vast majority of cases are reported from Brazil, with fewer reported from Venezuela, Colombia, and Argentina. The natural habit of the fungus is not known, but most infections are presumed to be acquired by inhalation of mycelial conidia from the environment.

There are several distinct clinical presentations of paracoccidioidomycosis. Subclinical infection is asymptomatic and usually accompanied by delayed-type hypersensitivity to antigen skin testing. Progressive disease is defined as an inability of the host to control fungal growth and results in diverse clinical presentations. It has been divided into two major forms. The chronic, adult form accounts for 90% of progressive cases of paracoccidioidomycosis. It occurs overwhelmingly among men, usually from 35 to 60 years. Pulmonary symptoms and signs are common as are lesions of the oral mucosa and skin. The acute juvenile form occurs principally in patients under 30 years with less male predominance. Pulmonary findings are uncommon and skin lesions of the face, neck, and trunk, with gastrointestinal ulcers and bone lesions, are frequent. The third major manifestation of paracoccidioidomycosis,

residual disease, is organ damage as a result of fibrosis from a previously active infection.

Like histoplasmosis and coccidioidomycosis, the diagnosis of paracoccidioidomycosis can be made in several ways. Biopsy of infected tissue may reveal the characteristic configuration of multiple attached yeasts in a pattern resembling a steering wheel. Cultures may take up to 30 days for the organism to grow as a mold without distinguishing characteristics. Several serologic tests are available but are not standardized.

In 1995, Goldani and Sugar reviewed the first 27 cases of paracoccidioidomycosis associated with HIV infection reported in the medical literature (Goldani and Sugar 1995). The median age was 31 years and 21 were male. Only one patient was receiving trimethoprim–sulfamethoxazole prophylaxis for pneumocystosis and the overall mortality was 30%. Paniago and colleagues reported 21 cases of paracoccidioidomycosis occurring during HIV infection from a single medical center in Mato Grosso, Brazil, in 2005 (Paniago et al. 2005). All were male with a mean age of 36 years. The clinical presentations seen, with lymph node and bone marrow involvement, corresponded to the acute juvenile form of paracoccidioidomycosis. A later retrospective case–control study compared the epidemiological and clinical data of 53 cases of paracoccidioidomycosis among patients with HIV infection to a control group of 106 patients without HIV (Morejon et al. 2009). Those with HIV infection were younger, more likely to be female, and were less likely to be involved in agricultural work compared to the control group. In the HIV group, 80% had CD4 < 200/μL and only 15 (28%) were on trimethoprim–sulfamethoxazole prophylaxis. After 24 months of follow-up, only 63% of those with HIV infection were improved or in remission, compared to 93% of those with HIV.

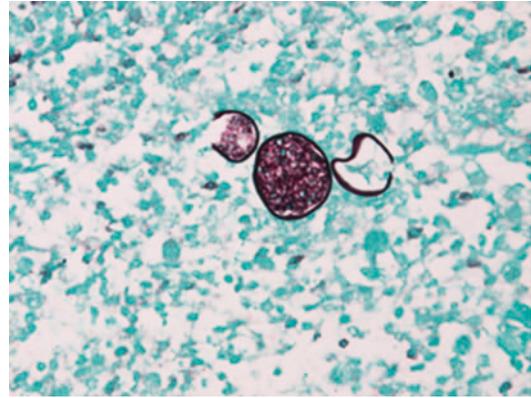

Treatment of Disease. There are no comparative trials of different therapies for paracoccidioidomycosis in the HIV-infected patient. Moreover, unlike histoplasmosis and coccidioidomycosis, sulfa drugs have been successfully used to treat various forms of this infection. In the case–control study cited above, therapy of HIV-infected patients included trimethoprim–sulfamethoxazole in 60%, some formulation of

amphotericin B in 45%, and a triazole antifungal in 32% (Morejon et al. 2009).

For severe disease, amphotericin B is recommended as initial therapy, either as AmBd at 0.7/kg daily or as a lipid preparation at 3 mg/kg daily. The choice of formulation should be based on cost and risk of renal toxicity. Amphotericin B therapy should be continued until the patient is clinically stable. For milder disease, trimethoprim–sulfamethoxazole or itraconazole can be employed.

Prevention of Relapse. Once clinical stability has been achieved, an azole antifungal or sulfa antimicrobials may be started. In a randomized trial, itraconazole up to 100 mg daily, ketoconazole up to 400 mg daily, and sulfadiazine up to 6 g daily were compared among 42 patients both acute and chronic progressive paracoccidioidomycosis. All three regimens led to statistically comparable rates of clinical cure (Shikanai-Yasuda et al. 2002). More recently, de Souza Calvacante and colleagues compared the efficacy of itraconazole 200 mg daily to trimethoprim–sulfamethoxazole in a quasi-experimental study among 177 patients with chronic progressive paracoccidioidomycosis. None were reported as having HIV infection. While overall results were comparable, the time to clinical cure was shorter for itraconazole (de Souza Cavalcante et al. 2014). Other agents used to treat paracoccidioidomycosis include sulfadoxine and voriconazole. Data are limited regarding use of any of these agents in HIV-infected patients with paracoccidioidomycosis. However, itraconazole at 200 mg daily would seem reasonable. An alternative would be trimethoprim–sulfamethoxazole given as up to 1200 mg of sulfamethoxazole twice daily (Marques 2013).

Discontinuation of Therapy After Immune Reconstitution. There are no studies regarding stopping therapy once immune reconstitution has occurred, but it would seem reasonable to continue therapy at least until the CD4 cell count exceeds 200/ μ L, based on the retrospective case review (Morejon et al. 2009) and observations in histoplasmosis and coccidioidomycosis. Given that therapy is recommended to be continued for

Treatment of Histoplasmosis, Coccidioidomycosis, and Paracoccidioidomycosis in Patients with HIV Infection, Fig. 1 Coccidioidal spherules in tissue. Gomori methenamine silver stain

up to 12 months for mild disease and up to 2 years for more severe illness among those without HIV infection, therapy for at least this long beyond the time from immune reconstitution should be considered.

Prevention of Disease. There are no environmental means to prevent infection. However, the use of trimethoprim–sulfamethoxazole as prophylaxis for pneumocystosis in those with CD4 cell counts $<200/\mu$ L likely has had a significant effect in either preventing infection with *Paracoccidioides* or ameliorating clinical infection. There are no studies on the use of azole antifungals in preventing paracoccidioidomycosis in the HIV-infected person.

Conclusion

Three endemic mycoses, histoplasmosis, coccidioidomycosis, and paracoccidioidomycosis, which can cause disease in the immunocompetent host, have been found to also act as opportunistic infections in those with HIV infection, particularly at low peripheral blood CD4 counts. Therapy of acute and severe disease frequently requires the use of an amphotericin B preparation. While the liposomal formulation is favored in histoplasmosis, no data exist for either coccidioidomycosis or paracoccidioidomycosis. Subsequent therapy

or therapy for milder disease can employ an azole antifungal or, in the case of paracoccidioidomycosis, a sulfa antimicrobial. With the use of potent antiretroviral therapy, the frequency and severity of these three fungal infections in the HIV-infected population are diminishing, and immune reconstitution allows discontinuation of antifungal therapy in many instances.

TRIM Protein Family and Viral Restriction

Sébastien Nisole
INSERM UMR-S 1124, Université Paris
Descartes, Paris, France

Definition

Tripartite motif (TRIM) proteins constitute a vast family of proteins characterized by a common motif, known as RBCC, as it is composed, from N- to C-terminal, by a RING (R) domain, one or two zinc finger domains, known as B-boxes (B) and a coiled coil (CC). TRIM genes are found in all metazoans and have rapidly expanded during vertebrate evolution. Although TRIM proteins are implicated in a plethora of biological processes, several lines of evidence indicate that many of them are key actors of cellular defense against viruses. In particular, many TRIM proteins have been found to interfere with various stages of HIV life cycle. Furthermore, an increasing number of TRIMs are found to be key

modulators of interferon (IFN) response and can therefore further impact viral spread and clinical course of infection.

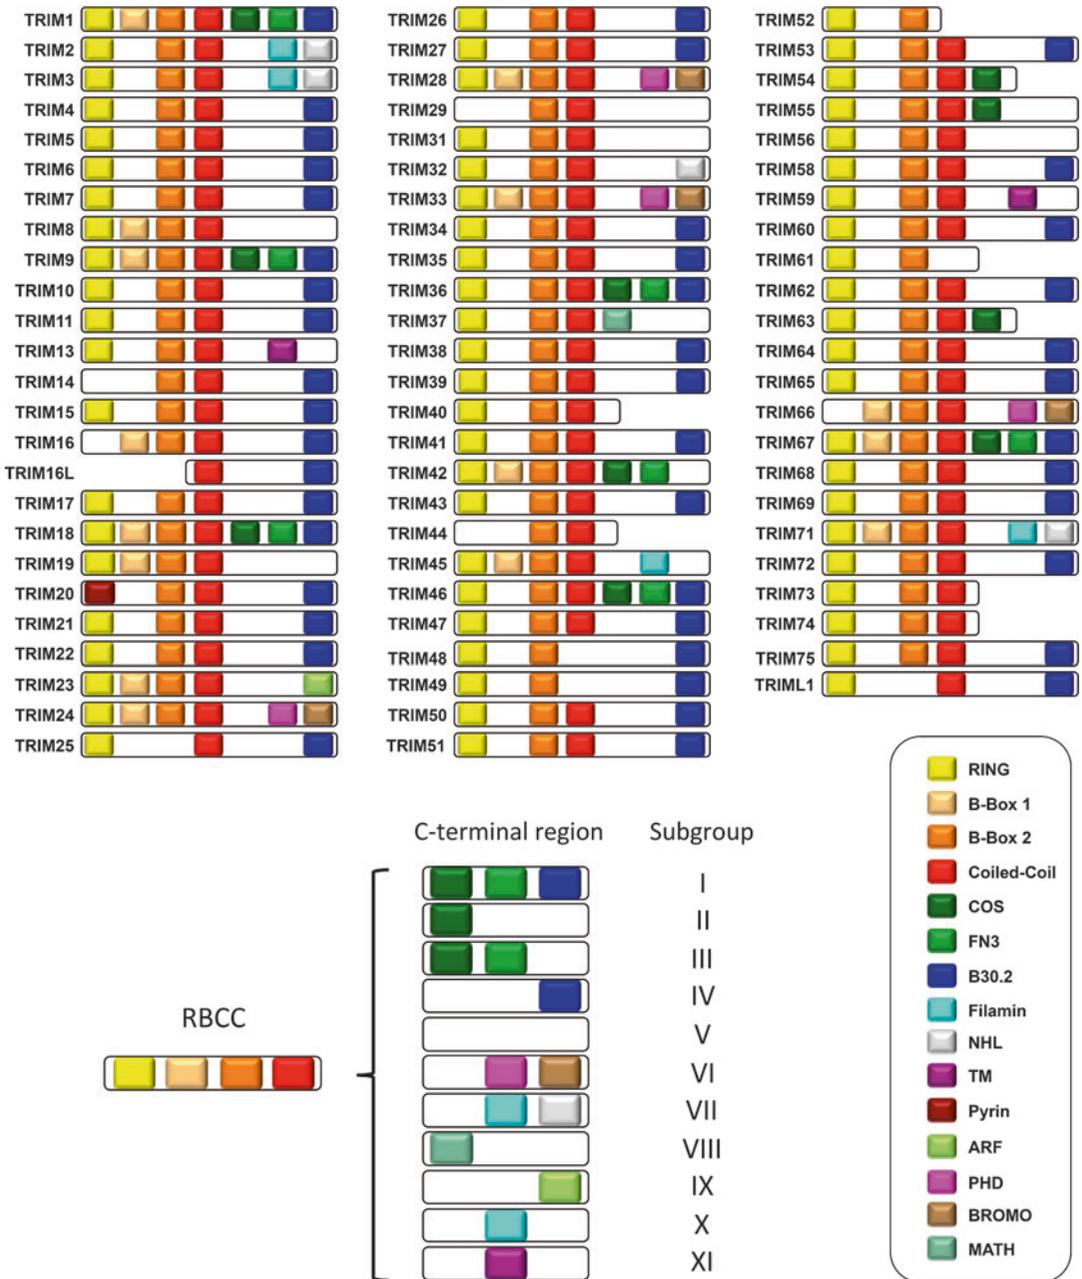

Introduction

Whereas there are a relatively small number of TRIM genes in lower eukaryotes, vertebrates and especially mammals have a vast TRIM repertoire, suggesting an extensive evolution of the TRIM family. In humans, the TRIM protein family consists of over 70 members that all harbor the RBCC motif, but differ from each other by the nature of their C-terminal region (Fig. 1). Short and Cox have proposed a classification of TRIM proteins into nine different subgroups, based on the domain composition of their C-terminal region (Short and Cox 2006). This classification was slightly modified, leading to the definition of 11 classes (C-I to C-XI) (Fig. 1).

However, this classification does not entirely reflect the complexity of this protein family, since most TRIM genes can generate multiple alternatively spliced transcripts encoding TRIM proteins with different C-terminal domains and thus different functions.

TRIM proteins have strong self-association ability, mainly mediated by their CC domain, which results in the formation of large protein complexes that in some cases form discrete nuclear and/or cytoplasmic subcellular structures (Reymond et al. 2001). TRIM proteins are implicated in a broad range of biological processes, such as transcriptional regulation, apoptosis, and development. As a result, TRIM protein dysregulations are implicated in numerous pathologies including genetic, developmental, or neurological disorders and cancer. Among these various cellular functions, one has rapidly emerged as an important and possible common feature of all TRIM proteins: their involvement in antiviral innate immunity (Rajsbaum et al. 2014).

In addition to their implication in various biological processes, the heterogeneity of TRIM proteins is further illustrated by the fact that they exhibit diverse expression patterns. They can be found either in the nucleus or in the cytoplasm,

TRIM Protein Family and Viral Restriction, Fig. 1 Schematic representation of the human TRIM protein family. The domain organization of individual human TRIM proteins together with their classification based on the domain composition of their C-terminal region proposed by Short and Cox is represented. Note that only “real” TRIM proteins are represented in the Short and Cox classification. Thus, proteins that do not possess a RBCC motif per se are absent from this classification. This is, for example, the case of TRIM20 that has a pyrin domain in place of the RING, or TRIM29 and TRIM44,

which have no RING. *RING* really interesting new gene, *COS* C-terminal subgroup one signature, *FN3* fibronectin type 3, *PHD* plant homeodomain, *NHL* NCL-1, HT2A, and LIN-41, *MATH* meprin, and TRAF homology, *ARF* ADP ribosylation factor-like, *TM* transmembrane. B30.2 domains are also called PRYSPRY as they are composed of a SPRY with an additional PRY domain. Although some TRIM proteins only have a SPRY domain, PRYSPRY and PRY domains are all referred to B30.2 in this representation. Also, the coiled-coil region is shown systematically, although its computer-based prediction is variable

some with a diffuse distribution and some others forming punctate structures. But the common N-terminal RBCC motif of TRIM proteins also confers them with common features, such as the capacity to homo- and hetero-oligomerize. Another general feature of this protein family is common enzymatic activity conferred by their RING domain, since TRIM proteins have emerged as a family of E3 ubiquitin ligases (Rajsbaum et al. 2014). Ubiquitination is a post-translational modification that consists in the covalent conjugation of ubiquitin moieties to lysine residues of specific substrate proteins. Conjugated ubiquitin itself can serve as a substrate for ubiquitination, leading to the formation of poly-ubiquitin chains. All seven lysine residues in ubiquitin contribute to the synthesis of poly-ubiquitin chains, and each type of chain has specific consequences for the substrate protein. Most TRIM proteins promote either K48 ubiquitination that is usually followed by the proteasomal degradation of target proteins or K63 ubiquitination, which is involved in protein activation. Furthermore, several TRIM proteins have been reported to function as E3 ligases for small ubiquitin-like modifier (SUMO) or ISG15.

TRIM Proteins and Intrinsic Immunity

In addition to the two main branches of immunity (i.e., innate and adaptive immunity), the notion of the so-called intrinsic immunity appeared with the discovery of antiretroviral restriction factors. These factors confer cells with a protection against specific viruses by inhibiting their replication independently of the immune system. Thus, intrinsic immunity constitutes a cell autonomous form of innate antiviral defense.

Since this intrinsic defense directly targets viral components, they have coevolved with virus, each providing a selection pressure to the other. Thus, a common feature shared by TRIM proteins with antiviral intrinsic properties is the fact that they have evolved under positive selection, especially in the regions that interface with the virus (Sawyer et al. 2005, 2007). These signatures can be detected through phylogenetic comparison of

synonymous and nonsynonymous substitution rates.

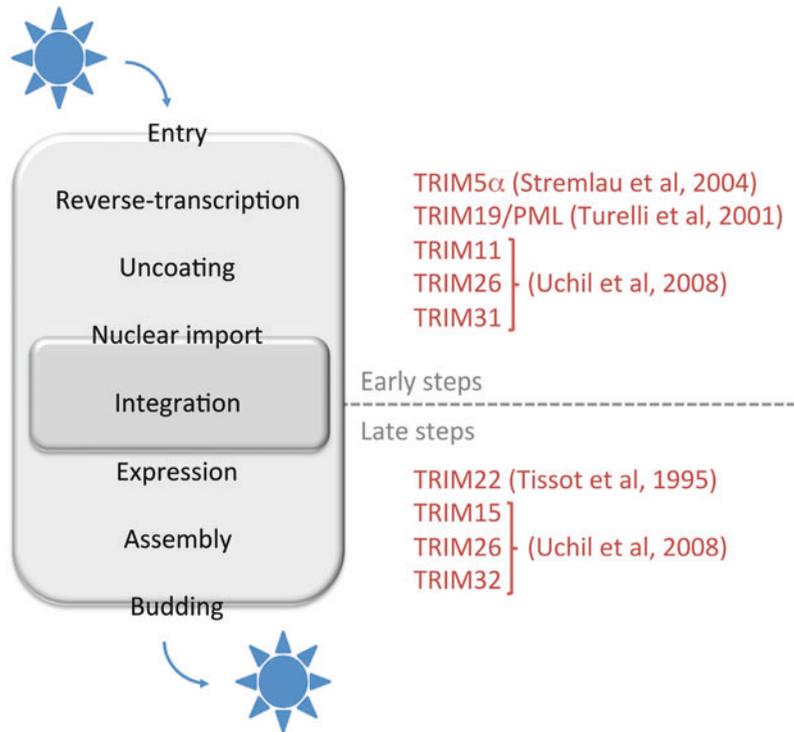

Many TRIM proteins have been identified as restriction factors. Although TRIM proteins can inhibit various viruses, HIV-1 is the most exemplified target (Fig. 2).

One of the best characterized TRIM proteins with intrinsic antiviral properties is TRIM5 α , the longest transcript encoded by the TRIM5 gene. Initially discovered as the protein that protects rhesus macaques from HIV-1 infection (Stremlau et al. 2004), TRIM5 α was later shown to display a broad antiretroviral intrinsic immunity in other primates, including humans. The C-terminal region of TRIM5 α , composed of a PRYSPRY (or B30.2) domain, allows the protein to recognize retroviral capsids. Due to a high degree of polymorphism within this domain of TRIM5 α between species, restriction patterns are species specific (Sawyer et al. 2005). For example, TRIM5 α from rhesus macaque inhibits HIV-1, but not SIVmac, whereas in humans, TRIM5 α restricts N-tropic murine leukemia virus (N-MLV) and equine infectious anemia virus (EIAV). Unlike those encoded by Old World monkeys, human TRIM5 α has only a modest restriction activity toward HIV-1, although more potent anti-HIV activity can be artificially conferred to the human protein by a single point mutation within the PRYSPRY domain (Yap et al. 2005). The targeted residue is located within a patch subject to intense selective pressure and presumably located at the interface with the viral capsid (Sawyer et al. 2005). TRIM5 α interferes with an early postentry step of retroviral replication, since its expression inhibits reverse transcription. Mechanistically, TRIM5 α binds the capsid protein lattice of incoming viruses and promotes their disassembly, thus inhibiting reverse transcription and subsequent steps of replication (Stremlau et al. 2006). The RING domain of TRIM5 α acts as an E3 ubiquitin ligase, but it is still unclear whether this activity is implicated or not in retroviral restriction. TRIM5 α is expressed constitutively in virtually all cells in the organism, where it is found both diffuse in the cytoplasm and within large dots, named cytoplasmic bodies. TRIM5 α was also recently found to shuttle

TRIM Protein Family and Viral Restriction,

Fig. 2 Human TRIM proteins interfering with HIV-1 replication.

The main steps of HIV-1 replicative cycle are schematically represented, along with TRIM proteins that have been found to interfere either with early or late stages of HIV cycle

between the nucleus and the cytoplasm, but the function of nuclear TRIM5 α is unknown (Diaz-Griffero et al. 2011).

Although TRIM genes are distributed throughout the human genome, TRIM5 gene resides in a cluster of four closely related TRIM genes that also include TRIM6, TRIM34, and TRIM22. While TRIM6 and TRIM34 have evolved under purifying selection, TRIM5 and TRIM22 underwent strong positive selection in primates (Sawyer et al. 2007). Accordingly, TRIM22, also known as Staf50, has also been identified as a potent antiviral protein. TRIM22 is an interferon-stimulated gene (ISG) product that inhibits transcription from the HIV-1 LTR (Tissot and Mechti 1995). In addition, it was later found to interact with the HIV-1 Gag protein and to interfere with its trafficking to the plasma membrane (Barr et al. 2008). Unlike TRIM5 α whose antiviral activity only targets retroviruses, TRIM22 also confers resistance to hepatitis B virus (HBV), EMCV, and influenza A virus.

Another TRIM protein with a broad antiviral activity is TRIM19, better known as PML

(promyelocytic leukemia). PML can interfere with the replication of members of many viral families, including *Arenaviridae*, *Herpesviridae*, *Orthomyxoviridae*, *Parvoviridae*, *Picornaviridae*, *Rhabdoviridae*, and *Retroviridae* (Nisole et al. 2013). In the case of retroviruses, PML was first shown to inhibit foamy virus transcription, by complexing the viral transactivator Tas, thereby preventing its binding to viral DNA (Regad et al. 2001). PML was also reported to interfere with HIV-1 replication. More specifically, HIV-1 infection was found to rapidly trigger the translocation of PML from the nucleus to the cytoplasm where it co-localizes with pre-integration complexes (Turelli et al. 2001). Interestingly, arsenic-induced degradation of PML has been reported to cause an enhancement of HIV-1 infection, suggesting that PML cytoplasmic export is deleterious for the virus (Turelli et al. 2001). However, this latter observation was later contradicted by other studies, and the implication of PML in HIV restriction remains controversial.

A study investigated the potential antiretroviral activity of 36 human and 19 mouse TRIM

proteins (Uchil et al. 2008). From their screen, they identified 20 TRIM proteins that interfere either with early or late stages of the retroviral replication cycle. In particular, murine TRIM8, TRIM10, TRIM11, and TRIM56 and human TRIM11, TRIM26, and TRIM31 were found to interfere with early steps of HIV-1 infection (Fig. 2). In contrast, HIV-1 release was affected by murine TRIM11, TRIM25, TRIM27, and TRIM56 and by human TRIM15, TRIM26, and TRIM32. This first large screen of antiretroviral TRIM proteins confirms that antiviral activity is a general feature of many (if not all) TRIM proteins.

However, it is difficult to tell from these studies whether the majority of TRIM proteins are targeting retroviruses because this particular viral family has coevolved with mammals for millions of years or whether this is simply due to the fact these viruses are more widely studied.

Besides HIV, however, some other TRIM proteins have been shown to display a direct antiviral activity toward other viruses (Rajsbaum et al. 2014). This is the case of the murine protein TRIM79 α , which restricts tick-borne encephalitis virus, and human TRIM56, which blocks pestivirus infection. Whereas TRIM21 was also identified as a potent antiviral protein, its activity could not be considered as intrinsic per se, since it facilitates the cytoplasmic detection of antibody-opsionized non-enveloped viruses, through the capacity of its PRYSPRY domain to act as an IgG Fc receptor.

Since positive selection is a hallmark of TRIM proteins implicated in intrinsic immunity, it should be possible to predict the potential antiviral activity of the entire family through a computational screen. Such a screen has been performed and revealed that ten uncharacterized human TRIM genes showed signatures of positive selection (Malfavon-Borja et al. 2013).

TRIM Proteins and Innate Immunity

In addition to their implication in intrinsic immunity, an increasing number of TRIM proteins have been found to control viral replication by regulating innate immune pathways (Rajsbaum et al.

2014). Once a virus enters a cell, its nucleic or proteic components are sensed by cellular pattern recognition receptors (PRRs), which trigger transduction pathways leading to the activation of transcription factors such as NF- κ B and interferon regulatory factors (IRFs). Once activated, these factors translocate into the nucleus and induce the expression of many cytokines, including IFNs and pro-inflammatory cytokines. Type I IFNs are the main inducers of innate immunity in the case of viral infections, since they initiate an antiviral program in infected and surrounding cells. Most recently identified restriction factors, such as TRIM5 α , APOBEC3G, and tetherin/BST-2, are induced by type I IFN. Furthermore, many TRIM proteins, in particular those known to display antiviral activity, are among the many antiviral factors whose expression is induced by type I IFN (Carthagen et al. 2009). In particular, some TRIM proteins have been identified as key mediators of the anti-HIV activity of type I IFN, such as TRIM5 α and TRIM22 (Barr et al. 2008; Carthagen et al. 2009).

IFNs exert both antiviral activity and immunostimulatory functions and are a key bridging mechanism between innate and adaptive immune responses. Despite their crucial role during acute viral infections, however, the prolonged stimulation of IFN has detrimental consequences. In this context, HIV-1 infection represents an example of how chronic IFN production could compromise long-term immune protection and contribute to the pathogenesis of the disease. Thus, since many TRIM proteins are not only able to interfere with HIV replication but also to modulate IFN synthesis, they are likely to have a major implication in the development of viral spread and pathogenesis. However, the global impact of TRIM proteins on the outcome of HIV infection will require a better understanding of their respective mode of action.

The list of TRIM proteins modulating innate immune pathways is expanding so rapidly that it is already almost impossible to review them all in detail (Rajsbaum et al. 2014). Therefore, only a few examples will be developed here to illustrate the heterogeneity of their mode of action. TRIM proteins can act directly on PRRs or on

downstream signaling pathways. Among the TRIM proteins that act as positive regulators of innate immune signaling, one of the best examples is TRIM25, which was identified as a positive regulator of retinoic acid-inducible gene-I (RIG-I) activation. RIG-I is a cytoplasmic dsRNA helicase that senses viral RNA within the cytoplasm of infected cells. During a viral infection, TRIM25 induces the K63-linked ubiquitination of RIG-I, thus allowing its binding to mitochondrial antiviral-signaling protein (MAVS, also known as VISA, IPS-1, or Cardif). This results in a marked increase of RIG-I downstream signaling activity and IFN production (Gack et al. 2007). TRIM25 can also catalyze the synthesis of unanchored K63-ubiquitin chains, which can activate RIG-I. Another TRIM protein, TRIM4, was also recently proposed to promote K63 ubiquitination-dependent activation of RIG-I. K63 ubiquitination seems to be a general mechanism used by TRIM proteins to activate innate immune signaling. Not only PRRs can be targeted, but virtually all intermediates of downstream signaling pathways. For example, TRIM56 targets STING for K63 ubiquitination to promote its dimerization and subsequent TBK1 activation, thus increasing dsDNA-induced IFN- β production (Fig. 2). Similarly, TRIM8 promotes TAK1 K63 ubiquitination to activate the NF- κ B pathway. TRIM23 is an exception to the rule as it activates NEMO through a K27-linked polyubiquitination. While most TRIM proteins modulate immune pathways leading to IFN production, some other TRIMs directly target IFN- β transcription. This is the case of TRIM19/PML, which enhances IFN- β transcription during viral infections through the sequestration Pin1, an enzyme that normally terminates IFN transcription (El Asmi et al. 2014). In addition to these various activators, some other TRIM proteins have been identified as negative regulators of innate immune signaling. Given the pleiotropic and opposite effects of TRIM proteins on innate immune pathways, evaluating the global impact of the whole TRIM family on innate sensing, IFN response and viral spread will need further intensive work once the mechanism of each individual TRIM has been deciphered.

In most cases, intrinsic antiviral activity and modulation of innate immunity are mutually exclusive. This can easily be explained by the fact that TRIM proteins that target viral proteins are under a strong selection pressure and thus evolve rapidly, whereas TRIMs that target cellular proteins to modulate innate immune signaling are likely to be well conserved among species. They are exceptions, including TRIM5 α and TRIM19/PML. TRIM5 α directly interferes with retroviral replication and also activates immune pathways, acting as a PRR (Pertel et al. 2011), whereas TRIM19/PML is able to restrict many different viruses from unrelated families and, at the same time, enhance IFN- β transcription through the inhibition of a cellular protein. However, despite its multiple roles in antiviral defense, the PML gene does not show any signature of positive selection (Malfavon-Borja et al. 2013), suggesting that PML does not directly interact with viral components.

Conclusion

It is now established that TRIM proteins constitute an ancient protein family that emerged during an early step of metazoan evolution and rapidly diversified by gene duplications in vertebrates driven by selective adaptation. In the case of TRIM proteins acting as restriction factors, this adaptation was imposed by continuous viral pressure. However, even if a growing number of TRIM proteins have been identified as antiviral proteins or as activators of innate immune response, the vast majority of TRIMs remain uncharacterized. Further investigations will be required to draw a complete picture of the implication of the whole TRIM protein family in viral infections, including HIV.

TRIM5 Alpha and HIV-2 Infection

Sabelle Jallow and Shmona Simpson
Nuffield Department of Medicine, University of Oxford, Oxford, UK

Definition

This entry discusses the restriction of HIV-2 by the host restriction factor TRIM5 α . Although most published studies focus on HIV-1, we looked at the parallels between the two viruses, paying particular attention to the differences between HIV-1 and HIV-2 and to studies that specifically focused on HIV-2, to put together a current synthesis of our understanding of HIV-2 restriction by TRIM5 α .

Introduction

HIV-2 is the second human retrovirus that can cause AIDS. While very similar to HIV-1 in terms of genomic sequence and protein function, HIV-2 infection usually leads to an attenuated disease course. About 80% of HIV-2 infections do not lead to AIDS; they are instead characterized by a longer asymptomatic stage, lower

plasma viral loads, slower decline in CD4 count, decreased mortality rate, and lower rates of vertical and sexual transmission (see “► [HIV-2 Transmission](#)”). Nonetheless, a significant proportion of HIV-2-infected individuals eventually progress to AIDS, with high viral loads, low CD4 counts, and a clinical picture indistinguishable from HIV-1 disease progression (see “► [Natural History and Clinical Features of HIV-2 Infection](#)”). The HIV-1 epidemic is characterized by extensive genetic variation, with four groups, several subtypes, and many circulating recombinant forms (CRF) (see “► [Origin and Distribution of HIV-1 Subtypes](#)”), while the HIV-2 epidemic consists of only two groups (A and B) and six non-epidemic groups (C–H) (see “► [HIV-2, Phylogeographic Insights into the Origins and Epidemic History](#)”). HIV-1 has spread throughout the world with high transmission rates, while HIV-2 is restricted mainly to West Africa, where prevalence has been declining (Tienen et al. 2010). The main difference between HIV-1 and HIV-2 is in their origin. HIV originated from SIV from chimpanzees (*Pan troglodytes troglodytes*), but HIV-2 arose from zoonotic transfer of SIV from the sooty mangabeys (*Cercocebus atys*) to humans (see “► [HIV-2, Phylogeographic Insights into the Origins and Epidemic History](#)”): consequently HIV-2 and SIV from sooty mangabeys (SIV_{sm}) and SIV-infected macaques (SIV_{mac}) share about 75% sequence homology compared to 40–50% homology with HIV-1 (Hirsch et al. 1989). Several studies have revealed factors, immunological, virological, and molecular, that contribute to the attenuated course of HIV-2 infection. More recently, studies on host genetic factors, such as TRIM5 α , have provided genetic contributions to understanding the reduced HIV-2 pathogenicity.

TRIM5 α is a member of the tripartite motif family of proteins that has the three protein domains: RING, B-box, and coiled coil (see “► [TRIM Protein Family and Viral Restriction](#)”). TRIM5 α has an additional domain, at its C-terminal, the PRYSPRY or B30.2 domain that interacts with the retroviral capsid and is responsible for species specificity (Stremlau et al. 2005). The retroviral restriction properties of TRIM5 α were discovered because HIV-1 could not grow

in certain Old World monkey cells. TRIM5 α can mediate a postentry block of lentiviral replication either before or after reverse transcription, in a species-specific manner. Although the exact mechanism of retroviral restriction is not fully understood, several mechanisms, some of which are interdependent, have been proposed, with supporting experimental data. Oligomeric TRIM5 α recognition of and binding to the incoming intact capsid destabilize the capsid core, leading to accelerated or premature uncoating, which perturbs reverse transcription. The E3 ligase activity of the RING domain can add ubiquitin molecules to itself and to other proteins, leading to proteasome-mediated protein degradation of the capsid-TRIM5 α complex. TRIM5 α forms occlusion bodies, where the virus is essentially trapped, and it also inhibits nuclear transport of the replicating virus (Veillette et al. 2013). TRIM5 α is a pattern recognition receptor that recognizes and binds to the viral capsid, causing a cascade of innate immune signaling that leads to an antiviral state, restricting retroviral replication (Pertel et al. 2011).

TRIM5 α and the Viral Capsid

HIV capsid was previously thought to be an inert packaging shell that protects the genomic material of the virus. However, it has emerged that it has several domains that allow interaction with host proteins, such as cyclophilin A, a peptidylprolyl isomerase. Cyclophilin A catalyzes the cis/trans isomerization of a surface-exposed proline (Pro-90) in a loop (residues 85–93) between helices 4 and 5 of the HIV-1 gag capsid (Gamble et al. 1996). Despite HIV-1 and HIV-2 capsids being very similar both in sequence and structure, HIV-1 has a high binding affinity for CypA, but HIV-2 does not. HIV-1 incorporates CypA into incoming and nascent virions, where they enhance viral infectivity. At the same time, this capsid-CypA interaction also increases HIV-1 sensitivity to restriction by Old World monkey TRIM5 α . Unlike HIV-1, HIV-2, as well as SIV_{mac}, and murine leukemia viruses (MLV) neither incorporate CypA into nascent

virions nor require it for infectivity. HIV-2 binds very weakly to CypA, mainly because its proline (Pro-88) is not positioned correctly in the catalytic site of CypA, unlike Pro-90 of HIV-1 (Lahaye et al. 2013). Despite weak binding and independence of CypA for infectivity, mutational analysis has revealed that the determinants of HIV-2 TRIM5 α sensitivity lie in the region of the HIV-2 capsid equivalent to the CypA binding loop of HIV-1, mapping specifically to the glycine-proline (Gly-Pro) motif at positions 87–88 on the HIV-2 capsid (Price et al. 2009). This Gly-Pro motif in HIV-1 has been linked to TRIM5 α sensitivity, and the G87A (glycine to alanine) mutation in HIV-2 was associated with reduced HIV-2 titers in cell lines from different species (Ylinen et al. 2005). Available crystal structures of retroviral capsids from different species show an exposed loop structure, like HIV-1, in the region equivalent to the HIV-1 CypA binding loop. It was suggested that this structure can be recognized by TRIM5 α from different species (Ylinen et al. 2005).

In at least two independent events, retrotransposition of the *CypA* gene into the C'-terminal into the *TRIM5 α* gene has occurred, essentially replacing the PRYSPRY/B30.2 domain to form the *TrimCyp* gene. In New World monkeys of genus *Aotus* (owl monkey), the TrimCyp replaces exon 8, accounting for most of the PRYSPRY domain, and this protein is able to restrict CypA-binding retroviruses like HIV-1 and FIV. In Old World monkeys of genus *Macaca* (macaques), sequences from *CypA* in the rhesus macaque replace both exons 7 and 8, removing the entire PRYSPRY domain, to produce a protein that can potentially inhibit HIV-2 and FIV, but not HIV-1 (Wilson et al. 2008). There are at least six species of macaques that express TrimCyp; some express this gene exclusively, while others express both TrimCyp and TRIM5 α (Dietrich et al. 2011). It was shown that the ability of the rhesus macaque (*Macaca mulatta*) RhTrimCyps to restrict HIV-2 was due to the presence of two amino acid changes, D66N and R69H, in the CypA domain of the TrimCyp, allowing it to bind strongly to the HIV-2 capsid (Price et al. 2009). In the longtail macaque

(*Macaca fascicularis*), HIV-2 specificity is mapped to amino acids 66 and 143 of the LtTrimCyp. The protein expressed by the 66 N-143E genotype binds to and potently restricts HIV-2 but not HIV-1, while that from the 66D-143 K genotype restricts HIV-1 and not HIV-2, while the 66D-143E protein restricts both viruses (Dietrich et al. 2011). Recent studies into host restriction factors have also shown that the capsid serves as a pathogen-associated molecular pattern (PAMP) for TRIM5 α which can therefore be thought of as a pattern recognition receptor (PRR) (Pertel et al. 2011).

TRIM5 α and HIV-2

Human TRIM5 α potently restricts N-MLV and can moderately limit HIV-2 replication but has an insignificant effect on HIV-1. TRIM5 α restriction has been shown to be mapped to the B30.2/PRYSPRY domain. Restriction of N-MLV is different from that of HIV-1, in that a larger area of the PRYSPRY domain is involved, as well as the coiled coil for restriction of the N-MLV mutant L117H (Yap et al. 2005). HIV-1 restriction by human TRIM5 α maps to the V1 region of the PRYSPRY domain of TRIM5 α , where a change from arginine (R) or any positively charged residue at position 332 to a proline (P) or any uncharged residue results in potent restriction of both HIV-1 and SIVmac (Yap et al. 2005; Li et al. 2006). This R332P change has been shown to lead to potent restriction of HIV-2 as well (Kono et al. 2008). In a study on HIV-2 restriction, another area of the V1 region, 337–339 (in human TRIM5 α), has been shown to be important for both HIV-2 and HIV-1 restriction. The change from QTF in the V1 region of human TRIM5 α to TRP found in some rhesus macaque (Rh) Trim5 α (339–341) has been shown to result in potent restriction of both HIV-2 and HIV-1 even in the presence of arginine at position 332 (Kono et al. 2008).

In addition to the TRIM5 α protein, the viral capsid also contains polymorphic determinants of TRIM5 α restriction. In HIV-1, capsid mutations in the CypA binding region, such as V86M, result

in resistance to RhTrim5 α (Veillette et al. 2013). Human TRIM5 α restriction of HIV-2 was mapped to a single amino acid at position 119 of HIV-2 ROD capsid that has no known link with CypA binding. HIV-2 viruses with a proline at this position were much more sensitive to human TRIM5 α restriction than those without (glutamine or alanine) (Song et al. 2007). Further studies showed that the presence of hydrophobic amino acids or those with ring structures was associated with sensitivity to TRIM5 α restriction and those with small side chains or amide groups were linked to TRIM5 α resistance (Miyamoto et al. 2011). A study from our group showed that the presence of three prolines at positions 119, 159, and 178 in the HIV-2 capsid was significantly associated with low viral load or viral control (Onyango et al. 2010). This report further showed that the presence of these prolines was predicted to reduce the dimer binding energies of the “PPP” capsid, resulting in a weaker core and more unstable protein (Onyango et al. 2010). Three-dimensional modeling of the HIV-1 and HIV-2 capsids showed that the N-terminal domain consists of seven α -helices from which three loops protrude. Position 119 of the HIV-2 capsid is located in the loop between helices 6 and 7. When a proline is present at position 119, the loop between helices 6 and 7 (L6/7) is closer to the loop between helices 4 and 5 (L4/5), a region that directly interacts with CypA in HIV-1 (Miyamoto et al. 2011). The presence of hydrophobic or ring-structure residues at position 119 of the capsid maintains a certain conformation at L4/5 that is characteristic of TRIM5 α sensitive viruses. Curiously, the equivalent position in N-MLV, at position 110, also determined N-MLV susceptibility to human TRIM5 α . It was suggested that while HIV-1 and HIV-2 are restricted by different mechanisms, human TRIM5 α utilizes a similar mechanism of recognition for N-MLV and HIV-2 (Miyamoto et al. 2011).

Studies utilizing the HIV-1 pNL43 backbone with the HIV-2 capsids from lab-adapted (HIV-2 ROD, HIV-2 GL) and primary isolates from different HIV-2 groups have shown that human TRIM5 α can restrict all these capsids with similar efficiency (maximum of fourfold median

difference) and restricts HIV-1pNL43 chimeras with an HIV-2 capsid (HIV-2 groups A, B, and AB) to a significantly higher extent than HIV-1pNL43 (mean range \sim 4.5–7-fold) (Takeuchi et al. 2013). However, chimeric viruses containing capsid sequences from non-epidemic HIV-2 groups C to H showed a wide range of susceptibilities to human TRIM5 α , ranging from 1.3 to 7.5 (Takeuchi et al. 2013). In contrast, capsid sequences from patients infected with circulating recombinant forms from group A and B (HIV-2A/B) were found to be highly resistant to human TRIM5 α (Miyamoto et al. 2012). Most HIV-2 infected individuals (\sim 75%) have asymptomatic disease, but interestingly, all three reported patients infected with HIV-2A/B presented at an advanced disease stage of AIDS (Miyamoto et al. 2012). Although the numbers were small, mainly due to very few reports of HIV-2A/HIV-2B, it may be that faster disease progression is a hallmark of HIV-2A/HIV-2B recombinant virus infection. The capsids of this recombinant virus were shown to be unique, possessing a glycine at position 119, instead of proline/glutamine/alanine, but most of the differences were observed in the C-terminal domain (CTD) (Miyamoto et al. 2012).

Studies on the association of human TRIM5 α single nucleotide polymorphisms (SNPs) with HIV-1 and HIV-2 disease progression are limited, and most show few or no differences between genotypes. A study in Japan showed that an SNP in the L2 linker region, G249D, was more prevalent in Asians and Africans compared to Caucasians (Nakayama et al. 2013). Our unpublished data supports this information; we found a minor allele frequency (MAF) of 27.6% for G249D, the second most frequent SNP in an HIV-2 cohort in Guinea-Bissau. The presence of this SNP was associated with reduced viral control for both HIV-1 and HIV-2 (Nakayama et al. 2013).

Conclusions

It has been postulated that the greater ability of human TRIM5 α to restrict HIV-2 may be partially responsible for the slower disease progression observed in HIV-2-infected individuals; however,

that does not fully account for the apparent dichotomy in outcome between progressors and non-progressors with HIV-2. Potentially, progression status may reflect particularly advantageous or disadvantageous combinations of TRIM5 α sequence and the capsid sequence of the infecting virus. Although currently rare, the few HIV-2 group A/B recombinants that have been reported are all associated with rapid disease progression. The fact that the capsids from these recombinants are more resistant to human TRIM5 α may indicate that viral evolution has occurred to provide escape from human TRIM5 α restriction, further supporting the *in vivo* role of human TRIM5 α in at least partial restriction of HIV-2. Further studies on the mechanism of restriction of HIV-2 may provide a better overall understanding of TRIM5 α restriction in humans.

Definition

Tripartite motif 5 alpha also known as TRIM5alpha (TRIM5 α) or TRIM5a is a cellular restriction factor that blocks the early stages of infection by retroviruses. TRIM5 α is a cytoplasmic E3 ubiquitin ligase protein (~55 kDa) expressed from *TRIM5* gene in most primate species and some mammals. Shortly upon infection of a cell by a retrovirus, TRIM5 α interacts with the incoming viral particle and precipitates its degradation, therefore interrupting precociously the viral replication cycle before reverse transcription (► [HIV Life Cycle: Overview](#)). The antiviral activity of TRIM5 α relies on its ability to recognize in a species-specific manner the capsid (CA) protein forming the shell of the retroviral core. TRIM5 α also acts as a pattern recognition receptor and elicits innate immune signals upon CA recognition. Thus TRIM5 α mediates antiviral activities through a dual function of restriction and innate sensing.

Introduction: Tripartite Motif Family, TRIM5 and TRIM5alpha

TRIM5 α belongs to the tripartite motif (TRIM) family, also referred to as RBCC family, with nearly 100 TRIM paralog genes scattered all over the human genome (a catalog of TRIM genes can be found on HGNC website <http://www.genenames.org/>). Clusters of TRIM genes resulting from tandem duplication are located on human chromosomes 5, 6, 11, and 17. The archetype TRIM protein is defined by an N-terminal tripartite motif called “TRIM” or “RBCC” composed of three motifs: a RING (really interesting

new gene) E3 ubiquitin ligase domain, one or two zinc-finger B-boxes (B-box1 and B-box2), and an α -helical coiled-coil motif mediating oligomerization. The tripartite motif coordinates homo- or heteromultimerization and functions as E3 ubiquitin ligase. In addition, most TRIM proteins carry a C-terminal domain (i.e., B30.2/SPRY, PHD, BROMO, COS, NHL, FN3, IGFLMN) with binding properties that dictates the specificity to a cellular substrate. Members of the TRIM family are implicated in a vast array of cellular processes. Remarkably, the expression of numerous TRIM genes is stimulated by interferons, and many TRIMs intervene in innate signaling and antiviral responses (► [TRIM Protein Family and Viral Restriction](#)). Like other families of genes involved in immunity (MHC, TLR, APOBEC, Mx, IFITM), the TRIM family has undergone gene expansion through duplications and rearrangements during evolution.

In the human genome, *TRIM5* gene is located on the short arm of chromosome 11 at position 11p15.4 as part of a cluster of closely related genes comprising TRIM6, TRIM34, and TRIM22. The cluster TRIM6/34/5/22 is also found on chromosome 11 and 14 in chimpanzee and rhesus macaque, respectively. Human *TRIM5* gene is about 22 kb long and is segmented into 8 exons. Multiple spliced variants, designated as TRIM5alpha, -beta, -gamma, -delta, -epsilon, -iota, and -kappa, are generated from TRIM5 mRNA. The most abundant 3-kb-long alpha isoform represents up to 50% of TRIM5 mRNAs and carries a 1.5-kb-long coding sequence for TRIM5 α protein (~55 kDa, 493aa) (Johnson and Sawyer 2009).

The prototypical TRIM5 α protein expressed in primates and some mammals contains four major domains, from N-terminus to C-terminus: a RING domain, a B-box2, a coiled-coil, and a B30.2/SPRY domain. The B30.2/SPRY domain, also referred to as B30.2, PRYSPRY, and RFP-like domain, corresponds to the fusion of PRY and SPRY (Sp1A and ryanodine receptor) motifs. Linker regions L1 and L2, respectively, separate the RING and B-Box2 motifs and the coiled-coil and B30.2/SPRY domains. Other human spliced variants encode for TRIM5 isoforms lacking the

B30.2/SPRY and deprived of antiviral activity; however, these isoforms can interfere with TRIM5 α activity through dominant negative effects by multimerizing via the coiled-coil. Some primates express an unusual *TRIM5* allele called *TRIMCyp* that encodes a TRIM5-cyclophilin A fusion protein. TRIM5 α is constitutively expressed in most tissues, and its expression is upregulated by type I interferons through an IFN-stimulated response element in its promoter. TRIM5 α localizes mainly in the cytoplasm under a diffuse form or in aggregates designated as cytoplasmic bodies; it can also shuttle between the nucleus and the cytoplasm.

Discovery of TRIM5 α and TRIMCyp

Restriction factors are germline-encoded factors engaged in cell-intrinsic immunity, building a frontline defense against viruses (► [Cell Intrinsic Immunity](#)). The first reports of restriction against a retrovirus date back to the early 1970s from studies that pinpointed an inheritable resistance to murine leukemia virus (MLV) strains in mice ascribed to *Fv1* gene (*Friend virus susceptibility gene 1*). *Fv1^b* and *Fv1ⁿ* alleles respectively conferred protection to mice against NIH-tropic MLV (N-MLV) and BALB/c-tropic MLV (B-MLV) strains but not against NB-MLV (NB-tropic) strains. *Fv1* gene is exclusively found in mice and derives from *gag* gene of the murine endogenous retrovirus type L (MERV-L). The restriction factor Fv1 imposes a postentry block of N- or B-MLV infection after reverse transcription but before integration. The restriction block targets specifically the viral CA and is abrogated by using high doses of virus, which can saturate Fv1 activity. The precise mechanism of restriction is still poorly understood (Sanz-Ramos and Stoye 2013).

Evidence for the existence of Fv1-like restriction factors in nonmurine mammalian cells accumulated in the 1990s and early 2000s. In human cells, an unidentified factor named Ref1 (restriction factor 1) potentially blocked of N-MLV infection but not B-MLV. Likewise, a factor termed Lv1 (lentivirus factor 1) restricted

lentiviruses including HIV-1 in simian cells originating from Old World monkeys (Asian and African species) and some rare New World monkeys (American species). Like Fv1, Ref1 and Lv1 mediated a restriction block, which was dominant and saturable, targeted the CA protein, and occurred prior reverse transcription. In 2004, TRIM5 α was identified as the postentry restriction factor blocking HIV-1 in rhesus macaque cells through a screen using a rhesus macaque cDNA library (Stremlau et al. 2004). TRIM5 α was subsequently shown as responsible for activities previously ascribed to Ref1 and Lv1. While TRIM5 α was identified in Old World monkeys, a TRIM5-cyclophilin A fusion protein called TRIMCyp was independently discovered by investigating HIV-1 restriction in New World primates (Sayah et al. 2004). Cyclophilin A (CypA) is a cellular chaperone (peptidyl-propyl isomerase) that interacts with HIV-1 CA (► [Cyclophilin A and HIV-1 Replication](#)). In human cells, CypA acts as a cofactor of HIV-1 since disrupting CypA-CA interaction by cyclosporine A treatment impairs HIV-1 replication. In contrast, in owl monkey cells normally refractory to HIV-1 infection, cyclosporine A treatment or CypA knock down alleviate the restriction against HIV-1. TRIMCyp was discovered by screening an owl monkey cDNA library in an effort to identify an isoform of CypA endowed of anti-HIV-1 activity. Owl monkey *TRIMCyp* gene originates from the retrotransposition of CypA mRNA into *TRIM5* gene leading to an in-frame coding sequence. The resulting protein contains TRIM5 RBCC fused to CypA (Nisole et al. 2004; Sayah et al. 2004). The mechanism of restriction of TRIMCyp is similar to that of rhesus TRIM5 α apart from the fact that the CypA domain mediates CA recognition.

TRIM5 α -Mediated Restriction Against Retroviruses

TRIM5 α intercepts incoming virions by recognizing specifically motifs of the CA assembled into viral cores and triggers their premature uncoating (► [Uncoating and Nuclear Entry](#)) (Stremlau et al.

2006). TRIM5 α from Old World monkeys, like rhesus macaque TRIM5 α , strongly restricts HIV-1. TRIM5 α orthologs from New World monkeys broadly counteract simian immunodeficiency viruses (SIVs). Human TRIM5 α does not significantly inhibit HIV-1 and SIVs, but it restricts lentiviruses from nonprimate mammals such as FIV (feline immunodeficiency virus) and EIAV (equine infectious anemia virus). Most TRIM5 α orthologs, including human TRIM5 α , are active against N-MLV but not against B-MLV and NB-MLV. Investigations on the spectrum of activity of TRIM5 α in primates and mammals indicate that TRIM5 α restricts a wide range of retroviruses (i.e., lentiviruses, gammaretroviruses, betaretroviruses, and spumaretroviruses) in a species-specific manner.

All protein domains of TRIM5 α are required for restriction. The RING E3 ubiquitin ligase domain recruits E2-conjugating enzymes involved in restriction and innate signaling (Pertel et al. 2011; Fletcher et al. 2015). The coiled-coil mediates antiparallel dimerization, and the B-Box-2 domain coordinates higher-order self-assembly of TRIM5 α dimers with enhanced avidity for viral CA (Goldstone et al. 2014; Sanchez et al. 2014). Species-specific recognition of CA is mainly determined by sequence variations in the B30.2/SPRY domain. Major determinants for recognition of retroviral CA have been mapped to variable regions (v1, v2, v3, v4) of the B30.2/SPRY that display strong interspecies sequence diversity and high rate of positive selection, typically observed in protein domains of restriction factors at binding interface with viral proteins (Sawyer et al. 2005). The B30.2/SPRY has a conserved hydrophobic core structure formed by a 13-stranded β -sandwich. Variable regions fold into flexible loops connecting β -stands and forming the CA-binding surface of the B30.2/SPRY that is reminiscent of binding sites of antibodies (Grutter et al. 2006; Biris et al. 2012).

The mature retroviral CA protein contains two independently folded α -helical domains, the N-terminal domain (NTD) and the C-terminal domain (CTD), that are connected by a flexible linker. The mature HIV-1 core is built with

multimers of CA proteins, namely, 12 pentamers and approximately 250 hexamers, forming a cone-shaped fullerene shell enclosing the viral RNA genome and proteins necessary for infection (► [HIV-1 Virion Structure](#)). CA NTDs form hexameric and pentameric rings exposed at the outer surface of the lattice, while CA CTDs connecting the rings are included in the inner face of the shell. Viral determinants for TRIM5 α restriction were mapped to CA NTD forming a binding interface on the outer CA lattice. Exposed surfaces of CA NTD, namely, the β -hairpin, the CypA-binding loop between helix 4 and 5, and the loop between helix 6 and 7, modulate the sensitivity of HIV-1, SIVs, and N-MLV to TRIM5 α . Direct interaction between TRIM5 α and viral CA has been difficult to establish because TRIM5 α recognizes the oligomeric CA lattice but not CA monomers. Electron microscope imaging allowed visualizing spontaneous self-assembly of TRIM5 α dimers into hexagonal arrays promoted by the presence of preassembled HIV-1 CA-NC crystals and matching the symmetry and spacing of the hexagonal CA lattice (Ganser-Pomillos et al. 2011). The resulting model of recognition suggests that molecules of TRIM5 α build a hexagonal scaffold surrounding viral core. This scaffold is formed by antiparallel TRIM5 α dimers stabilized via the coiled-coil and interconnected through the B-box2; the RING domain localized at the outer surface can recruit E2 ubiquitin enzymes and the B30.2/SPRY may directly interact with multiple epitopes of CA.

The mechanism underlying TRIM5 α -mediated restriction and by which TRIM5 α precipitates the disassembly of viral cores to terminate the infection has been extensively investigated. Multiple mechanisms have been envisaged including direct damage of core, recruitment of cofactors, proteasome-dependent degradation involving TRIM5 α E3 ubiquitin ligase activity and proteasome-independent activity. TRIM5 α constructs containing the coiled-coil and B30.2/SPRY domains are sufficient to induce structural damages on CA lattices in vitro. However in cells, binding between TRIM5 α and CA is necessary but not sufficient for restriction, and efficient restriction requires the B-box2 domain. TRIM5 α

may trigger a proteasome-dependent degradation of retroviral cores. Indeed, TRIM5 α is an E3 ubiquitin ligase and recruits E2 ubiquitin-conjugating enzymes via its RING domain. TRIM5 α -mediated inhibition of reverse transcription requires the recruitment of E2 enzymes Ube2W and Ube2N-Ube2V2 that anchor K63-linked polyubiquitin chains to process TRIM5 α auto-ubiquitination (Fletcher et al. 2015). TRIM5 α auto-ubiquitination, which leads to its rapid degradation by the proteasome, may precipitate TRIM5 α -bound viral cores to proteasomal degradation. However, proteasome inhibitors or depletion of E2 enzymes rescue the block of reverse transcription but do not restore viral infection, which remains impaired before integration, implying that TRIM5 α may restrict viral infections through multiple ways. TRIM5 α has also been proposed to act as an autophagic cargo and target viral cores to autophagic degradation (Mandell et al. 2014).

Role of TRIM5 α in Innate Immunity

The expression of human and simian TRIM5 α orthologs, including owl monkey TRIMCyp, is upregulated by type I interferons which may potentiate TRIM5-mediated antiviral activity. In addition to a direct antiviral effect, TRIM5 α functions as a pattern recognition receptor (PRR) by triggering a cascade of innate immune signals that lead to inflammatory cytokine production and contribute to the establishment of the antiviral state upon retroviral infection. In the absence of viral infection, TRIM5 α can promote innate immune signaling by triggering NF- κ B and AP-1 activation. To do so, TRIM5 α recruits E2 ubiquitin-conjugating enzymes UBC13-UEV1A (aka Ube2N-Ube2V1) via its RING domain to catalyze the synthesis of free K63 ubiquitin chains that activate TAK1 complex and downstream AP-1 and NF- κ B signaling (Pertel et al. 2011). This cascade of activation is enhanced in the presence of CA lattice that is sensed as a pathogen-associated molecular pattern (PAMP) by TRIM5 α . A large number of human TRIM proteins have the ability to activate NF- κ B in a

TAK1-dependent manner, AP-1 and interferons (Versteeg et al. 2013). An emerging concept is that TRIM E3 ubiquitin ligases can both play antiviral effector functions and enhance the innate antiviral response by inducing interferons and proinflammatory cytokines.

TRIM5 Evolution

The assembly of a RING, a B-Box, and a coiled-coil domain into a TRIM motif originates from metazoans. TRIM genes with SPRY and B30.2/SPRY domains are exclusively found in vertebrates, and from an evolutionary point of view, these genes are more recent, divergent, and dynamic than TRIM genes with other C-termini. SPRY-encoding TRIM genes have evolved through rapid expansions in vertebrates most likely as the result of selective pressure imposed by pathogens; they may constitute a reservoir of new antiviral genes.

TRIM5 gene originates from eutherian mammals about 90–180 million years ago (Johnson and Sawyer 2009). *TRIM5* locus has undergone many events of duplication, insertion, deletion, degeneration, and positive selection likely driven by ancient infections during mammalian evolution. *TRIM5* homologs are found in primates, scandents, rodents, lagomorphs (i.e., rabbit, hare, pika), and laurasiatheria (including cow, pig, horse, sheep, goat, cat, dog). The cow genome has expanded a cluster of eight *TRIM5* paralogs including three pseudogenes and five full-length genes. At least one of them encodes a functional TRIM5 α protein that is able to restrict several viruses but not the bovine immunodeficiency virus (BIV) that naturally infects cows. In carnivores, *TRIM5* locus was independently disrupted twice during evolution. On one hand, the dog genome has lost *TRIM5* due to an insertion between the exons 2 and 8 of *TRIM5* of which the remnants degenerated into pseudogenes. On the other hand, feliforms encompassing species such as cats, leopards, lions, and hyenas encode a truncated TRIM5 protein lacking the B30.2/SPRY domain due to a stop codon in 5' of exon 8. Lagomorphs (including rabbits, hares, pikas) express

an active TRIM5 α protein that is able to restrict several lentiviruses and N-MLV. The genome of mouse and rat respectively contain clusters of eight and three TRIM5-like genes (termed TRIM30 and TRIM12 in rodents) encoding proteins with no apparent restriction activity.

All primate species (hominoids, Old World monkeys, New World monkeys, and prosimians) encode a functional *TRIM5* gene, occasionally under the form of *TRIMCyp* fusion gene as in the case of owl monkeys and macaques. Like other restriction factors (APOBEC3G, SAMHD1, BST2/Tetherin) engaged in evolutionary arm races with retroviruses, TRIM5 α has rapidly evolved in primates and carry signatures of positive selection in domains interacting directly with viral proteins (► [Virus/Host Coevolution – Positive Selection Essay](#)). The molecular evolution of TRIM5 in primates is characterized by recurrent events of positive selection resulting in strong interspecies sequence diversity, balancing selection maintaining intraspecies allelic diversity, and genetic innovations providing selective advantages such as lineage-specific expansions of variable regions of the B30.2/SPRY domain and TRIM5-cyclophilin A gene fusions. Analyses of selective pressures show that *TRIM5* locus experienced positive selection in a majority of branches of the primate phylogeny and residues under positive selection localize predominantly the coiled-coil and the CA-interacting B30.2/SPRY domain (Sawyer et al. 2005; Johnson and Sawyer 2009). In addition, TRIM5 α B30.2/SPRY domain has also experienced lineage-specific expansion of the variable loops v1–v3. Hominoid and Old World monkey TRIM5 α proteins are characterized by expansions of the v1 loop (~10–30 residues), while in New World monkey TRIM5 α proteins, the v3 loop is 10–60 residues longer than in other orthologs. Similarly, v2 expansion (up to ~35 residues) is observed in prosimian TRIM5 α and some mammalian TRIM5 α and TRIM5-like proteins. Such adaptations may have been fixed during evolution as they brought beneficial advantages in combating infections by ancient viruses such as PSIV (prosimian immunodeficiency virus) in lemurs and RELIK (rabbit endogenous lentivirus

type K) in lagomorphs (Rahm et al. 2011; Yap and Stoye 2013).

Remarkably, events of LINE-1-dependent retrotransposition of *CypA* into *TRIM5* locus occurred independently in several lineages of primates, giving birth to *TRIMCyp* genes. In owl monkeys, which belong to New World primates, *TRIMCyp* gene results from an in-frame retrotransposition of *CypA* cDNA in intron 7 of *TRIM5* gene. Owl monkey TRIMCyp protein is therefore made of TRIM5 RBCC, encoded by exons 2–7, fused to CypA protein (Nisole et al. 2004; Sayah et al. 2004). First identified in *Aotus trivirgatus*, *TRIMCyp* exists in other owl monkey species from *Aotus* genus but not in other New World primates, meaning that the gene arose about 4–6 million years ago prior to *Aotus* radiation. Owl monkeys are homozygous for *TRIMCyp* and do not express other TRIM5 isoforms. Owl monkey TRIMCyp protein efficiently restricts HIV-1. A TRIM5-CypA chimeric gene also exists among Old World primates in macaques (genus *Macaca*), i.e., rhesus macaque (*Macaca mulatta*), pig-tailed macaque (*Macaca nemestrina*), and crab-eating macaque (*Macaca fascicularis*). In that case, *CypA* cDNA retrotransposed in the 3' untranslated region of *TRIM5* about 5–6 million years ago, and a single G-to-T point mutation additionally occurred at 3' splice acceptor site of *TRIM5* intron 6 resulting in exon skipping. Thus in macaques, TRIMCyp expression is the result of alternative splicing between *TRIM5* exon 6 and *CypA* exon, while exons 7 and 8 of *TRIM5* are skipped. Owl monkey TRIMCyp and macaque TRIMCyp proteins differ by the sequence (L2 linker) linking the coiled-coil and CypA. Traces of a third retrotransposition leading to an ancient *TRIMCyp* gene were detected in the genomes of Old World monkeys. The gene, which likely encoded an active antiviral protein, arose 43 million years ago and decayed into a pseudogene about 10 million years ago (Malfavon-Borja et al. 2013). A fourth event of *CypA* retrotransposition into exon 8 of *TRIM5* has also occurred outside the primate lineage, in the genome of tree shrews which contain a cluster of four TRIM5 paralogs and a functional *TRIMCyp* gene. *CypA* is one of the most common processed

pseudogene found in the human genome possibly due to the abundance of CypA mRNA. *TRIM5* is the only gene that experienced recurrent and independent *CypA* retrotranspositions leading to functional gene fusions.

Role of TRIM5 in Controlling Viral Infections in Nonhuman Primates

African primates are natural hosts of SIVs responsible of nonpathogenic infections in their natural host in most cases, with the exception of chimpanzees (► [SIV Infection of African Green Monkeys](#); ► [Nonpathogenic SIV Infection of Sooty Mangabeys](#); ► [SIV Infection in Mandrills](#)). Asian rhesus macaques (*Macaca mulatta*) are not natural carriers of SIVs, but cross-species transmission of SIV from sooty mangabeys (SIVsm) to captive Asian rhesus macaques occurred in US Primate Research Centers in the 1960s. SIVmac viruses isolated from captive macaques in the 1980s, including laboratory-adapted SIVmac239 and SIVmac251 strains, result from decades of adaptation of SIVsm in rhesus monkeys (► [SIVmac Infection of Macaques, Immunopathogenesis of](#)). Both SIVmac and SIVsm induce AIDS-like symptoms in rhesus macaques, which have become an invaluable animal model for AIDS research.

Rhesus macaque *TRIM5* gene is highly polymorphic; multiple alleles have been maintained in macaques as a result of long-term balancing selection. Strong intraspecies sequence diversity is especially detected in the coiled-coil and the B30.2/SPRY domains. An important six-nucleotide insertion/deletion TFP339-341Q polymorphism in variable region v1 of the B30.2/SPRY provides differential degrees of restriction against lentiviruses. Rhesus *TRIM5* alleles can be classified into three major functional alleles, from the most to the least frequent: TRIM5^{TFP} (TFP339-341), TRIM5^Q (Q339), and TRIM5^{CypA}. Rhesus TRIM5^{TFP} and TRIM5^{CypA}, but not TRIM5^Q, restrict efficiently SIVsm strains in vitro, while rhesus-adapted SIVmac viruses are relatively resistant to the three variants; in

some cases, moderate inhibition by TRIM5^{TFP} and TRIM5^{CypA} has been observed in vitro. Both protective TRIM5^{TFP} and TRIM5^{CypA} alleles are associated with a very drastic impact on viral acquisition and replication of SIVsm in rhesus macaques and with a moderate but significant in vivo control of SIVmac251. TRIM5^{TFP/TFP} homozygous macaques display lower SIVmac251 viral replication (1.3 log median difference in set point viral loads), an attenuated loss of CD4⁺ T cells and significant survival advantage compared to TRIM5^{Q/Q} homozygous animals (Lim et al. 2010). But restrictive rhesus *TRIM5* alleles may not provide protection against mucosal transmission of SIVmac251.

The most remarkable effect of rhesus TRIM5 in vivo is observed in animals infected with SIVsm strains (i.e., SIVsmE543, SIVsm041, SIVsmE660) that are less adapted to rhesus macaques than SIVmac. The viremia of SIVsm-infected macaques carrying two restrictive TRIM5^{TFP} and TRIM5^{CypA} alleles is about 2–3 log lower than that of TRIM5^{Q/Q} homozygous animals (Kirmaier et al. 2010). Animals with one restrictive allele display intermediate viral load. Efficient restriction also delays disease progression and increases the survival rate of macaques infected with SIVsm. Multiple studies support the role of restrictive *TRIM5* alleles in protecting rhesus macaques from mucosal transmission (i.e., penile and rectal) of SIVsm. These findings emphasize the requirement of considering *TRIM5* genotype, as well as protective MHC class I alleles, in the design of challenge studies and vaccine trials using rhesus monkeys. Restrictive rhesus *TRIM5* alleles select the emergence of escape mutations in CA NTD of SIVsm at late stages of infection. Mutations P37S and R98S in SIVsm CA are associated with escape from TRIM5^{TFP} restriction, and mutations in the CypA loop of CA (LPA89-91QQ) allow escaping TRIM5^{CypA} (Kirmaier et al. 2010; Wu et al. 2013). SIVmac strains isolated from captive macaques carry similar R-to-S and LPA-to-QQ adaptations, which likely result from selective pressure imposed by TRIM5^{TFP} and TRIM5^{CypA}. Thus, TRIM5 α efficiently modulates viral acquisition,

in vivo replication, and cross-species transmission of SIVs in rhesus macaques.

Polymorphisms in Human TRIM5 Gene and HIV Infection

Unlike its rhesus counterpart, human TRIM5 α seemingly fails to counteract HIV infection in vitro and in vivo. Various studies evaluated the impact of *TRIM5* polymorphisms on HIV-1 acquisition and in vivo infection by surveying single-nucleotide polymorphisms (SNPs) on *TRIM5* locus in HIV/AIDS cohorts. The most frequent nonsynonymous SNPs in human *TRIM5* lead to amino acid changes in RING (H43Y), B-Box2 (V112F), coiled-coil (R136Q), linker L2 (G249D), and B30.2/SPRY (H419Y). H43Y and R136Q TRIM5 α display respectively impaired and enhanced antiviral activities in vitro, while V112F, G249D, and H419Y polymorphisms do not affect the function of human TRIM5 α . Overall naturally occurring SNPs in human *TRIM5* gene have been only associated with weak effect or no statistically significant effect on HIV-1 susceptibility, infection, and AIDS progression (An and Winkler 2010). Homozygous H43Y individuals may progress faster to AIDS, and R136Q polymorphism has been associated with a protective effect and also with an increased risk of viral acquisition. Genome-wide association studies (► [Host Genetics and Genomics](#)) have not detected any common genetic in human *TRIM5* gene as important to the control of HIV-1 infection and to disease progression. Primary HIV-1 isolates, especially strains carrying CTL (cytotoxic T lymphocyte) escape mutations in Gag/CA, exhibit an increased susceptibility to human TRIM5 α -mediated restriction in vitro compared to laboratory-adapted strains, which have a low sensitivity (twofold) to human TRIM5 α . TRIM5 α has been proposed to contribute to the control of CTL-escape HIV-1 strains in patients carrying protective MHC class I alleles (► [HIV-1 Mutational Escape from Host Immunity](#)). Likewise, HIV-2 subtypes are more sensitive to restriction by human TRIM5 α compared to

HIV-1. The susceptibility to human TRIM5 α , even though moderate, may partially account for the overall lower infectivity and pathogenicity of HIV-2 in humans (► [TRIM5alpha and HIV-2 Infection](#)).

TRIM5-Based Therapeutic Strategies

Rhesus monkey TRIM5 α is a powerful inhibitor of HIV-1. Due to the possible antigenicity of rhesus TRIM5 α , recombinants based on the human protein have been engineered for potential application in gene therapy; these include punctual mutants, rhesus-human chimeras, and artificial human TRIM-CypA fusions. Single mutation at residue R332 or modifications in v1 of the B30.2/SPRY domain are sufficient to render human TRIM5 α active against HIV-1. Thus, restrictive human TRIM5 α mutants (R332, R335) have been optimized for the purpose of gene therapy. Another approach has consisted in generating an artificial human TRIMCyp protein, based on human TRIM5 α and CypA, able to elicit potent anti-HIV-1 activity in vitro and in vivo. Humanized Rag2^{-/-} γ c^{-/-} mice engrafted with human TRIMCyp-expressing CD4⁺ T cells display robust protection against HIV-1 infection, reduced HIV-1-induced loss of CD4⁺ T cells, and survival advantage (Neagu et al. 2009). This proof-of-concept study reveals that a TRIM5-derived transgene may confer protection against HIV-1 infection in vivo and highlights human TRIM5-based constructs as promising candidates for anti-HIV-1 gene therapy. Additional TRIMCyp chimeras based on human TRIM1, TRIM18, TRIM19, or TRIM21 have been developed and exhibit potent anti-HIV-1 activity in vitro. Alternative TRIM5-based strategies involve the delivery of a rhesus-human TRIM5 α chimera in human hematopoietic stem cells (HSC). Humanized mice engrafted with HSCs stably expressing rhesus-human TRIM5 α chimera, a CCR5 shRNA, and a TAR decoy display a survival advantage upon HIV-1 infection and maintenance of CD4⁺ T cells. HIV-1-resistant macrophages have also been generated by

reprogramming induced pluripotent stem cells (iPSCs) that express rhesus-human TRIM5 α chimera and a CCR5 shRNA (Anderson 2013). Despite promising results, the delivery of exogenous TRIM5 recombinants for gene therapy raises concerns such as the immunogenicity of the transgene, undesirable immune activation due to innate signaling properties of TRIM5 α , and the risk of insertional activation of neighboring genes. The genetic fragility of HIV-1 CA lattice also makes CA an attractive target for drug design and antiviral therapy. Small compounds mimicking the premature disassembly of HIV-1 capsid elicited by TRIM5 α may represent a new generation of antiviral agents (Bhattacharya et al. 2014).

Conclusions

Studies of the susceptibility of primate cells to retroviral infections led the identification of the intrinsic restriction factor TRIM5 α that inhibits retroviruses in a species-specific manner. TRIM5 α efficiently modulate SIV infection in rhesus macaques and has likely constituted a barrier against cross-species transmission of viruses in primates. To the contrary, human TRIM5 α has no significant impact on HIV infection. TRIM5 α mediates antiviral activities through restriction and innate sensing. This dual function illustrates how host retroviral restriction factors can act both as cell-intrinsic antiviral effectors and mediators of the innate immune response. Research on restriction factors has significantly expanded our knowledge on the strategies employed by viruses to escape and counteract restriction and has greatly contributed to improvement of models of HIV/AIDS infection and the development of therapeutic applications.

Definition

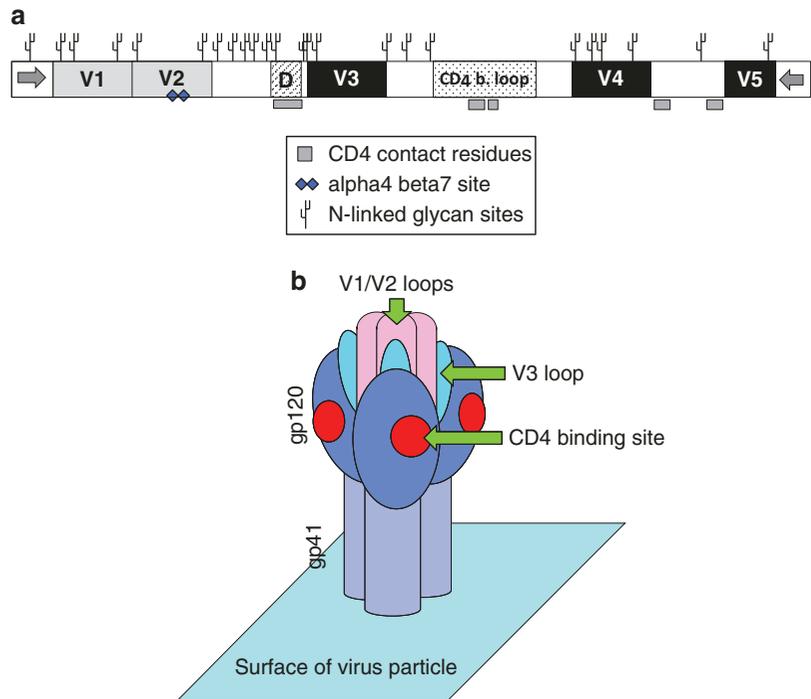

The envelope glycoprotein (Env) spikes on transmitting HIV-1 virus particles mediate infection of the first cells in the new host. These Envs must elude host defenses including innate inhibitors and sometimes neutralizing antibodies. They may also direct mechanisms to penetrate epithelial cell barriers to facilitate mucosal transmission.

Prophylactic vaccines that elicit neutralizing antibodies and microbicides need to be designed and optimized to target transmitting viruses. However, it is as yet unclear whether Envs of viruses that successfully transmit carry specific properties or vulnerabilities that can be targeted by such strategies. What we do know is that viruses that use the coreceptor, CCR5, are preferentially transmitted and that early data suggest these viruses primarily infect CD4+ T-cells over macrophages or dendritic cells.

Some transmitted viruses carry Envs with fewer surface sugars and shorter variable loops that usually protect against neutralizing antibodies. However, it is not known whether the structure of these Envs confers vulnerability to neutralizing antibodies that can be induced by vaccines or to inhibitors that may be used as prophylaxis. The challenge is to exploit our burgeoning knowledge of transmitted, founder

Tropism and Properties of the HIV-1 Envelope Glycoprotein in Transmission, Fig. 1

viruses to identify their Achilles' heels in order to design more effective vaccines and prophylactic microbicides.

Background

A comprehensive understanding of the mechanisms of HIV-1 transmission and establishment of infection in a new host is important for the development of effective vaccines and microbicides.

Vaccines that aim to elicit protective antibodies will need to target sites on the envelope glycoproteins (Envs) present on the surface of virus particles (Kwong et al. 1998). Inhibitors that block Env functions are candidates for inclusion in prophylactic microbicides. Further development of both strategies would be enhanced by specifically targeting the properties of the transmitting HIV-1. It is clear that HIV-1 variants that use the coreceptor, CCR5, to infect cells are usually transmitted regardless of how transmission occurs. However, it is unclear whether transmitted/founder (T/F) viruses carry specific properties that confer an advantage during transmission or whether transfer of virions into the

new host is a chance event involving viral variants that happen to be replicating at donor sites of transmission. Several characteristics associated with T/F viruses have been reported but are unlikely to represent the complete picture. Here, the current knowledge of the different routes and mechanisms of transmission is reviewed. Focusing on the HIV-1 Env spike (Fig. 1), the properties associated with transmission, the origins of the transmitting virus in the donor, and the early cell targets for infection in the recipient are discussed.

Themes and Questions About HIV-1 Transmission

HIV-1 is transmitted via sexual contact, from mother to child and via blood contact (Table 1). However, whichever route is used, similar questions arise. Where is the transmitted virus (es) coming from? Is it cell-free or carried in by infected cells? Which and where are the first target cells in the new host during transmission? How does the transmitting virus avoid host innate inhibitory factors, breach protective epithelial cell

Tropism and Properties of the HIV-1 Envelope Glycoprotein in Transmission, Table 1 HIV-1 routes of transmission

Route of infection		Target tissue	Predominant vehicle	Epithelial cell barrier
Male to female		Vagina, cervix	Semen	Stratified in vaginal and ectocervix, single columnar in endocervix
Male to male		Rectum	Semen	Single columnar
		Penis	Feces, rectal secretions	Stratified
Female to male		Penis	Cervical and vaginal secretions	Stratified
Intravenous drug use			Blood	None
Mother to child	In utero	Placenta	Unknown	Syncytiotrophoblast and cytotrophoblast layers
	Intrapartum	Oropharynx, intestine	Maternal blood and cervicovaginal secretions	Stratified in oropharynx, single columnar in intestine
	Breast-feeding	Oropharynx, intestine	Breast milk	Stratified in oropharynx, single columnar in intestine

barriers, and access target cells? What is the receptor use and cell tropism of T/F viruses? If CD4+ T-cells are major early targets for infection, then what are the roles of other immune cells that express CD4 and CCR5 including dendritic cells and macrophages? Does transmitting virus need to target activated CD4+ T-cells for successful transmission or do resting CD4+ T-cells contribute? What are the soluble factors at transmission sites that protect or enhance Env-mediated infection? Do transmission routes or mechanisms vary depending on HIV-1 clade?

It is clear that R5 variants are predominantly transmitted regardless of route, while early data indicates that they are mainly non-macrophage-tropic (non-mac-tropic). Several studies suggest that transmitted viruses carry a heightened replicative fitness. However, it is unclear how this property influences the structure and function of the Env trimer or whether it provides vulnerability that can be specifically targeted in the design of vaccines and microbicides.

Routes of Transmission, Numbers of Viruses Transmitted, and Identification of Transmitted/Founder Viruses

Most people infected with HIV-1 reside in resource-limited settings where infection is

mainly spread via heterosexual contact or from infected mothers to their children (MTCT) (Table 1). Sexual transmission and MTCT occur more readily from individuals who have high viral loads in their plasma, particularly during the acute and later stages of disease (Powers et al. 2008, 2011). Infection of genital tissues by other sexually transmitted pathogens and the resulting inflammatory responses greatly increases the chances of HIV transmission (Powers et al. 2008).

The different routes of transmission vary in the source of virus in the donor and target tissues in the recipient. However, it is unclear whether this affects the composition of HIV-1 variants that reach sites of transmission in the donor and/or the phenotypes of variants transferred into the new host. It has also been unclear whether the initial cell type infected in the new host varies depending on route.

In recent years, extensive sequencing of plasma samples within days or weeks of infection has allowed characterization of viral variants that establish infection. Such sequencing yields information on the number of distinct variants transmitted, while consensus sequences have been deduced to be representative of the virus that was transmitted, i.e., the T/F virus (Keele et al. 2008). A single virus variant is transmitted in 64–90% of heterosexual transmission cases, in approximately 60% of men who have sex with

men, but only in 40% of infections through injection drug use. Generally, single or a few viral variants have been detected in intrapartum-infected infants, while more variants have been detected in utero-infected infants. The transmitted variants that establish infection in the new host are frequently derived from a minor variant present in the donor. Is this chance or selection?

The HIV-1 Envelope Glycoprotein Spike and Cell Tropism

HIV-1 particles bind the receptor CD4 and coreceptor proteins on the surface of immune cells to trigger entry into cells (Clapham and McKnight 2002). Virus strains that use CCR5 as a coreceptor have been designated as R5, those that use CXCR4 are termed X4, and those that can use both coreceptors as R5X4. While HIV-1 R5 viruses are usually transmitted, CXCR4-using variants generally emerge late in disease in up to 50% of individuals infected with clade B HIV-1, although this happens less frequently in subjects infected with clade C HIV-1, the predominant type of HIV-1 in Africa and globally. The designation R5 has often been used interchangeably with the terms mac-tropism or M-tropism, while X4 viruses are assumed to be T-tropic, infecting mainly T-cells. However, this interpretation is an oversimplification (Goodenow and Collman 2006). R5 viruses are generally able to infect CD4+ T-cells. However, they vary extensively in macrophage infection, with highly mac-tropic variants present in the brain and non-mac-tropic R5 viruses predominant in immune tissue (Duenas-Decamp et al. 2010). CXCR4-using variants do target CD4+ T-cells when they emerge. However, highly mac-tropic X4 virus isolates have also been described including CNS-derived ones.

Macrophages express much lower amounts of CD4 compared to T-cells. An important determinant of macrophage infectivity for R5 viruses is an Env adaptation to use these low amounts of CD4 on the cell surface for infection (Duenas-Decamp et al. 2010). Current data suggest that successfully transmitting viruses are predominantly non-mac-tropic R5, although little is

known about the factors during transmission that confer this selection.

How Does HIV Penetrate Epithelial Cell Barriers at the Mucosa?

Except for infection via the blood, HIV must penetrate protective epithelial cell layers at the mucosa. These epithelial cells do not express CD4 and are not usually susceptible to HIV infection. Stratified epithelia line the vagina, while a single layer of columnar epithelial cells protects the endocervix and intestine. Syncytiotrophoblast and cytotrophoblast cell layers line the fetal side of the placenta. Epithelial cells at these different sites form a system of tight junctions that effectively eliminate passive diffusion of donor virions or infected cells through the epithelial barriers to reach susceptible cells underneath. Mucosal epithelial cells in the vagina, endocervix, and rectum express SDF-1 (CXCL12), which binds and downregulates CXCR4 from cells in the proximity (Agace et al. 2000), helping to explain why CXCR4-using variants are infrequently transmitted.

Several mechanisms have been proposed for HIV-1 penetration of epithelial cell layers. First, damage and breaches in the system of tight gap junctions caused by other infectious agents and resulting inflammation will allow virus or infected cells to enter. Further, inflammation may induce CD4+ T-cells to penetrate the stratified epithelia of the vagina, ectocervix, and foreskin from the underlying submucosa to facilitate their infection by transmitting virions. Second, maturing dendritic cells including LC and other DCs within or close to epithelial layer(s) can trap virus particles before migrating into the submucosa or to lymph nodes and transferring virus to susceptible T-cells (Hladik and McElrath 2008). A third potential mechanism involves transcytosis where virus particles are delivered to the submucosal sites via a vesicular route through the cytoplasm of epithelial cells. This process is initiated by virion attachment to cells via Env interactions with cell surface receptors including galactoside ceramide and heparin sulfate proteoglycans. Whether T/F viruses

confer more efficient transcytosis has not yet been reported. The extent each of these different mechanisms contributes to transmission is not resolved.

The Role of Virus Transfer via Cell: Cell Contact During Transmission

The relative contributions of cell-free and cell-associated virus to transmission are unclear. However, it is strongly believed that virus transfer via cell-to-cell contact plays an important role during different stages of transmission. There are several mechanisms that confer infection via cell-to-cell transfer that could be relevant for transmission. However, transfer across synapses that form between cell contacts is likely to be the most significant (Chen et al. 2007; Geijtenbeek et al. 2000).

HIV-1 infection of CD4⁺ T-cells can be mediated via immunological or virological synapses. DCs present antigen to T-cells by forming immunological synapses. HIV exploits this system. Maturing DCs capture virus particles via interactions between GM3 glycosphingolipids assembled on particles and SIGLEC-1 on the surface of DCs. -C-type lectins expressed on DCs including DC-SIGN also augment attachment by binding Env on virions. However, these receptors are downregulated on DC maturation, while SIGLEC-1 is upregulated. Immature DCs may degrade captured virions via a lysosomal route, with trans-infection occurring predominantly from mature DCs. Captured virions are transported into a surface-accessible compartment that releases them into synapses as they form at T-cell contacts.

Virological synapses occur between infected and uninfected T-cells and direct a polarized burst of virus budding into the intercellular space. They are believed to support substantial levels of HIV replication particularly in immune tissue where cell-to-cell contact is extensive. T-cell-to-T-cell synapses are initiated by interactions between Env on the infected cell and CD4 on the target cell and are supported by further interactions involving integrins. It is possible that infected cells from the HIV-1⁺ donor form synapses with cells in the HIV-negative recipient at sites of transmission resulting in bursts of virus

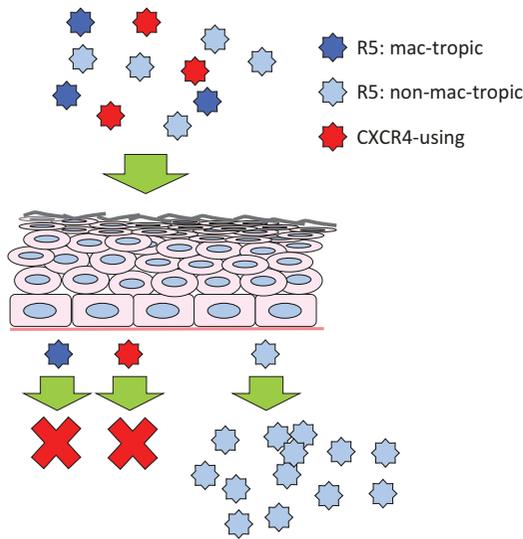

production that facilitate transmission. Regardless, synaptic transfer of virions is likely to be an important mode of virus expansion after infection.

It is not clear whether T/F HIV variants confer more efficient infection via synapses compared to non-transmitted HIV. One study reported T/F virus particles had nearly twice as much Env and bound more efficiently to DCs. However, if the primary mode of virion capture by DCs results from interactions between SIGLEC-1 and host moieties on virus particles, then capture may be primarily Env independent.

Finally, non-mac-tropic R5 viruses that require high levels of CD4 for infection may preferentially infect CD4⁺ T-cells via synapses. Infection by these T/F viruses will be greatly enhanced by the high levels of both CD4 and CCR5 that become concentrated on the target cell side of the synapse.

The Properties of Transmitting Viruses

Different studies have sought to identify properties of T/F viruses that are unique or different from those of viruses in the donor (transmitter) or from later stages of disease. These studies included investigation of T/F viruses deduced from newly infected female subjects, from heterosexually or homosexually infected males, and from neonates (Kishko et al. 2011). They have been augmented by the study of HIV-1 variants derived from early infection and by investigating Env genes as well as complete viruses. Transmitted HIV-1 variants are predominantly R5 that require high levels of CD4 for infection and do not confer efficient infection of macrophages. Most sexually transmitted T/F Envs also differ from about half of Envs derived from the chronic stage in how they use CCR5. About 50% of chronic stage R5 Envs confer some ability to exploit CCR5 occupied by the CCR5 antagonist, maraviroc, while few T/F Envs do this. The significance of this observation for transmission is unclear. However, it suggests that HIV-1 in late disease carry Env that can exploit different levels or conformations of CCR5 for infection, while T/F viruses usually cannot.

Tropism and Properties of the HIV-1 Envelope Glycoprotein in Transmission, Fig. 2 The transmission bottleneck: chance or selective transfer? Mac-tropic and non-mac-tropic R5 viruses as well as CXCR4-using viruses have been detected in semen, yet current data suggests that non-mac-tropic R5 variants are preferentially transmitted in sexual transmission. Is this because they have an overall predominance over other variants at sites of transmission or do they carry characteristics that favor transmission and replication in the new host? Transmitted variants have been reported to have fewer protective glycans and shorter variable loops and to replicate faster. Do these properties confer more efficient transmission (not shown)?

Several studies have reported that T/F Envs carry fewer protective sugars and have shorter variable loops on gp120 (Fig. 1) compared to Envs after seroconversion. These observations were made for T/F Env in sexual and mother-to-child transmission. However, some studies failed to confirm this, with sexually transmitted clade B Envs being least clear. Fewer glycans and shorter variable loops may increase the exposure of Env sites that interact with CD4 and enhance replication efficiency. T/F viruses were reported to be 1.7-fold more infectious compared to chronic stage viruses. Shorter variable loops and fewer glycans may increase sensitivity to neutralizing antibodies and could represent a potential vulnerability to vaccines and inhibitors. Neutralizing antibodies are absent during the acute phase, and these conditions should favor neutralization

sensitive strains, particularly if they confer an increased replication capacity that promotes transmission. Moreover, for viruses transmitted sexually, there is evidence that T/F viruses may be modestly more sensitive to different neutralizing antibodies, including pooled HIV-1+ plasma and Mabs that target the CD4 binding site on gp120 or sites on gp41. However, infant T/F Env and Env from breast milk of transmitting mothers did not differ in a range of properties including DC-mediated trans-infection, CCR5-use, infectivity and sensitivity to neutralizing antibodies, and inhibition by breast milk (Fouda et al. 2013). Nevertheless, at least for sexually transmitted Envs, current data is consistent with the selection of HIV-1 variants that carry increased replication capacity and may be more neutralization sensitive during and following transmission.

The Role of Neutralizing Antibodies in Transmission

Sexually transmitted virus usually enters an individual who has no immunity to HIV. However, this is not always the case and examples of superinfection have been documented. It is not clear whether the presence of immunity including neutralizing antibodies impacts on the efficiency of superinfection. Estimates of superinfection frequency vary from zero to levels similar to the infection rate for seronegative individuals. Some studies have suggested a level of protection. For example, among female sex workers, the incidence of superinfection was estimated at 4.7% compared to 7.8% for infection of seronegative women, although this difference was not statistically significant (Chohan et al. 2010). There is no data yet to suggest that superinfecting viruses are inherently more resistant to neutralizing antibodies. However, no studies have yet deduced T/F sequences and Env for superinfections.

Mother-to-child HIV-1 transmission usually occurs in the context of maternal antibodies that are passively transferred to the fetus over the last trimester of pregnancy. Maternal IgG is transferred through the placenta beginning around the 20th week of gestation. Secretory IgA, IgM, and

IgG are also present in colostrum and breast milk. These antibodies do not cross the infant's intestinal epithelium in substantial quantities. However, they may help protect against infection or penetration of the intestine. For example, purified dimeric IgA and IgM prepared from pooled HIV-1+ sera were shown to inhibit HIV-1 transcytosis *in vitro* using epithelial cell lines.

Placental-transferred neutralizing antibodies can reach high levels in the infant and potentially confer protection from HIV infection during later stages of pregnancy, delivery, and breast-feeding. Nonetheless, the role of maternal and infant neutralizing antibodies in transmission is controversial. Several studies of MTCT have indicated that mothers who do not transmit HIV carry higher levels of autologous neutralizing antibodies in plasma, while other studies did not support this (Fouda et al. 2013).

Many studies have tested whether the levels of heterologous neutralizing antibodies in the mother protected against MTCT, with several showing a positive correlation. Most studies on neutralization sensitivity have exploited maternal plasma or serum. Fewer have investigated neutralizing antibodies in breast milk or in secretions from other mucosal sites. However, Fouda et al. reported that plasma-derived antibodies in breast milk confer most of neutralizing activity present, albeit at levels that are likely too low to be protective (Fouda et al. 2011). Antibodies that conferred antibody-dependent cell-mediated cytotoxicity (ADCC) are present in breast milk and have been associated with reduced MTCT from mothers with high viral loads.

In summary, current data indicates that maternal antibodies transferred across the placenta *in utero* confer some level of protection in MTCT so that more neutralization-resistant viruses may carry an advantage for transmission to the neonate or infant.

Inhibitory and Enhancing Factors at Sites of Transmission

Cervical secretions, breast milk, and semen have been reported to inhibit HIV-1 infection, while semen also contains enhancing activity.

Numerous factors have now been described as either inhibiting or enhancing infection. These include semen-derived enhancer of virus infection (SEVI) and other amyloid peptides in semen that enhance HIV-1 infection by over 100-fold by increasing virion attachment to cells (Munch et al. 2007). A number of cationic peptides that are inhibitory have also been described. Human α -defensins HD5 and HD6 (small cysteine-rich cationic proteins) are present in vaginal, cervical lavage (where they are increased in the presence of STIs), in the intestine, and sometimes in breast milk. HD5 was reported to inhibit HIV-1 infection by blocking entry via an interaction with a site on gp120 that overlapped the CD4 and coreceptor binding sites. Human neutrophil defensins (HNPs 1–3 and LL-37) are also present in vaginal fluids and inhibit HIV-1 infection. HNP-1 was shown to bind both Env and CD4 and to block HIV-1 entry at several stages as well as inhibiting at later stages of replication. Whether SEVI or α -defensins have distinct effects on T/F Envs has not yet been extensively studied.

Breast milk also contains inhibitory activity effective against HIV-1 *in vitro*. This activity correlated with the level of sialyl-Lewis^x motifs, tetrasaccharide carbohydrates, usually attached to O-glycans on mucin including MUC1 and other glycoproteins or glycolipids. MUC1, MUC6, bile salt-stimulated lipase (BSSL), and Lewis X (LeX)-containing glycoproteins were each shown to block trans-infection from DCs to T-cells and sometimes cell-free infection. The mechanism of inhibition for sialyl-Lewis^x containing factors has not been reported although Env is a likely target. Finally half of breast milk samples contained factors that enhanced R5 virus infection mediated via cell-to-cell contact.

Source of HIV-1 at Sites of Transmission and Initial Cells Targeted in the New Host

If transmitting R5 viruses are predominantly non-mac-tropic and require high levels of CD4 for infection, it would implicate CD4+ T-cells that (express high CD4) as the source of HIV at

donor sites of transmission and as initial targets in the new host. Infection via synapses (where CD4 is concentrated) is also likely to play an important role. However, it may rule out macrophages and DC populations (which express low CD4) as viral sources in the donor and as early targets for infection. The predominance of T/F viruses and Env identified as non-mac-tropic is intriguing, since mac-tropic R5 variants and CXCR4-using viruses both confer efficient infection of CD4⁺ T-cells *in vitro*. The role of CD4⁺ T-cells as initial targets is supported by experiments where cervical explant tissues were tested for infection *in vitro* and by vaginal SIV inoculation of rhesus macaques. In the SIV model, CD4⁺ T-cells that included minimally activated (but not truly resting) as well as activated and proliferating T-cells are targeted (Haase 2010). It is possible that immunological synapses formed between LC/DCs and T-cells may act to simultaneously transfer activation signals and captured virions to T-cells.

Sources of HIV for Sexual Transmission

Our knowledge of HIV-1 variants and their properties at sites of transmission is incomplete. However, it is clear that R5 viruses predominate over CXCR4-using variants at least in semen and breast milk. "Opportunity" therefore partly explains why R5 viruses are preferentially transmitted in sexual and MTC transmission.

Semen mediates HIV-1 transmission via vaginal and rectal routes. HIV-1 is shed intermittently into semen and is present as cell-free and cell-associated virus comprising both T-cells and cells of macrophage lineage (Le Tortorec and Dejudic-Rainsford 2010). Spermatozoa themselves are not infected and not thought to play a significant role in capturing and delivering viral particles (Le Tortorec and Dejudic-Rainsford 2010).

Virus in semen is derived from both genital tract tissues and blood. Cell-free virus in semen is also sometimes genetically distinct from proviral DNA implicating a distinct tissue source. The tissue origins of HIV-1 tropism variants in semen have not been precisely established. The seminal vesicles and prostate, which contribute up to 90% of seminal plasma, are likely sources. Seminal

vesicles contain susceptible CD163⁺ macrophages, while the prostate contains infected T-cells. The testes and epididymis may be less significant contributors since vasectomy does not greatly affect semen viral loads, although the testes contain infected T-cells.

Several studies indicate that HIV-1 R5 variants are predominant in semen consistent with their preferential transmission over CXCR4-using viruses. However, CXCR4-using variants do reach the semen and are sometimes detected at lower levels. Full-length R5 Env sequences PCR-amplified from either proviral DNA or vRNA in semen from later stages of infection varied extensively in macrophage infectivity, although most were non-mac-tropic. No studies on the tropism of HIV-1 Env present in semen have been reported for the acute phase of infection when a substantial number of transmissions occur.

Cervical and vaginal secretions of HIV⁺ women contain sCD25 and sCD14, soluble markers for lymphocytes, and macrophages, respectively. Generally, inflammation and the presence of STIs are associated with increased virus shedding into transmission tissues and fluids of HIV⁺ subjects. R5 variants are predominantly detected in cervicovaginal secretions. However, there are no reports that assessed whether mac-tropic or non-mac-tropic HIV-1 R5 is present.

Initial Target Cells in Sexual Transmission

In the vagina, ectocervix, and particularly the transitional zone, there are microenvironments that are rich in immune cells including CD4⁺ T-cells. These foci of immune cells are concentrated close to the surface. Similarly, the rectal canal may be an area of high susceptibility mediating a higher rate of infection compared to the vaginal route (Powers et al. 2008). Submucosal DCs are enriched in the rectal canal and may extend dendrites into the lumen for initial capture of virions. High concentrations of highly permissive $\alpha 4\beta 7 + CD4^+$ T-cells (Arthos et al. 2008) are also present in the lamina propria of the rectum with their frequency correlating with susceptibility to rectal SIV infection.

Submucosal macrophages in the intestine are not susceptible to HIV due to reduced CD4 and

CCR5 expression as well as post-entry restrictions further highlighting T-cells as initial targets for infection although those in the anal canal express higher levels of CCR5 and may be more susceptible. In contrast, vaginal/cervical macrophages are susceptible to mac-tropic R5 viruses at least *in vitro*.

Contact with cervical and vaginal secretions or rectal material mediates infection of the penis. Circumcision reduces the risk of infection in men by >50%, indicating that the foreskin is an important site for the infection. Men with the largest foreskin surface area are the most susceptible. However, the tip of the urethra has also been implicated as a site for infection. The inner foreskin is more susceptible to infection containing a higher density of potential target cells compared to the outer foreskin with LCs found within the stratified epithelium, while CD4+ T-cells, macrophages, and DCs usually reside in the submucosa, although as discussed above, inflammation can lead to the recruitment of CD4+ T-cells into the stratified epithelium.

Mother-to-Child Transmission

MTCT can occur *in utero*, at the time of delivery, and during breast-feeding (Table 1).

Transmission *in utero* across the placenta is inefficient with most infections during pregnancy occurring late on when the placenta begins to separate from the uterus, and there is potential exposure to maternal blood. HIV-1 clade C viruses were reported to transmit *in utero* more efficiently compared to clades A and D, although whether this is due to Env is not known. On the maternal side of the placenta, the decidua basalis usually contains only low levels of T-cells along with macrophages, both of which have been shown by immunohistochemistry to be occasionally infected *in vivo*. However, while decidua basalis macrophages are permissive, the T-cells are poorly permissive to HIV-1 R5 infection *in vitro*.

Precisely how HIV-1 traverses the syncytiotrophoblast and cytotrophoblast layers and enters infant tissue beneath is not understood. These outer cell layers are CD4 negative and not easily infected. Few T-cells are usually present within the placental villi on the fetal side of the

trophoblast layers, although Hofbauer cells (macrophage lineage) have been shown to be occasionally infected using immunohistochemistry. Inflammation of the placenta increases the risk of transmission and may encourage the infiltration of CD4+ T-cells and other immune cells into maternal and fetal sites. The tropism and properties of virus transmitted via this route are not known.

During delivery, infants are exposed to amniotic fluid, genital tract secretions, and maternal blood, which are likely swallowed before infecting fetal cells. Amniotic fluid only occasionally carries HIV-1, leaving genital secretions and blood contamination as likely viral sources. Both cell-free and cell-associated viruses have been implicated in transmission during delivery.

Both R5 and X4 viruses have been detected in breast milk. Mastitis (even subclinical) increases viral load. Moreover, both cell-free and cell-associated viruses have been implicated in transmission via breast milk. Variants detected in breast milk are frequently distinct from plasma virus. However, breast tissue does not form a truly independent compartment for HIV replication.

Infants are infected *intrapartum* and *postpartum* after swallowing infected maternal fluid and breast milk. It is unclear where the initial infection event occurs with the oral cavity, the tonsils, and the upper gastrointestinal tract as possible entry sites. Higher LPS levels in the plasma of infants (a measure of intestinal permeability) were recently reported to be a predictor of infection via breast milk. Alternatively, virions may penetrate the intestinal epithelial layer via transcytosis through enterocytes or M cells.

Conclusion

The various routes of mucosal HIV-1 transmission usually require the virus to (1) evade innate inhibitory factors and sometimes neutralizing antibodies and (2) penetrate epithelial cell barriers to access susceptible host cells. The different routes into the new host may exert distinct selection pressures on viruses (and their Env) that have the potential to transmit. Current data indicates that R5 HIV-1 variants that are non-macrophage-

tropic are preferentially transmitted targeting CD4+ T-cells in or close to the mucosa of the new host. At least for some clades, Envs of transmitted variant Env have shorter variable loops and fewer glycans. Such variants may replicate faster but also offer potential vulnerabilities to neutralizing antibodies or inhibitors. Our knowledge of the properties of T/F viruses for different routes of transmission is growing. The challenge is to understand how T/F Env properties impact on Env structure and to exploit this information to design more effective vaccines and microbicides.

HIV-related immune compromise, compounded by immune immaturity in the very young (Perez-Velez and Marais 2012).

There are specific management challenges in HIV-associated tuberculosis, including selection and timing of antiretroviral therapy (ART) and recognition and management of shared drug toxicities and pharmacokinetic interactions. Immune reconstitution inflammatory syndrome (IRIS) is a common complication during treatment of HIV-associated tuberculosis and results in substantial morbidity. The problems of limited drug options and prolonged duration of therapy for drug-resistant tuberculosis are further exacerbated in HIV-infected patients because of overlapping toxicity with ART.

For the future, key challenges in HIV-associated tuberculosis include development of sensitive and low-cost point of care diagnostic tests to hasten appropriate initiation of anti-tuberculosis therapy and widespread implementation of existing evidence-based prevention strategies supported by the discovery of a more effective tuberculosis vaccine that can be used in HIV-infected people. New antituberculosis drugs are now in advanced clinical development and show potential for shortening the duration of therapy and improving cure rates in drug-resistant tuberculosis, but there remain concerns about toxicity and pharmacokinetic interactions with ART. This chapter provides an up to date overview of these issues with an emphasis on high burden and resource poor settings.

Tuberculosis and HIV

Introduction

HIV is a major driver of the global tuberculosis epidemic. The immune dysfunction associated with HIV increases susceptibility to tuberculosis, influences its clinical presentation, and alters the performance of diagnostic tests. Extrapulmonary tuberculosis is more common in HIV, and rapid progression of disease and a predilection for the central nervous system both contribute to the higher overall mortality in coinfecting patients.

Children also suffer a high burden of tuberculosis disease in areas where *M. tuberculosis* transmission is poorly controlled (Graham et al. 2014). HIV-infected children are especially vulnerable due to (1) increased tuberculosis exposure in HIV-affected households and (2) increased risk of disease progression following infection due to

Epidemiology

A third of the world's population have been infected with *M. tuberculosis* and of these around nine million people developed active tuberculosis disease in 2013 (WHO Global Tuberculosis Report 2014a). After HIV itself, tuberculosis is the second most common infectious cause of death in adults globally, and with 13% of all new tuberculosis cases occurring in HIV-infected people, tuberculosis is the most important opportunistic infection in HIV-infected people worldwide. Tuberculosis has a disproportionate impact on developing nations,

Tuberculosis and HIV, Fig. 1 Estimated HIV prevalence in new and relapse TB cases, 2013 (WHO global report 2014a)

with 22 of these countries accounting for 82% of all incident tuberculosis cases globally. Average incidence rates in high-burden countries are around 150–300 cases per 100,000 population per annum, while in Southern Africa rates are above 500 per 100,000. Sub-Saharan Africa experiences the greatest burden of HIV-associated tuberculosis, where around 80% of the global cases and deaths occur, and in Southern Africa over 50% of new tuberculosis cases are HIV-infected (Fig. 1). The HIV epidemic has profoundly influenced the epidemiology of tuberculosis in the region: in South Africa, Lesotho, and Swaziland, three countries with the highest per capita HIV prevalence in the world, active tuberculosis develops in ~1 person in every 100 per year, the majority of whom are HIV coinfectd.

Although global tuberculosis mortality has been declining over the past decade, an estimated 1.5 million people died from the disease in 2013, with a quarter of these deaths occurring in HIV-infected people; in Africa up to 40% of all AIDS deaths are from tuberculosis. These outcomes are unacceptable in the context of effective antituberculosis therapy that consistently results in treatment success in over 80% of drug susceptible cases in

functional tuberculosis programs, as well as improving ART coverage in notified HIV-infected tuberculosis patients, and fall short of Millennium Development Goal targets. Parts of the explanation for this are the worse treatment outcomes and higher mortality in HIV-associated tuberculosis. Globally the mortality during tuberculosis treatment is threefold higher amongst those coinfectd with HIV, and even in Africa where overall mortality from tuberculosis is higher, HIV-infected tuberculosis patients are twice as likely to die as HIV-negative patients within tuberculosis programs.

The burgeoning drug-resistant tuberculosis (Box 1) epidemic represents a major threat to global tuberculosis control. In 2013, 3% of new cases and 20% of retreatment episodes were estimated to have multidrug-resistant (MDR) tuberculosis, with almost half a million cases occurring worldwide. In MDR tuberculosis programmes, fewer than half of patients initiating therapy are successfully treated, largely because of the higher mortality associated with MDR tuberculosis and frequent disengagement from care due to drug toxicity and extended treatment durations. High rates of loss to follow-up contribute to the widening gap between detection and

treatment, and together with inadequate coverage of diagnostics for drug-resistant tuberculosis and long duration required for culture-based confirmation, results in only around 10% of global cases of MDR tuberculosis achieving cure.

Box 1 Definitions of drug-resistant TB

Multidrug resistant (MDR)	Resistance to rifampicin plus isoniazid
Pre-extensively drug resistant (pre-XDR)	MDR plus resistance to either a fluoroquinolone or an injectable agent ^a
Extensively drug resistant (XDR)	MDR plus resistance to both a fluoroquinolone and an injectable agent ^a

^aAmikacin, kanamycin, or capreomycin

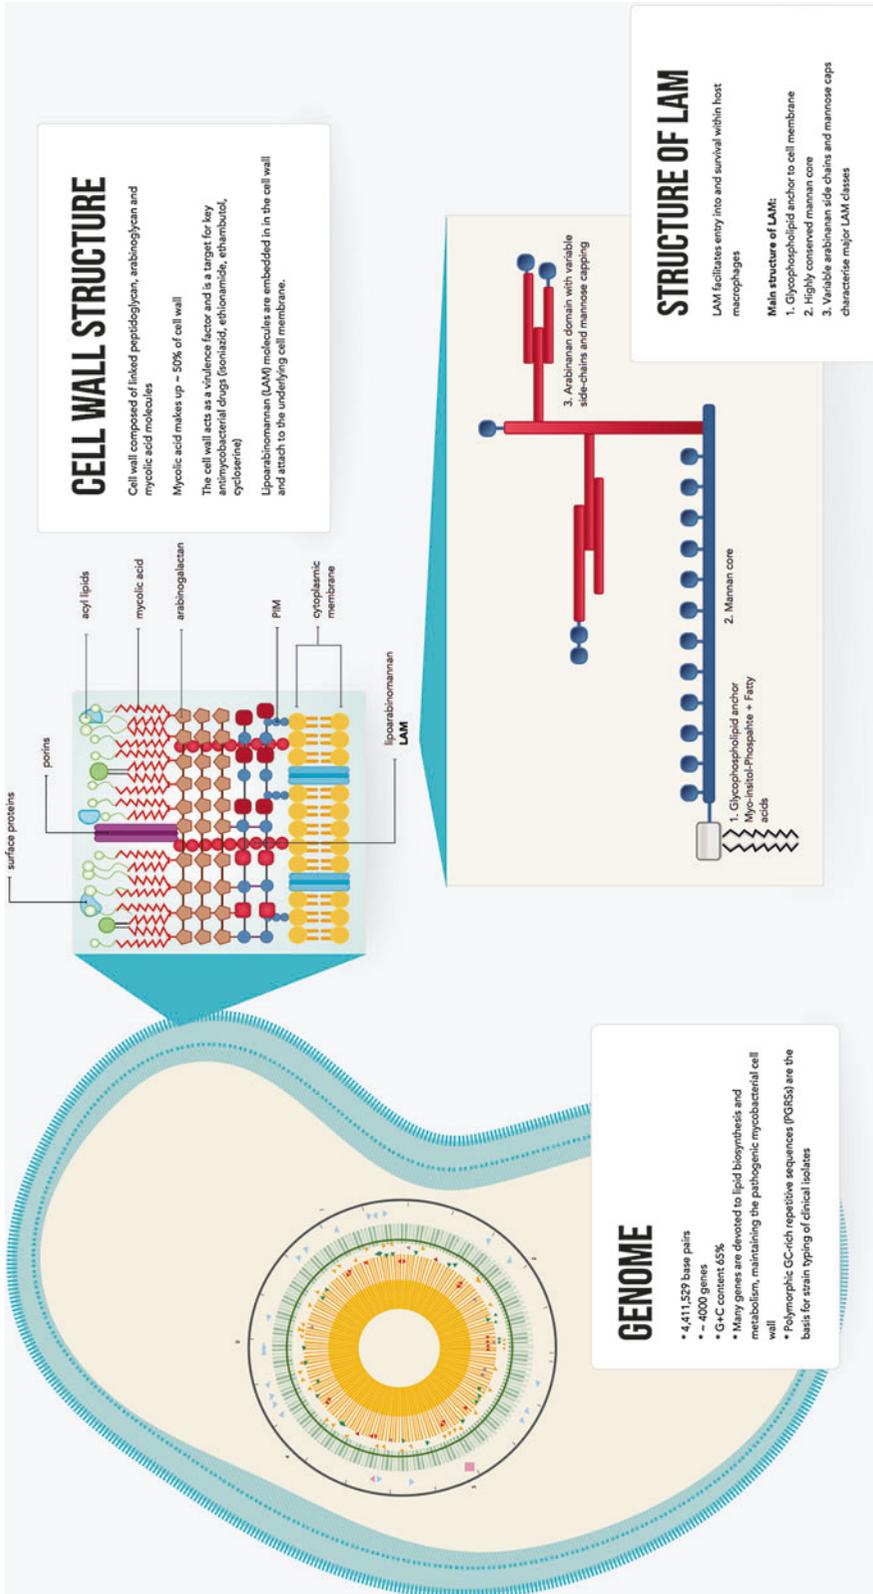

Almost a third of all cases with MDR tuberculosis have additional resistance to fluoroquinolones or injectable agents or both, a consequence of widespread misuse of anti-tuberculosis agents, difficulties in retaining patients in care and transmission of resistant tuberculosis. Less than a quarter of patients successfully complete treatment for extensively drug resistant (XDR) tuberculosis, with an average global mortality of 35%. In South Africa, the mortality and treatment failure rate for XDR tuberculosis is even higher, influenced by the subgroup of HIV-infected patients not yet on ART (Pietersen et al. 2014). The greatest burden of MDR tuberculosis is in the Russian Federation, India, and China, where HIV prevalence is increasing, but sub-Saharan Africa represents 15% of global cases, and therefore a substantial number of patients will be coinfecting with HIV. Similarly to drug sensitive tuberculosis, patients with HIV-associated drug-resistant tuberculosis have worse outcomes than HIV-uninfected patients, although this difference is mitigated by ART.

Microbiology

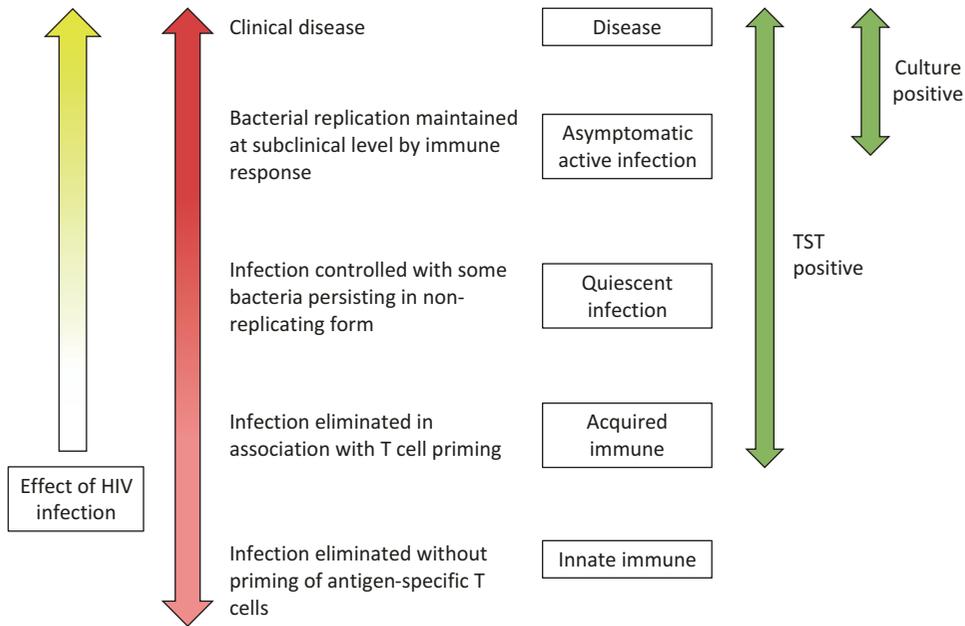

The causative organisms of tuberculosis belong to a family of seven species of mycobacteria in the

M. tuberculosis complex. *M. tuberculosis* is by far the most important cause of tuberculosis in humans. The other species are predominantly zoonoses, but *M. bovis* does uncommonly cause human disease through animal contact or from drinking unpasteurized milk. Humans are the only natural reservoir for *M. tuberculosis*, and transmission takes place exclusively from symptomatic individuals with pulmonary disease via expectoration of small respiratory droplet nuclei containing *M. tuberculosis* bacilli.

M. tuberculosis has a number of unique biological characteristics that directly impact on the pathophysiology and diagnosis of tuberculosis. It is an aerobic nonspore-forming Gram-positive bacillus surrounded by a cell wall of mycolic acids and lipopolysaccharides (Fig. 2). This waxy lipid layer is responsible for the characteristic phenomenon of “acid-fast” staining where aniline dyes such as carbol fuchsin are not removed by the addition of an acid alcohol decoloriser and retained within the cell wall, facilitating smear microscopy, the most common diagnostic test in use in developing countries. Mycolic acids are also implicated in the characteristic serpentine cording pattern (where *M. tuberculosis* bacilli are seen to clump together in parallel under light microscopy) and are involved in eliciting granuloma formation in host tissue. Lipoarabinomannan (LAM) antigens embedded in the cell wall and attached to the underlying plasma membrane act as major virulence factors by inhibiting crucial innate immune responses, thus enhancing survival of *M. tuberculosis* in the human host. The detection of LAM antigen in urine is being exploited as a promising diagnostic test for tuberculosis in patients with advanced HIV (discussed below). *M. tuberculosis* is a slow-growing organism with a generation time of around 24 h in vitro, resulting in prolonged time to recovery from laboratory culture media, a feature that impacts greatly on the ability to diagnose and control this disease in high-burden settings. The genome is large, containing around 4000 genes housed within a circular chromosome made up of 4.4 million base pairs, a large proportion of which are devoted to the production of enzymes involved in lipogenesis and lipolysis

Tuberculosis and HIV, Fig. 2 Structure of *M tuberculosis*

Tuberculosis and HIV, Fig. 3 Spectrum of infection (Adapted from: Barry et al. (2009))

required for the maintenance of its pathogenic and complex cell wall (Cole et al. 1998).

Latent TB Infection

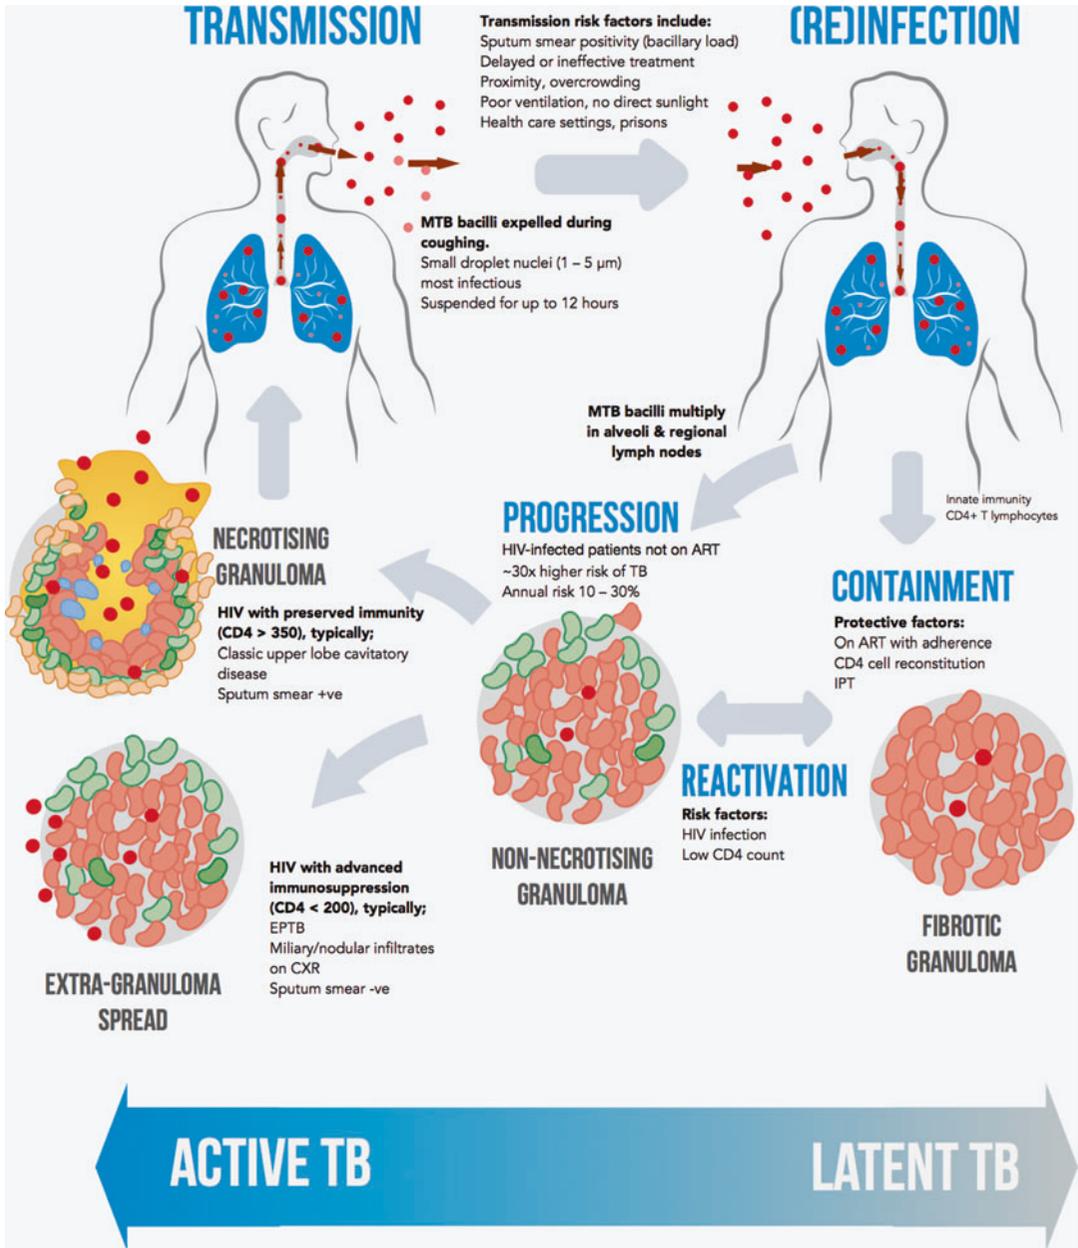

As in all infectious diseases, the clinical manifestations of tuberculosis result from a dynamic interaction between the host immune response and virulence factors of the organism. Perhaps the key reason for the success of *M. tuberculosis* to persist and spread globally is its ability to become metabolically inactive and enter a state of dormancy in host tissues, setting up chronic subclinical latent infection (LTBI). The organism is held in check by a competent cell-mediated immune response but may later reactivate when immunity is perturbed. During treatment, slowly dividing subpopulations enable *M. tuberculosis* to evade the action of many antimicrobial agents (i.e., phenotypic insensitivity) requiring prolonged treatment regimens to achieve sterilization.

The development of specific cell-mediated immunity against *M. tuberculosis* coincides with tuberculin skin test (TST) positivity, a delayed hypersensitivity reaction to the subcutaneous

injection of purified *M. tuberculosis* antigens; in asymptomatic people, a positive skin test signifies LTBI. Because of immune dysfunction, patients with HIV have reduced overall positivity rates and less vigorous responses to TST; the size of induration indicating a positive TST is lowered to ≥ 5 mm in HIV-infected individuals (from ≥ 10 mm in immunocompetent adults) to account for this. Although tuberculosis has traditionally been understood as a bimodal disease with patients having either latent or active infection depending on the absence or presence of clinical symptoms, it is increasingly being recognized that latent tuberculosis is part of a spectrum that spans from the possible elimination of *M. tuberculosis* by the innate immune system, through immune containment, to asymptomatic yet culture-positive disease, through to active and symptomatic disease (Fig. 3).

Pathophysiological Interactions Between HIV and TB

Because of the centrality of CD4 lymphocytes in granuloma formation and controlling *M.*

Tuberculosis and HIV, Fig. 4 Transmission and pathophysiology of HIV-associated tuberculosis

tuberculosis infection, it is predictable that HIV infection, the hallmark of which is CD4 cell depletion and dysfunction, has profound effects on the incidence, course, and clinical presentation of tuberculosis. HIV-infected individuals have a ~30-fold higher risk of developing tuberculosis than the immunocompetent population, due to

both reactivation of LTBI and progression from infection or reinfection to disease (Fig. 4). The risk of developing tuberculosis doubles within the first year after HIV-seroconversion and progressively increases with declining CD4 counts (Lawn et al. 2009). But even when on effective ART and with CD4 counts in the normal range, HIV-

infected people have a roughly fourfold higher risk of tuberculosis compared to HIV-uninfected people in high-burden communities, suggesting incomplete restoration of tuberculosis-specific immune function.

HIV-infected individuals with low CD4 counts are unable to mount an adequate inflammatory response, thereby limiting tissue damage but allowing unrestrained bacillary replication and spread. Rather than causing localized apical cavitary lung disease, tuberculosis becomes disseminated resulting in extrapulmonary organ involvement, intra-thoracic adenopathy, and military infiltration of the lung parenchyma. In addition to its impact on the clinical manifestations, HIV infection causes a more rapid progression of tuberculosis from the onset of symptoms to severe disease. Many patients with low CD4 counts who are sick enough to be hospitalized with HIV-associated tuberculosis report that they have been ill for less than 4 weeks.

Active tuberculosis also has detrimental effects on HIV infection, including significant increases in HIV viral load and a higher risk of progression to AIDS and death. There are a number of potential mechanistic explanations for this, including the increased expression of cell surface coreceptors CCR5 and CXCR4 required for HIV entry and enhanced transcription of HIV-associated proteins and thus viral replication because of upregulation of NF- κ B in HIV-infected monocytes.

Clinical and Radiological Manifestations

Because the pathology of *tuberculosis* is largely determined by host immune response, the clinical presentation depends on the degree of immunocompromise. HIV-infected patients with preserved CD4 cell counts, particularly >350 cells/ μ L, are therefore more likely to manifest similar symptoms and signs to those who are HIV-uninfected: a chronic cough that may be associated with hemoptysis, accompanied by weight loss, night sweats, and fever. The chest X-ray may demonstrate upper lobe cavitation that is also associated with high bacillary load in sputum and greater chance of diagnosis by smear microscopy.

By contrast, the clinical presentation of tuberculosis in HIV-coinfected patients with CD4 counts <200 cells/ μ L and advanced immunosuppression is often nonspecific, with atypical pulmonary manifestations, frequent extrapulmonary involvement, and a higher prevalence of smear-negative disease. Although respiratory symptoms may be completely absent, the majority of HIV-infected patients with disseminated disease will have pulmonary involvement as evidenced by positive sputum cultures. The mean CD4 count at ART initiation in sub-Saharan Africa remains below 200 cells/ μ L, but with improved access to ART and higher CD4 count thresholds for treatment initiation in high-burden settings, the clinical presentation of HIV-associated tuberculosis may begin to shift towards the typical syndrome seen in immunocompetent individuals.

Establishing a diagnosis of tuberculosis can be particularly problematic in HIV-infected children, since the TST is less sensitive than in HIV-uninfected children, failure to thrive is a typical feature of both tuberculosis and HIV, and chronic pulmonary symptoms may be due to other HIV-related conditions such as gastroesophageal reflux and bronchiectasis. Chest X-ray interpretation is complicated by HIV-related comorbidity such as recurrent bacterial pneumonia, lymphocytic interstitial pneumonitis (LIP), pulmonary Kaposi sarcoma and atypical tuberculosis presentations with disease phenotypes reflecting poor organism containment (Marais et al. 2007).

Extrapulmonary tuberculosis associated with HIV may manifest either as a systemic illness or with involvement of a particular organ system dominating. The former syndrome is often referred to as “disseminated tuberculosis,” where patients may present with weight loss, prolonged fevers, pallor of mucous membranes, lymphadenopathy, and/or abdominal tenderness. In contrast to the chronic indolent course of pulmonary disease in immunocompetent people, disseminated tuberculosis can progress rapidly in patients with advanced HIV, necessitating more urgent diagnosis and treatment initiation. Mild hepatosplenomegaly can occur from infiltration by tuberculous granulomas, and this is exploited diagnostically with the use of ultrasonography to

demonstrate microabscesses in the spleen. Large tender hepatomegaly occurs mainly, but not exclusively, in the context of unmasking or paradoxical tuberculosis IRIS, where an exaggerated immune reaction to *M. tuberculosis* antigen causes widespread expansion of intrahepatic granulomas. Chest radiography may be completely normal in up to 30% despite a positive sputum *M. tuberculosis* culture or reveal subtle nodular infiltrates, miliary patterns or consolidation, with or without intrathoracic lymphadenopathy or pleural effusions. Anaemia is common and results from a number of factors including iron malutilization from chronic inflammation, nutritional deficiencies, bone marrow suppression from HIV itself, and infiltration by tuberculosis. Bone marrow dysfunction may lead to pancytopenia. Renal impairment frequently accompanies disseminated tuberculosis in HIV-infected patients, and although often multifactorial, in certain cases it may result from direct involvement of the renal parenchyma by tuberculosis. This is the basis for the urine LAM antigen test, which, as discussed below, performs much better in patients with very low CD4 counts where renal tuberculosis is more likely. Although often accompanied by organ dysfunction, disseminated tuberculosis may have no localizing features, and in high-burden settings, tuberculosis is a common cause of pyrexia of unknown origin in hospitalized patients with HIV.

The most important discreet sites of extrapulmonary involvement in HIV are lymph nodes, pleura, the central nervous system (CNS), and pericardium, but virtually any organ system can be affected including the skeletal system, genitourinary tract, and skin.

Tuberculous Adenitis

Extrathoracic lymph nodes are affected in around a fifth of patients with HIV-associated tuberculosis, commonly in the cervical and axillary regions. Involved nodes are typically soft, tender, and fixed to underlying tissue. Groups of nodes can become matted together and coalesce to form massive swellings which may develop fluctuant areas and open onto overlying skin as chronic discharging sinus tracts. Lymphoma is the most important alternative diagnosis to consider in

HIV-infected patients with adenopathy and constitutional symptoms and should be excluded with an excisional lymph node biopsy, particularly in those not improving on empiric antituberculosis therapy. Other causes of adenopathy in HIV include Kaposi sarcoma, multicentric Castleman's disease, and infection due to cryptococcus or dimorphic fungi.

Pleural tuberculosis

Pleural effusions are more common in HIV-associated tuberculosis and occur more frequently in those with CD4 cell counts < 200 cells/microL. In high-burden settings, the finding of a unilateral lymphocytic pleural effusion in a young person has a very high positive predictive value for tuberculosis and can be used as a basis for empiric antituberculosis therapy. Symptoms include pleuritic chest pain and dry cough, which may progress to cause dyspnoea as the effusion enlarges; the indolent nature of the disease can allow effusions to become massive, occasionally leading to respiratory compromise and requiring urgent intercostal needle drainage. Simple pleural effusions may become complicated to form empyema, either due to superadded bacterial infection or from tuberculosis itself. Other causes of pleural effusion in HIV include parapneumonic effusion (due to bacterial organisms), Kaposi sarcoma, cryptococcosis, and primary effusion lymphoma.

CNS Tuberculosis

CNS disease is the most devastating form of tuberculosis – it is difficult to diagnose, requires prolonged therapy, and leaves a large proportion of patients disabled or dead. The three clinical categories of CNS tuberculosis, meningitis, intracranial tuberculoma, and spinal arachnoiditis, occur more commonly in HIV-infected patients and have been reported in up to a quarter of extrapulmonary tuberculosis presentations.

In sub-Saharan Africa, tuberculosis causes over a third of all cases of meningitis in HIV-infected adults (Veltman et al. 2014). The overall inpatient mortality from tuberculous meningitis (TBM) is up to 60%, but those with HIV coinfection have higher rates of death at 6–9 months after starting antituberculosis therapy compared to

HIV-uninfected patients (up to 67 versus 30%). Factors consistently associated with reduced survival in HIV include prolonged duration of symptoms, reduced level of consciousness, and lower CD4 cell counts. The presentation of HIV-associated TBM is similar to that in HIV-uninfected patients and has a broad clinical spectrum, ranging from a subacute illness with constitutional symptoms and chronic headache to sudden onset of severe meningitis progressing rapidly to coma. Stroke, cranial neuropathies, and hydrocephalus are important complications of TBM. Evidence of extracranial tuberculosis is found in about half of patients with HIV coinfection and TBM. Cerebrospinal fluid (CSF) analysis typically shows a lymphocytic pleocytosis with low glucose and raised protein, but this pattern is extremely variable, and up to 5% of patients with culture-confirmed TBM have a completely normal initial CSF examination. In a randomized controlled trial, the addition of corticosteroids to anti-tuberculosis therapy resulted in a 31% reduction in mortality in patients with TBM, including those with less severe presentations. This survival benefit was not statistically significant in the smaller HIV-infected subgroup, but the finding was similar in terms of direction of effect (Thwaites et al. 2004), and on the basis of this, corticosteroids are recommended for all patients with TBM. The most important differential diagnosis is cryptococcal meningitis, the commonest cause of meningitis in HIV-infected patients in developing countries and clinically indistinguishable from TBM. Cryptococcal meningitis should therefore be excluded in all patients with suspected TBM by performing a cryptococcal antigen test and fungal culture on the CSF. Other aetiologies that may mimic TBM include bacterial meningitis, neurosyphilis, and encephalitis caused by cytomegalovirus (CMV) or herpes simplex virus (HSV), particularly at CD4 counts <50 cells/ μ L.

Cerebral tuberculomas may occur with or without concomitant meningitis, and present with headache, focal neurological deficits, seizures, or reduced levels of consciousness. On contrast computed tomography (CT) imaging the lesions show variable central density surrounded by peripheral ring enhancement and

edema, often with mass effect. The number and distribution of the lesions is not specific, and CT cannot reliably distinguish tuberculomas from other causes of mass lesions in HIV, especially toxoplasmosis.

Spinal tuberculous arachnoiditis typically presents with mixed upper and lower motor neuron signs of the legs and sphincter dysfunction. The CSF may show the typical changes of TBM but can be normal, and the diagnosis is usually made with magnetic resonance imaging (MRI) demonstrating nodular arachnoiditis in the appropriate clinical context. Infections that may mimic this disease in HIV-infected patients include cytomegalovirus (CMV) polyradiculopathy and neurosyphilis.

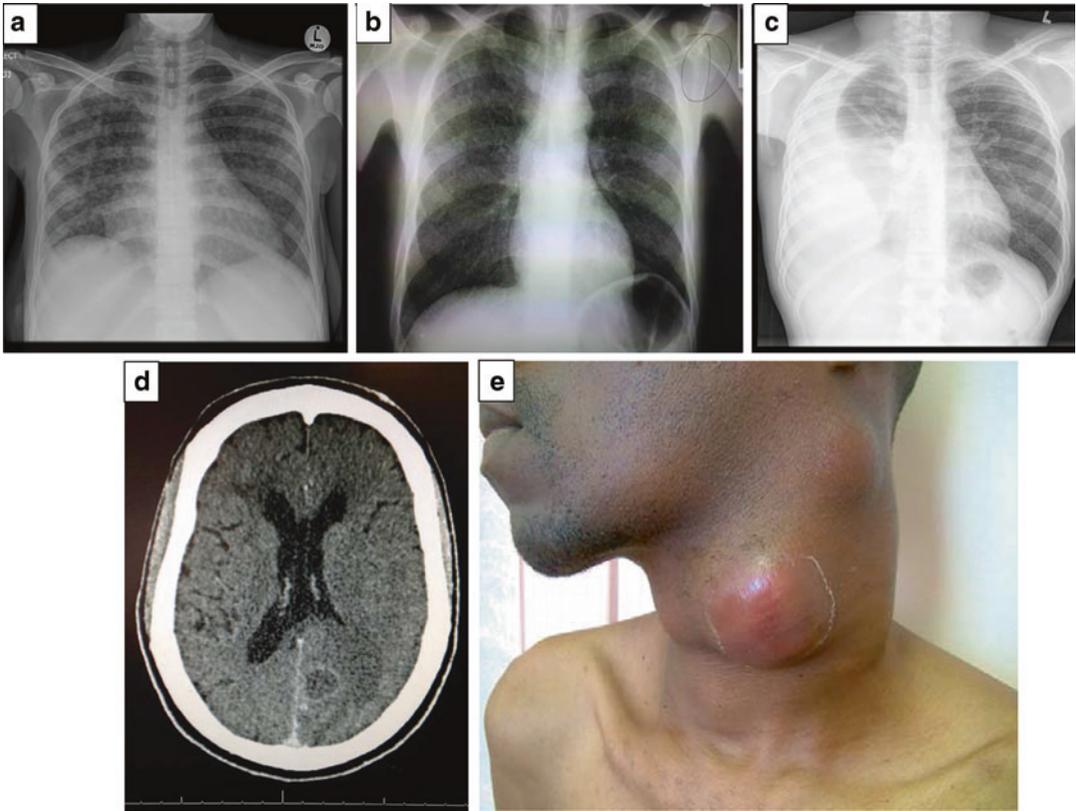

Tuberculous Pericarditis

The incidence of tuberculous pericarditis has risen dramatically in HIV-endemic regions. In developing countries, tuberculosis is responsible for over 50% of cases of pericarditis, and up to 75% of patients with large pericardial effusions in sub-Saharan Africa are HIV-infected, with tuberculosis the cause in most. Disseminated disease is more common in HIV-infected patients with tuberculous pericarditis, who present more frequently with myopericarditis, dyspnoea, and hemodynamic instability and have higher 6-month mortality (40%) than those who are HIV-uninfected. Corticosteroids are not recommended for tuberculous pericarditis in HIV as they have no significant impact on a composite outcome of death, tamponade, and constriction, and are associated with an increased risk of HIV-associated cancers. Other possible causes of pericardial effusion in HIV are pyogenic (may be as coinfection with tuberculosis), cryptococcosis, Kaposi sarcoma, and lymphoma.

Representative clinical and radiological images are presented in Figs. 5 and 6.

Diagnosis

Clinicians should have an especially high index of suspicion for tuberculosis in any HIV-infected

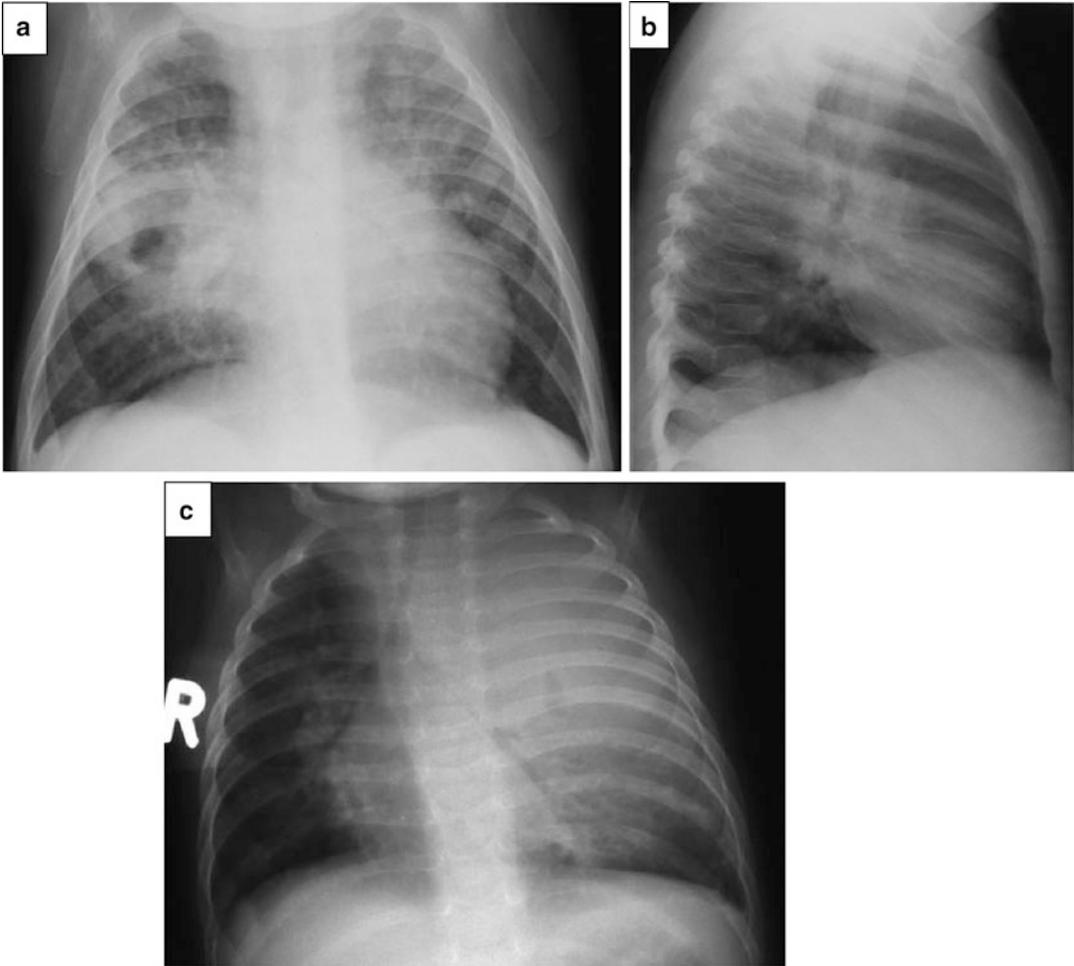

Tuberculosis and HIV, Fig. 5 Representative images of the clinical and radiological spectrum of HIV-associated TB in adult patients. Clockwise from top left: (a) Chest radiograph showing nodular parenchymal infiltrates, pericardial effusion, and mediastinal adenopathy; (b) Chest radiograph showing a diffuse miliary infiltrate with hilar and mediastinal adenopathy; (c) Chest radiograph showing a large right pleural effusion

with nodular parenchymal infiltrates; (d) Contrast-enhanced CT scan showing a ring enhancing mass lesion with central hyperdensity in the posterior fossa, surrounded by edema and causing generalized brain swelling; (e) massive cervical adenopathy with cold abscess formation (reproduced from Meintjes et al, *Lancet Infect Dis.* 2008 Aug;8(8):516-23 with permission from Elsevier)

patient with rapid loss of weight and a reduced level of function in the absence of chronic diarrhoeal illness as an explanation. The decision to start empiric antituberculosis therapy depends mainly on the severity of the clinical presentation and access to diagnostic tests, with a lower threshold in ill patients or those with a rapidly deteriorating condition. Potential pitfalls of empiric treatment include missing another serious opportunistic disease or drug-resistant tuberculosis and exposing patients unnecessarily to prolonged courses of antituberculosis therapy. Therefore, although the clinical pretest probability of tuberculosis in endemic regions may be high, it is

important to send clinical samples to the laboratory to confirm the diagnosis and obtain drug susceptibility data. Establishing microbiological confirmation of disease is particularly problematic in HIV-infected children who are unable to expectorate. However the principles of case detection and management are similar to those in adults, with collection of alternative respiratory specimens such as induced sputum, gastric aspirates or stool in children who are too young to expectorate, and nonrespiratory specimens such as fine needle aspiration biopsy (FNAB) in children with peripheral lymph node masses (Siberry et al. 2013; Marais et al. 2011).

Tuberculosis and HIV, Fig. 6 Representative images of the clinical and radiological spectrum of HIV-associated tuberculosis in paediatric patients. Clockwise from top left: (a) Chest radiograph showing a complicated Ghon focus. This reflects poor disease containment at the point of entry – infants and severely immune compromised individuals are particularly vulnerable; (b) Lateral Chest radiograph showing hilar adenopathy. The dense circular ring around the hilum (so-called doughnut sign) is indicative of perihilar lymph

node involvement; (c) Chest radiograph showing caseating (expansile) pneumonia. Tuberculous lymph nodes cause airway narrowing (almost pathognomonic), since unlike other mass lesions it traps and compresses the airway. Lymph nodes can also “rupture” (with sinus formation) into the airway which may result in aspiration of caseous material and development of dense caseating pneumonia. Tuberculosis causes radiological appearances that are often more severe than the clinical signs and symptoms

T

Commonly used diagnostic tests are discussed below and their key performance characteristics are summarized in Table 1.

Growth-Based Detection

The reference standard for diagnosing tuberculosis is a positive culture of *M. tuberculosis* on a clinical specimen. Culture remains the most

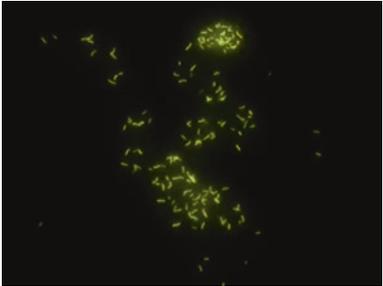

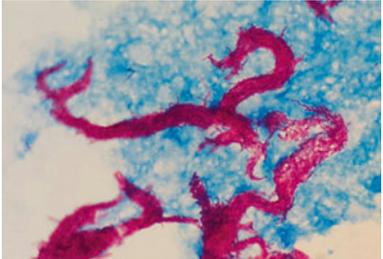

sensitive method for diagnosis (with an ability to detect 10 bacteria per mL of sputum) and allows for subsequent speciation, drug susceptibility testing, and monitoring of microbiological response to therapy. Automated liquid culture systems such as the mycobacterial growth indicator tube (MGIT; Becton Dickinson Diagnostic Instruments Systems) have largely replaced

Tuberculosis and HIV, Table 1 Key performance characteristics of diagnostic tests for tuberculosis when performed in HIV-infected patients

	Limit of detection (bacilli per ml of sputum)	Sensitivity (on sputum unless other specified)	Comments
<p>Solid culture</p>  <p><i>M. tuberculosis</i> colonies on Löwenstein-Jensen (LJ) medium</p>	10–100	Reference test	Reference test Can be used for speciation and drug susceptibility testing Used to monitor response to therapy 2–6 weeks for result (median time to detection ~ 24 days)
<p>Liquid culture</p>  <p>BACTEC MGIT system [Becton Dickinson, Sparks, MD]</p>	10–100	Slightly higher sensitivity than solid culture media	Reference test Automated system More rapid results than solid culture media Higher contamination rates Can be used for speciation and drug susceptibility testing Used to monitor response to therapy 1–6 weeks for result (median time to detection ~15 days)
<p>Smear microscopy</p>  <p>Acid-fast bacilli (ZN stain) seen on a direct clinical specimen</p>	≥10,000	30–40% Higher sensitivity with fluorescence microscopy Yield can be increased by collecting two early morning specimens	Most widely used test in developing countries Cannot distinguish nontuberculous mycobacteria from <i>M. tuberculosis</i> Identifies the most infectious patients Used to monitor response to therapy

conventional solid media culture because of simpler laboratory workflows, higher sensitivity, and earlier detection times. However, the median time to detection still ranges between 11 and 15 days, and therefore cultures cannot be used to guide initial treatment decisions in HIV-infected patients with severe tuberculosis. A drawback of liquid culture systems is the high rate of contamination, causing 5–10% of tests to fail.

The yield of culture in extrapulmonary specimens varies depending on the clinical site and degree of immunosuppression. The sensitivity when performed on CSF and pleural fluid is relatively low compared with sputum. Growth of *M. tuberculosis* from a clinical site represents viable

replicating bacilli and should be interpreted as indicating active disease and a need for anti-tuberculosis therapy. However, there are a substantial proportion of patients with so-called culture-negative tuberculosis who will respond to treatment; these patients should be evaluated according to the WHO 2007 algorithm (WHO 2007).

Smear Microscopy

Sputum smear microscopy, traditionally performed with Ziehl-Neelsen (ZN) staining, is a rapid, specific method of detecting infectious patients with tuberculosis and for monitoring response to therapy. Microscopy requires at least

10,000 organisms per mL of sputum, and therefore will detect fewer cases in HIV-infected patients who frequently have sputum paucibacillary or extrapulmonary disease (Reid and Shah 2009). In some settings, over two-thirds of HIV-infected patients with active tuberculosis requiring therapy may be missed by sputum smear microscopy. Although sputum induction with nebulized hypertonic saline potentially identifies approximately 25% additional cases in symptomatic patients who are smear-negative or unable to spontaneously produce sputum, a negative smear never excludes the diagnosis of tuberculosis in HIV-coinfected patients. Smear microscopy has a poor yield when performed on CSF and pleural fluid but is a useful investigation for needle biopsy material from lymph nodes.

Molecular Methods

With the limitations of delayed time to detection for culture and poor sensitivity of smear, more rapid and reliable diagnostics are needed. Xpert[®] MTB/Rif (Cepheid, Sunnyvale, CA, USA) is a closed real time polymerase chain reaction (PCR) assay that amplifies an 81 base-pair region of the *M. tuberculosis* RNA polymerase β subunit (*rpoB*) gene. This target is specific for *M. tuberculosis* complex and is the site of mutations that underlie rifampicin resistance in the majority of MDR tuberculosis strains, therefore allowing rapid detection of rifampicin resistant tuberculosis directly from clinical specimens. The cartridge-based system minimizes contamination, requires minimal technical skills, and, importantly, is able to produce a result within 2 h.

Compared with culture as the reference test for confirmed tuberculosis, the overall sensitivity of Xpert is 88%, and slightly lower in HIV at 79%. As an add-on test after a negative smear microscopy result, the sensitivity drops to 68% (Steingart et al. 2014). Therefore, a third of smear-negative culture-confirmed tuberculosis cases may still be missed by Xpert testing. The diagnostic yield of sputum Xpert has been shown to be poor in hospitalized acutely ill HIV-infected inpatients, identifying only 28% of confirmed tuberculosis cases in one study from a high-burden setting. The major reason for this is such

Tuberculosis and HIV, Table 2 Performance of Xpert for the diagnosis of extrapulmonary tuberculosis on selected specimens (compared against culture) (WHO 2013)

	Lymph node	CSF	Pleural fluid
Sensitivity	84.9 %	79.5% relative to culture-positive TBM (50% relative to clinical reference standard)	43.7%
Specificity	92.5%	98.6%	98.1%

patients have difficulty producing a sputum specimen for testing.

Because PCR is able to detect DNA from both live and dead organisms, molecular-based diagnostics may test positive despite being culture-negative. There is evidence that around a quarter of patients successfully treated will remain Xpert positive at 6 months. Thus, Xpert should not be used to monitor response to therapy and cannot be used alone to confirm a recurrent episode of tuberculosis after a recent treatment episode (the precise duration has not been defined but we suggest confirming with culture if treated for tuberculosis within the last year).

Xpert is being increasingly used for the diagnosis of tuberculosis from extrapulmonary specimens. It performs especially well on lymph node aspirates and other tissue samples and is a useful rule-in test for TBM using CSF; the WHO recommends its use on these specimens as a replacement for smear microscopy in the appropriate clinical setting (WHO 2013). Clinicians should, however, be aware that Xpert still lacks sensitivity to exclude TBM in patients in whom the diagnosis is clinically suspected, and empiric therapy should not be withheld because of a negative CSF result. Xpert performs poorly on blood and pleural fluid and is not recommended for use on these specimens (Table 2). An additional limitation of Xpert is that it is unable to differentiate *M bovis* and *M bovis*-associated Bacille Calmette-Guérin (BCG) disease from tuberculosis. This is especially relevant in children with BCG-induced axillary adenitis, which is often misdiagnosed as tuberculosis (Hesseling et al. 2006). There is emerging

evidence that the assay has good performance characteristics on urine when used in patients with low CD4 counts and disseminated tuberculosis.

Other molecular diagnostic tests are available, including line probe assays (LPA) that use reverse hybridization technology to speciate and detect drug resistance mutations in mycobacteria. Unlike Xpert, LPA assays are prone to contamination and perform unreliably on direct clinical specimens. The value of LPA is its ability to detect resistance to other antituberculosis drugs in addition to rifampicin as well as in detecting dual strain infection. Its use on microscopy-positive specimens or cultured isolates has reduced time to initiation of drug-resistant tuberculosis therapy.

Urinary Lipoarabinomannan (LAM)

Detection of LAM in the urine represents renal tract involvement with tuberculosis and is therefore found more commonly in patients with more severe immune compromise and disseminated disease (Lawn 2012). The test is available as an immunochromatographic lateral flow assay (Determine[®] TB-LAM Ag [urine LAM], Alere, Waltham, MA, USA) that can be used at point of care by adding unprocessed urine onto the test strip.

When used for screening outpatients entering an ART program in a high-burden setting, the overall sensitivity of the urine LAM for diagnosing culture-confirmed tuberculosis is less than 30%, but it detects up to two-thirds of cases in the subgroup with CD4 counts <50 cells/ μ L. The specificity is excellent, exceeding 98%, and the positive predictive value is over 90% in patients with advanced HIV.

Urine LAM can provide a rapid diagnosis of tuberculosis in hospitalized patients. In unselected HIV-infected medical admissions with a high prevalence of extrapulmonary tuberculosis, urine LAM detects 40% of confirmed cases. When combined with urine Xpert, testing the overall sensitivity may rise to 70%, and for those with CD4 counts <100 cells/ μ L, the combined urine tests have the ability to diagnose tuberculosis in 85% of cases. In HIV-infected inpatients with suspected tuberculosis in another high-burden setting, urine LAM detected two thirds of confirmed

cases overall and half of cases with negative sputum smear microscopy. Unfortunately yields in children have been disappointing.

Histopathology

Pathological examination of biopsied tissue is frequently performed in addition to microbiological and molecular testing. This often provides important supportive diagnostic information and can be used as a basis for empiric antituberculosis therapy while awaiting culture results or if culture is not possible. The characteristic pathological lesion of tuberculosis infection is the granuloma, but these may be poorly formed, lacking the caseating centre, in HIV-infected patients with advanced immunosuppression. Other conditions associated with HIV, such as deep fungal infection and lymphoma, may also lead to granuloma formation, limiting the specificity of the finding. ZN (or equivalent) stains can be performed in tissue samples but do not distinguish tuberculosis from infection with nontuberculous mycobacteria. However, the finding of granulomas and acid fast bacilli within tissue macrophages is strongly supportive of tuberculosis in high-burden settings.

Management

Antituberculosis Therapy

The antimicrobial therapy for HIV-associated drug sensitive tuberculosis is the same as in HIV-uninfected patients. WHO recommends a standard regimen of 2 months of rifampicin, isoniazid, ethambutol, and pyrazinamide followed by 4 months of rifampicin and isoniazid, preferably in fixed dose combination tablets and dosed according to weight. Therapy should be administered 7 days a week throughout the course. Generally the duration of therapy for extrapulmonary tuberculosis is the same as for pulmonary tuberculosis but is extended for neurological and bone involvement. The treatment of MDR tuberculosis is more toxic and, because no drug in the standard WHO second line regimen is as effective in terms of sterilizing activity as the rifamycins, it requires an extended course. At least 2 new bactericidal agents (preferably a fluoroquinolone plus an

injectable) should be included in a regimen for any isolate with rifampicin resistance, together with 2–3 other antituberculosis drugs to which the isolate is likely to be susceptible. Treatment should be continued for at least 18 months following conversion of sputum cultures to negative. Constructing treatment regimens for pre-XDR and XDR-TB is complex, particularly in HIV-infected patients requiring ART, and should be done in consultation with an expert.

In general, TB treatment recommendations in HIV-infected children are similar to HIV-uninfected children, but given an increased risk of disease relapse in children with significant immune compromise, treatment for drug-sensitive TB may be prolonged from 6 to 9 months (Siberry et al. 2013).

Adjunctive Therapy

Unless contraindicated because of previous intolerance, all HIV-infected patients with tuberculosis should receive co-trimoxazole preventive therapy and pyridoxine. Co-trimoxazole prophylaxis prevents bacterial infections, diarrhoea, malaria, and pneumocystis pneumonia and has been shown to reduce mortality by over 40% in patients with HIV-associated tuberculosis. In developed countries co-trimoxazole can be safely stopped when the CD4 count is above 200 cells/ μ L, but long term provision is recommended in sub-Saharan Africa because of ongoing protection against malaria and bacterial infection (Church et al. 2015). The recommendation for pyridoxine supplementation is based on the observation that sensory polyneuropathy is more common in patients with HIV and tuberculosis, possibly because of vitamin B6 deficiency caused by isoniazid therapy.

Antiretroviral Therapy

Observational studies demonstrated a reduction in mortality risk of over 65% in patients with HIV-associated tuberculosis who are receiving concurrent ART, and a randomized controlled trial performed in South Africa showed improved survival for patients with CD4 counts \leq 500 cells/ μ L who started ART during antituberculosis therapy (Abdool Karim et al. 2010). WHO

recommends that all HIV-infected patients with active tuberculosis be initiated on ART regardless of CD4 count.

ART initiation in patients with tuberculosis is, however, accompanied by potential complications, including the risks of IRIS and overlapping drug toxicities, which are more likely to occur if ART is started early after the initiation of antituberculosis therapy. Clinical trials have demonstrated a survival benefit for patients with CD4 counts $<$ 50 cells/ μ L starting ART within 2 weeks of antituberculosis therapy compared to deferring to around 8 weeks; this should be done in all patients with CD4 count $<$ 50 cells/ μ L unless there is TBM or concomitant cryptococcal meningitis. In contrast, those with higher CD4 counts do not have an increased risk of death or AIDS-defining events if ART is delayed up to 8 weeks. This provides an important opportunity to establish patients on antituberculosis therapy and a window to offer adequate counseling for lifelong ART. Those with CD4 counts $>$ 220 cells/ μ L can safely delay ART until after completing the full course of antituberculosis therapy, but this may not be advisable on a programmatic level because of the potential for loss to follow up with such delays. Unless there is another compelling indication to initiate ART urgently, such as an additional AIDS-defining disease, patients with CD4 counts $>$ 50 cells/ μ L should therefore have linkage to ART services and start ART within 8 weeks of antituberculosis treatment. In TBM, although a clinical trial showed no mortality difference between early versus deferred ART, it has been recommended that ART be delayed for 4–8 weeks regardless of CD4 count to reduce risk of neurological tuberculosis-IRIS.

The WHO-recommended ART regimen for patients with tuberculosis is tenofovir, lamivudine/emtricitabine, and efavirenz. These drugs are available in fixed-dose combination tablets and do not require dose adjustment when given with antituberculosis therapy. Despite an FDA recommendation to use higher doses of efavirenz during treatment with rifampicin, there is no evidence that efavirenz concentrations are lower or virological outcomes worse in patients being treated for tuberculosis and with standard

efavirenz doses, and the practice of increasing efavirenz to 800 mg daily is not advised.

Nevirapine based ART is inferior to efavirenz based regimens in patients with tuberculosis, with fewer patients achieving HIV-viral suppression. Nevirapine results in higher rates of cutaneous drug reactions and liver injury and undergoes significant enzyme induction by rifampicin, with the potential for subtherapeutic concentrations. If nevirapine is prescribed for patients on rifamycin-containing antituberculosis therapy, the starting dose should be 200 mg twice daily (i.e., the lead-in dose of 200 mg daily is omitted).

Drug Toxicity and Drug-drug Interactions

There are multiple potential drug-drug interactions and shared toxicities between ART and anti-tuberculosis therapy, especially when treating drug-resistant tuberculosis or using second-line ART. Tables 3 and 4 list the most clinically significant drug-drug interactions and toxicities of commonly used agents with advice on coadministration. Significant drug-drug interactions between rifampicin and protease inhibitors used as first-line treatment in young children is problematic, with a need to “superboost” standard lopinavir/ritonavir combinations by adding additional ritonavir to overcome the inducing effect of rifampicin.

Cutaneous drug reactions (CDRs) are common in HIV-associated tuberculosis and have a wide spectrum of clinical presentations. These range from mild morbiliform rashes to Steven-Johnson syndrome and toxic epidermal necrolysis or systemic involvement with eosinophilia and hepatitis. Mild rash can be treated symptomatically with continuation of all drugs and close clinical observation. Patients with severe CDRs need to immediately stop all potentially offending agents and be admitted to hospital. Co-trimoxazole is an important cause of adverse drug reactions in HIV and should be stopped in all cases of suspected CDR. In general, non-nucleotide reverse transcriptase inhibitors (NNRTIs) should be avoided once implicated in a severe CDR, but it is often possible to successfully rechallenge antituberculosis drugs. Expert advice should be sought in all cases.

Derangement of liver functions occurs in up to 30% of patients receiving antituberculosis therapy or first-line ART, but only the minority represents significant drug-induced liver injury (DILI). The clinical spectrum ranges from mild transient asymptomatic transaminitis (termed “hepatic adaptation”) to severe hepatitis and liver failure. Mild asymptomatic liver enzyme elevations are benign and do not warrant a switch in therapy. Examples include mild derangement of canalicular liver enzymes in HIV-infected patients that is usually multifactorial and without clinical significance, and isolated hyperbilirubinaemia in patients on rifampicin or atazanavir. It is important to exclude other potential causes of liver injury such as other hepatotoxic agents (e.g., co-trimoxazole and fluconazole), hepatitis viruses, and toxins. Table 5 lists common indications for changing regimens in CDRs and DILI.

Immune Reconstitution Inflammatory Syndrome

IRIS results from rapid restoration of pathogen-specific immunity after the initiation of ART. The resulting inflammatory reaction leads to either a clinical deterioration of tuberculosis for which the patient is on treatment (paradoxical TB-IRIS) or the atypical inflammatory presentation of active tuberculosis during early ART where the diagnosis was missed prior to ART (unmasking TB-IRIS) (Meintjes et al. 2008).

Paradoxical TB-IRIS is common, occurring in up to 54% of patients starting ART while on antituberculosis treatment. Risk factors include lower baseline CD4 count, shorter interval to starting ART, disseminated tuberculosis or extrapulmonary tuberculosis, and a rapid rise in CD4 count. Symptoms usually occur in the first few weeks (median 10–14 days) and up to 3 months after ART initiation. Clinical manifestations may include new constitutional, respiratory, or abdominal symptoms or new or worsening focal lesions such as enlarging lymph nodes, tuberculous abscesses, or pleural effusion. There may also be worsening radiological features of tuberculosis such as a new chest X-ray infiltrate or enlarging

Tuberculosis and HIV, Table 3 Common drug interactions between antituberculosis therapy and ART in adults^a

Anti-tuberculosis therapy	Antiretroviral	Interaction	Comments
Rifampicin-based	Efavirenz	Efavirenz concentrations not significantly reduced	No dose adjustment required
	Nevirapine	Reduced concentrations of nevirapine	Preferably use efavirenz Omit 200 mg daily lead-in dose and start with 200 mg BD
	Rilpivirine	Reduced concentrations of rilpivirine	Do not coadminister
	Etravirine	Reduced concentrations of etravirine	Do not coadminister
	Lopinavir/ ritonavir	Markedly reduced concentrations of lopinavir	Requires double dose with 4 tablets (800/200 mg) BD in adults Increase the dose gradually: 3 tabs BD for a week then 4 tabs BD for duration of rifampicin use Reduce dose back to 2 tabs BD (400/100 mg) 1–2 weeks after rifampicin stopped
	Atazanavir/ ritonavir	Markedly reduced concentrations of atazanavir	Do not coadminister
	Darunavir/ritonavir	Markedly reduced concentrations of darunavir	Do not coadminister
	Raltegravir	Reduced concentrations of raltegravir	A recent clinical trial suggests that dose increase is not required
	Dolutegravir	Reduced concentrations of dolutegravir	Requires increased frequency of dolutegravir dosing with 50 mg BD
Rifabutin-based	Efavirenz	Reduced concentration of rifabutin	Requires increased dose of rifabutin 450 mg daily
	Nevirapine	Non-significant increase in rifabutin	No dose adjustment required
	Rilpivirine	Reduced concentrations of rilpivirine	Avoid if possible, otherwise requires increased dose of rilpivirine 50 mg daily
	Etravirine	Reduced concentrations of etravirine	Do not coadminister if used together with a boosted protease inhibitor
	All ritonavir-boosted protease inhibitors	Increased concentrations of rifabutin	Requires reduced dose of rifabutin 150 mg alternate days or 150 mg daily (guidelines vary) Standard doses of ritonavir-boosted lopinavir, atazanavir, and darunavir
	Raltegravir	No significant interactions	No dose adjustment required
	Dolutegravir	No significant interactions	No dose adjustment required

^aGuidelines for dosing and coadministration of rifamycins and ART in children are different. Expert consultation should be sought

tuberculoma on brain imaging. IRIS is a diagnosis of exclusion, and other potential causes of clinical deterioration in patients with tuberculosis need to be investigated, such as poor treatment adherence, poor drug absorption, drug toxicity, a new

opportunistic infection, and especially drug-resistant tuberculosis.

Non-neurological TB-IRIS is usually a self-limiting condition with a low mortality but is associated with significant morbidity and

Tuberculosis and HIV, Table 4 Important shared toxicities of ART and antituberculosis treatment and other drugs used in HIV-infected patients

Adverse effect	Antituberculosis drug	Antiretroviral	Other

frequently results in hospital admission (25% of cases). In children who received a BCG vaccination at birth, axillary BCG adenitis (ipsilateral to the site of vaccination) is common following ART initiation in infancy but rarely requires medical intervention. Patients with TB-IRIS should almost always be continued on ART. Those with paradoxical TB-IRIS should be continued on anti-tuberculosis therapy and those with unmasking tuberculosis should be initiated on anti-tuberculosis treatment. The addition of corticosteroids is strongly recommended for patients with neurological involvement and for any life-threatening manifestation (e.g., massive

mediastinal adenopathy causing airway compression or rapidly enlarging pericardial effusion (together with pericardiocentesis)). Also, corticosteroids (starting at a dose of 1.5 mg/kg/day of prednisone) were shown in a clinical trial to provide more rapid symptomatic relief and reduce hospitalization in patients with IRIS that was not immediately life-threatening (Meintjes et al. 2010). Corticosteroids should only be prescribed when the diagnosis of paradoxical TB-IRIS is certain. Patients with mild symptoms can be offered symptomatic treatment alone. Therapeutic needle aspiration of fluctuant lymph nodes, symptomatic abscesses, and rapidly enlarging effusions is an important component of the management of IRIS. Guidelines for corticosteroid prescription in HIV-associated tuberculosis, including paradoxical TB-IRIS are listed in Table 6.

Prevention

Although ART has a major impact on reducing incidence of TB (~65% risk reduction), it is often initiated at low CD4 counts in high tuberculosis-burden areas and does not mitigate the heightened risk of tuberculosis associated with HIV completely. Reactivation of LTBI and transmission of active tuberculosis will therefore

Tuberculosis and HIV, Table 6 Use of corticosteroids in HIV-associated TB

Indication	Drug and dose
TBM or tuberculoma	Dexamethasone (or equivalent steroid) 0.4 mg/kg/day, reduce by 0.1 mg/kg every week until week 4 Thereafter 4 mg daily, tapering by 1 mg per week (total duration 6–8 weeks)
Paradoxical TB-IRIS with significant symptoms	Prednisone 1.5 mg/kg/day for 2 weeks Then 0.75 mg/kg/day for 2 weeks Some patients relapse on stopping steroids after 4 weeks and require steroids for longer duration and in such cases steroids should be restarted at 1.5 mg/kg/day and then weaned according to symptom control
Pericardial effusion	Corticosteroids not indicated

persist at high levels in areas of high HIV and tuberculosis prevalence despite expanding ART programs unless additional public health interventions are implemented. As a response to this, WHO launched the “3I’s” policy, a package of interventions for tuberculosis control that in addition to earlier ART initiation (regardless of CD4 count) includes intensive case finding, infection control, and isoniazid preventive therapy (IPT).

Universal early ART is standard of care in children with HIV infection, irrespective of CD4 count or clinical staging, and offers good protection against tuberculosis disease (Violari et al. 2008). However, as in adults, tuberculosis vulnerability remains elevated and WHO guidelines advise that all HIV-infected children in close contact with an infectious tuberculosis case, irrespective of age, should receive a course of preventive chemotherapy once active tuberculosis has been excluded; using a symptom-based approach (WHO 2014b). Reexposure to an infectious case justifies repeat preventive therapy, since past therapy provides no protection against reinfection. In sub-Saharan Africa, many women in their reproductive years are dually infected with tuberculosis and HIV. Active tuberculosis case finding among HIV-infected pregnant women

presents an important opportunity to decrease the perinatal risks for mother and baby. If a baby is born to a HIV-infected mother with active tuberculosis, it is essential to ensure that the mother is on antituberculosis and HIV treatment, while the baby is assessed for tuberculosis, HIV, and other congenital infections. In the absence of tuberculosis disease, the baby should receive preventive therapy if the mother remains symptomatic or has been on antituberculosis treatment for less than 2 months.

IPT is also a safe and effective measure to reduce tuberculosis in HIV-infected adults and has an additive effect when given together with ART. Studies in the pre-ART era demonstrated that IPT reduced the incidence of tuberculosis by 33% overall, with greater benefit (60%) and a reduction in mortality in those that are TST positive (Akolo et al. 2010). In Botswana, a recent randomised controlled trial showed a 74% reduced risk of tuberculosis in TST positive HIV-infected adults who received 36 months versus 6 months of IPT (Samandari et al. 2011). Clinical trial data from South Africa also suggest that long term (up to 6 years) IPT is without major complications and effective in ART-naïve patients with positive tuberculin skin tests (Martinson et al. 2011).

An ideal setting to upscale IPT is in ART clinics, where patients are already established in care and are more likely to adhere to IPT. In a clinical trial conducted in a high-burden area, 12 months of IPT reduced the incidence of tuberculosis by almost 40% when given together with ART. Importantly, benefit was also seen in the subgroup of TST-negative patients, thus removing the requirement for TST testing prior to IPT in this setting (Rangaka et al. 2014). Together, these findings have led to the WHO recommendation to provide IPT to all HIV-infected people in whom active tuberculosis is not suspected.

The two main exclusion criteria for IPT are medical contraindications to isoniazid (such as hypersensitivity to the drug, peripheral neuropathy, severe liver disease, or alcohol abuse) and evidence of active tuberculosis disease. Although the rates of isoniazid monoresistance in people who develop tuberculosis while on IPT are similar to controls,

*If TST -ve or not done continue for 1 year; if TST+ve continue for ≥ 3 years

Tuberculosis and HIV, Fig. 7 Approach to prescribing IPT

the potential for this complication is greater if patients with active tuberculosis are inadvertently placed on isoniazid monotherapy. WHO recommends using a 4-symptom screen for active case finding prior to initiating IPT, and any adult patient with current cough, fever, night sweats, or weight loss should not receive IPT until active tuberculosis is ruled out by a negative sputum culture and the symptoms have resolved. An approach to IPT in adults that synthesizes the evidence from different studies is presented in Fig. 7.

Despite the strong evidence base for efficacy and safety, large scale uptake of IPT amongst HIV-infected adults has been slow. The reasons

for this are complex but include toxicity associated with isoniazid, the long duration of therapy, and adherence concerns. Clinical trials have shown equivalent effectiveness, reduced toxicity, and higher completion rates with 3 months of isoniazid combined with a rifamycin compared to the longer courses of isoniazid monotherapy. However, WHO has not endorsed any other regimen besides isoniazid monotherapy for the prevention of tuberculosis, and further study is needed to evaluate the durability of short-course combination preventative therapy, particularly in HIV-infected patients in high tuberculosis-burden settings.

New Developments and Research Priorities

The collision of the HIV and tuberculosis epidemics has created a resurgence of tuberculosis as a global health crisis, and improved control of tuberculosis is an international public health priority. Global funding for tuberculosis research, however, needs to increase substantially if game-changing breakthroughs in tuberculosis diagnosis, treatment, and prevention are to be made. Although provision of ART and IPT will likely reduce tuberculosis incidence in high-HIV prevalence areas, this protection is incomplete and will not lead to achievement of the Stop TB Partnership and WHO goal of a tuberculosis-free world by the year 2050 without the discovery of novel preventive strategies.

Diagnosis. Early detection and treatment are important aspects of tuberculosis infection control and could help in reducing transmission in the community. Although Xpert has been a major advance in early tuberculosis diagnostics, it still lacks sensitivity compared with culture, especially in HIV-infected patients, and has not been shown to reduce mortality when used in clinics. The WHO symptom screen has a lower sensitivity when used for active case finding in HIV-infected patients on ART, and a better tool is needed to facilitate the scale-up of IPT in this high-risk population. Thus, the development of rapid low-cost point of care tests with a similar sensitivity to culture is a key research priority.

Treatment. A key obstacle to tuberculosis control is the reliance on prolonged and poorly tolerated treatment regimens, particularly for drug-resistant tuberculosis. This leads to suboptimal levels of adherence (which promotes further drug resistance) and treatment failures favoring ongoing transmission. Recent trials of treatment shortening regimens (to 4 months) for drug-sensitive tuberculosis have been disappointing. However, the drug development pipeline has yielded a number of new agents, some with novel mechanisms of action against *M. tuberculosis* and with promising results in clinical trials.

Bedaquiline is a diarylquinoline drug that inhibits mycobacterial ATP synthase and

demonstrates potent bactericidal activity against replicating and nonreplicating bacilli. In phase II clinical trials and in a larger open label study of patients with MDR-tuberculosis, including a number with HIV coinfection, the addition of bedaquiline to MDR regimens led to higher rates of culture conversion in a significantly shorter time. An important consideration with bedaquiline is that it prolongs the QT interval, potentially predisposing to tachyarrhythmias and requiring ECG monitoring. Bedaquiline cannot be coadministered with efavirenz due to its inducing effect on efavirenz metabolism; concomitant use with protease inhibitors increases bedaquiline concentrations two- to threefold, raising concerns about toxicity. Further study is needed to confirm the efficacy and assess safety of this promising new drug in HIV-coinfecting patients but results from patients in bedaquiline access programs are encouraging.

Other agents that have shown promise in clinical trials include linezolid, an oxazolidinone antibiotic that has been repurposed as an anti-tuberculosis agent; delamanid, a nitroimidazooxazole derivative that inhibits mycolic acid synthesis and demonstrates similar early bactericidal activity (EBA) to rifampicin; and pretomanid (PA824), a nitroimidazole that kills rapidly dividing and dormant bacilli with EBA comparable to isoniazid, suggesting a potential use in treatment shortening.

Prevention. The ultimate long-term intervention for the control of epidemic infectious diseases is effective vaccination. WHO recommends universal neonatal BCG vaccination in areas with moderate to high prevalence of tuberculosis. The efficacy rate has a wide range, from 0% to 80% in clinical trials; this variable protection against pulmonary disease is influenced by age of administration, geographic location, and environmental exposure to nontuberculous mycobacteria. Vaccination is most effective in mycobacteria-naïve newborns and infants in whom it reduces the risk of tuberculosis by about 80%, particularly meningitis and disseminated disease, and also results in a mortality benefit. Besides this incomplete protection to *M. tuberculosis* infection, the main drawback of BCG is that protective immunity is

lost in early adulthood when risk of HIV acquisition and tuberculosis disease is highest. The vaccine also performs less well in infants in sub-Saharan Africa where more frequent environmental mycobacterial exposures may “mask” and/or “block” immune responses to *M. bovis* antigens contained in the BCG vaccine. Furthermore, BCG vaccination is contraindicated in HIV-infected infants in whom it may cause disseminated BCG disease (Hesseling et al. 2006). WHO emphasizes that all pregnant women in tuberculosis- endemic settings should be tested for HIV infection and receive optimal care to prevent vertical HIV transmission. When a baby born to a mother with HIV-associated tuberculosis receives antituberculosis treatment or preventive therapy, a decision on BCG vaccination can be postponed until both the HIV and tuberculosis infection status is known.

These significant limitations have given impetus to the development of new vaccine strategies, but unfortunately, clinical trials of candidate vaccines have been disappointing to date. A recent phase 2 study of a promising Vaccinia Ankara virus-vectored vaccine termed MVA85A failed to demonstrate efficacy against tuberculosis disease or *M. tuberculosis* infection in HIV-uninfected infants primed with BCG in a high-burden setting, despite being immunogenic in animal studies and healthy adults. This vaccine also failed to show protection in HIV-infected adults. Understanding correlates of protection and identifying surrogate endpoints of protective immunity against active disease remain challenges in tuberculosis vaccine development and are important areas of ongoing research that could potentially accelerate vaccine development.

U

Uncoating and Nuclear Entry

Vaibhav B. Shah and Christopher Aiken
Department of Pathology, Microbiology and
Immunology, Vanderbilt University School of
Medicine, Nashville, TN, USA

Definition

Uncoating is defined as disassembly of the viral capsid and release of the viral ribonucleoprotein complex (vRNP), including the viral genome and its associated proteins, following fusion of HIV-1 with target cells. By contrast to most retroviruses, HIV-1 and other lentiviruses are capable of infecting nondividing cells. Entry into the nucleus of nondividing cells requires facilitated transport of the reverse transcribed viral genome across the nuclear membrane through nuclear pore complexes (NPC).

Introduction

Following budding from an infected cell, HIV-1 particles undergo a proteolytic maturation process that results in formation of the mature viral capsid, a distinct feature of the infectious virion. The viral capsid, consisting of a regular hexagonal array of capsid protein (CA) subunits in the shape of a cone, plays a critical role following entry into target cells. This overview describes the current

state of knowledge of the viral capsid and its functions in the early phase of HIV-1 infection, including the mechanism of uncoating and the interaction of CA with host factors that are necessary for nuclear entry and integration.

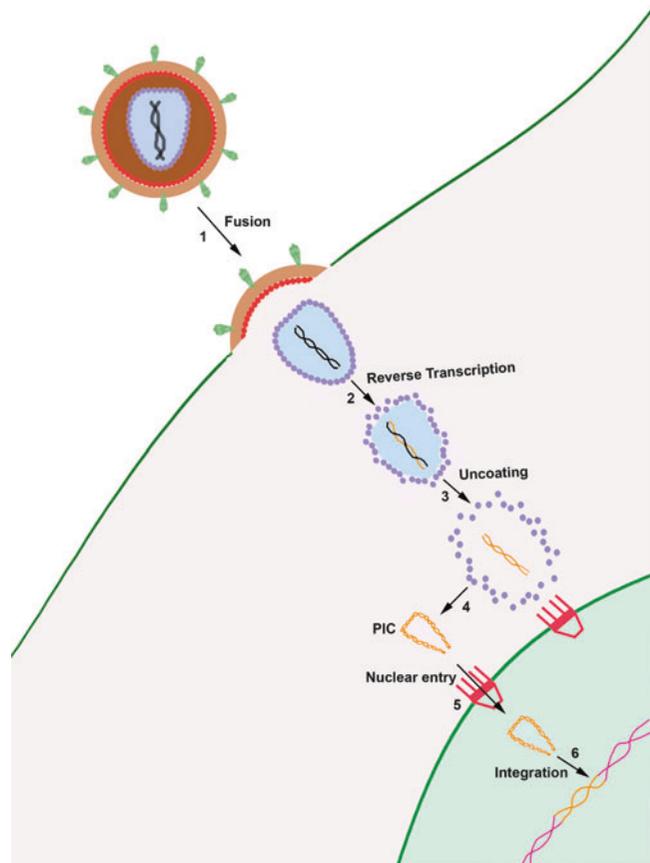

The HIV-1 life cycle can be divided into early and late phases. The early phase includes processes occurring before integration of viral DNA into the host genome. The late phase is comprised of post-integration processes including transcription, mRNA export, translation, particle assembly, budding from the host cell membrane, and maturation. The early phase (Fig. 1) begins with the fusion of the viral membrane with the cell membrane, enabled by binding of viral glycoproteins gp120 and gp41 to the host cell receptor CD4. Besides CD4, a coreceptor, CCR5 or CXCR4, is also required for fusion (► [HIV Life Cycle: Overview](#)). Upon fusion, the viral core is released into the cytoplasm where it undergoes reverse transcription and uncoating. Reverse transcription begins with the formation of a reverse-transcription complex (RTC) which subsequently converts into a high molecular weight DNA-protein complex termed the pre-integration complex (PIC), which is then transported into the nucleus where it integrates into the host chromosomal DNA.

The mature HIV-1 capsid is a conical structure comprised of ~1,500 CA subunits arranged as a fullerene cone (reviewed in Ganser-Pornillos et al. 2012; Fig. 2). The capsid is composed of ~250 CA hexamers and 12 pentamers, with 7

Uncoating and Nuclear Entry,

Fig. 1 Schematic of the early phase of HIV-1 infection.

(1) An HIV-1 particle fuses with the host cell membrane and releases its core into the cytoplasm. (2) While traversing the cytoplasm, the core undergoes reverse transcription and uncoating. (3) Uncoating occurs in the cytoplasm, but the temporal and spatial details of this step are not clear. (4) Upon completion of reverse transcription, the preintegration complex (PIC) is formed. (5) The PIC is imported to the nucleus through the nuclear pore complex. (6) In the nucleus, the viral DNA is integrated into the host chromosome.

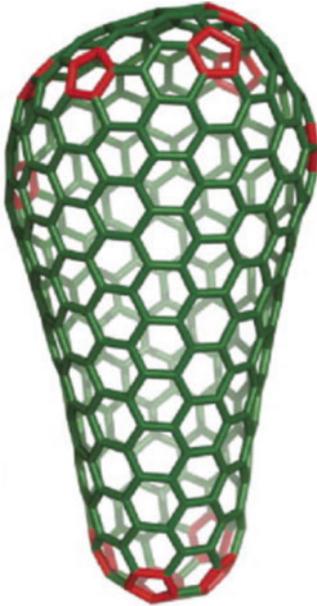

pentamers at the broad end and 5 at the narrow end. CA contains distinct amino-terminal and carboxy-terminal domains (NTD and CTD, respectively) joined by a flexible hinge. CA-NTD forms hexameric and pentameric rings that are connected by CTD-CTD intersubunit contacts.

The HIV-1 capsid is a metastable structure, and its main function is to properly deliver the viral genome and associated proteins into the cell. The architecture and stability of the capsid is important for HIV-1 infectivity: mutations in CA that alter the morphology of the capsid also compromise infectivity (reviewed in Ganser-Pornillos et al. 2012). Similarly, mutations in CA that alter the intrinsic stability of the capsid also impair viral infectivity (Forshey et al. 2002). While the structure of the HIV-1 capsid and its interactions with host proteins have received much attention in

recent years, the mechanism of uncoating, including temporal and spatial aspects, is poorly understood. Therefore, uncoating is a relatively new and active area of HIV-1 research.

Assays of HIV-1 Uncoating

Uncoating is challenging to study, owing to the difficulty of analyzing the process as it occurs in the target cell. Various approaches have been employed to study uncoating, including biochemical, imaging, and cell fractionation. One approach involved isolating reverse-transcription complexes (RTCs) from HIV-1 infected cells by sedimentation ultracentrifugation and probed for co-sedimented CA (reviewed in Arhel 2010). In another approach, CA was immunoprecipitated from HIV-1-infected cell extracts and assayed

Uncoating and Nuclear Entry, Fig. 2 Geometry of the HIV-1 capsid. The capsid is modeled as a cone consisting of a hexameric lattice with five pentamers at the narrow end and five at the broad end. The pentamers allow closure of the fullerene cone. The viral genome and associated proteins reside within the structure in mature HIV-1 particles (Reprinted from *Current Opinion in Structural Biology*, Vol. 18, B. K. Ganser-Pornillos, M. Yeager, and W. I. Sundquist, “The Structural Biology of HIV Assembly” pages 203–217 (2008), with permission from Elsevier)

for the levels of the associated viral genome by PCR. Only small quantities of CA were found associated with RTCs recovered from the cytoplasm of infected cells, which suggested that uncoating occurs within a few hours following cell entry.

A quantitative biochemical approach that has been employed involves isolation of purified cores from concentrated HIV-1 virions by detergent treatment of virions followed by sucrose gradient ultracentrifugation (Aiken 2009). Cores isolated from wild-type HIV-1 virions in this manner contain 10–15% of the CA present in the original virions. Incubation of these cores at 37 °C promotes their uncoating in a time-dependent manner. This cell-free assay permits analysis of the effects of CA mutations and

putative host factors on capsid stability. A variation of this approach allows study of uncoating in infected cells (Stremlau et al. 2006). This method, known as the “fate-of-capsid” assay, involves ultracentrifugation of infected cell lysates through a sucrose cushion and determination of the quantity of pelletable CA as a percentage of total CA within the cell. This assay is useful for studying the effects of host factors on uncoating as well as the uncoating of viral mutants in target cells.

Imaging-based assays to study uncoating in the cells have also been developed. A fluorescence microscopy-based assay that detects association of capsid with viral components following entry into cells has been described (Hulme et al. 2011). Results from this assay suggest that uncoating occurs relatively rapidly (within 1–2 h) after fusion. Similar to the fate-of-capsid assay, the imaging assay is also useful to study effects of CA mutations on uncoating in HIV-1-infected cells. A similar approach employs scanning electron microscopy in combination with immunolabeling of CA to visualize intracellular viral complexes (reviewed in Arhel 2010). In one study, intact cores were observed at the periphery of the nuclear membrane several hours after infection (Ref?), suggesting that uncoating occurs after docking to the nuclear pore, presumably following completion of reverse transcription.

Collectively, these assays have initiated an understanding of the process of uncoating and its importance in HIV-1 infection. However, there remains no clear consensus on the timing or location of uncoating within the cell. Biochemical assays are inherently limited due to the obvious lack of the complete repertoire of cellular components; by contrast, imaging-based assays must be interpreted carefully owing to the uncertainty of whether the virion being imaged represents an infectious event. The fate-of-capsid assay, which has proven useful for studying capsid-targeting inhibitors of infection including TRIM5 α , has yet to be fully validated as a bona fide uncoating assay and often exhibits a poor signal-to-noise ratio. Because each assay has its limitations, uncoating is currently best studied through a combination of approaches.

Uncoating and Reverse Transcription

CA mutations that alter intrinsic capsid stability and reduce viral infectivity frequently result in impaired reverse transcription in target cells (Forshey et al. 2002), suggesting a functional connection between reverse transcription and uncoating. A recent study has revealed a role for reverse transcription in promoting HIV-1 uncoating (Hulme et al. 2011). Using fluorescent-image-based and restriction-based assays, it was observed that pharmacological inhibition of reverse transcription slowed the rate of HIV-1 uncoating. Molecular events occurring in the core during the process of reverse transcription may apply pressure on the capsid and thereby promote uncoating. Interestingly, another study also demonstrated that reverse transcription is necessary for uncoating (reviewed in Arhel 2010). In HIV-1-infected cells treated with a reverse transcriptase inhibitor, imaging by scanning electron microscopy revealed intact HIV-1 capsids at the nuclear membrane and nuclear pore. Taken together, these studies provide compelling evidence that reverse transcription induces HIV-1 uncoating.

Modulation of Uncoating by Host Factors

The tripartite motif 5- α protein (TRIM5 α) is a cytoplasmic host factor that restricts retrovirus infection in a species-specific manner. TRIM5 α was originally discovered as a host factor that inhibits infection of old-world monkey cells by HIV-1 (Stremlau et al. 2006). TRIM5 α restricts a broad range of retroviruses, including HIV-1, HIV-2, simian immunodeficiency viruses (SIVs) from several primate species, N-tropic murine leukemia virus (N-MLV), and equine infectious anemia virus (EIAV) (reviewed in Luban 2007). Analysis of incoming HIV-1 particles by the fate-of-capsid assay has indicated that TRIM5 α results in accelerated uncoating (Stremlau et al. 2006). In addition, TRIM5 α also alters the normal passage of viral DNA to the nucleus. Human and new-world monkey TRIM5 α associate less

efficiently with the HIV-1 capsid and therefore do not restrict infection (Stremlau et al. 2006). In some monkey cells, TRIMCyp, a fusion protein derived from the TRIM5 α gene, also restricts HIV-1 by inducing premature uncoating of the capsid. These findings reinforce the conclusion that premature uncoating is detrimental to infection.

Cyclophilin A (CypA) is an abundant cytoplasmic host protein. It binds to the HIV-1 capsid and facilitates replication in a cell-type-dependent manner (reviewed in Luban 2007). Besides HIV-1, CypA interacts with a minority of lentiviral capsids, including SIVcpz and FIV. CypA appears to act at an early stage of HIV-1 infection before reverse transcription. Several lines of evidence suggest that CypA modulates HIV-1 uncoating. Depending on the target cell type, CypA may either stimulate or inhibit uncoating (Li et al. 2009). In addition, CypA also promotes restriction of HIV-1 by TRIM5 α in rhesus macaques and African green monkeys by an unknown mechanism (reviewed in Luban 2007).

Uncoating and Integration

In addition to reverse transcription, there is evidence for a link between uncoating and proviral integration. HIV-1 CA mutants T54A/N57A and Q63A/Q67A are impaired for infection yet are competent for reverse transcription and nuclear entry. In the case of Q63A/Q67A, PICs recovered from the cytoplasm contained more CA than the wild-type PICs and were impaired for integration *in vitro* (Dismuke and Aiken 2006). These mutants exhibit altered capsid stability *in vitro* and uncoating defects in target cells, suggesting that completion of uncoating is necessary for integration. The association of CA with PICs in the nucleus can also be inferred from artificial restriction factors generated by fusion of CypA with the mouse restriction factor Fv-1 or TRIM proteins. These engineered proteins recognize CA via CypA and restrict HIV-1 at a post-nuclear entry step. Moreover, the small-molecule Coumermycin-A1 inhibits HIV-1 infection at a step between nuclear

entry and integration, and mutation A105S in CA renders the virus resistant to the inhibitor (reviewed in Fassati 2012). Another mutation N74D in CA alters the integration pattern of HIV-1 to genomic regions sparse in transcription units, indicating that CA controls integration site preferences (Ocwieja et al. 2011). Collectively, these findings suggest that uncoating influences HIV-1 integration.

Small-Molecule Modulators of HIV-1 Uncoating

Highly active antiretroviral therapies (HAART) against HIV-1 have proven very effective in reducing viral loads and delaying progression to AIDS. However, emerging viral resistance against drugs even in the HAART era has pressed the need for novel classes of HIV-1 inhibitors. Since the viral CA protein plays important roles in both early and late stages of HIV-1 infection, it represents an attractive target for antiretroviral therapy.

As mentioned previously, HIV-1 uncoating is a finely tuned process, and the proper stability of the capsid during early post-entry stage is critical for efficient infection. PF-3450074 (PF74) is a member of a novel class of small-molecule compounds identified in a high-throughput screen for inhibitors of HIV-1 replication (Blair et al. 2010). Mechanistic studies of PF74 action demonstrated that the compound induces premature uncoating of the capsid prior to completion of reverse transcription. Serial passage of the virus in cells led to emergence of a resistant mutant with five point mutations in CA. The mutations inhibited binding of PF74 to HIV-1 particles. Interestingly, PF74 also affected a late stage of the virus life cycle, resulting in the production of particles with morphologically aberrant cores. The crystal structure of HIV-1 CA-NTD protein in complex with PF74 demonstrated that the compound binds a pocket on CA that had not been previously identified as a small-molecule binding site.

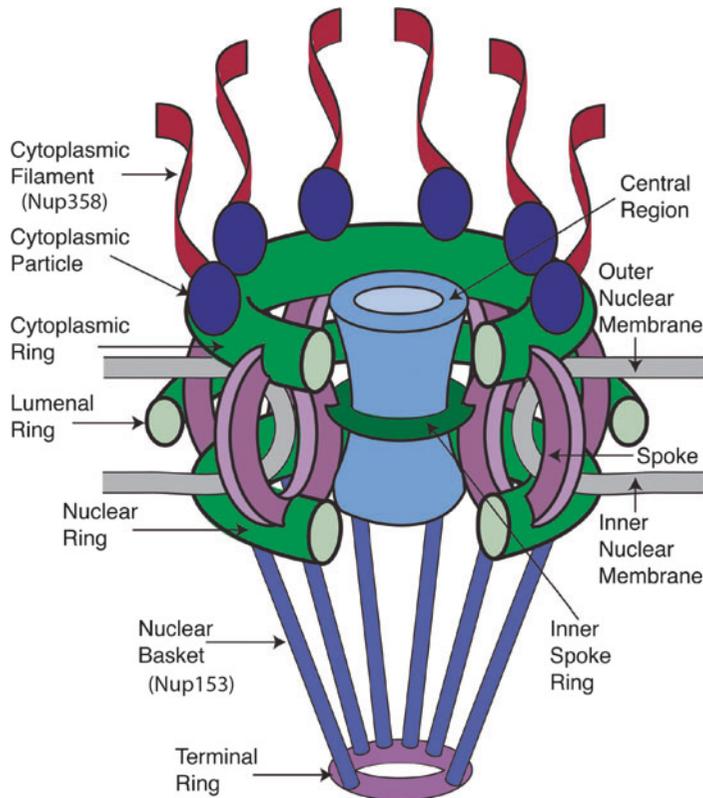

Another small-molecule compound, I-XW-053, was also identified as a specific inhibitor of HIV-1 replication (Kortagere et al. 2012). The compound bound CA protein in the NTD. Mutations I37A and R173A in CA caused pronounced decrease in

compound binding. Functionally, I-XW-053 inhibited HIV-1 reverse transcription, indirectly pointing to modulation of uncoating. Collectively, these studies underscore the potential of CA as a therapeutic target.

Uncoating and Nuclear Entry

A distinguishing feature of lentiviruses is their ability to infect nondividing cells such as macrophages and microglia. To infect a nondividing cell, the viral genome must traverse the intact nuclear membrane. Embedded in the nuclear membrane are nuclear pore complexes (NPC). NPCs are composed of ~30 different proteins known as nucleoporins (Nups), each in multiple copies per NPC (Fig. 3). In the center of the NPC, perpendicular to the nuclear membrane, is a central channel, called the nuclear pore, through which molecules can pass. Nuclear pores have a maximum diameter of 90 nm, a depth of 180 nm, and a mass of 125 MDa. The nuclear pore allows diffusion of ions and molecules smaller than 9 nm across the nuclear envelope and facilitated transport of molecules up to 39 nm in diameter. HIV-1 PICs are too large (~56 nm) to pass through the nuclear pore by passive diffusion and must therefore be actively transported through it in nondividing cells. Accordingly, several viral and cellular factors appear to control nuclear entry of the HIV-1 PIC.

Several viral proteins such as MA, Vpr, and IN were originally identified as components containing putative nuclear localization signals (NLS) and were therefore suggested to mediate the entry of HIV-1 into the nucleus. However, it now appears that none of these viral proteins is necessary for infection of nondividing cells. Genetic studies of chimeric HIV-1 viruses containing portions of the murine leukemia virus (MLV), which cannot infect nondividing cells, indicated that CA is the key (Yamashita and Emerman 2004). How does CA confer HIV-1 with the ability to traverse the nuclear pore? One potential explanation is that the uncoating is different between the two viruses. HIV-1 sheds its capsid quite early after infection, as evidenced by

Uncoating and Nuclear Entry, Fig. 3 Schematic of the nuclear pore complex. Embedded in the nuclear membrane, the NPC consists of a series of concentric rings surrounding a central channel with limited diameter. Cytoplasmic filaments containing Nup358/RanBP2 extend into the cytoplasm, while the Nup153-containing nuclear basket projects into the nucleoplasm. Other Nups project into

the pore, creating a hydrophobic channel through which proteins and RNA must pass (Reprinted from *Developmental Cell*, Vol. 4, M. Sundtharalingam and S. Wentz, "Peering through the Pore: Nuclear Pore Complex Structure, Assembly, and Function" pages 775–789 (2011), with permission from Cell Press)

the low abundance of CA associated with the RTC and PIC, morphological analysis of the RTC by electron microscopy, and ability of RNA aptamers and specific nucleoporins to interact with the incoming viral RNA genome. By contrast, MLV retains the capsid shell at least until nuclear entry, as evident by the higher amount of RTC-associated CA and electron microscopic examination of MLV-infected cells. Moreover, a CA mutant exhibiting higher levels of PIC-associated CA was impaired for nuclear entry (Dismuke and Aiken 2006). Thus, the rate and extent of uncoating may be key to HIV-1 nuclear entry in nondividing cells.

Host Cell Factors Influencing HIV-1 Nuclear Entry

Several genome-wide siRNA screens have identified host proteins that are important for early stages of HIV-1 infection. One widely studied factor is transportin 3 (TNPO3/TRN-SR2). TNPO3 is a member of the importin β superfamily of proteins, whose physiological function in the cells is translocation of proteins from the cytoplasm into the nucleus. Importins bind to their cargo in the cytoplasm and traverse through the nuclear membrane. Inside the nucleus, binding of RanGTP to the importin: cargo complex causes a

conformational change in the importin leading to release of cargo from the complex (reviewed in Fassati 2012). It was initially thought that TNPO3 facilitates nuclear import of HIV-1 via binding to IN. However, it is now apparent that CA is a major viral determinant of the TNPO3 dependence of HIV-1 infection and that TNPO3 does not facilitate nuclear entry. Moreover, TNPO3 was also shown to bind directly to the viral capsid and is necessary for efficient integration. Depletion of TNPO3 in target cells also alters the integration site preference of HIV-1; in TNPO3-depleted cells, HIV-1 predominantly integrated in gene-sparse regions versus normal cells where integration was observed in gene-dense regions (Ocwieja et al. 2011). Additionally, the CA mutant N74D, which does not depend on TNPO3 for infection, also favors integration into gene-sparse regions (Schaller et al. 2011). Collectively, these findings provide strong evidence for requirement of TNPO3 in a post-nuclear entry step in HIV-1 infection.

TNPO3 also promotes nuclear entry of the SR-rich proteins. Cleavage and polyadenylation specificity factor 6 (CPSF6) is an SR-rich protein which could be a potential candidate for TNPO3-mediated nuclear import. An artificially truncated form of this protein, CPSF6-358, reduces HIV infectivity at the level of nuclear import. Notably, CPSF6-358 is predominantly localized in the cytoplasm presumably because it cannot bind TNPO3; however, it can bind to capsid-like CA complexes *in vitro*. Thus, TNPO3 may act by sequestering endogenous CPSF6, which could otherwise delay HIV-1 uncoating, thereby inhibiting nuclear entry and/or integration.

Several nucleoporins were also identified as HIV-1 dependency factors in genome-wide siRNA screens. Nup153 is important for HIV-1 infection, and the viral determinant was mapped to CA (reviewed in Fassati 2012). Interestingly, the N74D mutation in CA reduced the dependence of HIV-1 infection on Nup153. Thus, Nup153 dependence of infection is genetically linked to the viral capsid. Depletion of Nup153 in target cells caused moderate reduction in HIV-1 nuclear entry but a pronounced reduction in integration.

Nup358/RanBP2 is also important for HIV-1 infection. This large protein contains a filamentous phenylalanine/glycine (FG)-rich domain that protrudes on the cytoplasmic side of the NPC. It also contains a cyclophilin-like domain on its C-terminus. HIV-1 CA binds directly to the Cyp-domain of Nup358/RanBP2, and depletion of Nup358/RanBP2 results in reduction in nuclear import. Thus, HIV-1 may engage the NPC via Nup358/RanBP2. This implies that some CA remains bound to the PIC prior to docking to the NPC. The ability to use Nup358/RanBP2 is dependent on CA-CypA interaction. In addition to nuclear import, depletion of Nup358/RanBP2 reduced integration of HIV-1 in gene-dense regions, and this may influence transcription of the integrated viral genome (Ocwieja et al. 2011).

Conclusion

Uncoating is a critical step in HIV-1 life cycle, but an understanding of the mechanism and timing of uncoating is incomplete. Through the development and application of biochemical, cell fractionation, and cell imaging approaches, it has become apparent that capsid stability is very important for efficient HIV-1 infection. Mutations in CA that modulate capsid stability affect reverse transcription, nuclear entry, and integration efficiency and targeting. Host restriction factors perturb uncoating and inhibit infection, while other host proteins promote HIV-1 infection by modulating proper uncoating and facilitating nuclear entry of the PIC. A more complete understanding of HIV-1 uncoating will facilitate the development of inhibitors targeting this key step in HIV-1 infection.

Definition

Dual HIV-1 and HIV-2 infection is the coexistence of the two viruses in an individual. It is most frequent in West Africa where HIV-2 is endemic. Dual HIV infection can be proven only by the presence of both HIV-1 and HIV-2 DNA or RNA using type-specific PCR for the isolation of both viruses from the same individual. However, HIV-2 RNA may not be detectable and therefore cannot be used as a diagnostic test. In addition, diagnosis based on rapid HIV testing, often used in West Africa, is often unreliable.

Introduction

Although human immunodeficiency virus type 1 (HIV-1) infection is responsible for most of the global AIDS pandemic, HIV type 2 (HIV-2) is an important cause of disease in a number of regions of the world. However, based on this origin (Kanki et al. 1987), HIV-2 epidemic has remained essentially confined to West Africa with a limited spread to other regions (Kanki et al. 1987). In West Africa, 9–16% of

Potential conflicts of interest: the authors do not have conflicts of interest

HIV-infected patients are estimated to be dually infected with both HIV-1 and HIV-2 (Chang et al. 2002; Rouet et al. 2004). Although dual seropositivity is common in the West African region, the true rate of dual infection remains unclear. Being infected by one type of HIV does not protect against the other type, and transmission may occur in patients already infected (e.g., superinfected). This entry provides information on the epidemiology, diagnosis, and clinical manifestations of dual HIV seropositivity, presenting the treatment options for these patients.

Epidemiology

Coinfection with both HIV-1 and HIV-2 occurs in countries where both viruses circulate, e.g., the West African region. The distribution of these two viral infections is both heterogeneous and unstable; however, HIV-1 and HIV-2 overlap in West Africa. In this region, the prevalence of dual infection with the two viruses has been ranged between 1% and 15% (Rouet et al. 2004; Holmgren et al. 2003; van der Loeff et al. 2006; van Tienen et al. 2011). It is not clear whether social factors, biological factors, or both account for the less worldwide spread of HIV-2.

In mid-1999, a study in Ghana, which included 854 outpatients, reported that HIV-1 infection alone accounted for 84.5% of cases, compared with 9.5% and 6.0% for HIV-2 and dual HIV-1/HIV-2 infection, respectively (Chang et al. 2002). A study in Guinea-Bissau, a country where HIV-2 infection is endemic, reported that in 2006, among the 2,548 people tested for HIV, 106 (4.2%) were HIV-1 infected, 100 (3.9%) HIV-2, and 12 participants (0.5%) positive for both viruses, thus indicating that dual HIV infection accounted for 10% of HIV-positive patients (da Silva et al. 2008). The incidence of dual HIV-1/HIV-2 seropositivity has also been estimated in Gambia. Indeed, in 1996, 654 participants (279 men and 375 women) were negative for dual infection and were then reexamined in 2006, which contributed to a total of 6,222 person-years. Four female participants had

become HIV-1/HIV-2 seropositive, which corresponded to an incidence of HIV-1/HIV-2 reaction of 0.06 per 100 person-years (da Silva et al. 2008). Another study at the sexually transmitted infections research clinic of the Medical Research Council (MRC) laboratories near the capital of Banjul in Gambia reported that the prevalence of dual HIV-1/ HIV-2 reaction varied between 0.8% (1988–1991) and 1.2% (1998–2000) over a 16-year observation period, and thus, the prevalence of dual HIV reaction neither increased nor decreased during this period. Dual HIV infection accounted for 4–6% of all HIV infections during the study period in these countries (van der Loeff et al. 2006).

Transmission and Disease Progression

HIV-1 and HIV-2 share the same transmission route via sexual contact, perinatal, or parental transmission. However, the frequency of transmission is less than that of HIV-1, which is most likely due to a very low viral load in many asymptomatic individuals (Kanki et al. 1994). HIV-2 is thought to have a protective effect against HIV-1 superinfection or limited HIV progression (Otten et al. 2004).

Several important issues raised about the impact of the dual-infection single host, for example, what is the potential for HIV-1/HIV-2 recombinant formation, are there synergistic or inhibitory mechanisms that result in distinct viral replication dynamics in dual-infected individuals compared to that of HIV-1 or HIV-2 in mono-infected individuals, and what factors should be considered when choosing antiretroviral regimens in HIV-1/HIV-2 dual-infected individuals? In nonhuman primates, HIV-2 was reported to have a protective effect against SHIV superinfection or HIV progression (Otten et al. 2004).

In the 1990s, there was controversy over whether infection by HIV-2 would protect against HIV-1 and whether the HIV-1 epidemic would, therefore, slow down in the regions affected by HIV-2 (Travers et al. 1995; Wiktor et al. 1999). Unfortunately, several subsequent studies did not find this protective effect

(Schim van der Loeff et al. 2001). It is important to distinguish coinfection from superinfection as well as reinfection with HIV-1 or HIV-2. One case of asymptomatic superinfection with HIV-1 subtype AG was reported in a woman infected with HIV-2 who did not have cross-neutralizing autologous HIV-1 antibodies before and soon after HIV-1 superinfection. This evidence supports a mechanism other than cross-neutralizing antibodies for the mild course of HIV-1 infection in this woman (Gunthard et al. 2009). In fact, superinfection is defined as the reinfection of an individual who already has an established infection with a heterologous HIV-1 or HIV-2 strain. Reports in West Africa noted that dual HIV reaction was more common in older women (Holmgren et al. 2003) and the clinical manifestations of dual HIV infection are similar to those of HIV-1.

Finally, infection with both HIV-1 and HIV-2 generally carries the same prognosis and a similar mortality rate as HIV-1, except one study in rural community in Gambia which reported lower mortality among HIV-2-infected patients (van Tienen et al. 2011). Two studies in Guinea-Bissau found conflicting results: (1) among 285 HIV-2- and 53 dual-infected patients, there found no difference in mortality with follow-up to 19 years in rural Caio (van Tienen et al. 2011), and (2) among 223 patients that included 32 dually infected (14.3%), it was suggested that being infected with HIV-1 and HIV-2 is associated to a slower rate of disease progression particularly in patients in whom HIV-2 infection preceded HIV-1 infection. These observations in a cohort with a long follow-up (approximately 20 years) showed that HIV-2 has an inhibitory effect of the rate of HIV-1 disease progression (Esbjornsson et al. 2012). In this latter study, the rate in CD4+ T-cell percentage was similar with 1 infection only and dual infection, with an average decline of 1.2% per year ($P = 0.36$, with the use of a mixed model with interaction term removed). However, the CD4+ T-cell percentage was significantly higher in participants with dual infection (31.3%) than in those with HIV-1 infection only (23.3%) ($P < 0.001$) (Esbjornsson et al. 2012).

Screening and Diagnosis of Dual Infection with HIV-1 and HIV-2

The detection of HIV-2 infection is based on the demonstration of virus-specific antibodies using enzyme-linked immunosorbent assay-based techniques. In suspected HIV-1/HIV-2 cases, dual seroreactivity of both HIV-1 and HIV-2 alone is not sufficient for diagnosis. Dual infection can be proven only by the presence of both HIV-1 and HIV-2 DNA or RNA using specific PCR for the isolation of both viruses from the same individual (Peeters et al. 1992). However, HIV-2 RNA may be negative and, therefore, cannot be used to rule out dual infection. HIV-2 proviral DNA may be low or repeatedly negative in certain asymptomatic individuals, thereby confounding the diagnostic confirmation (Damond et al. 1998).

Serology based on specific synthetic peptides has proven to be useful for diagnosing dual infection. In West Africa, rapid HIV assays are being used for the diagnosis of dual reactivity. The serological diagnosis of dual infection is based on similar high levels of antibodies binding to the immunodominant epitope of gp41 as well as the V3 region of both HIV-1 and HIV-2.

In West Africa, current serological tests for the diagnosis of HIV-2 include the following, and two consecutive rapid tests are recommended by the national HIV program:

- For screening purposes: Determine (Abbott Diagnostic Division, Hoofddorp, Pays-Bas, Netherlands), ELISA (Murex Diagnostics Limited, Dartford, United Kingdom), and Murex ICE VIH 1.0.2 (Abbott, Murex Diagnostics Limited, Dartford, United Kingdom).
- In case of positivity with screening tests: Genie II HIV-1/2 (Bio-Rad Laboratories, Marnes-la-Coquette, France), ImmunoComb HIV 1&2 BiSpot II (Orgenics Ltd., Yavne, Israel), Bioline HIV-1/2 (Standard Diagnostics, Inc., Republic of Korea), or western blot analysis.
- Final confirmation is performed using Pepti-LAV 1–2 (Bio-Rad Laboratories), HIV-1 and HIV-2 western blot analyses, and HIV-1- and HIV-2-type-specific DNA PCR and is dependent on the type of tests used in the laboratory.

Update on HIV-1 and HIV-2 Dual Infection, Table 1 Serological and viral characteristics of 35 women diagnosed on-site with dual HIV-1 and HIV-2

HIV test used	HIV-2 n (%)	HIV-1 n (%)	HIV-1 and 2 n (%)	Negative n (%)
Pepti-LAV assay	19 (54.3)	2 (5.7)	14 (40.0)	–
Western blot for HIV-1 and HIV-2	17 (48.6)	3 (8.6)	15 (42.8)	–
Homemade EIAs (gp41/36 and V3)	20 (57.2)	6 (17.1)	9 (25.7)	–
HIV-1 and HIV-2 proviral DNA detected by real-time PCR assays	17 (48.6)	6 (17.1)	9 (25.7)	3 (8.6)

infection using the Genie II assay (Adapted from Rouet et al., Abidjan, Côte d'Ivoire (Rouet et al. 2004))

In the final meeting report of the Réseau Africain des praticiens assurant la prise en charge médicale des personnes vivant avec le VIH/SIDA (African Network of Practitioners on AIDS (ANEPA)) (RESAPSI) and the International epidemiological database to evaluate AIDS (IeDEA), workshops on HIV-2, it was stated that 30–70% of HIV-1 + HIV-2 seroreactive patients are misdiagnosed, and the use of rapid testing is not recommend for diagnosis due to the unreliability of these methods (RESAPSI et al. 2011; RESAPSI et al. 2009). For example, in 2004, a study in Abidjan assessed dual reactivity in specimens from HIV-infected patients using the Genie II assay. Rouet et al. (Table 1) demonstrated that the rates of concordance between real-time PCR and serological assays were 25.7%, 82.9%, 74.3%, and 80.0% for the Genie II, Pepti-LAV, WB, and custom ELISA assays, respectively (Rouet et al. 2004).

A cohort of 47 HIV-1 and HIV-2 dually seropositive individuals from Senegal, West Africa, was screened for the presence of HIV-1 and HIV-2 gag and env PBMC viral DNA sequences using PCR. Of the 47 dual HIV-1/HIV-2 seropositive individuals that were tested, 19 (40.4%) had infection with both HIV-1 and HIV-2, which was confirmed by genetic sequence analysis, whereas HIV-1 or HIV-2 was confirmed in 17 (36.2%) and 9 (19.1%) of cases, respectively (Gottlieb et al. 2008a). Due to the lack of commercially available tests, or assays approved by the Food and Drug Administration (FDA), HIV-2 RNA levels generally cannot be monitored in patients that have started ART. Certain HIV-1 RNA assays, such as the Roche AMPLICOR HIV-1 Monitor and NucliSENS EasyQ, may detect HIV-2 RNA. However, these commercial HIV-1

assays are not approved for the quantification of HIV-2 RNA. A report has also shown that ImmunoComb had a high degree of concordance with PCR testing and provided confirmation of HIV-1/HIV-2 dual infection (Walther-Jallow et al. 1999). Recently, a highly sensitive HIV-2 VL assay that is suitable for clinical and research use was developed (Chang et al. 2012).

Clinical Manifestations

In the pre-ART era, studies showed that people reactive to both HIV-1 and HIV-2 as well as those who were infected to HIV-2 had a frequency of AIDS-associated symptoms and signs similar to that in HIV-1-infected patients (Whittle et al. 1992). In the IeDEA West Africa Collaboration Cohort, dual-infected patients tend to present at a more advanced stage of the disease than those with only HIV-2 (44% vs. 36%) (Drylewicz et al. 2010). Preliminary data showed that patients on ART that were infected with both HIV-1 and HIV-2 were younger (40 years at the initiation of ART) and were more likely to be men (46%) than those infected with HIV-1 (37%) (Drylewicz et al. 2010) and HIV-2 mono-infection (Holmgren et al. 2003; Schim van der Loeff et al. 2002).

Antiretroviral Therapy for HIV-1/HIV-2 Dual Infection

There has been minimal experience regarding the use of antiretroviral therapy for HIV-2 infection as well as HIV-1 and HIV-2 coinfection. In coinfecting patients, HIV-1 typically outcompetes the lower replicative capacity of the HIV-2 virus

(Koblavi-Deme et al. 2004). This assumption is supported by frequent reports of low viral loads in the majority of studies that compared HIV-2-infected and HIV-1-infected persons (Koblavi-Deme et al. 2004). These findings suggested that in vivo immunodeficiency must be driven mainly by HIV-1 in coinfecting persons. Accordingly, the treatment of HIV-1 infections may be considered a priority in coinfecting persons.

When to Start Treatment

The lack of randomized treatment studies in dually reactive patients makes it difficult to determine when therapy should be initiated (Gottlieb et al. 2008b). The treatment of dually infected individuals should be performed using an HIV-2 active regimen to ensure effective treatment of both viruses. Given that the HIV-2 plasma viral load is usually undetectable or low in dual infections, both viruses should be treated and monitored. WHO guidelines for middle- and low-income resource countries recommended to start ART for HIV-1 + HIV-2 as the same threshold than HIV-1 below 350 cells/mL (WHO 2010). The results obtained with the HIV-2 cohort ANRS C05 showing lesser immunological response to ART in HIV-2 infected patients compared with those only infected with HIV-1 (Drylewicz et al. 2008). These findings have not been documented in HIV-1-/HIV-2-infected patients. So in France, the threshold to initiate ART in dual infection is similar for HIV-2 mono-infections (<500 cells/mm³). In developed countries where viral load measurement is available for the two viruses, HIV-2 viral load (>100 copies) should be a criteria to start above 500 CD4 cells/. (Ref)

Clinical Studies

Clinical studies of HIV-2 infection have been limited to a small number of case series and cohort reports. Based on a case series study at Bichat Claude Bernard Hospital, Landman et al. (2009) reported that 36 patients were identified as being dual seropositive for HIV-1 and HIV-2. This diagnosis was confirmed by specific env (V3 and gp36) peptide serology and HIV-1 and HIV-2 western blot analyses. Among these 36 patients, 17 (10 women) with regular clinical,

immunological, and virological follow-up for at least 1 year were included in the retrospective observational study. Eleven patients received 1 to 7 different antiretroviral regimens. At the time of the first-line regimen, the median CD4 cell count was 130 cells/mm³ (16–290), the median HIV-1 viral load was 4.6 log copies/ml (2.8–5.8), and HIV-2 viral loads were detectable in two patients (4.47 and 4.74 log copies/ml). After a median follow-up of 2.6 years (0.3–7.6), the median CD4 cell count was 338 cells/mm³ (102–654), and plasma HIV-1 and HIV-2 RNA were undetectable in 10 of 11 cases. The ongoing treatment included lopinavir/ritonavir in nine cases and two or three nucleoside reverse transcriptase inhibitors. Detectable HIV-2 plasma RNA was observed in two of the 11 patients during their follow-up. Jallow et al. reported that in Gambia, eight dually infected individuals were successfully treated with AZT/3TC/LPV/r, and a complete suppression of both viruses for more than 3 years was achieved (Jallow et al. 2009). In the IeDEA West Africa collaboration, which studied changes in CD4 levels over a 12-month period in patients taking ART, the observed baseline median CD4 counts were marginally comparable in the three groups: 155 cells/μL in HIV-1-positive patients ($n = 9,842$), 148 cells/μL in HIV-2-positive patients ($n = 270$), and 152 cells/μL in dually positive patients ($n = 321$) ($P = 0.52$). Among patients treated with a PI-containing regimen, the CD4 response did not differ significantly between HIV-1-positive, HIV-2-positive, and dually reactive patients before ($P = 0.73$) and after 3 months of treatments ($P = 0.37$). The estimated CD4 counts at 12 months were similar in HIV-2-positive (278 cells/μL, CI = 248; 307, $P = 0.22$) and dually positive (271 cells/μL, CI = 238; 303, $p = 0.25$) patients compared to HIV-1-positive patients (303 cells/μL, CI = 292; 315) (Drylewicz et al. 2010).

Options for ART Regimen Sequencing in HIV-1/HIV-2 Dual Infection

Given the different susceptibilities of HIV-2 strains to protease inhibitors as well as the more

Update on HIV-1 and HIV-2 Dual Infection, Table 2 Preferred and alternative first-line and second-line regimens in HIV-1 and HIV-2 dually reactive patients

	First line	Second line
Preferred regimen	2 NRTIs + boosted HIV-2 active PI	2 NRTIs + boosted PI ± INI
	Zidovudine (ZDV) + lamivudine (3TC) or tenofovir (TDF) + 3TC or emtricitabine (FTC)	TDF + 3TC/FTC if ZDV + 3TC first line ZDV + 3TC if TDF + 3TC/FTC first line
	+ <i>Lopinavir/r or saquinavir/r or darunavir/r</i>	+ <i>Darunavir/r + raltegravir or elvitegravir/c</i> <i>if lopinavir in first line</i>
Alternative regimen	3 NRTIs	2 NRTIs + boosted PI ± INI
	TDF + 3TC or FTC + ZDV if CD4 > 200 cells/mm	TDF + 3TC/FTC + <i>Saquinavir/r or lopinavir/r or darunavir/r</i> <i>Or boosted PI + raltegravir or elvitegravir/c</i>
	2 NRTIs + 1 INI	2 NRTI + PI/r
	ZDV + 3TC or TDF + 3TC or FTC + <i>raltegravir or elvitegravir/cobicistat</i>	TDF + 3TC/FTC if ZDV + 3TC first line ZDV + 3TC if TDF + 3TC/FTC first line + <i>lopinavir/r or saquinavir/r</i>

NRTI nucleos(t)ide reverse transcriptase inhibitor, *PI* protease inhibitor, *PI/r* protease inhibitor boosted with ritonavir, *INI* integrase strand transfer inhibitor

limited options for the treatment of HIV-2 infection, there is a need for caution prior to initiating antiretroviral therapy in patients with both HIV-1 and HIV-2 infection. In the case of dual infection, antiviral drugs active against both viruses should be given, and both plasma HIV-1 and HIV-2 RNA levels should be periodically measured. The recommended regimen should be similar to the regimen recommended for HIV-2 patients. Treatment-naïve, coinfecting patients should be treated with ritonavir-boosted protease inhibitors plus 2 NRTIs. If treatment fails, the resistance patterns of both viruses should be evaluated. Some protease inhibitors such as nelfinavir, atazanavir, or fosamprenavir are less effective against HIV-2 and may be used as part of a regimen for HIV-1-/HIV-2-reactive patients if adequate treatment for HIV-2 is also included.

The preferred option in first line should be 2 NRTI plus lopinavir/r particularly in resource-limited settings, ideally TDF/FTC/LPV/r. Lopinavir resistance in HIV-2 occurs with the V47A mutant, and evidence suggests V47A retains susceptibility to saquinavir making it an attractive choice in second line. The issue there is the risk of HIV-1 PI cross-resistance to saquinavir. Thus, the recommendation in case of dual infection if genotype test is not available is to use

darunavir/r as a second-line PI ideally with an integrase inhibitor. Initiating second-line therapy following a confirmed failure with a boosted PI must be considered as a salvage therapy based on genotype test. In fact, using a PI-sparing first-line regimen (e.g., INI based) in dually infected patients may allow them a potent second-line regimen based on a boosted PI plus 2 NRTI and a chance at an effective third-line regimen that is determined by genotyping.

In this case, the sequencing regimen could be based in the first line on 3 NRTI or 2 NRTI plus an integrase inhibitor (e.g., raltegravir) (Table 2). The advantages of a raltegravir- or elvitegravir-based are that HIV dually infected patients may spare PI regimens in first line and represent an alternative in case of tuberculosis with rifampin-based regimen. Currently, rifabutin, a safe and effective alternative to rifampicin, is not available and affordable in resource-limited settings. To date tuberculosis programs provide only rifampicin in most resource-limited settings (RLS). A less than optimal regimen in dually infected patients with TB coinfection in RLS is a 3 NRTI-regimen; however, failure rates in mono-HIV-1 infection are high, and in HIV-2, 3 NRTIs are less potent below 200 CD4 cells/mm³ and the higher failure rate reported comparing to PIs boosting regimen

(Benard et al. 2011). The main limitation of an INI regimen is the cost 7–10 as high as 3 NRTI regimens. Despite limited cases, most of the data of the efficacy of integrase inhibitors are in vitro study. Genetic barrier is low, and the risk of rapid resistance emergence is a key issue (Roquebert et al. 2008). The advantages are to reduce of pill burden, with a possibility of one pill once a day if TDF/FTC/EVG/c is used, a strong option in first line for HIV dually infected patients.

The second-line treatment regimens are the same for those with HIV-1 infection. Landman and colleagues reported good viral response to raltegravir combined with an active protease inhibitor (e.g., darunavir) (Landman et al. 2009).

Monitoring of Treatment Responses and HIV-2 Drug Resistance

Immunological and virological follow-up of both HIV-1 and HIV-2 in dually seropositive patients is recommended. In the case of dual infection, both plasma HIV-1 and HIV-2 RNA levels should be periodically measured because the replication of both viruses can occur before ART treatment is initiated. A French cohort reported HIV-2 protease resistance mutations in two cases, which emphasizes the importance of selecting drugs that are active toward both viruses (Landman et al. 2009). These two patients had received atazanavir/ritonavir and did not respond to the subsequent lopinavir/ritonavir regimen. These findings are consistent with the several studies that report reduced HIV-2 sensitivity to several protease inhibitors, which include atazanavir/ritonavir, fosamprenavir/ritonavir, and tipranavir/ritonavir.

Conclusion

The diagnosis of dual HIV infection remains difficult without the measurement of both viruses by PCR and the appropriate detection algorithms when using a serological testing Tchounga et al. 2014. Immunological and virological follow-up of both HIV-1 and HIV-2 in dually seropositive patients is recommended.

HIV dual infection may not be a static condition. Levels of HIV-2 may decrease with disease progression or sequester in tissue reservoirs. The choice of ART treatment should consider the efficacy of drugs toward both viruses. A limited number of studies are available on dual HIV infection, and we encourage a large prospective cohort to better describe their experience regarding the management of both the HIV-1 and HIV-2 viruses in coinfecting individuals Landman et al. (2009).

Use of Technology and Social Networking in HIV Prevention

Nadav Antebi and Eric W. Schrimshaw
Sociomedical Sciences, Mailman School of
Public Health, Columbia University, New York,
NY, USA

Definition: Technology and Social Networking

In this discussion, the term *technology* is used to specifically refer to various devices used to access the Internet, including both traditional desktop and laptop computers, and more recent mobile technologies, such as tablets and smartphones. The term *social networking websites* (web 2.0) is used to refer to Internet applications in which the content of a website is mostly driven by the users of the site (Rietmeijer and McFarlane 2009). These technologies are widely used for social communication, enabling them to be used for HIV prevention among both at-risk populations and the general public.

Background

The proliferation of new technologies and social networking websites creates new and exciting opportunities for HIV prevention. Used by more than 273 million people in the United States and over two billion people worldwide, the Internet has undoubtedly changed how its users access information and communicate. Social networking websites (e.g., Facebook, Twitter, Google+, YouTube) are increasingly popular, with 68% of Internet users accessing such websites at least once per month (eMarketer 2013). Similarly, increasing numbers of people from diverse social groups (e.g., ages, genders, and races/ethnicities) are now owners of mobile devices such as smartphones and tablets, connecting billions of users to the Internet.

These trends allow the general public to easily retrieve and share health information from across the globe. Population-based studies have found

that 59% of US adults have consulted the Internet for health-related information in the past year (Pew Internet and American Life Project 2013). Additionally, 15% of all adults who access social networking websites have used them to seek out health-related information (Pew Internet and American Life Project 2013). Altogether, these technologies and websites represent important opportunities to enhance targeted recruitment for HIV prevention and interventions among Internet users.

Technology/Virtual Space as a New Sex Venue

In the past decade, the Internet has been increasingly utilized as a means to seek romantic and sex partners (Chiasson et al. 2006; Liao et al. 2006), replacing other traditional venues for meeting partners such as neighborhoods, friends, and the workplace (Ross 2005; Rosenfeld and Thomas 2012). Indeed, a large US study (Cooper et al. 2002) found that 9.8% of the people using the Internet for online sexual activities were also using it to find people to date. Potential partners can be found through numerous online venues, such as chat rooms, discussion forums, instant messaging systems, web-based personal advertisements, websites soliciting sex (Liao et al. 2006), and dating websites, mobile device applications (i.e., apps), and social networking websites.

The Internet facilitates communication of sexual desires as well as increased numbers of sexual and romantic in-person meetings (Ross 2005) due to its accessibility, affordability, and anonymity (Cooper 1998). This facilitating effect of the Internet on sexual behavior applies to both heterosexual and nonheterosexual individuals (Rosenfeld and Thomas 2012). Gender differences have been noted in individuals' preferred online sexual activity. For example, men most frequently use the Internet to view sexually explicit material (i.e., pornography), whereas women often use the Internet to stay in contact with existing sex or love partners (Cooper et al. 2002).

The Internet is especially useful as a sex venue when partners are particularly hard to find.

Individuals who face a smaller market for meeting potential partners, such as gay men (including men who have sex with men, or MSM), lesbians, bisexuals, and middle-aged or older heterosexuals, are especially likely to use the Internet for this purpose (Ross 2005; Rosenfeld and Thomas 2012). These groups may prefer online sex venues rather than offline locations because of their heightened perceived privacy and safety as well as their anonymity, accessibility, and affordability (Cooper 1998). As such, same-sex couples have a remarkably higher rate of meeting through the Internet (>60% compared to 22% for heterosexual adults) (Rosenfeld and Thomas 2012).

Although gay men, bisexuals, and other MSM represent approximately 2% of the US population, they are one of the populations most severely affected by HIV (Centers for Disease Control and Prevention 2013). Compared to other groups, MSM utilize the Internet as a primary means for sexual and romantic partners. Chiasson et al. (2006) noted in their review article that MSM who use the Internet to find sex partners are younger, are more likely to frequent public and commercial sex environments, do not identify as gay, report sex with women, and are more likely to have a previous sexually transmitted infection (STI) compared to MSM who do not use the Internet to find sex partners. More recently, researchers have begun to explore heterosexuals' use of the Internet for seeking sexual partners. Available evidence suggests that heterosexuals' use of the Internet to meet partners for both short- and long-term romantic and sexual relationships is increasing rapidly (Cooper 1998; Rosenfeld and Thomas 2012). Thus, further investigation of the Internet as a mediator of sexual (risk) behaviors among heterosexuals is needed to elucidate the processes and mechanisms unique to this community.

Technology/Virtual Space as a New STI/HIV Risk Venue: The Contribution of Technology to HIV/AIDS Risk

The Internet is already being conceptualized as a risk environment that can facilitate the spread of

HIV and other STIs. Research supports the notion that people who use the Internet for sexual purposes experience a sense of disinhibition due to the vast variety of sexual interests and activities available to them, such as viewing pornography, engaging in cybersex, and seeking sex partners online. Moreover, it has been proposed that the disinhibition experienced online might expedite and carry over into offline sexual behavior. Conversely, it has been suggested that the distance afforded by the Internet allows people to reassess sexual boundaries and to experiment with one's sexuality, which may have a positive influence on one's sexual experience and well-being (Ross 2005).

Existing empirical evidence supports the conceptualization of the Internet as a fairly new HIV/STI risk venue. People who seek sex on the Internet are more likely to have concomitant risk factors for HIV/STI than people who do not seek sex on the Internet (McFarlane et al. 2000). In fact, some scholars further argue that for populations with levels of education and income sufficient to support computer use, the Internet has become an efficient facilitator of behavior and practices that have been taking place for many years among certain high-risk individuals (Toomey and Rothenberg 2000).

Most of the research conducted on Internet-mediated sexual behavior, so far, has focused on MSM (Chiasson et al. 2006). In their meta-analytic review article of online sex-seeking MSM, Liau et al. (2006) reported that 40% of MSM use the Internet to look for sex partners, and those who seek sexual partnerships online have riskier sexual behavior profiles than their counterparts who do not use the Internet to meet partners. Serosorting tendencies (i.e., condomless anal intercourse (CAI) between men of the same serostatus) are more prevalent among MSM who look for partners online versus MSM who do not. Furthermore, HIV-positive men who meet sexual partners through the Internet are more likely to report CAI with other HIV-positive men (Liau et al. 2006). HIV-negative men with online partners are also more likely to report having HIV-positive partners and more likely to report CAI with serodiscordant partners. It is hence plausible that the Internet may be creating a network of

high-risk men, facilitating transmission of HIV and other STIs among its sex-seeking users, who may also spread infection to other partners met offline (Liau et al. 2006).

Technology/Virtual Space as a New Prevention Venue

The Internet is rapidly becoming an important site for HIV prevention and other STIs due to its wide outreach and availability as well as its affordability and perceived privacy. Additionally, the Internet has numerous advantages relevant to HIV prevention efforts, including interactivity and multimedia features, the ability to deliver individualized content (Noar and Willoughby 2012), the ability to reach diverse and geographically dispersed populations (Chiasson et al. 2006), the automated delivery of interventions, and rapidly-attained large sample sizes (Birnbaum 2004) which can result in lower program costs (Rietmeijer and McFarlane 2009). There are three categories of existing HIV/STI prevention interventions on the Internet: (1) enhancing STIs and HIV testing, (2) increasing partner notification and treatment, and (3) encouraging behavior change for the prevention of HIV and other STIs (Rietmeijer and Shamos 2007).

Social networking websites are also increasingly used for the purpose of HIV prevention. Social networking websites serve HIV prevention efforts in three main areas: (1) as sources of publicly available information, (2) as intervention venues, and (3) as recruitment tools (Young 2012). The potential of utilizing social networking websites for HIV prevention purposes is enormous. 13% of US adults have gone online to find others who might have health concerns similar to theirs. Seven percent of US adults have gotten any health information on these websites (Pew Internet and American Life Project 2013). Social networking websites are an exciting prevention platform given their potential to reach vulnerable populations such as adolescents and young adults. Indeed, adolescents are gradually spending large amounts of time on these

websites (Pew Internet and American Life Project 2013).

There is growing evidence that the use of different technologies and Internet applications leads to improved health and health care. Numerous studies have demonstrated the effectiveness of computer- and Internet-based programs in promoting HIV/STI awareness and safer sex knowledge, attitudes, self-efficacy, and other theoretical mediators of safer sex. More importantly, such interventions have been found to increase reported safer sexual behaviors, most notably condom use, among its participants (Noar and Willoughby 2012).

Recent evidence suggests that MSM who frequent a variety of (offline) venues can also be reached on the Internet (Groves et al. 2013), thus potentially broadening the impact of prevention messages delivered in virtual environments. In fact, many MSM access HIV prevention information online. Some scholars suggest that men who seek sex with men on the Internet may be particularly in need of Internet-based HIV prevention because they tend to be more educated, insured, and less likely to be exposed to offline public health messages (Bull et al. 2001; Chiasson et al. 2006). Other unreachable populations, such as men resistant to in-person prevention efforts and high-risk individuals, like HIV-positive men who use the Internet for sex and are engaged in high-risk practices, may also be successfully targeted through the Internet (Chiasson et al. 2006).

Although not yet well studied, mobile devices are another useful tool for HIV prevention dissemination. Young adults are much more likely than older adults to have a smartphone and to use it to look for health information. Nearly 10% of US adults who have mobile phones – and more than half of American adults currently own one (Pew Internet and American Life Project 2013) – have registered to use a mobile health app (Pew Internet and American Life Project 2013). Smartphone applications designed for the dissemination of health-related information, social networking, and romantic and sexual partnering are an understudied platform for HIV prevention that may attract various high-risk and vulnerable populations such as MSM, Latinos,

and African Americans. In fact, it was found that Latinos and African Americans are more likely than Whites to own a smartphone and that African Americans are also more likely than Whites to connect to the Internet using their smartphone (Pew Internet and American Life Project 2013). Smartphone applications can also be used for seeking sex partners. For example, Grindr is a GPS-based application designed for social networking as well as romantic and sexual partnering among MSM and is extremely popular with millions of users worldwide. These features make Grindr and similar mobile devices apps potentially useful for different types of HIV prevention among MSM and possibly other populations.

Suggested Guidelines for Designing Online Prevention Intervention

When designing an online prevention intervention program/application, several issues should be taken into consideration. First, technologies are constantly being developed and modified, and prevention interventions require thorough understanding and technical proficiency of the specific program being used. Moreover, each online environment has its own unique microculture and norms that are usually acquired and learned through active participation. For those reasons, it is highly recommended to include a program collaborator who is an expert in the field of online technologies and cultures as early as possible in the planning process (Gold et al. 2012; Young 2012). Second, different populations have different levels of technological skills, knowledge, and health literacy. Thus, it is important to be familiar with these characteristics of the target population and design the program with its intended users in mind. Third, when dealing with online settings, it is somewhat more difficult to measure and monitor which health information and delivery mechanisms users were exposed to. Hence, it is crucial to predetermine desirable outcomes and to define what would be considered as a successful prevention program (Gold et al. 2012). Fourth, it is necessary to address users' privacy and

confidentiality issues by getting familiarized with the common concerns of the targeted population as well as the hosting technology (e.g., social networking website, smartphone app; Young 2012). Fifth, the Internet may introduce ethical, legal, and organizational concerns and, as a result, further delays in implementing and launching the prevention program. In order to avoid unexpected delays and schedule changes, it is important to plan the program ahead of time and consult with the Institutional Review Board during the planning phase (Gold et al. 2012). Sixth, it is helpful to have an established base of prospective users prior to the launching of the program, which can be cultivated by spreading the word about the planned prevention program in both online and offline venues (Gold et al. 2012). Seventh, researchers should investigate what future users would find most appealing and design the program accordingly. In case of using an existing website (e.g., Facebook), researchers can explore the available features to maximize participation. For example, Gold et al. (2012) used an *edutainment* (education and entertainment) approach to maximize appeal to their target audience (MSM and young people aged 16–29 years). Eighth, in order to attain a large enough pool of participants and to recruit high-risk populations, prevention messages should be designed to spread virally on the Internet. Imaginative, emotion-inspiring, fun, and intriguing messages that are accessible and engaging have been found to be most viral (Gold et al. 2012). Ninth, it is important to anticipate the loss of participants over time, which is usually due to loss of interest of participants (Gold et al. 2012). Finally, when the prevention program comes to end, it is imperative to revisit the original aims and outcomes of the program to evaluate the level of success achieved.

Future Directions for Research and Practice

As suggested above, the use of technology and social networking in HIV prevention presents

innovative mechanism for this purpose and is growing rapidly. Yet, increased participation of the public health community is crucial to improve the quality of existing HIV prevention information on the Internet, as well as offer new programs and applications. Providing Internet users worldwide access to comprehensive, reliable, intelligible, and up-to-date HIV prevention information is an important step for decreasing HIV/STI incidence. Furthermore, following and adopting newer technologies for the purpose of HIV prevention will keep this field relevant and accessible to diverse populations, including high-risk populations. In addition, most online HIV/STI prevention interventions have not been thoroughly evaluated, and therefore, more studies are needed to evaluate the quality and outcomes (short- and long-term) of these programs. It would also be informative and of high relevance to have longitudinal (i.e., prospective) data on the effects of different online HIV/STI prevention applications on sexual behavior. It is even more crucial for future studies to focus on evaluation of prevention programs dedicated to high-risk and HIV-positive populations. Lastly, it is necessary to better understand how to functionally translate and disseminate online prevention efforts into real-world settings, more specifically, into high-risk and HIV-positive populations' lives where they can have a positive impact (Noar and Willoughby 2012).

Conclusion

The emergence of new technologies, particularly the Internet, social networking websites, and mobile devices, has had far-reaching consequences for HIV/STI prevention and continues to introduce exciting platforms for the delivery of health-related information. High-speed technological changes may also present new ethical, legal, and organizational concerns and thus require further examination of these issues. These ever-developing technologies may strongly influence the future spread of HIV and other STIs;

adopting and thoroughly investigating the characteristics of such technologies will allow for a better understanding of their influences and consequences on the health of individuals.

V

Vaccine Efforts Against AIDS

Jose M. Martinez-Navio and
Ronald C. Desrosiers
Department of Pathology, University of Miami
Miller School of Medicine, Miami, FL, USA

Definition

A vaccine is an antigenic preparation that confers immunity or protection against a particular pathogen or disease. In the classic approach to vaccination, a microbial immunogen is delivered, there is an immune response to the immunogen, and it is hoped that immune response is protective. Mainly used as preventive, vaccines can also be of benefit in a therapeutic setting. The historical success of vaccines in preventing a variety of viral diseases has raised hopes that the world would soon have an effective vaccine against HIV/AIDS. In this chapter we discuss the global efforts of the scientific community in obtaining a prophylactic vaccine against HIV and highlight the reasons why it has thus far proven difficult.

Background: Viral Vaccines in Human Use

The world we live in is bursting with pathogens: viruses, bacteria, fungi, prions, protists, and helminths. Many individual members of these

microbial classes are relatively innocuous; some can cause mild diseases, while others cause death in a high percentage of those infected. Historically, vaccines have unquestionably been our most powerful weapon against viral diseases of medical importance. The list of viral diseases that have been controlled, or even eliminated, is indeed quite impressive (Table 1). The most remarkable example is of course smallpox. As recently as 1967, it is estimated that two million deaths occurred that year from smallpox (Koplow 2003). As a consequence of the worldwide eradication campaign organized by the World Health Organization and the effectiveness of the live attenuated vaccine that was used, smallpox was declared eradicated from the face of the earth on December 9, 1979 by a commission of eminent scientists. The eradication was subsequently endorsed by the World Health Assembly on May 8, 1980. The last naturally occurring case was recorded in Somalia in 1977. The last actual case was laboratory-acquired in England in 1978. Stocks of live wild-type smallpox virus remain stored in freezers at two locations, one in the United States and one in Russia.

While poliovirus has not been eradicated from the face of the earth, at least as yet, families living in the developed world no longer need to live through the harrowing experience of poliovirus circulating in the neighborhood, and cases of paralytic poliomyelitis in their neighborhood, in the summer months (Roth 2010). Only three countries report polio infections at the current time:

Vaccine Efforts Against AIDS, Table 1 List of human viral diseases for which there are vaccines

Disease	Status	Virus	Vaccine type
Smallpox	Eradicated worldwide	Variola major and Variola minor (<i>Fam. Poxviridae</i>)	Live attenuated
Poliomyelitis (polio)	Eradication attempts underway	Poliovirus, types I, II, and III (<i>Fam. Picornaviridae</i>)	Inactivated (Salk) Live attenuated (Sabin)
Measles	Regional elimination established or underway	Measles virus (<i>Fam. Paramyxoviridae</i>)	Live attenuated
Rubella		Rubella virus (<i>Fam. Togaviridae</i>)	Live attenuated
Rabies		Rabies virus (<i>Fam. Rhabdoviridae</i>)	Inactivated
Mumps	Controlled or at least preventable by vaccination	Mumps virus (<i>Fam. Paramyxoviridae</i>)	Live attenuated
Hepatitis B		Hepatitis B virus (<i>Fam. Hepadnaviridae</i>)	Subunit (particle)
Yellow fever		Yellow fever virus (<i>Fam. Flaviviridae</i>)	Live attenuated
Influenza		Influenza virus, types A, B, and C (<i>Fam. Orthomyxoviridae</i>)	Live attenuated/ inactivated
Hepatitis A		Hepatitis A virus (<i>Fam. Picornaviridae</i>)	Inactivated
Hepatitis E		Hepatitis E virus (<i>Fam. Hepeviridae</i>)	Subunit
Tick-borne encephalitis		Tick-borne encephalitis virus (<i>Fam. Flaviviridae</i>)	Inactivated
Chickenpox and shingles		Varicella-zoster virus (<i>Fam. Herpesviridae</i>)	Live attenuated
Cervical carcinoma		Human papilloma virus (<i>Fam. Papillomaviridae</i>)	Subunit
Rotavirus gastroenteritis		Rotavirus enteritis (<i>Fam. Reoviridae</i>)	Live attenuated
Japanese encephalitis	Japanese encephalitis virus (<i>Fam. Flaviviridae</i>)	Inactivated/DNA	

Afghanistan, Pakistan, and Nigeria. Nigeria, which had not reported a case of wild poliovirus since July 24, 2014 and was taken off the list of polio endemic countries in September 2015, has recently confirmed a few cases during August 2016. International efforts are currently underway to completely eradicate poliovirus, including extensive vaccination campaigns. Additionally, a global switch to inactivated polio vaccines instead of live attenuated shall eliminate prolonged excretion of poliovirus in immunodeficient individuals and vaccine-associated paralytic poliomyelitis,

intending to facilitate complete worldwide eradication.

Viral vaccines currently in human use are of three types: live attenuated, whole killed (inactivated), and subunit. Live attenuated vaccines replicate sufficiently in the host to elicit a protective immune response, but not so much as to cause disease, at least in the vast majority of individuals. Given the historic nature of live attenuated vaccines in human use, they have been attenuated in general by nonspecific means. These include extensive passage in cell culture,

extensive passage in cells of a different species, selection of small plaque variants, or the use of related virus from a different species. Inactivated vaccines use purified whole virus which has been inactivated, usually with heat or chemicals. Since this process can alter the protein structure and antigenicity, inactivation needs to be done in a way that preserves antigenic structures but ensures complete inactivation of the virus. Last but not least, subunit vaccines consist of purified protein components of virions. In some cases (hepatitis B and papilloma), the protein component may assemble into a virion-like structure. Besides the antigenic component, inactivated and subunit vaccines typically contain an adjuvant, used to improve immune responses to the antigens in the preparation. See Table 1 for examples of each type of viral vaccine.

The term *vaccine* likely originated from the Latin *vaccinus* “from cows,” deriving from *vacca*, “cow.” Its origins rest with Edward Jenner (1749–1823), the discoverer of the world’s first vaccine, that for smallpox. Milkmaids who had acquired cowpox infection through their daily work suffered little or no disease from this infection with the cow virus. However, they appeared to be protected against subsequent exposure to the more dangerous and lethal smallpox virus. Jenner soon started *vaccinating* people with cowpox with great success; the rest is history. Jenner’s smallpox vaccine can thus be categorized as a live attenuated vaccine, the most common form of viral vaccine currently in human use (see Table 1). Prior to Jenner’s development of the cowpox virus as the vaccine for smallpox, the risky procedure known as *variolation* was commonly used worldwide as a preventive measure against smallpox. *Variolation* involved scarification of the skin of the subject with material obtained from the lesion of an individual with actual smallpox virus infection. The smallpox disease resulting from this intentional smallpox virus transmission was often, but not always, less severe than naturally occurring smallpox. The origins of the vaccinia virus used as the vaccine for worldwide eradication are a bit murky, but it is generally believed to be derived from passaged cowpox virus.

In this modern era of recombinant DNA, it has become possible to envision other means to approach vaccine development efforts: recombinant viral vectors, recombinant bacterial vectors, and use of DNA expression vectors. DNA vaccines deliver genetic material coding for one or more viral antigens, so that the immunogen can be properly expressed in the body and then recognized by the immune system. The advantages of this approach are that the immunogen would be expressed in its native structure (preserving the antigenicity) and that DNA is cheaper to produce than recombinant protein. A DNA vaccine approved for use in humans has been recently developed against the Japanese encephalitis virus.

Scientific Barriers to an HIV Vaccine: It’s the Virus!

Many consider the search for a safe, effective, affordable vaccine for HIV to be the greatest public health challenge of our time. With more than 36 million people currently living with HIV worldwide, more than 5400 new infections per day, and 3300 AIDS-associated deaths daily, HIV infection is one of the worst pandemics we have ever faced. Due to a broader access to anti-retroviral therapies and other interventions worldwide, AIDS-associated morbidity and mortality have dropped considerably in recent years. But long-term use of antiretroviral therapy is not without complication. Some of the problems appear to relate to long-term side effects associated with the HIV medications themselves. These include lipodystrophy, insulin resistance, decrease in bone density, and lipid abnormalities. Others, particularly chronic immune activation, inflammation, and hypercoagulation, appear to relate to the HIV. While a number of underlying causes have been proposed, microbial translocation across the gut is almost certainly a critical factor. Although it is possible that some low level of HIV replication in the presence of antiviral drugs could contribute to the chronic immune activation, it also seems likely that damage to the gut mucosa during the initial weeks of HIV infection never gets adequately repaired and is an important factor

in the chronic activation of the immune system in the face of effective therapy. In any event, effectively treated HIV-infected adults are increasingly manifesting signs of “accelerated aging,” to include cardiovascular disease, neurocognitive disease, osteoporosis, and kidney disease. These issues, compliance issues, and the difficulties of achieving lifetime supplies of antiviral drugs to developing nations underscore the continuing need for a “one shot and you are good for life” vaccine for HIV/AIDS.

Unfortunately, there are great difficulties associated with creating a successful HIV vaccine. The problem all relate to the properties of the virus itself. First is the huge sequence variability of the virus. It has been estimated that the variability in the HIV sequences found in one single individual is greater than the variability found for the influenza virus worldwide in one whole season (Korber et al. 2001). To put this into perspective, the influenza virus is variable enough so that a new vaccine must be created each year. When an individual becomes infected with HIV, the neutralizing antibody response is specific for the infecting strain but these antibodies have no neutralizing activity against the vast majority of other HIV strains circulating in the population. While this initial anti-HIV antibody response likely serves to limit the extent of viral replication to some extent, it is certainly of limited effectiveness. Viral sequence variants that emerge in the subsequent weeks and months resist neutralization by the antibodies made to the infecting strain (Richman et al. 2003). We currently have no idea what to put in an immunogen to cover the enormous sequence variability among HIV strains.

The very same high mutation rate that is responsible for the extreme diversity of HIV in the population confers upon the virus a unique ability to stubbornly adapt to immune responses within a single infected individual. The virus mutates and by so doing is able to generate escape mutants for both arms of the immune system: the humoral (antibodies) and the cellular (cytotoxic T-lymphocytes or CTLs). HIV is therefore able to persistently replicate in the face of an apparently strong host immune response, staying one step ahead of the host’s ability to respond. Even the

strongest host natural immune response to HIV is indeed completely unable to clear the infection. In fact, infection of an individual with one HIV strain does not routinely protect against superinfection by another strain.

Besides this very unique ability of this member of the lentivirus subfamily of retroviruses to generate and tolerate a wide range of mutations during the course of infection, the virus has also evolved an additional collection of mechanisms to evade the host’s immune system. Among those mechanisms is the poor immunogenicity of the HIV envelope spike. HIV has constructed its envelope glycoprotein in such a way that makes it difficult for antibodies to be elicited and difficult for antibodies to access. Generation of neutralizing antibodies to the viral envelope protein is hampered by its tightly closed configuration in which the variable loops mask or occlude vulnerable epitopes. The trimer also has a huge amount of glycosylation, which further reduces the protein immunogenicity. Gp120 envelope is actually one of the most heavily glycosylated proteins in the mammalian protein database; glycans account for approximately 50% of its molecular mass. This unusual glycosylation found on the envelope spike is an important factor for its low immunogenicity and high resistance to neutralization by antibodies. Indeed it has been suggested that HIV/SIV has an *ever-evolving glycan shield* in which the virus accumulates persistent glycosylation changes surrounding neutralizing epitopes that can block neutralizing antibody recognition of neighboring epitopes (Pikora 2004).

Additionally, several proteins coded by the virus have specific immune evasion activities. These include Nef (Negative factor) which is known to downregulate MHC-I thus preventing the infected cell from being recognized and killed by CTLs, Vif (Viral infectivity factor) which overcomes the host antiviral factors of the APOBEC3 family, and Vpu (Viral protein U) which counteracts the antiviral function of tetherin/BST-2 (also known as CD317).

Besides the CD4 helper cell depletion, which is a hallmark of HIV infection, many other cell types are directly or indirectly negatively affected by the virus (macrophages, B cells, dendritic cells,

monocytes, microglia, etc.). Since HIV primarily targets the very cells in charge of fighting back the infection, it leaves the host in an immunocompromised state characterized by a particular vulnerability to opportunistic infections in which persistent viral replication can occur.

Furthermore, HIV has an ace in the hole: the seeding of a viral reservoir. Soon after infection, the virus can hide in some cells by integrating a copy of its genome into the host cell genetic material. The integrated copy has the potential to remain silent for months or even years, eventually allowing for virus production. The existence of reservoirs is a continuous source of virus *in vivo* and allows viral loads to rebound quickly after antiretroviral therapy interruption.

Because of the reasons outlined above, once HIV enters the body, it is able to replicate continuously and relentlessly, no matter what the host immune system throws at it. Therefore, we do not know what constitutes a protective immune response. Additionally and perhaps more strikingly, HIV infection does not confer immunity: superinfection or reinfection with a second strain of HIV can occur. If the natural immune responses to HIV infection does not routinely protect against the virus, it becomes clear that generating an immunogen able to generate a better immune response than the natural infection is going to be a highly challenging task.

Given these factors, it is perhaps not surprising that development of an effective prophylactic vaccine against HIV is proving to be a difficult uphill struggle. Nonetheless, extensive efforts to find an effective vaccine approach are continuing.

Summary of Efficacy Trials in Humans

Soon after the discovery of HIV in the 1980s, many thought that finding a vaccine would be straightforward. Initial attempts followed the traditional vaccine paradigm and focused on attempting to generate neutralizing antibodies by immunizing with recombinant envelope proteins from various strains. Two phase III trials were conducted between 1999 and 2003, the VaxGen trials (with [ClinicalTrials.gov](https://www.clinicaltrials.gov) identifiers:

NCT00002441 and NCT00006327), in which the use of gp120 protein in adjuvant resulted in no protection against acquisition and no lowering of viral loads in those vaccinated individuals who did become infected. The first study enrolled 5403 healthy volunteers that were randomized in a 2 to 1 vaccine-to-placebo ratio. Volunteers received seven intramuscular vaccinations (at months 0, 1, 6, 12, 18, 24, 30) containing either the AIDSVAX B/B vaccine (MN rgp120/HIV-1 and GNE8 rgp120/HIV-1 in alum adjuvant) or a placebo (alum adjuvant only). They were followed for a total of 16 visits beginning at screening and continuing until month 36. Individuals who became HIV infected were followed every 4 months for at least 24 months. The second study enrolled 2546 participants. Volunteers were randomized (1:1) to receive AIDSVAX B/E (MN rgp120/HIV-1 and A244 rgp120/HIV-1 in alum adjuvant) or placebo (alum adjuvant only) and were followed for a minimum of 2 years. Individuals who became HIV infected were followed every 4 months for up to 36 months. While these studies showed that both binding and neutralizing antibodies could be generated, they also demonstrated that the latter were mostly limited to the very strain used in the vaccine. After these initial attempts, the field focused on eliciting cytotoxic cellular responses, hoping that they would target relatively conserved epitopes and could have breadth to achieve significant levels of protection.

The first T-cell vaccine to achieve efficacy trials was a replication-defective recombinant adenovirus serotype 5 (Ad5) vector with HIV-1 clade B *gag/pol/nef* inserts. This first study was divided in two: the Step trial and the Phambili (Zulu term for forward) trial. Both, Step and Forward (Phambili), were double-blind randomized placebo-controlled phase IIB test-of-concept studies to evaluate the safety and efficacy of a three-dose regimen (intramuscular injection on a 0, 1, 6 month schedule) of the clade B-based Merck trivalent Ad5 vaccine (MRKAd5 HIV-1 *gag/pol/nef*) in HIV-1 uninfected and sexually active adults. Both trials were aimed at assessing the efficacy of a cell-mediated immunity vaccine to protect against HIV-1 infection or change in

early plasma HIV-1 levels. The Step trial (Identifier: NCT00095576) involved 3000 HIV-1-seronegative participants in North America, the Caribbean, South America, and Australia. This study had to be stopped before completion because it unexpectedly met the prespecified futility boundaries in the first interim analysis. It was determined that vaccine recipients with pre-existing antibody titers to Ad5, and/or were uncircumcised, had a statistically significant increased rate of infection when compared with the placebo group.

While still somewhat uncertain, increased risk of HIV acquisition in uncircumcised vaccine recipients with higher preexisting adenovirus titer was initially related to a higher immune activation in those individuals, which could have made them more susceptible to infection. Further follow-up and analysis suggested that the vaccine may have undermined some immune mechanism that normally protected uncircumcised penises through the mucosa of the foreskin. It was also proposed that the Ad5 antibody titers could just be a surrogate for some other factor, like risk behaviors.

In light of the Step trial results, enrolment and vaccination in the Phambili trial (Identifier: NCT00413725) were halted although follow-up continued. This study involved only 801 participants of the 3000 initially scheduled in South Africa. With the same clade B-based vaccine designed to elicit T-cellular immunity and the same aims of safety and protection as the Step trial, the Phambili study was targeting people in an area where the major circulating clade is subtype C: the study was ultimately aimed at investigating cross-clade protection. While the vaccine elicited IFN- γ -secreting T cells that recognized both clade B and C antigens, it was eventually shown that it also increased the rate of HIV acquisition among vaccinated individuals. The outcome of these two trials, with increased rate of infection in vaccine recipients, was a huge setback for the scientific community.

Because the Step data showed that vaccine recipients with preexisting antibody titers to Ad5 and/or that were uncircumcised had an increased risk of infection when compared to the placebo

group, an additional clinical trial known as the HVTN 505 trial (NCT00865566) recruited only Ad5-seronegative circumcised men (and male-to-female transgender persons) that have sex with men. It was also a phase IIB, randomized, placebo-controlled test-of-concept study. The HVTN 505 trial utilized a DNA prime using *gag*, *pol*, and *nef* from clade B and *env* from clades A, B, and C followed by recombinant Ad5 boost using clade B *gag-pol* fusion protein and *env* glycoproteins from clades A, B, and C. This trial, which had enrolled 2504 individuals, used a DNA/Ad5 immunization regimen, which is qualitatively different from the three Ad5 immunizations used in the Step and Phambili trials. Additionally, the HVTN 505 included three different *env* genes to investigate whether the inclusion of Env, missing in the Step and Phambili trials, could result in measureable protective effects. The HVTN 505 trial did not see an increased rate of HIV infection, but also resulted in no protection against acquisition and no lowering of viral loads among vaccinated individuals who did become infected.

Most recently, and perhaps most controversially, is the RV144 Thai trial (NCT00223080), where claims of protection against acquisition have been made. The RV144 recruited 16,402 subjects and was a phase III trial of Sanofi-Aventis Pasteur live recombinant ALVAC-HIV priming (vCP1521, a recombinant canarypox vector vaccine with *env* and *gag* inserts) with two booster inoculations of VaxGen gp120 B/E (AIDSVAX B/E, a recombinant glycoprotein 120 subunit vaccine) in HIV-uninfected Thai adults. In the per-protocol analysis involving 12,542 subjects (those who remained eligible to participate in the study and received the entire series of vaccinations within the defined time period), the vaccine efficacy was 26.2% with a nonsignificant P value of 0.16. In the intention-to-treat analysis involving 16,402 subjects, there was a trend toward the prevention of HIV-1 infection among the vaccine recipients, with a vaccine efficacy of 26.4%, but this was not statistically significant with a P value of 0.08. When excluding from the analysis seven subjects who were found to have had HIV-1 infection at baseline, the efficacy was 31.2% with a

significant P value of 0.04. This has been the first trial of a candidate HIV vaccine regimen to demonstrate some level of apparent protection against HIV acquisition. Vaccination did not affect viral loads or the CD4⁺ T-cell count in subjects that became infected (Rerks-Ngarm et al. 2009, Gilbert et al. 2011).

Due to the surprising lack of effect on viral loads initially seen in RV144, the RV152 trial (NCT00337181) followed up a proportion of participants in RV144 to investigate whether longer-term effects on viral load could be seen. The conclusions drawn from this study confirmed that vaccination did not affect the clinical course of HIV disease after infection. An additional trial that began in 2012 in Thailand, RV305 (NCT01435135), is currently investigating late boost strategies for HIV-uninfected participants in the RV144 study. In fact, a number of additional trials are building on RV144: a study similar to RV305 was initiated in 2013, RV306 (NCT01931358). This trial is using the RV144 vaccine regimen, and it will study boosting strategies after vaccination in new individuals that did not participate in RV144. Similarly, the RV328 trial (NCT01933685), which started in 2014, will evaluate the sequential administration of gp120 B/E (AIDSVAX B/E) with 1-year boosting in HIV-uninfected Thai adults. Another follow-up of RV144 is the HVTN 100 study (NCT02404311). This is a phase I/II randomized, double-blind, placebo-controlled clinical trial of clade C ALVAC-HIV (vCP2438) and bivalent subtype C gp120 with MF59 adjuvant in HIV-uninfected adults at low risk of HIV infection. This trial is currently ongoing and is estimated to be completed at the beginning of 2017. On 2016 HIV Vaccine Awareness Day (May 18), the NIH announced the decision to move forward with HVTN 702, a new phase IIB/III HIV vaccine efficacy clinical trial in South Africa. According to the NIH, this decision was taken based on early data from the HVTN 100 trial showing that the new vaccine regimen is safe and produces a robust immune response. This new trial began in November 2016, after obtaining regulatory approval. It is testing a new HIV vaccine regimen designed to improve upon the efficacy observed in

the RV144 trial and to evaluate the vaccine in a higher risk population. HVTN 702 will enroll 5400 HIV-uninfected men and women who are at risk for HIV infection. Both the DNA and the protein vaccine have been modified from RV144 to be specific to HIV subtype C, the predominant in southern Africa. The adjuvant to be used with the protein vaccine will be MF59, an oil-in-water adjuvant that uses squalene (a natural organic compound originally present in shark liver oil and some plants) and two nonionic surfactants: polysorbate 80 and sorbitan trioleate. This is a different adjuvant than the one used in RV144, thus aiming for a more robust antibody response. In addition, the vaccine regimen will include boosters at the 1-year mark in an attempt to prolong the early protective effect seen in RV144. A summary of the efficacy trials in humans, including the ones undergoing, can be found in Table 2. For more details on RV144 follow-up studies, please see Kim et al. (2015).

Chemoprophylaxis

Preexposure prophylaxis, or PrEP, is one approach where unambiguous protection against acquisition has been achieved. PrEP is when people take a drug before being exposed to the virus thus aiming to diminish the risk of infection. Because of the side effects of these drugs, including the risk of serious adverse events, this strategy is only indicated for HIV-negative people who are at substantial risk of HIV infection.

Indeed PrEP has proven very effective, but for achieving the desired level of efficacy, it is very important that individuals take it as directed. As reported in a phase III clinical trial in 2499 men who have sex with men (the iPrEx study, NCT00458393), taking one pill per day of FTC/TDF (emtricitabine/tenofovir disoproxil fumarate) antiretroviral drugs can reduce an individual's risk of contracting HIV infection by up to 92%. Similarly, the FTC/TDF PrEP has shown strong protection against HIV acquisition in heterosexually active men and women, reducing the risk of HIV infection by 62% (the BOTUSA MB06 trial, NCT00448669). Moreover, up to

Vaccine Efforts Against AIDS, Table 2 Summary of human efficacy trials

Trial	Identifier	Phase	Vaccine	Outcome
VaxGen	NCT00002441	III	gp120 B/B in adjuvant	No protection
VaxGen	NCT00006327	III	gp120 B/E in adjuvant	No protection
Step	NCT00095576	IIB	<i>gag/pol/nef</i> B rAd5	Enhancement
Phambili	NCT00413725	IIB	<i>gag/pol/nef</i> B rAd5	Enhancement
HVTN 505	NCT00865566	IIB	<i>env</i> A,B,C/ <i>gag/pol/nef</i> B DNA + rAd5	No protection
RV144	NCT00223080	III	<i>env/gag/pro</i> B rPox + gp120 B/E	Modest protection?
RV152	NCT00337181	III	Long-term follow-up on RV144	Unaffected viremia

90% protection was seen with the same drugs in discordant couples that adhered to the regimen (the Partners PrEP study, NCT00557245). TDF alone also reduced the risk of HIV infection in injection drug users by almost 50% (the Bangkok Tenofovir Study, NCT00119106). Another interesting study is the VOICE trial or MTN-003 (NCT00705679), aimed at assessing the effectiveness of TDF and FTC/TDF tablets in preventing HIV in women. Besides investigating prophylaxis with oral drugs, this trial also evaluated the effectiveness of tenofovir 1% gel, a vaginal microbicide, with the same purpose. While initial analysis suggested that none of the drug regimens reduced the rates of HIV-1 acquisition, post-trial analysis suggested that the application of the tenofovir gel could confer a good degree of protection but only when consistent adherence was observed. This and other studies evidenced the surprisingly low adherence of the enrolled individuals to the PrEP, despite continuously reporting its proper use (Marrazzo et al. 2015). In the same line of chemoprophylaxis, a separate study (NCT00074581) demonstrated that initiating antiretroviral therapy in therapy-naive, HIV-infected people could prevent the sexual transmission of HIV among HIV-discordant couples. Other drugs such as maraviroc, an entry inhibitor (it is a CCR5 receptor antagonist), have also been explored in clinical trials alone or in combination (see, for instance, clinical trials NCT01505114, NCT01719627, and NCT01749566).

Another form of prevention is the post-exposure prophylaxis (PEP). PEP should be used in emergency cases and consists of taking a strong dose of antiretroviral drugs soon enough after viral exposure (usually less than 72 h) and during approximately a month, in an attempt to inhibit viral infection. A number of different clinical trials have compared different drugs alone or in combination, for instance, the phase IV trial NCT01533272 in Barcelona, Spain, in which no seroconversions were observed during the study.

Use of Antibodies for Prophylactic Immunization

Another strategy to prevent HIV infection is the antibody-based approach. It is reasonable to think that the presence of antibodies with potent neutralizing activity against a broad range of HIV isolates would be able to provide a sterilizing barrier to infection against most HIV strains circulating in the population. Unfortunately, even HIV-infected people rarely make such antibodies. Certainly no one has yet figured out how to elicit them. But over the last several years, a remarkable collection of monoclonal antibodies with such broad, potent activity has been isolated and characterized (Halper-Stromberg and Nussenzweig 2016). Novel high-throughput technologies, including single-cell sorting combined with the use of improved baits and

single-cell antibody cloning, have made possible the isolation of a good number of potent and broadly neutralizing antibodies from HIV-infected people. One creative strategy is to bypass the immune system and deliver already known and well-characterized broadly neutralizing antibodies isolated from selected donors directly to the host. Delivery of these antibodies as an attempt to prevent HIV infection will be endeavored in two trials: the HVTN 703/HPTN 081 trial (NCT02568215) and the HVTN 704/HPTN 085 trial (NCT02716675). The first is a phase IIB study that started on April 2016 and will evaluate the safety and efficacy of the broadly neutralizing antibody VRC01 in reducing acquisition of HIV-1 Infection in 1500 women in Botswana, Kenya, Malawi, Mozambique, South Africa, Tanzania, and Zimbabwe. The latter will similarly evaluate VRC01 efficacy against HIV acquisition but among men (and transgender persons) who have sex with men. The study is currently enrolling 2700 individuals and will take place in several locations in Brazil, Peru, and the United States.

It is worth mentioning that broadly neutralizing antibodies can also be used as a therapeutic approach in already infected individuals. For instance, 3BNC117, 10-1074, and VRC01 are currently being used for that purpose in human clinical trials. While passive administration of neutralizing antibodies can be considered for both the prevention and treatment of HIV infection, the large-scale applicability of passive administration is hampered by cost and compliance considerations. Long-term delivery of such broadly neutralizing monoclonal antibodies using vectors such as adeno-associated virus (AAV) has enormous potential for greatly impacting the worldwide epidemic (Fuchs and Desrosiers 2016).

Summary of Preclinical Vaccine Trials in Monkeys

Two monkey model systems have been used extensively for preclinical vaccine research in the HIV/AIDS arena: SIV in macaque monkeys

and SHIV in macaque monkeys. The SIV strains that have been most extensively used were derived from sooty mangabey monkeys (SIV_{sm}) or from macaque monkeys (SIV_{mac}). SIV_{mac} has its origins from cross-species transmission from sooty mangabey monkeys in captivity, and thus, these SIVs are closely related. While SHIV strains have been less commonly used than SIV for challenge of vaccinated monkeys, recent advances in the consistency of SHIV performance (Li et al. 2016) may portend greater use in the coming years. While rhesus monkeys (*Macaca mulatta*) of Indian origin have far and away been the most frequently used species, other species of macaque have also sometimes been used. These include the pig-tailed macaque (*Macaca nemestrina*) and the cynomolgus macaque (*Macaca fascicularis*) (Ansari and Silvestri 2014). Some investigators have preferred to use cloned virus stocks for challenge, while others have preferred to use passaged stocks of uncloned virus, whether SIV or SHIV. Advantages of using cloned virus stocks include homogeneity of a defined virus sequence, better control of the laboratory research conditions, clarity in the meaning of antibody-mediated neutralization, and ability to exactly match, or mismatch, the sequences in the challenge virus with the sequences in the vaccine (Korioth-Schmitz and Schmitz 2014). Arguments for using uncloned virus include a better reflection of the real-world situation of HIV infection of humans. Additionally, many of the initial cloned SHIV stocks have required passage in monkeys in order to yield reasonably consistent viral loads upon monkey infection. Cloned SIVs used for vaccine studies include the most frequently used SIV_{mac}239, SIV_{mac}766, and SIV_{sm}E543; uncloned SIVs include the most frequently used SIV_{mac}251. Cloned SHIVs include the nicely performing SHIV-AD8eo cloned virus, while examples of uncloned SHIVs include SHIV 89.6PD and SHIV DH12R. Notably, a very interesting version of SHIV with an envelope that shows enhanced CD4 binding and replication in rhesus macaques has been recently described (Li et al. 2016). Modified versions of HIV-1 able to infect monkeys weakly have also been generated.

Besides having the choice of the appropriate virus strain, there are additional advantages of using the macaque model: the dose of virus and the challenge route can also be carefully selected (Del Prete et al. 2016). Studies in monkeys can also be more invasive than in humans and therefore more thorough and detailed. An additional advantage of doing vaccine trials in monkeys is that a variety of approaches and strategies can be compared for far less cost than efficacy trials in humans, and the studies can be completed faster. Different approaches and strategies can be rank-ordered in order to inform and guide selections for efficacy trials in humans (Shedlock et al. 2009).

The greatest degree of protection has unquestionably been achieved using live attenuated strains of SIV, including strains with an inactivating deletion of the *nef* gene (Koff et al. 2006). However, even live attenuated SIV has provided unimpressive protection against SIV strains not matched in sequence to the vaccine. This situation is perhaps analogous to the inability of infection with one HIV-1 strain to routinely protect against superinfection by a different HIV-1 strain following an infectious exposure. In any event, live attenuated strains of HIV are not seriously being considered for use in humans because of concerns for safety.

In terms of viable vaccine approaches, perhaps the most impressive results have been obtained by Dr. Louis Picker's group in Oregon using recombinant cytomegalovirus. The recombinant rhesus monkey CMV strain that has been used contains a deletion of several nonessential genes and results in a highly unusual, nonclassical cellular immune response. Approximately 50% of the challenged monkeys showed aviremic control of infection with the highly pathogenic strain SIVmac239. Replication-competent SIV was not detected in protected vaccine recipients, providing evidence for clearance of a pathogenic lentiviral infection (Hansen et al. 2013). While the results are indeed impressive, this vaccine approach has unfortunately not provided protection against acquisition (or delayed the time to acquisition), and these studies have utilized challenge virus (SIVmac239) exactly matched to the sequences present in the vaccine.

It is worth mentioning that a different viral vector, the Ad5 like the one used in the Step trial, was tested beforehand in macaques. Results were initially very encouraging since good T-cell responses could be measured, and even reduction in viral loads was observed in vaccine recipients when challenged with SHIV. Nevertheless, it was soon realized that these vaccines were only efficient in protecting against the same SHIV strain used for the vaccine and were not offering the same degree of protection against a more pathogenic SIV.

As mentioned above, the human trial RV144 used both DNA inoculation (ALVAC-HIV) with *env* and *gag* inserts and protein boosts (VaxGen gp120) in alum adjuvant. Various follow-up clinical trials to the RV144 study are now using MF59 as a new adjuvant, which is considered more immunogenic. Interestingly, recent monkey studies have shown that the SIV equivalent vaccine ALVAC-SIV + gp120 with MF59 adjuvant was not efficacious in delaying the onset of infection with SIVmac251 in rhesus macaques, while ALVAC-SIV + gp120 with alum did show some efficacy in this regard (Vaccari et al. 2016).

In the antibody arena, successful passive immunization studies in macaques showing that broadly neutralizing human monoclonal antibodies could prevent the acquisition of infection via many different routes have definitely encouraged the use of these antibodies in clinical trials in humans (as seen in previous sections). Thanks to additional monkey studies, we also now know that the seeding of the viral reservoirs after infection happens very quick (at least as soon as in 3 days, during the eclipse phase and before detectable viremia). In line with this, early passive immunotherapy with broadly neutralizing antibodies can prevent the establishment of viral reservoirs when inoculated 24 h after SHIV oral challenge in 1-month-old rhesus macaques as a model of mother-to-child transmission (Hessell et al. 2016).

It is also important to mention that in the last few years, a better understanding of the HIV envelope trimer configuration and structure has been achieved, thus allowing a better design of immunogens, like the SOSIP trimers. Pathways for the generation of broadly neutralizing antibodies

from the germ line have also been investigated in the macaque model and are currently better understood. Attempts at these approaches in humans will probably happen sooner rather than later. It is also worth mentioning that one of the most potent and broad entry inhibitors discovered so far, the eCD4-Ig (a fusion of CD4 and the Fc portion of an IgG with a small CCR5-mimetic sulfopeptide), is planned to reach clinical trials at the end of 2018 after very promising results in monkey studies in which it provided complete sterilizing protection against SHIV challenges (Gardner et al. 2015).

Conclusion

After more than three decades on the quest to find a prophylactic vaccine against HIV, success remains elusive. The difficulties all relate to the properties of the virus itself. These include but are not limited to immune evasion strategies employed by the virus, the ability to replicate continuously in the face of apparently strong host immune responses to the virus, extreme heterogeneity in the sequences of the virus, and the inability of infection by one strain to protect against superinfection by another strain. The predicted difficulties have more or less been borne out by six large efficacy trials in people. Promising strategies emerging from studies in monkeys include live, replication-competent, persisting, recombinant herpesvirus (CMV) and long-term delivery of monoclonal antibodies with potent broadly neutralizing activity. It is likely that studies in monkeys will become increasingly important in order to inform and guide the field regarding most promising strategies.

Viral Fitness in Hosts

Angela Ciuffi

Institute of Microbiology, University Hospital Center and University of Lausanne, Lausanne, Switzerland

Definition

The fitness of an organism can be defined as its ability to survive and successfully replicate in a specific environment.

Introduction

Once the host has been effectively invaded, the virus needs to spread and replicate successfully, finding target cells and escaping host defenses at the same time. During this time, virus-host interactions take place, impacting viral fate. Each player has thus to obey certain constraints to survive and resist to selective pressures at the same time, implying some needs to adapt and evolve.

Viral fitness estimates the ability of a virus (or a virus genome sequence) to survive and reproduce in a specific environment (Fig. 1). Although conceptually simple, viral fitness results from a complex interplay between the virus and its host and implies that to adapt and survive, the virus has to evolve in a dynamic environment. Therefore, viral fitness is a relative value rather than an absolute measurement.

Assessing viral fitness is a challenging task, and replication assays are common surrogate assays to investigate virus-host interactions. In the last decade, many efforts have been concentrated in identifying the factors promoting and facilitating HIV replication, as well as the factors from intrinsic cellular defenses that restrict its replication at the cellular level.

Virus Evolution and Constraints

Human immunodeficiency virus (HIV) is an enveloped RNA virus from the *Retroviridae*

family; it is thus characterized by two hallmarks: reverse transcription of the viral RNA genome into a double-stranded DNA and its subsequent integration into the viral host genome. The evolution potential of HIV is determined by three features: (i) a high mutation rate, (ii) a short generation time, and (iii) a large production size (Fig. 1a; Dykes and Demeter 2007; Clementi and Lazzarin 2010; Lauring and Andino 2010; Domingo et al. 2012).

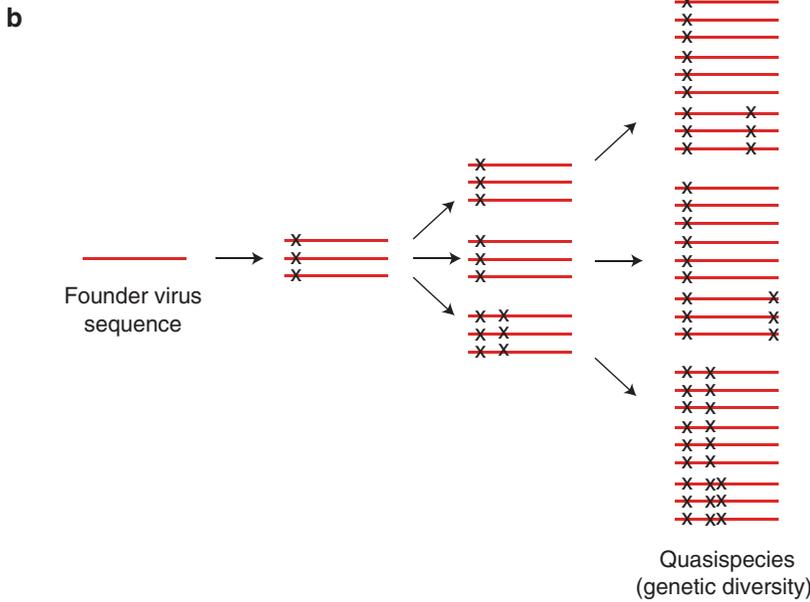

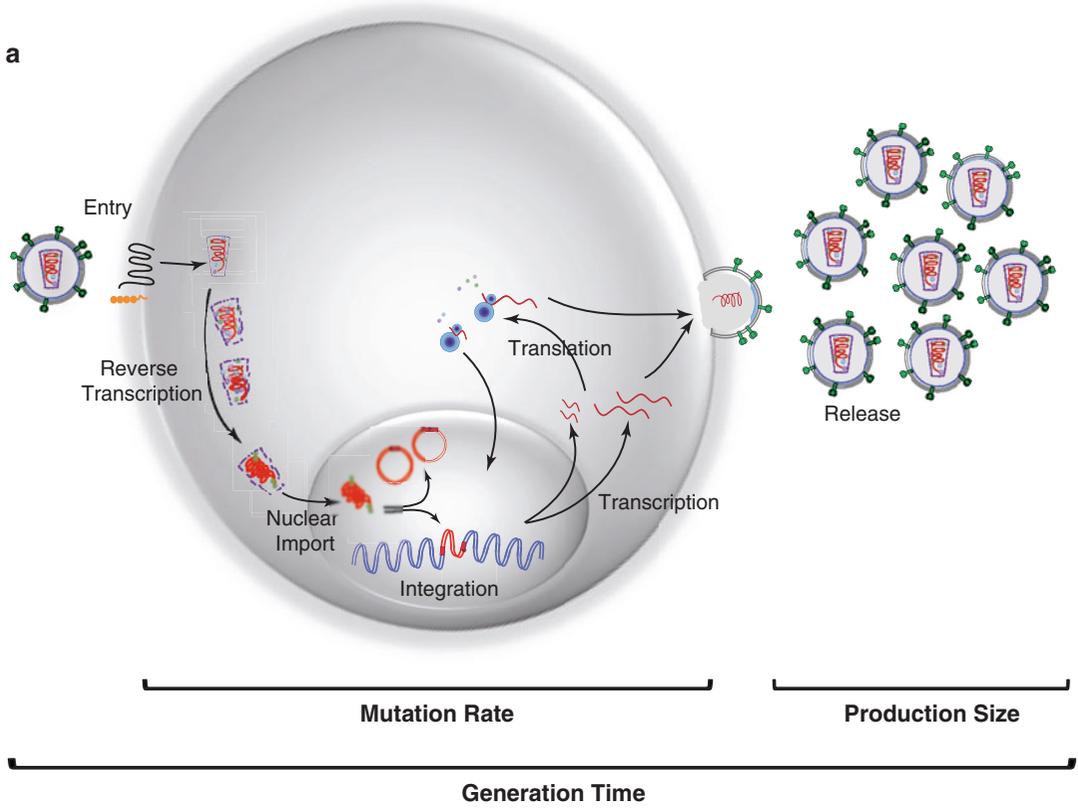

Mutation Rate

A high mutation rate is necessary to generate new variants (or mutants) and thus provides an opportunity to increase genetic diversity.

The mutation rate provides the opportunity to generate a variant sequence. In the case of HIV, mutations are thought to occur principally at the reverse transcription step (Hu and Hughes 2012; Coffin and Swanstrom 2013). The high mutation rate is mainly attributed to the error-prone reverse transcriptase (RT) activity that produces a double-stranded DNA molecule starting from the viral RNA genome. Indeed, this enzyme has no proof-reading activity and thus a poor fidelity. In addition to the RT enzyme activity *per se*, four additional events occurring at the reverse transcription or at the transcription steps can contribute to HIV mutagenesis.

The first one is known as template switch or copy-choice determination: As mentioned earlier, the virion contains two copies of viral RNA genomes, and both can be used as template by the RT to produce the viral DNA copy. During reverse transcription, the RT can thus switch from one copy to the other, thereby providing additional opportunity to add genetic diversity if the two copies are not identical.

The second one is due to the host cellular enzyme APOBEC3G and its cytidine deaminase activity occurring during viral reverse transcription, which results in G-to-A mutations in the reverse-transcribed DNA. Therefore, cellular enzymes can also participate and increase the mutation rate during HIV reverse transcription. Of note, APOBEC3G is a part of the innate immunity, and its hypermutating activity aims at introducing an excessive number of mutations that

Viral Fitness in Hosts, Fig. 1 Evolution rate and genetic diversity. (a) HIV life cycle and processes contributing to genetic diversity. HIV viral particles contain

two copies of viral RNA molecules. Upon binding to CD4 and a CCR5 coreceptor at the surface of the target cell, the viral core is released in the cytoplasm. The viral RNA

would be incompatible with viral functions and thus virus survival (discussed below).

In addition to error incorporations during reverse transcription, HIV genome can also evolve through viral genome recombination (Simon-Loriere and Holmes 2011; Simon-Loriere et al. 2011; Vuilleumier and Bonhoeffer 2015). To occur, several requirements need to be fulfilled: (i) a cell has to be infected by two HIV variants; (ii) during packaging of two copies of viral RNA genomes, one of each viral RNA has to be selected, thereby generating a “heterozygous-like” virion; and (iii) both viral RNA genomes have to be used for reverse transcription (template switch) to generate a recombinant viral DNA genomic sequence. Viral genome recombination represents an additional mechanism for HIV genome evolution.

Finally, another cellular enzyme unrelated to reverse transcription may contribute to the global HIV mutation rate: the host RNA polymerase II. Like for any host gene, this cellular enzyme transcribes the proviral genome into RNA, more particularly into mRNA. Some of these viral RNA molecules contain the whole viral RNA genome that is subsequently packaged into the nascent virions. As the cellular RNA polymerase II lacks a proofreading activity, it can introduce mutations during this transcription process. Although its exact contribution has not been quantified, the cellular enzyme may still add to the global HIV mutation rate (Coffin and Swanstrom 2013).

For HIV, this mutation rate has been estimated to be $\sim 3 \times 10^{-5}$ mutations/nucleotide, corresponding approximately to one mutated nucleotide arising every three ~ 10 kb viral genomes at each viral replication cycle (Fig. 1b; Coffin and Swanstrom 2013).

Generation Time

The generation time is the time required by the virus to complete its replication cycle, i.e., from entry to release. A rapid replication kinetic implies a short progeny generation time, which accelerates the potential to evolve. The duration of a complete HIV life cycle varies depending on the target cell but can be roughly estimated to be around 1–2 days (Coffin and Swanstrom 2013; Mohammadi et al. 2013).

Production Size

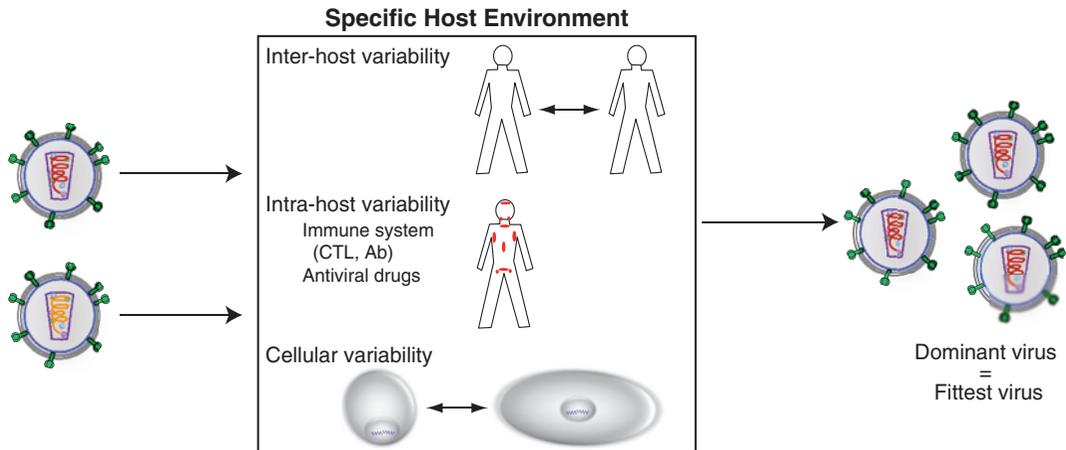

A large population size, i.e., a high virion production rate, increases exponentially the evolution rate as it increases the number of possibilities to evolve. In an infected individual, 10^{10} – 10^{11} particles can be produced per day (Nordkin 2009).

Evolution Rate: Balance Between Adaptation and Survival

All together, these three features ensure that from one transmitted virus genome sequence, HIV rapidly evolves to a swarm of quasispecies that are all genetically distinct but related and that may differ in their viral fitness at a given time and in a specific local environment (Fig. 2). The broad

Viral Fitness in Hosts, Fig. 1 (continued) genome is reverse-transcribed by the viral reverse transcriptase (RT) enzyme in a double-stranded DNA copy, which is in turn translocated to the nucleus and integrated into the host cellular genome (host genome, *blue*; HIV provirus, *red*). The proviral DNA genome is transcribed and translated by the cellular machinery, allowing assembly and release of viral particles to take place. The evolution rate depends on three parameters of the viral life cycle depicted on the bottom. (i) The mutation rate, which provides the opportunity to generate a variant sequence and occurs mostly during the reverse transcription step. (ii) The generation time, which is the time required from virion entry to release of new infectious viral particles. (iii) The production size,

corresponding to the amount of infectious virions produced. All together, these three parameters contribute to the fast evolution rate typical of HIV. (b) Generation of viral genetic diversity. One founder virus sequence (*red line*) can be mutated during reverse transcription (marked by x), estimated to be around one mutation every three genomes (marked by x). The large production size and the short generation time accelerate the evolution rate of HIV, thereby generating a large genetic diversity characterized by a swarm of viral quasispecies (that are genetically related but distinct). Selection of the fittest quasispecies is then dependent on viral constraints and host-specific selective pressures.

Viral Fitness in Hosts, Fig. 2 **Viral fitness.** Two variants of a virus (depicted as virions containing respectively a *red* or an *orange* viral genome sequence on the *left*) may be able to replicate differentially in a specific host environment (*black rectangle*). This environment is variable and can be considered as being the whole organism, a local

environment present in a specific organ or tissue (*red*), or a specific cell type. The fittest virus (here the *red* one) outcompetes the other one (that may be eliminated by the immune system, lethally mutated and thus unable to replicate, or less fit) and is thus overrepresented in the viral population. *CTL* cytotoxic T lymphocytes, *Ab* antibodies

genetic diversity accumulated over time within an HIV-infected individual identifies HIV as being the human virus with the fastest rate of evolution to date (Coffin and Swanstrom 2013).

The evolution potential reflects the ability of a virus to adapt to a specific environment and to its selective pressures, with the mutation rate being one key component (Clementi and Lazzarin 2010; Lauring and Andino 2010). A very low level of mutations leads to low opportunities to adapt and evolve and therefore also lower probabilities to escape to elimination by the adaptive immune system. In contrast, an excessive mutation rate leads to lethal mutagenesis, i.e., to hypermutated sequences likely resulting in nonfunctional proteins and thus incompatible with viable infectious viruses. Indeed, HIV has to obey to specific viral, immunological, and structural constraints in order to successfully replicate. These include (i) the expression of virally encoded proteins able to fulfill specific functions such as catalytic activities, binding to nucleic acids or interacting with other protein partners, (ii) the escape to host recognition and immune-mediated elimination, and (iii) the maintenance of the viral RNA structure necessary for viral function such as tRNA binding, dimerization, binding to viral proteins, and

packaging into virions (Dykes and Demeter 2007; Snoeck et al. 2011; Telenti and Johnson 2012; Bartha et al. 2013).

The equilibrium between mutation rate increasing genetic diversity, adaptation to host-specific environment, and ability to survive and complete replication cycle can also be illustrated at the level of HIV quasispecies that are not equally fit. Viral quasispecies that do not mutate may not survive due to host selective pressures (for instance, adaptive immunity) to which they did not adapt to. In contrast, HIV quasispecies that mutated too much may be incompatible with virus survival. Therefore, adaptation of HIV to a specific environment results from a trade-off between the mutation rate and virus survival.

The number of mutations per genome after which virus viability starts to be compromised is known as the error threshold and is implicated in the error catastrophe scenario (Clementi and Lazzarin 2010; Lauring and Andino 2010). Proteins able to modify the error rate of viruses may thus affect the balance between evolution potential and lethal mutagenesis and start that catastrophe scenario. These proteins may thus represent a cellular defense mechanism. In the case of HIV, this is exemplified by the cytidine deaminase

enzyme APOBEC3G that hypermutates the viral genome during the reverse transcription process, rendering it incompatible with virus survival.

Host-Specific Environment

The environment in which HIV evolves needs to consider three levels of variability: (i) inter-host variability, (ii) intra-host variability, and (iii) cellular variability (Fig. 2). It is important to note that specific environments are also not static but rather dynamic and vary over time, for example, upon aging, immune system changes, or cellular activation states. Finally, all these specific environments coexist at the same time, adding complexity in the selective forces and in the characterization of viral fitness.

Due to the variable nature of the viral environment within the same host, assessing viral fitness is a real challenge. To date, multiple assays have been developed to estimate viral fitness, including replication kinetics, competition assays between viruses, and single-round infectivity assays (van Opijnen and Berkhout 2005; Dykes and Demeter 2007). These assays vary according to the virus and to the cell type used. At the virus level, whole patient-derived virus isolates, viral portions subcloned into a reference vector, or mutated reference vectors are used. Target cells used are either T-cell lines, primary cells (peripheral blood mononuclear cells, monocyte-derived macrophages, CD4⁺ T cells), or indicator cell lines. Although these assays provide valuable information, they fail to recapitulate all the selective pressures existing in the host environment.

Inter-Host Variability

Inter-host transmission represents a bottleneck, as only one virus is successfully transmitted: the founder virus (Gutierrez et al. 2012). Thus, both the donor host and the recipient host may affect viral fitness of the founder virus and thus contribute to shape the genetic viral background. Two different hosts that are genetically different provide two specific environments in which a same HIV variant may evolve differently as they will provide different selective pressures, such as

different adaptive immune responses or different concentrations of antiviral drugs (Telenti and Goldstein 2006; Fellay et al. 2010).

Intra-Host Variability

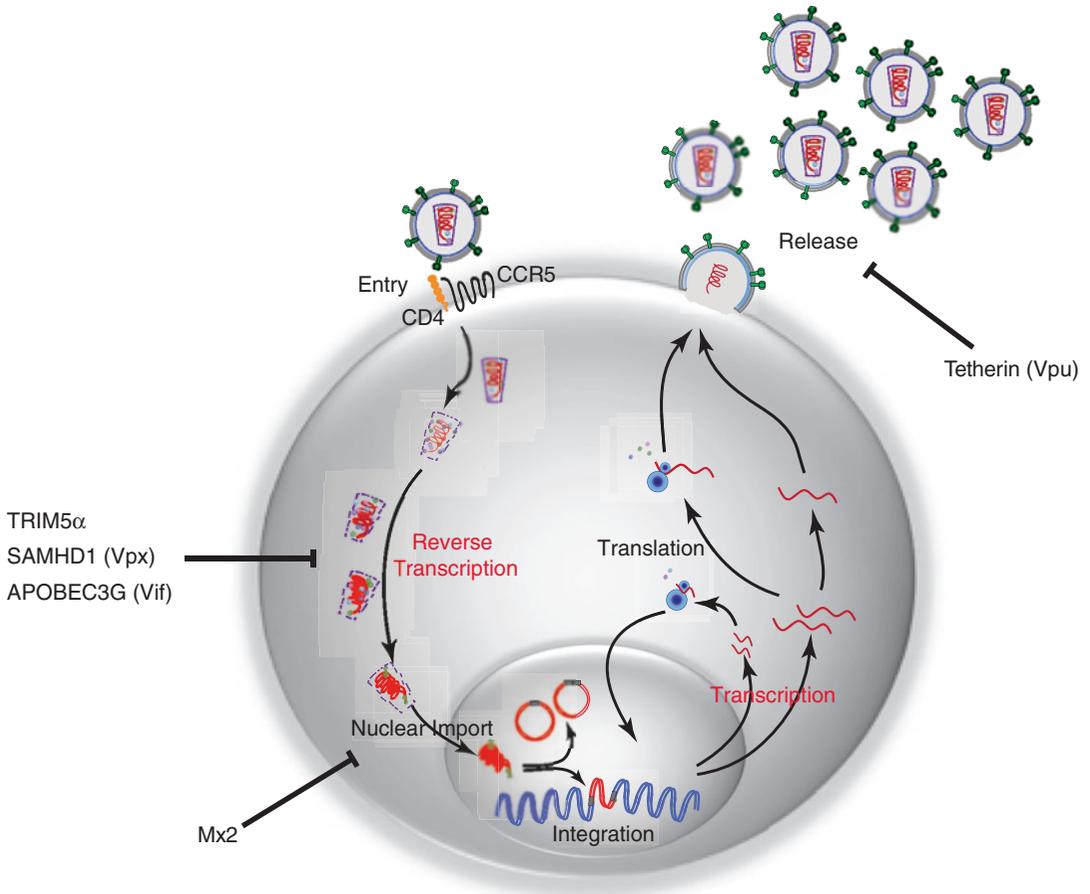

Within the same infected host, different sites of viral replication provide specific local environments. These include blood vessels, lymph nodes, gut-associated lymphoid tissue (GALT), the central nervous system, and the genital tract. The extracellular environment exerts multiple selective pressures, characterized by adaptive immunity (cytotoxic T lymphocytes (CTL), antibodies, cytokines) as well as the presence of antiviral drugs (Fletcher et al. 2014). Of note, these selective pressures change during the clinical course of HIV infection, as illustrated by the absence of specific anti-HIV antibodies during the first weeks of HIV infection or by the increase of CTL upon HIV infection.

Viral replication occurs at multiple sites or organs, thus constituting different local environments that may promote evolution of compartmentalized quasispecies.

Cellular Variability

HIV can infect differently multiple cells, characterized by specific proteomes and transcriptomes, such as memory CD4⁺ T cells, naïve CD4⁺ T cells, activated or resting CD4⁺ cell subsets, and macrophages. The cellular environment plays an essential role in viral replication as HIV interacts with many proteins. Indeed, to survive and successfully reproduce, a virus has to deal with a specific cellular environment, hence profiting from factors promoting and facilitating its replication as well as coping with factors blocking it. Viral replication success will thus result from a balance of HIV interactions with these two types of players, HIV dependency factors (HDF) and restriction factors (Fig. 3).

During its progression through the cell, HIV interacts with a plethora of cellular proteins that are essential to successfully replicate (Bushman et al. 2009; Jager et al. 2012). Among this large list of HIV dependency factors, key cellular proteins include the viral receptor CD4 and the coreceptor CCR5 (or CXCR4) that are essential

Viral Fitness in Hosts, Fig. 3 **Viral replication success in a specific cellular environment.** In a specific cellular environment, viral fitness can be measured as the size of viral progeny particle or in replication kinetic assays. In these systems, success will depend on virus ability to efficiently complete its replication cycle and thus produce progeny virions, by (i) providing viral proteins executing

the required enzymatic activities and exploiting HIV dependency factors (HDF) and (ii) providing viral countermeasures or adaptive mutations to evade restriction factors and cellular antiviral defenses. Restriction factors are indicated at the level where they block HIV replication cycle. Viral countermeasure proteins are indicated in brackets.

for viral entry, TNPO3/TRN-SR2 and LEDGF/p75 that are essential for viral genome nuclear import and integration, multiple cellular transcription factors such as cyclinT1/cdk9 and NF-κB that facilitate viral transcription, proteins involved in nuclear export pathways allowing to translocate viral RNA to the cytoplasm, and ESCRT complex proteins that are required for budding and release.

On the other hand, innate immunity is a natural barrier against infections that aims at recognizing the invading virus, at promoting an antiviral state through the production of interferon and

interferon-stimulated genes, and finally at blocking and eliminating the viral pathogen (Schoggins and Rice 2011; Schoggins et al. 2011, 2014; Sandler et al. 2014; Schoggins 2014). Restriction factors are part of the innate immunity cascade; they are induced by interferon and directly interact with viral proteins in order to impede HIV progression and replication. Examples of restriction factors include TRIM5α, SAMHD1, APOBEC3G, and tetherin (Kirchhoff 2010; Blanco-Melo et al. 2012; Harris et al. 2012; Malim and Bieniasz 2012; Pyndiah et al. 2015).

TRIM5 α binds to the viral core and promotes its premature disassembly, thereby impairing efficient viral reverse transcription. SAMHD1 is an enzyme that hydrolyzes deoxynucleoside triphosphates to deoxynucleosides, thereby reducing the concentration of intracellular nucleotides necessary for viral reverse transcription completion. APOBEC3G is a cytidine deaminase acting at the minus-strand DNA during the reverse transcription process, resulting in G-to-A mutations in the positive-strand DNA and eventually leading to lethal mutagenesis. Tetherin is a membrane-anchored protein that incorporates into virion membranes, thereby retaining viral particles at the cell surface and impeding their full release. Because restriction factors represent selective pressures exerted by intrinsic cellular defenses, escape mutants or counteracting proteins encoded by the virus have been selected over time: a mutation in the viral capsid protein to escape TRIM5 α recognition and mediated degradation; the accessory viral Vif protein that binds and promotes proteasome-mediated APOBEC3G degradation to block its packaging in viral particles and thus its action during reverse transcription in the subsequent infected cells; and the accessory viral Vpu protein that mediates endocytosis and degradation of tetherin. Although no HIV-1 protein counteracts SAMHD1, HIV-2 encodes the Vpx accessory protein that is able to inhibit SAMHD1 restriction activity by promoting its proteasomal degradation. Identifying these restriction factors is essential to understand the role of innate immunity in shaping and selecting for viral sequences within a given cellular environment. The presence of restriction factors and viral countermeasures illustrates the continuous virus-host interplay and evolutionary race toward selective pressures.

Impact of HIV Integration

An additional complexity linked to HIV relies to its ability to integrate. Indeed, integrated HIV implies that viral genome sequences can persist within long-lived cells and can be archived, offering an opportunity for later reemergence. This may provide a second chance to poorly fit viruses under specific environmental conditions at one

time point, to become the fittest viruses under a novel environment at another point in time. The reemerging viruses may thus face a different fitness landscape.

Conclusion

The evolution potential of HIV allows for generation of rapid and unprecedented genetic diversity. Although genetic diversity provides the opportunity to adapt to environmental constraints, it also has a cost at the viral success level. In other terms, adaptation is not free for all possibilities as the virus maintains conserved regions, as compensatory mutations are needed to allow certain mutations to be retained, and as there may be extensive evolutionary dependencies, in particular upon recombination. Because of these multiple viral, cellular, and structural constraints, many quasispecies are dead viruses, unable to replicate and continue spreading.

On another hand, although production of a large amount of viral quasispecies among which only a few are infectious may be considered as a waste of cellular and viral resources, it may also be considered as a way to divert the attention of the host immune system, as the infectious virions could hide and thus possibly escape. All together, viral fitness of quasispecies contributes to replication success, to adaptation to multiple environments, and thus to the epidemiological success of HIV, although the link between viral fitness and clinical outcome has still to be fully established.

Viremic Nonprogressors

Julie Christine Gaardbo, Jan Gerstoft and Susanne Dam Nielsen

Department of Infectious Diseases, University of Copenhagen, Rigshospitalet, Copenhagen, Denmark

Definition

Viremic nonprogressors are untreated HIV-1-infected individuals who maintain stable CD4+ T cell counts within the normal range for more than 10 years, despite moderate to high levels of HIV-1 replication. However, in most viremic nonprogressors, slow disease progression with gradual CD4+ T cell decline occurs at one point, and these individuals may eventually develop AIDS when left untreated. Viremic nonprogressors are therefore also referred to as viremic slow progressors. Viremic nonprogressors should not be confused with HIV-infected controllers who are able to control viral replication resulting in very low or undetectable viremia and stable CD4+ T cell counts.

Introduction

Prior to the introduction of effective ART, it was observed that a minority of HIV-infected patients did not progress to AIDS or death. These individuals, termed long-term nonprogressors (LTNP), maintained normal CD4+ T cell counts in the absence of treatment for several years – in some cases for more than two decades, as opposed to the majority of HIV-1-infected persons who typically progressed to AIDS and death within a median of approximately 8 years. When PCR assays for measuring HIV RNA were introduced, it was evident that some of these patients with preserved CD4+ T cell counts had low or even undetectable viral replication. This phenomenon leads to the classification of HIV-infected controllers defined by their ability to control viral replication in the

absence of ART. Controllers can be further divided into elite controllers (EC) and viremic controllers (VC), most commonly with HIV RNA <50 copies/mL and 50–2,000 copies/mL, respectively, although variations with higher levels are found as well (Okulicz et al. 2009; Hunt 2009; Saag and Deeks 2010). In contrast, true viremic nonprogressors typically display HIV-1 viral loads >10,000 copies/mL (Poropatich and Sullivan 2011), while maintaining similar or only slightly lower levels of CD4+ T cells compared to HIV-1 controllers. Today, the term “long-term nonprogressors” is widely used as a collective name for controllers and viremic nonprogressors.

It is well established that viremic nonprogressors and controllers are different subpopulations (Okulicz et al. 2009; Grabar et al. 2009; Petrucci et al. 1997; Lambotte et al. 2005), suggesting that different immunological mechanisms are responsible for the preserved CD4+ T cell counts. Viremic nonprogressors and controllers are described as rare populations, with little overlap between them (Okulicz et al. 2009; Hunt 2009; Grabar et al. 2009; Petrucci et al. 1997; Lambotte et al. 2005; Boufassa et al. 2011). Viremic nonprogressors are, along with elite controllers, reported from different cohorts to comprise <1% of HIV-infected individuals, whereas viremic controllers are more frequent depending on the level of viremia (Okulicz et al. 2009; Hunt 2009; Grabar et al. 2009; Petrucci et al. 1997; Lambotte et al. 2005; Boufassa et al. 2011). However, the definition of the populations suffers from lack of consensus in terminology and inclusion criteria, impeding the comparison of findings. In addition, a central problem in defining the nonprogressor phenotype is a complete lack of inclusion of the viral load in some cohorts, thereby confusing viremic nonprogressors with controllers and vice versa.

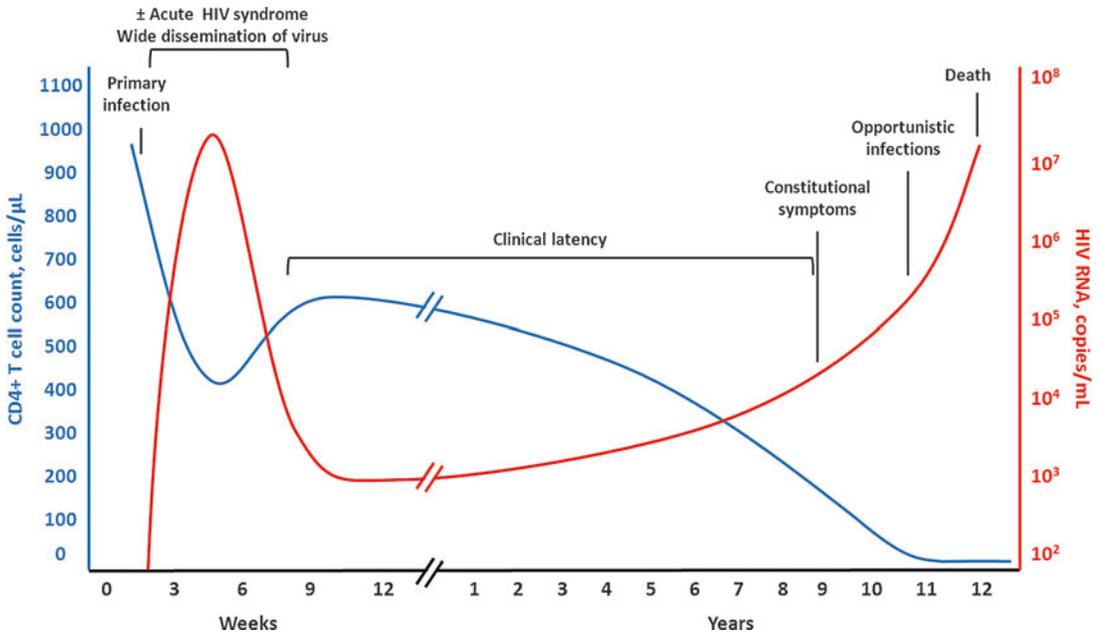

Patients need not necessarily be infected for a long period of time in order to be categorized as controllers. Thus, a single measurement of spontaneous control may be used as sufficient for defining a controller, whereas others demand several years of infection. In contrast, viremic nonprogressors due to the nature of the case definition

have a long duration of infection, most often 7–10 years. Viremic nonprogressors present with more or less stable CD4+ T cell count within the normal range (390–1,600 cells/ μ L) (Okulicz et al. 2009; Grabar et al. 2009; Petrucci et al. 1997; Rodes et al. 2004). Due to the low prevalence of viremic nonprogressors, it is tempting to relax the inclusion criteria. However, the stringency of inclusion criteria seems to predict the clinical outcome. Thus, a better survival among viremic nonprogressors defined by 10 years of stable CD4 T cell counts versus 7 years is reported (Okulicz et al. 2009), suggesting that even 7 years of stable infection does not distinguish adequately between true viremic nonprogressors and progressors.

This entry focuses on viremic nonprogressors, while controllers are discussed in a separate entry of this encyclopedia. However, as data on viremic nonprogressors are very limited, some data referring to LTNP without further classification based on viral load or plasma viremia are also included.

The Normal Course of HIV Infection

Three to 6 weeks following primary infection, 50–70% of infected individuals experience an acute clinical syndrome characterized by fever, “flu-like” symptoms, and other neurological, dermatological, or hematological manifestations. This acute infection is characterized by severe depletion of CD4+ T cells in the gut-associated lymphoid tissue (GALT), where most CD4+ T cells reside. During acute infection, high-level viral replication takes place in almost all body compartments, particularly in the GALT and other lymphoid organs, leading to increased immune activation. As activated cells are more susceptible to HIV infection, this massive viral replication is the beginning of a vicious cycle where viral replication drives the infection of newly activated CD4+ T target cells (Fig. 1). Along with the establishment of a partly efficient adaptive immune response leading to suppression of replication and elimination of virus-producing CD4+ T cells, the balance between viral replication and target cells eventually reaches equilibrium. This leads to a decrease in viral replication

Viremic Nonprogressors, Fig. 1 CD4+ T cell count (*blue*) and viral load (*red*) during untreated HIV infection (Adapted from Pantaleo et al. 1993)

and a subsequent stabilization of the levels of HIV RNA, *the viral set point*, which is specific for a given individual. This is accompanied by an increase in CD4+ T cells to normal or more often subnormal levels. The viral set point predicts the rate of disease progression, including the rate at which the CD4+ T cells are lost. When the CD4+ T cell count decreases below 200 cells/ μ L, HIV infection is often associated with symptoms of immune deficiency. The infection has now progressed to late stage disease, and the patient may acquire AIDS and may die within a short time if treatment is not initiated (Harrison's).

SIV Infection

Given that the case definition of nonprogressors requires multiple years of follow-up, patients are typically not identified as nonprogressors until late in the disease process. This fact represents a considerable challenge for investigations of viremic nonprogressors, as data and biological samples from acute infection of patients who eventually develop a viremic nonprogressor phenotype are

typically not readily available. Therefore, animal models of non-pathogenic SIV infection in natural hosts, such as sooty mangabeys and African green monkeys, are helpful to delineate the pathogenesis of HIV/SIV infection not leading to CD4+ T cell losses and clinical immune deficiency. In fact, despite clinical nonprogression, natural hosts of SIV infection experience high levels of viral replication and can therefore be considered as functional analogues to viremic nonprogressors (Brenchley and Paiardini 2011). This assumption is supported by gene expression similarities between non-pathogenic SIV infection in sooty mangabeys and human viremic nonprogressors, while HIV-infected rapid progressors exhibited a gene expression profile more closely related to rhesus macaques with progressive SIV infection (Rotger et al. 2011).

Reasons for Nonprogression in Viremic Nonprogressors: Virology

No specific viral variation has so far been identified in viremic nonprogressors that distinguish

these individuals from other HIV-1-infected persons. Also, viral Nef proteins that modulate T cell activation and play a key role in the pathogenesis of AIDS have not been found to be abnormal in viremic nonprogressors (Heigele et al. 2014). Thus, host genetics or host immune responses appear to be the main reason responsible for viremic nonprogression of HIV-1 infection (Gaardbo et al. 2012).

Reasons for Nonprogression in Viremic Nonprogressors: Host Genetics

Prior genome-wide association studies have demonstrated that a number of factors are involved in viral control and a delayed disease progression. In contrast, little is known about genetic determinants for viremic nonprogression. Recently, a single nucleotide polymorphism (SNP) 35 kb upstream of the HLA-C gene locus (−35C/T) that correlates with increased HLA-C expression and improved control of HIV-1 was shown to be possibly enriched in viremic nonprogressors (Ballana et al. 2012). However, these findings will have to be verified in future studies. To what extent other genetic variations, such as specific HLA class I alleles, KIR alleles, or chemokine receptor polymorphisms, are associated with a viremic nonprogressor phenotype is not known. Given that the frequency of viremic progressors is extremely low, it is difficult to appropriately power immunogenetic association studies in this specific patient population.

Immunology in Viremic Nonprogressors: Production of Cells

T cells originate from hematopoietic progenitor cells and mature in the thymus. HIV influences both bone marrow and hematopoietic progenitor cells, and impaired hematopoiesis in HIV infection was demonstrated years ago (Marandin et al. 1996; Moses et al. 1998). Furthermore, progenitor cells themselves may be susceptible to HIV infection as they express CD4, CXCR4, and CCR5. Preservation of cellular immunity in

viremic nonprogressors may therefore be possibly related to a selective sparing of hematopoietic and lymphoid precursor cells from cytopathic effects of HIV infection. Indeed, in a study comparing HIV controllers with normal or reduced CD4+ T cell counts, controllers with progressive CD4+ T cell losses displayed signs of exhausted lymphopoiesis compared to controllers with normal CD4+ T cell counts (Sauce et al. 2011). This supports the idea of a sufficient hematopoiesis as a contributing factor to nonprogressive disease, implicates that viral replication in itself is not the only driver of disease progression, and may suggest that a preserved hematopoietic resource is involved in maintaining CD4+ T cell counts in viremic nonprogressors. Also, it was recently shown that viremic nonprogressors display limited HIV infection of central memory and stem cell memory CD4+ T cells compared to patients with progressive infection who had similar total CD4+ T cell counts (Klatt et al. 2014). This suggests that more immature and long-lived CD4+ T cell populations from viremic nonprogressors may be partially resistant against HIV-1 infection. Notably, a reduced ability to support SIV infection was also noted in central memory and T memory stem cells from sooty mangabeys (Cartwright et al. 2014).

The CD4+ T cell count is maintained by de novo production in the thymus and lymphoid tissue or by homeostatic proliferation of naive CD4+ T cells in the periphery. It is now evident that the thymus is active not only in childhood but also in adulthood, particularly during lymphopenic conditions such as HIV infection (Douek et al. 1998). Thymic function can be assessed as T cell receptor excision circles (TRECs) or as the naive CD4+ T cell count. HIV infection leads to reduced numbers and impaired function of naive CD4+ T cells in blood as well as in lymphoid tissue (Douek et al. 1998). As illustrated by the sink model (Ho et al. 1995), a well-functioning thymopoiesis (the tap) is central in preserving the CD4+ T cell count and is therefore likely to be involved in nonprogression in viremic nonprogressors. In nonprogressors, similar and lower numbers of naive CD4+ T cells have been found compared to progressors (Gaardbo

et al. 2012), and TRECs may be higher in viremic nonprogressors compared to progressors (Gaardbo et al. 2013). The contribution of a well-functioning thymopoiesis to nonprogression is further supported by the findings of strong correlations between TRECs and nonprogression in SIV-infected rhesus macaques (Ho Tsong et al. 2005). Also, normal levels of memory cells and preserved IL-2 secretion capacities have been shown in nonprogressing SIV-infected rhesus macaques compared to progressors (He et al. 2011). For this reason, it seems plausible that viremic nonprogressors possess an extraordinary ability to produce CD4⁺ T cells possibly contributing to the preserved CD4⁺ T cell counts in viremic nonprogressors. Furthermore, it is worth noticing that with increasing age, thymic output is reduced. Thus, the reported loss of the non-progressor status in some viremic nonprogressors may be due to age-related decrease in thymic output. This age-related output could potentially be enhanced by a premature aging which have been suggested to take place in HIV-infected individuals (Sauce et al. 2011).

Secondary Lymphatic Tissue

One of the central challengers in understanding how HIV interacts with the immune system is why lost CD4⁺ T cells are only partly being replaced. One reason may be an HIV-induced damage of the structures in lymphoid tissue where the functional space becomes replaced with collagen (Estes et al. 2008). Lymphoid tissue is important for production, survival, and proliferation of cells. The amount of the collagen-deposition has been associated with the CD4⁺ T cell count and number of naive CD4⁺ T cells (Schacker et al. 2002). At present, it is unknown if viremic nonprogressors are less likely to generate fibrosis in their lymphatic tissue, or if the lymphatic tissue is more effective in producing new cells. In contrast, the amount of lymphoid tissue in viremic non-progressors was found to be reduced in a single study, suggesting that a larger amount of lymphoid tissue is not the main reason for viremic nonprogression (Gaardbo et al. 2013).

Destruction of Cells

Activation of the immune system is a main feature in HIV infection and a recognized predictor of disease outcome. Immune activation has a stronger prognostic value than CD4⁺ T cell count or viral load alone (Grossman et al. 2002). It is therefore reasonable to assume that limited immune activation may be involved in lack of progression in viremic nonprogressors. In non-progressors, immune activation is one of the better examined features, and lower immune activation in comparative studies of controllers and progressors is well documented (Gaardbo et al. 2012). In SIV infection immune activation distinguishes pathogenic infection from the benign outcome seen in the natural hosts, as these animals do not show signs of increased immune activation or T cell turnover during the chronic phase despite significant viral replication (Brenchley and Paiardini 2011; Broussard et al. 2001; Kaur et al. 1998). However, this does not seem to be the case in the human immune system as viremic nonprogressors have been demonstrated to display elevated levels of immune activation compared to HIV-negative individuals (Gaardbo et al. 2013).

Destruction of cells in HIV infection – the drain in the sink model – is partly a consequence of increased immune activation as activated cells are both more likely to become infected with HIV and to undergo apoptosis. However, much of the uncontrolled immune activation is also believed to be a consequence of non-HIV-specific mechanisms including microbial translocation.

Immune Regulatory Cells and Microbial Translocation

Regulatory T cells (Tregs) are anti-inflammatory T cells with an important function in preventing immune responses from becoming overactivated. Tregs are more prevalent in HIV-infected, untreated, progressing patients compared to healthy controls (Kanwar et al. 2010; Chevalier and Weiss 2013), suggesting high levels of Tregs to be harmful, possibly because they

downregulate beneficial HIV-specific immune responses. Indeed, controllers exhibit lower levels of Tregs than progressors according to some studies, while the prevalence of Tregs in viremic nonprogressors may be elevated like in progressors (Gaardbo et al. 2014). Interestingly, it may be of importance if the Tregs are activated or not, based on expression levels of CD45RA+ and the level of FoxP3. Thus, both elite controllers and viremic nonprogressors displayed elevated percentages of activated Tregs in one study (Gaardbo et al. 2014). Finally, Tregs may increase with age possibly contributing to the slow progression or loss of nonprogression in viremic nonprogressors. Thus, the role of Tregs in regard to HIV infection is likely to be a two-edged sword being beneficial in some settings and harmful in others.

Tregs are closely related to IL-17-producing Th17 cells which are pro-inflammatory cells and involved in autoimmune responses. Tregs and Th17 cells function together in opposing ways to control the inflammatory response upon infection, and while Tregs are likely to become more prevalent during HIV infection, Th17 cells are depleted. Th17 cells are believed to play a pivotal role for the mucosal integrity in the gut by stimulating epithelial proliferation and inducing a pro-inflammatory environment by recruiting neutrophils. GALT is the main defense against infectious microorganisms in the gastrointestinal tract and host of the majority of Th17 cells. Thus, the depletion of CD4+ T cells in the GALT during acute HIV infection includes depletion of Th17 cells. The consequence is damage to the mucosal barrier resulting in a continuing leak of microbial remnants to the systemic circulation, a phenomenon termed microbial translocation. These microbial products may activate the immune system and may therefore contribute to HIV progression (Brenchley et al. 2006). In non-pathogenic SIV-infection CD4+ T cells including Th17 cells in the gastrointestinal tract are relatively preserved. One study of HIV nonprogressors, most of whom met the viremic nonprogressor criteria, demonstrated elevated levels of Th17 cells compared to progressors (Gaardbo et al. 2012). Another study of 4 viremic nonprogressors

suggested lower microbial translocation in these patients compared to rapid progressors (Rotger et al. 2011). However, more studies are needed to more definitively analyze the possible contribution of Th17 cells to a viremic nonprogressor phenotype.

HIV-Specific Immune Responses and Neutralizing Antibodies

HIV-specific CD8+ T cells and neutralizing antibodies are believed to be an important but in many cases insufficient element in suppressing viral replication. While the importance of HIV-specific T cell responses on viral control is well established (Gaardbo et al. 2012; Migueles et al. 2004; Porichis and Kaufmann 2011), little is known about HIV-specific T cell responses in viremic nonprogressors. A small study of three viremic nonprogressors found a preserved HIV-specific T cell response, while responses in progressors were found to be reduced (Choudhary et al. 2007). The contribution of neutralizing antibodies on viremic nonprogression is even less clear, but represents an important area for future investigations.

Innate Immune Activation

The innate immune response is the earliest response to HIV infection. Effectors of the innate immune system include plasmacytoid dendritic cell, Toll-like receptors (TLRs), and NK cells. One study evaluated the phenotypic and functional properties of CD56+ CD16+ natural killer (NK) cells in controllers and viremic nonprogressors. Cytolytic activity against autologous CD4+ T cells was found to be abrogated after treatment with an antibody to NKp44L, the cellular ligand of the natural cytotoxicity receptor NKp44 which is specifically induced on CD4+ T cells during HIV-1 infection in LTNP and HIV progressors. In contrast, in HIV controllers and uninfected persons, NKp44L expression on CD4+ cells and autologous NK lysis were both poorly detected (Vieillard et al. 2010).

Conclusion

The reasons for lack of HIV-associated immune deficiency in viremic nonprogressors are multifactorial and appear to involve a broad range of components. However, data on viremic nonprogressors are very limited, studies are small, and case definitions differ among studies. Nevertheless, it is clear that these rare individuals are infected with replication-competent virus, and therefore, host immune factors or specific host-virus interactions seem to represent the main determinants. An extraordinary ability to produce and regenerate T cells and a lower rate of CD4⁺ T cell death are currently assumed as main driving forces that lead to the viremic nonprogressor phenotype. However, only few empiric studies investigating CD4⁺ T cell production or destruction in these patients are available at present to support this hypothesis. Likewise, solid evidence of reduced immune activation in the innate and adaptive compartment in viremic nonprogressors is currently lacking. Thus, understanding the underlying mechanisms underlying viremic nonprogression remains one of the most difficult but also one of the most important fields of future investigation.

Virus Assembly

Philip R. Tedbury and Eric O. Freed
 HIV Drug Resistance Program, Frederick
 National Laboratory, Frederick, MD, USA

Definition

Assembly is the process whereby the components necessary for transmission of HIV to a new cell come together to form a viral particle or virion. These principal components are the proteins Gag and GagPol, the envelope glycoproteins, the viral genome, and some of the HIV accessory proteins. Assembly occurs on cellular membranes; immature virions bud through the cell membrane and are released by the action of host-cell cofactors recruited by Gag. Maturation, which occurs during or immediately following ► [budding](#), involves the cleavage of Gag and GagPol by HIV protease and subsequent modification of the internal structure of the virion necessary for infectivity. Assembly can be considered complete once an infectious virion has been generated.

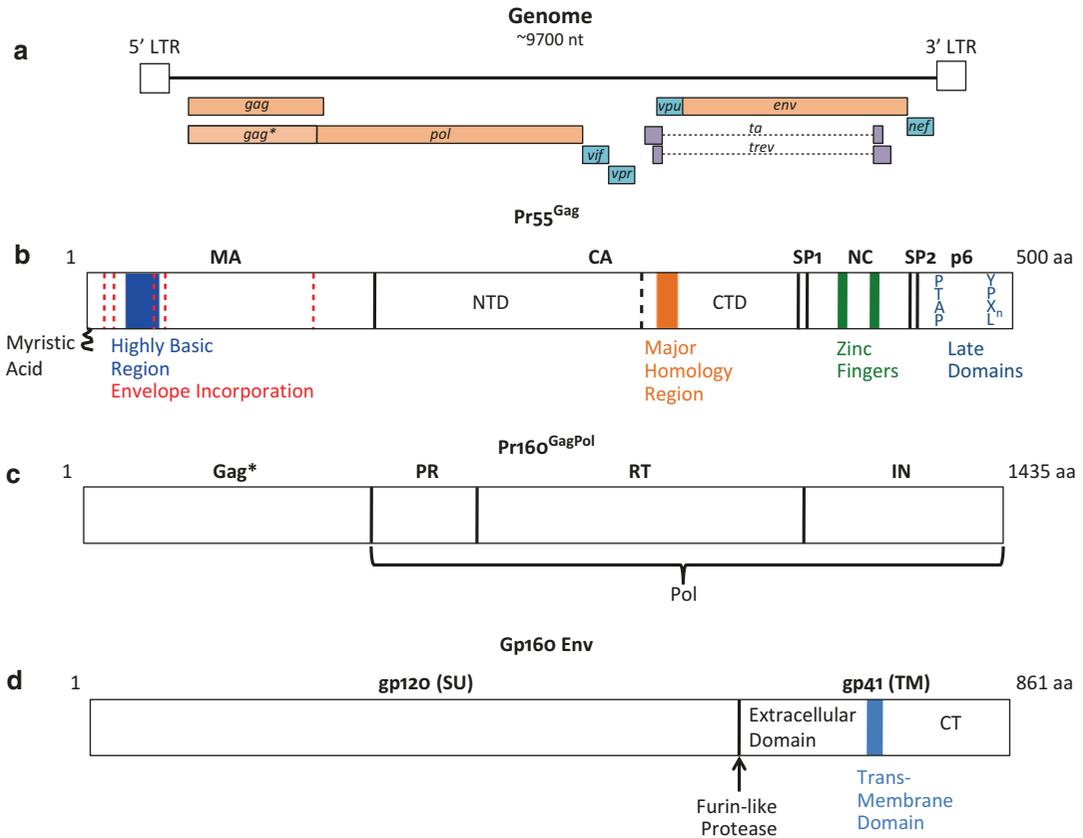

Although AIDS is caused by both HIV-1 and HIV-2, the majority of human infections and the majority of research involve HIV-1. This review will therefore deal almost exclusively with HIV-1; however, it is probable that HIV-2 behaves similarly if not identically for the processes discussed in this review.

HIV-1 Replication

HIV-1 infection begins when the viral envelope (Env) glycoproteins on the virion bind to the viral receptor (CD4) and coreceptor (CCR5 or CXCR4) on the surface of the target cell. Conformational changes in Env, induced by receptor and coreceptor binding, trigger the fusion of viral and target cell membranes, leading to the entry of the viral core into the cytoplasm. After target cell entry, the viral RNA genome is converted to double-stranded DNA by the enzyme reverse transcriptase (RT). The newly synthesized viral DNA translocates across the nuclear envelope as part of the preintegration complex. The process of nuclear import remains poorly defined, though recent evidence suggests that interactions between the Gag-capsid (CA) protein and components of the nuclear pore may play a positive role. Having gained entry to the nucleus, the HIV genome is integrated into the host genome by the viral integrase (IN) protein. The integrated provirus is transcribed by host RNA polymerase II to produce the viral mRNAs encoding the viral proteins and the full-length viral RNA that is packaged into new particles. The integrated provirus is maintained in infected cells until they die; cell death may occur rapidly in some cell types, such as activated T cells, or cells may survive for many years, as in memory T cells. The viral structural proteins assemble, together with two single-stranded copies of the viral RNA, into a new generation of viral particles (Freed and Martin 2012). The assembly process is the focus of this chapter.

The HIV-1 Proteins

HIV-1 is a complex retrovirus that encodes 15 proteins (Fig. 1). These can be categorized into five groups: Gag, Pol, Env, regulatory, and accessory proteins. The principal driver of virus assembly is the Gag polyprotein, a 55-kDa precursor (Pr55^{Gag}) to the mature Gag proteins matrix (MA), CA, nucleocapsid (NC), and p6. Each of these proteins is derived from functional domains in the Gag precursor, playing key roles in virion

Virus Assembly, Fig. 1 Schematic of the HIV-1 genome and polyproteins. (a) The HIV-1 genome with long terminal repeats (LTRs) and protein products indicated. The polyproteins (Gag, GagPol, and Env), regulatory proteins (Rev and Tat), and accessory proteins (Vif, Vpr, Vpu, and Nef) are indicated. HIV-2 has similar genomic organization, but lacks Vpu and encodes an extra protein, Vpx. (b) Pr55^{Gag}. The domains comprising the mature protein products are separated by *solid lines* (matrix, MA; capsid, CA; spacer peptide 1, SP1; nucleocapsid, NC; spacer peptide 2, SP2; p6). Major domains involved in virus assembly and release are indicated. The N-terminal and C-terminal domains of CA are separated by a *dashed line*. (c) Pr160^{GagPol}. GagPol is generated through a mechanism of ribosome slippage during translation of Gag, resulting in a frameshift. The resultant Gag* lacks the p6 domain and its stop codon; translation therefore

continues through Pol generating the GagPol protein that assembles with Gag in the viral particle and during maturation releases the enzymes (protease PR, reverse transcriptase RT, integrase IN). (d) Gp160 Env. The gp160 Env glycoprotein precursor is translated in the endoplasmic reticulum and traffics to the cell membrane via the Golgi apparatus. In the Golgi, it is cleaved by a host furin-like protease to generate the mature products, gp120 and gp41. The mature proteins remain non-covalently associated and form a trimer. Gp120 is responsible for the recognition of the receptors and coreceptors for HIV entry, while gp41 contains an extracellular domain necessary for membrane fusion and a cytoplasmic tail (CT). The function of the cytoplasmic tail is not entirely clear, but it appears to affect cell signaling, immune functions, and incorporation of Env into viral particles

assembly and ► **budding**. Via a process known as ribosomal frameshifting, Gag protein synthesis occasionally (5–10% of the time) leads to the synthesis of a longer GagPol product. Pol, like Gag, is a precursor polyprotein; it encodes the viral enzymes protease (PR), RT, and IN. While RT and IN function early in the infection process,

PR is required for the final step of the replication cycle – virion maturation. The third viral precursor protein is the Env glycoprotein. Synthesized as a 160-kDa polyprotein, gp160, it is cleaved by a cellular protease during trafficking through the Golgi apparatus to form the surface Env glycoprotein gp120 and the transmembrane Env

glycoprotein gp41. The Env glycoproteins are exposed on the surface of the virion; gp120 is responsible for recognizing the viral receptors on target cells, and gp41 catalyzes a membrane fusion reaction between viral and cellular membranes to release the contents of the virion into the target cell.

The regulatory proteins, Tat and Rev, control viral protein expression. The accessory proteins, Vif, Vpr, Vpu, and Nef, play roles in regulating the cellular environment to make it compatible with HIV-1 replication. While in many cases they are dispensable for virus replication in cultured cells, they are critically important during infection of the human host (Freed and Martin 2012).

Following successful infection of a cell, the HIV-1 genetic material resides in the host genome in the form of an integrated provirus. The host-cell transcriptional and translational machinery generates HIV-1 proteins much as it would human proteins, and many of these go on to form the virions responsible for initiating subsequent rounds of infection.

HIV-1 Gag

The Pr55^{Gag} precursor is able to drive the formation and budding of virus-like particles (VLPs) in the absence of any other viral component; for this reason it is sometimes referred to as the assembly machine (Sundquist and Kräusslich 2012). Like any machine, the Gag precursor possesses multiple components each of which plays a specific role in virus assembly (Fig. 1).

The MA domain directs Pr55^{Gag} to bind membranes. Gag–membrane binding is achieved primarily through two features: a myristic acid group covalently attached to the N-terminus of MA and a highly basic region. The MA domain also promotes the incorporation of the Env glycoprotein complex into virions.

The CA domain is comprised of two structural and functional units – the amino-terminal domain (NTD) and carboxy-terminal domain (CTD) –

which are connected by a flexible linker. CA-CA interactions mediated by both the NTD and the CTD allow CA to form a continuous hexameric lattice. The CTD also includes the major homology region (MHR), an essential domain conserved throughout many genera of retroviruses that plays an important role in Gag multimerization and virus assembly.

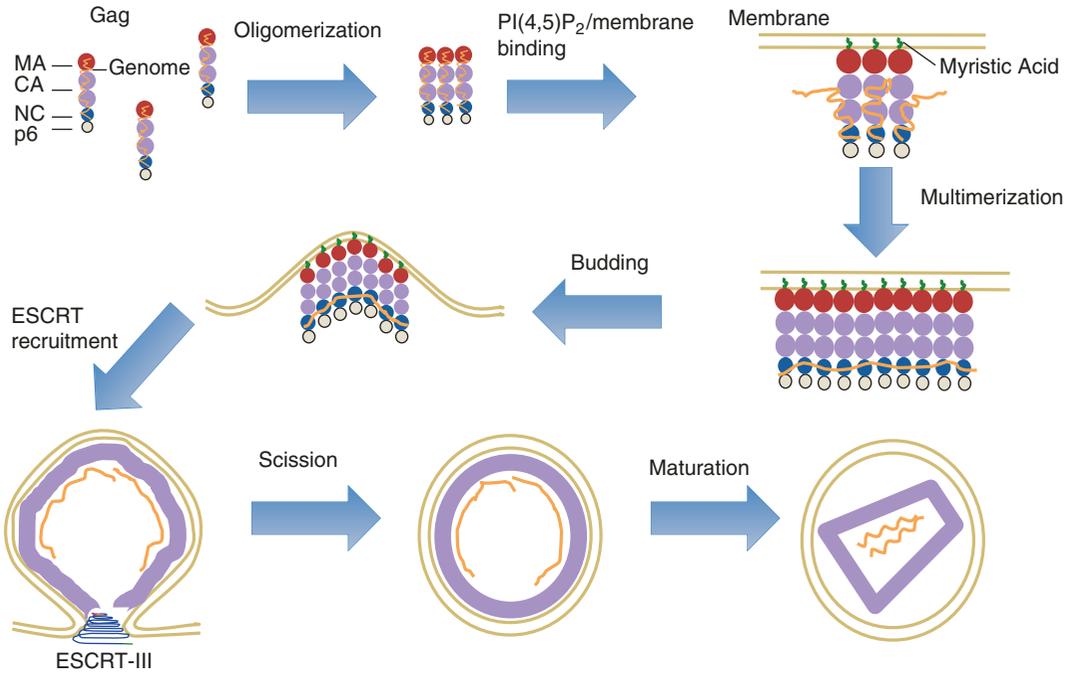

NC forms the third domain of Gag. It is small, highly basic, and possesses as its most distinctive feature two zinc-finger motifs. These motifs are well conserved among retroviruses and are connected by a flexible linker. NC can bind RNA nonspecifically because of its overall positive charge, but exhibits selectivity for HIV-1 genomic RNA. This selectivity is conferred to a large extent by the zinc fingers. In addition to its role in assembly, NC has important post-entry functions as a nucleic acid chaperone.

P6, the most C-terminal domain in Gag, possesses the “late domains,” so-called because they function late in the virus budding process. Gag mutants that lack either the late domains or the entirety of p6 are able to assemble particles but are unable to bud from the cell and instead remain tethered to the cell membrane.

In addition to the four major Gag domains discussed above, Pr55^{Gag} contains two small spacer peptides located between CA and NC (SP1) and between NC and p6 (SP2). These spacer peptides help regulate the kinetics of Gag processing, and SP1 contributes to Gag multimerization.

Gag Trafficking

The newly translated Gag molecules begin the process of assembly in the cytoplasm (Fig. 2) (Balasubramaniam and Freed 2011). Early in the assembly process, Gag forms low-order oligomers, comprising just a few Gag molecules that bind to the membrane. Gag oligomerization and membrane binding are thought to be primed by Gag–RNA interactions, mediated by NC. Phosphatidylinositol-4,5-bisphosphate [PI(4,5)P₂], a phospholipid concentrated on the inner

Virus Assembly, Fig. 2 A schematic representation of the processes that take place in particle assembly and release. The Gag polyprotein (MA, maroon; CA, pink; NC, blue; p6, beige) is synthesized in the cytoplasm where it oligomerizes. MA binds PI(4,5)P₂ at the cell membrane, promoting exposure of the myristic acid (green), anchoring Gag to the membrane. Binding of the

genome (orange) by NC leads to large-scale multimerization of Gag, driven by CA-CA interactions. The nascent Gag particle buds from the cell and recruits ESCRT machinery via p6 to achieve membrane scission. Maturation to the infectious particle occurs during or immediately following release

leaflet of the plasma membrane, is a major cellular determinant in directing Gag to the plasma membrane. PI(4,5)P₂ binding by the MA domain of Gag triggers exposure of the myristic acid group. This so-called myristyl switch permits the hydrophobic acyl chain of the myristic acid moiety to insert into the hydrophobic interior of the lipid bilayer, anchoring Gag to the membrane. HIV-1 assembly takes place in membrane microdomains (often referred to as lipid rafts) that are enriched in cholesterol and highly saturated sphingolipids; the HIV-1 lipid bilayer is therefore enriched in PI(4,5)P₂, cholesterol, and sphingolipids relative to bulk plasma membrane. In addition to promoting virus assembly, this specific lipid composition may also function in the infection process, as virions depleted of cholesterol and raft lipids demonstrate reduced infectivity.

Assembly of the Gag Lattice

After initial membrane binding, low-order Gag oligomers assemble into a more extensive Gag lattice (Mateu 2009). Interactions between Gag and RNA play a crucial regulatory role in the assembly process. Mutating the regions of NC necessary for RNA binding inhibits virion assembly. The current model is that RNA provides a scaffold for assembly, bringing together Gag molecules, thereby promoting their multimerization. The CA-SP1 region of Gag is sensitive to Gag concentration, and the concentration-dependent modification of the structure in this region contributes to the multimerization of thousands of Gag molecules (2,000–5,000/particle) into an ordered lattice. Support for the hypothesis that NC–RNA interactions help to initiate the assembly process derives from the observation that Gag

will efficiently assemble into a multimeric lattice if NC is replaced with a leucine zipper motif. Leucine zippers oligomerize, increasing the clustering of Gag independently of RNA. Thus, the local concentration of Gag is increased by activities encoded at both ends of the Gag precursor; the N-terminal MA domain binds to specific lipid microdomains, and the more C-terminal NC domain interacts with RNA. Once Gag has been concentrated, Gag multimerization domains in CA and SP1 drive assembly into an organized protein lattice. In the immature lattice, the hexameric sheet formed by the CA domain adopts a closed, roughly spherical structure via inclusion of gaps in the lattice. In contrast, the hexameric CA lattice in the mature core closes off by inclusion of pentamers (see below).

Virion Budding

Although p6 plays no role in the formation of the Gag lattice, it is required to promote ► budding and release of the virion after the immature particle has been assembled. The membrane scission event that allows the virus particle to pinch off from the plasma membrane requires the late domains. The common role of all retroviral late domains is to recruit components of the endosomal sorting complex required for transport (ESCRT) machinery. ESCRT functions in processes requiring the formation of a bud protruding out of the cytoplasm, such as during cell division and the formation of intracellular multivesicular bodies. Such processes topologically resemble virus budding, and a number of enveloped virus families take advantage of this cellular machinery to effect particle release. The ESCRT machinery is comprised of four multisubunit complexes known as ESCRT-0, -I, -II, and -III. A variety of accessory molecules also function in ESCRT-mediated membrane budding and scission events (Martin-Serrano and Neil 2011).

Retroviruses interact with ESCRT or accessory endosomal sorting machinery via three types of late domain. Specifically, a Pro-[Thr or Ser]-Ala-Pro [P(T/S)AP] motif interacts with Tsg101; a Tyr-Pro-Asp-Leu (YPDL) motif, or

related sequence, binds the ESCRT accessory factor Alix; and a Pro-Pro-Pro-Tyr (PPPY) motif interacts with Nedd4 family ubiquitin ligases. HIV-1 has both a PTAP and a YPDL-like motif in its p6 domain. Tsg101 is a component of ESCRT-I, whereas Alix bears interaction sites for both ESCRT-I and ESCRT-III. The PTAP motif plays the primary role in HIV-1 budding, at least in cell culture; however, the high degree of conservation of both sequences suggests that both are important to virus replication in a natural setting.

While the various retroviral late domains interact with different components of the ESCRT machinery, the ultimate outcome of these interactions is to recruit ESCRT-III to the site of budding (Fig. 2). ESCRT-III is composed of the charged multivesicular body proteins (CHMPs 1–7). Typically, ESCRT-III function is nucleated by CHMP6, which in turn recruits multiple CHMP4 monomers, in an ever-tightening helix, to pinch off the budding vesicle. Addition of CHMP4 monomers ends with capping by CHMP3 and CHMP2 and the final recruitment of the ATPase Vps4, which disassembles the ESCRT-III complex. Surprisingly, HIV-1 requires only a subset of the CHMP proteins (CHMP2 and CHMP4) to achieve budding and does not require ESCRT-II, while most analogous cellular processes seem to require the full complement of ESCRT components (Morita 2012).

Restriction of Virus Release by Tetherin

After membrane scission has been effected by ESCRT-III and PR has cleaved the Gag polyprotein into the mature Gag proteins, mature, cell-free virions can initiate new rounds of infection. However, under some circumstances, release of budded virions is blocked by the cellular innate immune system. A principal signal in the induction of an “antiviral state” is interferon. A well-studied interferon-stimulated gene (ISG) with respect to HIV-1 replication is tetherin, originally known as CD317, BST2, or HM1.24 (Martin-Serrano and Neil 2011). Tetherin is a raft-localized protein that possesses two

membrane-anchored regions and a surface-exposed coiled-coil domain that mediates dimerization. Dimerization between tetherin molecules on the cell surface and within the viral membrane leads to the accumulation of virions on the cell surface, where they remain “tethered.” HIV-1 encodes viral protein U (Vpu) that counteracts tetherin by removing it from sites of virus ► [budding](#) and inducing its degradation. Other lentiviruses use their Env glycoproteins or the accessory protein Nef to counteract tetherin. The precise role of tetherin in the natural course of HIV-1 replication remains uncertain. Although tetherin clearly inhibits the release of cell-free virus *in vitro*, there is some evidence that, under certain circumstances, tetherin may actually promote virus transmission between cells. Nevertheless, the fact that lentiviruses have evolved diverse strategies to counteract tetherin argues that it serves a predominantly restricting role in lentiviral replication.

The Site of HIV-1 Assembly and Budding

HIV-1 predominantly infects T cells, leading to their eventual depletion and the induction of AIDS. However, lentiviruses including HIV-1 also infect cells of the myeloid lineage such as macrophages. Although currently a matter of debate, macrophage infection may contribute to the virus’ ability to persistently infect its host. The site of virus assembly and budding differs in certain respects between T cells and macrophages. In T cells, the overwhelming majority of Gag traffics to the plasma membrane where virus assembly occurs and virions are released to the extracellular medium or are transferred across synapses between T cells. In macrophages, Gag localizes to apparently intracellular compartments (Benaroch et al. 2010). Initially, these sites were thought to be multivesicular bodies, but more recent studies using a range of histological and imaging techniques have revealed that the internal virus-containing compartments in macrophages are in fact deep invaginations of the plasma membrane that are contiguous with the extracellular environment. These invaginations appear to function as sites of particle assembly and storage from

which mature virions can be released into the synapse formed between infected macrophages and uninfected T cells. Such a strategy allows virus particles to remain relatively hidden from the host immune system until the opportunity for cell–cell spread arises.

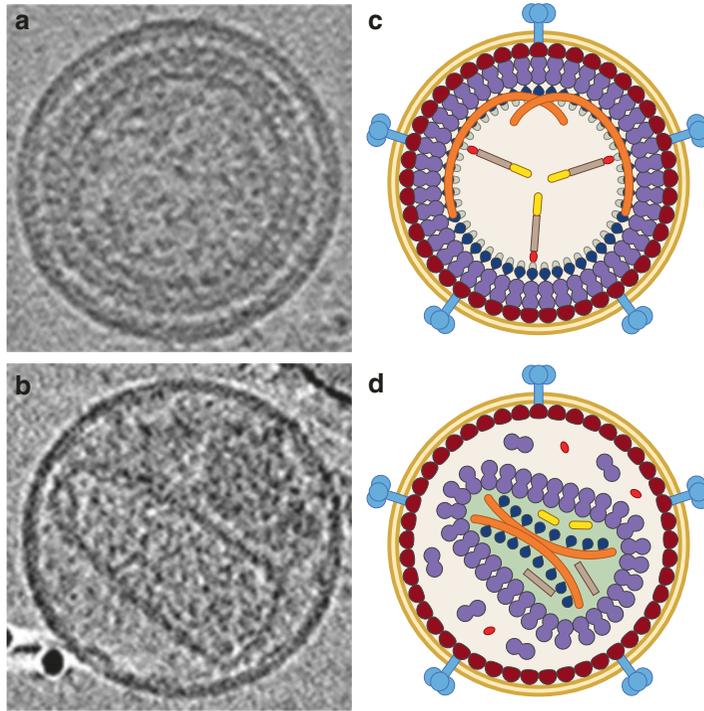

HIV-1 Particle Maturation

Pr55^{Gag} contains five major cleavage sites for the viral PR, located between functional domains of the polyprotein (Fig. 1). The final step in the generation of the infectious HIV-1 particle is maturation (► [HIV-1 Maturation](#)), which is triggered by PR-mediated processing at each of these cleavage sites (Sundquist and Kräusslich 2012). Gag cleavage by PR occurs concomitant with virion release from the host membrane, leading to the liberation of CA from the immature Gag lattice and its subsequent reassembly to form the outer shell of the conical capsid core that is characteristic of the mature virion (Fig. 3). PR-mediated Gag processing is a highly ordered, sequential process, with some cleavage events taking place early in the cascade and others occurring later and less efficiently. In the core, the CA protein is arranged in a hexameric lattice that is closed off at both ends by the asymmetric inclusion of twelve CA pentamers within the lattice (five at the narrow end, seven at the broad end) to produce a core with the characteristic conical shape. Virion maturation is critical for productive infection in the next cycle of replication; immature virions are both fusion-defective – likely owing to suppression of Env fusion activity resulting from gp41 interactions with the immature Gag lattice – and are incompetent to initiate reverse transcription in the target cell.

Additional Virion Components

The Env Glycoproteins

The Env glycoproteins are not required for particle assembly and budding, but they are necessary for the formation of an infectious virion (Fig. 1). The precise mechanism of Env glycoprotein

Virus Assembly, Fig. 3 Cryoelectron micrographs and schematic representations of immature and mature HIV-1 particles. Central slices through cryo-EM tomograms of immature (a) and mature (b) virus particles that are ~130 nm in diameter. Schematic representation of immature (c) and mature (d) HIV-1 particles. Color scheme is consistent with Fig. 2: MA, maroon; CA, pink; NC, blue;

p6, beige; genome, orange. Additionally, GagPol products are shown: protease, red; reverse transcriptase, gray; integrase, yellow. Env glycoprotein trimers are shown in light blue on the particle surface (Figure originally appeared in Balasubramaniam and Freed (2011)). Parts of figure were adapted from Ganser-Pornillos et al. (2008) and used with permission from Elsevier)

incorporation remains under investigation, particularly the question of whether or not a direct interaction between Gag and Env is required for Env recruitment into virions. It is nevertheless clear that two viral components are critical for Env incorporation. In cells that are physiologically relevant to HIV-1 infection *in vivo* (e.g., primary lymphocytes and macrophages), the cytoplasmic tail of gp41, which is unusually long for a viral glycoprotein, is required for Env incorporation (Postler and Desrosiers 2012). The long tail is not a universal requirement; however, in some laboratory cell lines (e.g., HeLa and 293T), a tail-deleted gp41 is incorporated into virions and is functional. The gp41 cytoplasmic tail plays a role in Env glycoprotein trafficking and localization to specific plasma membrane microdomains

(e.g., lipid rafts) and may interact, directly or indirectly, with Gag (see below).

The second viral determinant that is required for Env glycoprotein incorporation is the MA domain of Gag. Various single-amino-acid mutations in MA prevent the incorporation of Env without affecting any other aspect of virus assembly or release. Indeed, when such MA mutants are expressed in the presence of gp41 cytoplasmic tail-deleted Env in permissive cells (e.g., HeLa or 293T), the resulting particles are fully infectious. Evidence for an association between MA and the gp41 cytoplasmic tail is also provided by the observation that a mutation in gp41 that blocks Env incorporation can be rescued by a mutation in MA. Together, these findings are consistent with the existence of an interaction between Env and

MA. It remains unclear, however, whether the inability to incorporate Env in the presence of MA or gp41 cytoplasmic tail mutations is due to a loss of a positive Env recruiting signal or the introduction of a steric block to Env incorporation. In other words, is the long gp41 cytoplasmic tail actively recruited, or simply accommodated, by MA? This continues to be an active area of investigation.

RNA Packaging

The viral RNA genome plays two roles in the assembly of infectious HIV-1 particles. The role it plays in regulating the assembly process itself is detailed above. No less important is that the virus particle exists as a vehicle to transfer the viral genome – full length, capped, and polyadenylated – to new cells (Lu et al. 2011). To this end, a dimer of genomes is recognized and packaged by Gag, primarily via the NC domain. Although NC is highly basic and binds non-specifically to negatively charged molecules, such as RNA, it achieves selectivity for the HIV-1 genome by recognizing a packaging site in the 5' end of the genome. The packaging site (often referred to as ψ) is composed of four stem-loop structures that encompass the dimerization initiation signal (DIS), the splice donor, and the Gag start codon. The positioning of a large portion of ψ after the splice donor ensures that full-length genomes, rather than spliced mRNAs, are preferentially packaged into the particle. During reverse transcription, the RT enzyme jumps frequently from one molecule of RNA to the other, increasing the frequency with which reverse transcription is successfully completed, i.e., a break in the RNA genome would be lethal if only one molecule of RNA were present. This “template switching” also drives recombination between the two packaged RNAs, thereby increasing viral genetic diversity.

The viral genome is not the only RNA in the particle; transfer RNA for lysine (tRNA^{Lys3}) is also incorporated, in part by binding to a specific site at the 5' end of the viral genome. The tRNA is required for the initiation of reverse transcription after the particle infects a cell. Other cellular RNAs are also found in the particle, although it

is not clear whether they play a specific role or are simply incorporated nonspecifically owing to their intracellular abundance and binding to basic residues in NC.

Viral Enzymes

The viral enzymes PR, RT, and IN are not required for particle formation per se, but are critical components of the mature, infectious virion. As discussed above, these enzymes are initially synthesized as domains within the 160-kDa GagPol precursor (Pr160^{GagPol}) which is incorporated into virions primarily by Gag–GagPol interactions; as Pr160^{GagPol} possesses the MA, CA, and NC domains, it is able to bind to the membrane in the same manner as Pr55^{Gag} and oligomerize with Gag into nascent particles. Reflecting the ~5% rate of ribosomal frameshifting during Gag translation, the abundance of Pr160^{GagPol} in virions is ~20-fold lower than that of Gag. If Pr160^{GagPol} is artificially overexpressed relative to Gag, assembly is disrupted, primarily as a result of excess of PR activity cleaving Gag before assembly has been completed. The first event in maturation is PR autoproteolysis, whereby PR cleaves itself out of Pr160^{GagPol}, allowing formation of the fully active, dimeric PR enzyme and subsequent proteolytic processing of the remaining sites in Gag and GagPol (Hill et al. 2005).

Accessory Proteins Packaged into Virions

Vpx (which is unique to HIV-2 and closely related simian lentiviruses) and Vpr are recruited into particles via binding to sequences in p6. A number of functions have been ascribed to Vpr, including the induction of cell-cycle arrest and increasing particle infectivity in nondividing cells. Vpx has recently been shown to induce the degradation of the myeloid-specific host restriction factor SAMHD1 early postinfection. In the absence of Vpx, SAMHD1 suppresses the cellular levels of deoxynucleotide triphosphates, which are required for reverse transcription. The absence of Vpx in HIV-1, and its presence in HIV-2/SIV, likely accounts for the relative inefficiency with which HIV-1 infects myeloid cells (macrophages and dendritic cells) relative to HIV-2/SIV (Fujita et al. 2012).

Vif is also found at low levels in virions, probably due to interactions with RNA. The primary function of Vif is to induce the degradation of the host restriction factor apolipoprotein B mRNA-editing enzyme catalytic polypeptide-like 3 (APOBEC3). Nef is also found in HIV-1 particles, where it is cleaved by PR. There is limited evidence for direct (active) incorporation of Nef; its presence in virions is likely due to its membrane association. Vpu, discussed above as the viral protein that counteracts tetherin, is not packaged into virions to an appreciable extent.

Host-Cell Proteins in HIV-1 Particles

A large number of cellular proteins are incorporated into HIV-1 virions. Mass spectrometry analysis of highly purified HIV-1 virions revealed the presence of ~250 host proteins; these include membrane proteins, cytoskeletal elements, soluble cytosolic factors, and nuclear components (Ott 2008). In most cases, these proteins are probably incorporated nonspecifically and are unlikely to serve any particular function in the virus replication cycle. However, some host proteins are actively incorporated into virions through direct interactions with viral structural proteins. An example is the peptidyl prolyl *cis-trans* isomerase cyclophilin A, which binds to a Pro-rich loop in the NTD of CA. Despite this active incorporation, there is no definitive evidence for a functional role of cyclophilin A in HIV-1 assembly and budding. Instead, it seems likely that CA–cyclophilin A interaction plays a role early postentry in the next round of infection.

APOBEC3G and a subset of other APOBEC3-family proteins (most notably APOBEC3F) are host-cell restriction factors that are incorporated into virions. These cytidine deaminases possess the ability to introduce mutations into the HIV-1 genome during reverse transcription, blocking viral infectivity. APOBEC proteins are packaged into virions most likely by binding to RNA or RNA in complex with NC. The viral accessory protein Vif targets APOBEC3G and APOBEC3F proteins for degradation in the virus-producer cell, preventing their incorporation into particles and preserving particle infectivity.

Particle Assembly and Maturation as Drug Targets

Steps in assembly and maturation mediated by the Gag proteins are crucial to the virus replication cycle; however, there are currently no approved drugs targeting these steps. In contrast, drugs that target the PR enzyme have been in widespread clinical use for more than 15 years. By blocking PR-mediated cleavage of Gag, PR inhibitors prevent the generation of mature infectious virions from immature particles. PR inhibitors such as ritonavir, darunavir, and atazanavir are among the most potent components of highly active antiretroviral therapy (HAART).

Because resistance to PR inhibitors and other antiretroviral drugs can emerge in treated patients, efforts are underway to develop inhibitors that block maturation by an alternative strategy, i.e., by disrupting processing at specific sites in Gag rather than by targeting PR itself (Waheed and Freed 2012). Thus far, two so-called maturation inhibitors with this mode of action have been reported. The first-in-class compound is bevirimat, a betulinic acid derivative. Bevirimat is thought to bind to the assembled Gag complex and, by a still poorly defined mechanism, prevent PR cleavage at the CA-SP1 junction. The accumulation of the CA-SP1 processing intermediate interferes with particle infectivity by disrupting formation of the conical core. Although in clinical trials bevirimat was able to significantly reduce viral loads in many HIV-1-infected patients, naturally occurring sequence polymorphisms in the SP1 region of Gag limited the efficacy of the compound in a significant percentage of patients. More recently, Pfizer developed another maturation inhibitor, PF-46396, again targeting CA-SP1 processing but possessing a chemical structure distinct from that of bevirimat. It is hoped that development of such structurally diverse inhibitors, and second- and third-generation derivatives, will ultimately make the maturation inhibitor class of compounds a valuable addition to the current portfolio of therapeutic options.

Attempts to target Gag oligomerization and particle assembly are at a much earlier stage of development. A variety of CA assembly inhibitors

have been reported (e.g., CAP-1, CAI, NYAD-1, PF74). These compounds are peptide-based or small molecules that target Gag at several distinct steps in the virus replication cycle, affecting immature Gag–Gag interactions (CAI, NYAD-1), mature core formation (CAP-1, PF74), and potentially post-entry functions (NYAD-1). At present all of these compounds are at the proof-of-concept stage; a great deal of work remains before these compounds or their derivatives can be brought to clinical trials.

Conclusions

Studying the process of HIV-1 assembly has provided fresh insight into basic cellular processes, such as the regulation of protein trafficking by phosphoinositides and ESCRT-mediated membrane budding and scission. Nevertheless, there remain many unanswered questions. For example, the route taken by Gag to reach the plasma membrane and the role played by host-cell factors in Gag trafficking remain incompletely understood. Elucidating the structures of viral proteins has had a transformative impact on the development of antiretroviral compounds targeting the viral enzymes RT, PR, and IN. Other structures, such as the Gag lattice, are now being actively pursued as potential novel drug targets. While much can be gleaned from structural studies of the mature CA lattice, it is the uncleaved Gag precursor that drives virus assembly. Thus, an atomic-resolution structure of Gag in the immature virion would be of great value from both a basic science and a drug development perspective. Recent developments in structural and cellular biology are likely to have a profound impact on the rapidly moving field of retroviral assembly.

Definition

Viruses, including HIV-like viruses, have been infecting primates and other hosts for millions of years. During this long-term common history, viruses and hosts have constantly put pressure

on each other for survival. Over time, hosts have evolved first lines of defense against viruses, the cellular restriction factors, while pathogens have developed mechanisms of evasion and antagonism. These antagonistic relationships have set up genetic conflicts between viruses and hosts that drive their evolution and interactions. Therefore, over evolutionary time and as a result of virus-host arms races, host restriction factors have been rapidly evolving and display signatures of positive selection, in particular at the virus-host interface.

Introduction

Lentiviruses are retroviruses that have been infecting various mammals and in particular primates for millions of years (Gifford 2012). The virus responsible for the AIDS (acquired immune deficiency syndrome) pandemic in humans, HIV (human immunodeficiency virus), has originated from cross-species transmissions of simian immunodeficiency viruses, SIVs, from non-human primates (Sharp and Hahn 2011). Recent studies using various temporal markers and strategies have estimated that ancestors of the modern-day lentiviruses existed in primates more than 10 million years ago (Compton et al. 2013). The long-term antagonistic coevolution of lentiviruses with their primate hosts has set up an evolutionary arms race between the two adversarial entities. These ancient genetic conflicts can notably be witnessed today by signatures of positive selection in the host genome as a result of constant innovations at the virus-host interface. Understanding these long-term virus-host evolutions help in understanding current virus-host interactions and host susceptibility to modern-day pathogenic viruses.

Hosts have Evolved Specialized Genes, the Cellular Restriction Factors, to Block Viral Replication

Cellular restriction factors are host proteins from the innate immune system that potentially block viral replication. These antiviral proteins target

many stages of the viral life cycle, they may have different mechanisms of viral inhibition that can be direct or indirect, and some are broadly acting while others are very specific to a virus or a viral protein. Despite this diversity of antiviral function, restriction factors share a common evolutionary feature: restriction factors are immune genes that are rapidly evolving and display signatures of positive selection as a result of genetic conflicts with pathogens (Duggal and Emerman 2012).

In lentiviral infection, cellular restriction factors play a key role in host susceptibility and pathogenesis. Although there is currently no strong evidence that restriction factors control viral replication of HIV in humans, they may be a first line of defense and protect a host species against the emergence of new lentiviruses. Examples of restriction factors with anti-lentiviral activity include: APOBEC3G (apolipoprotein B mRNA editing enzyme, catalytic polypeptide-like 3G), a cytidine deaminase that targets the reverse transcription step of HIV, TRIM5 (tripartite motif protein) that impairs viral uncoating, SAMHD1 (SAM domain and HD domain-containing protein 1) that blocks reverse transcription, and Tetherin/BST-2 (bone marrow stromal antigen 2) that restricts viral budding.

Viruses have Evolved Means to Counteract Restriction Factors by Evasion or Antagonism

Because viruses are obligate intracellular pathogens, they have evolved means to evade or counteract host restriction factors to complete their life cycle.

Certain restriction factors directly target a viral protein to restrict viral replication. In these cases, viruses can escape from this restriction by avoiding to be recognized by the host protein, a mechanism of *evasion or escape*. Viruses will therefore evolve very rapidly at the virus-host interface to evade host recognition by single amino acid changes or more complex evolutionary strategies such as recombination. Evasion is for example used by the capsid of lentiviruses to

escape recognition from the restriction factor TRIM5 (see details below).

Viruses have also evolved *antagonists* to directly target the cellular restriction factors and counteract their action. This mechanism is largely used by lentiviruses. It is particularly efficient to antagonize cellular factors that target another viral protein constrained in its evolution or to antagonize restriction factors that do not directly target the virus (i.e., indirect restriction). Indeed, several cellular restriction factors broadly block viruses by restricting steps of viral replication that are common to several virus families. For example, host factors can restrict several viruses by decreasing the level of nucleic acids in cells necessary for viral replication, inhibiting viral budding, recognizing viral RNA in the cytoplasm, or inhibiting mRNA translation. Viral antagonists are therefore specialized viral proteins that can interact with cellular restriction factors and inhibit their action, often by inducing their proteasomal degradation, relocalizing them to a different compartment, producing competitive inhibitors by mimicry, or using other functional inhibition mechanisms. The lentiviral antagonists are mainly encoded by viral accessory genes that are not strictly necessary for replication and therefore bear more plasticity. For example, the accessory proteins Vpr and Vpx antagonize SAMHD1, the accessory protein Vif counteracts APOBEC3G and other APOBEC3 proteins, and the viral proteins Vpu, Nef, or Env antagonize Tetherin/BST-2.

Adversarial Virus-Host Interactions Set Up a Genetic Conflict

These antagonistic relationships between the host and the virus proteins set up an evolutionary genetic conflict between the two entities (Daugherty and Malik 2012). This genetic battle is often referred as a “virus-host arms race,” which follows the Red Queen hypothesis where organisms constantly evolve and adapt to survive in an ever-changing environment (Van Valen 1973). Indeed, when a host protein restricts a virus, it puts pressure by natural selection on the virus to evolve and evade or counteract the host protein in

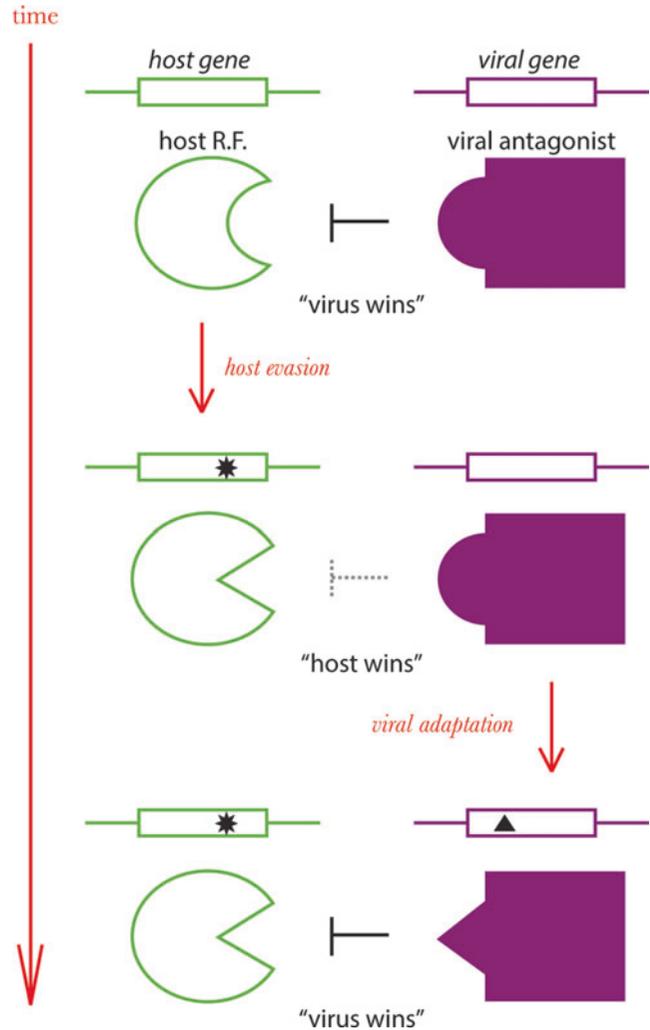

order to complete its viral cycle. As a result, the “successful virus” is the one with changes that allow the pathogen to win the virus-host battle. In response to the new selection exerted by the virus, the host will in turn evolve and adapt to re-gain antiviral capacity. Over evolutionary times, these recurrent cycles of rapid virus-host evolution leave signatures of positive selection in both the virus and the host genome, in particular at sites of interactions (Fig. 1). The primate restriction factors capable of blocking lentiviruses, such as APOBEC3G, SAMHD1, TRIM5, or Tetherin/BST-2, all bear signatures of positive selection. Furthermore, the identification of the specific sites that are under strong positive selection within the gene has powerfully aided the discovery of virus-host interacting domains and the characterization of host protein functions (Daugherty and Malik 2012).

Host Evolutionary Analyses of Long-Term Virus-Host Genetic Conflicts: Methods to Analyze Positive Selection

Evolutionary analyses of the host genome may be performed to discover which host genes have been under genetic conflict and identify potential virus-host interfaces. During a viral-host arms race, changes that result in a fitness gain are frequently due to mutations that result in amino acid changes. Therefore, at sites of virus-host interaction, a greater likelihood of non-synonymous substitutions (changes of amino acids; dN) are observed over synonymous changes (changes in nucleotides that conserve amino acids; dS), which is a signature of positive selection. The estimation of the dN/dS ratio, ω , can be used to identify such sites of adaptive evolution. Positive selection is characterized by $dN/dS > 1$, while purifying and neutral selection (characteristics of most host genes) are characterized by $dN/dS < 1$ and $dN/dS = 1$, respectively. Because the antagonistic virus-host evolution has been ongoing for million years, one can use orthologous gene sequences from host species that have diverged millions of years ago to reconstruct ancestral gene sequences and infer the dN/dS ratio. Studies of

Virus-Host Evolution and Positive Selection,

Fig. 1 Long-term viral-host genetic conflict. Virus and host proteins are engaged into a “Red Queen” conflict inducing rapid adaptive evolution of the host antiviral gene over evolutionary time. This leaves signatures of positive selection in the host genome, in particular at the virus-host interface. Steps: The viral protein is able to antagonize the restriction factor (i.e., the “virus wins”). This puts a selective pressure on the host that will evolve and evade the antagonist, leading to a situation where the “host is winning.” Such selective pressure will, in turn, induce a rapid viral evolution and only viruses able to block the new host protein will be selected. These virus-host interactions therefore set up unceasing evolutionary arms races. *R.F.* restriction factor. *Black stars* and *triangles* within genes represent amino acid changes. *Dashed lines* represent loss of block

primate phylogeny are therefore ideal to understand the viral-host arms races that have been ongoing in the primate lineage, including in the ancestors of humans. The analyses of where and when the virus-host genetic conflicts have occurred improve our understanding of the current viral epidemic, pathogenesis, and evolution.

Several statistical methods exist to detect such adaptive evolution (Pond et al. 2005; Yang 2007; Delpont et al. 2010); a summary of the most commonly used tools is given here. First, to identify overall signature of positive selection, one can estimate the dN/dS ratio across the gene using PARRIS from HYPHY/Datamonkey or Codeml from the PAML package. Second, to identify specific sites evolving under strong positive selection,

one can estimate the dN/dS ratio at individual sites along a gene (i.e., site-by-site selection analyses) using MEME from HYPHY/Datamonkey or BEB from PAML. Third, to identify lineage-specific selection (i.e., episodic selection), one can estimate the dN/dS ratio for each lineage, using BranchREL from HYPHY/Datamonkey or the “free-ratio model” from PAML.

Examples of Major Virus-Host Genetic Conflicts in Lentiviral Infection

Several genetic conflicts between cellular restriction factors and lentiviral proteins have been characterized in recent years. The main ones are

Virus-Host Evolution and Positive Selection, Table 1 Examples of major genetic conflicts between primate cellular restriction factors and lentiviral proteins

Cellular restriction factor	Viral evasion or antagonism		Evidence (in the host genome) of	
	Mechanism	Viral protein	Long-term genetic conflict	Ongoing or recent genetic conflict
APOBEC3G	Antagonism	Vif	Positive selection in primates	Polymorphism* in AGMs and rhesus macaques
APOBEC3D, APOBEC3H, APOBEC3F	Antagonism	Vif	Positive selection in primates. Gene family (duplication)	Polymorphism* in humans
SAMHD1	Antagonism	Vpr or Vpx	Positive selection in primates	Polymorphism* in AGMs
TRIM5 α and TRIMcyp	Evasion	Capsid	Positive selection in primates. Gene fusion that led to the creation of TRIMcyp	Polymorphism* in rhesus macaques
Tetherin/BST-2	Antagonism	Vpu, Nef, or Env	Positive selection in primates	Specific 5-aa deletion in the human lineage

AGMs African green monkeys, *aa* amino acids, * polymorphism that impacts virus-host interaction or the host antiviral gene function

summarized in Table 1 and some are further described here as examples.

APOBEC3G (and Other APOBEC3 Members) and the Viral Protein Vif

In early 2000s, the HIV-1 accessory protein Vif was found to be necessary for efficient HIV infection in primary human cells and certain cell lines (Sheehy et al. 2002). Several studies then characterized that Vif was allowing viral replication by inhibiting a cellular factor called APOBEC3G (Malim and Bieniasz 2012). APOBEC3G is a member of the *APOBEC3* gene family that is constitutively expressed in many cell types. APOBEC3G primarily restricts lentiviral replication by being incorporated in nascent virions and deaminating cytidine to uracil in single-stranded viral DNA during reverse transcription, thereby inducing lethal G-to-A hypermutation in the viral genome. In turn, the viral antagonist Vif has the capacity to bind host APOBEC3G and the Cul5-EloBC ligase complex, targeting the cellular factor for proteasomal degradation. This antagonistic function of Vif is essential for lentiviral infection as it has been retained in all extant primate lentiviruses and is therefore one of the most studied viral-host arms races. Because no crystal structure

of the complex has been solved yet, the interaction between Vif and APOBEC3G has only been studied through mutational screens and evolutionary analyses. The analyses of positive selection as well as of the inter-species variations in the host gene have therefore aided our understanding of this ancient and ongoing genetic conflict (reviewed in: (Duggal and Emerman 2012)). The viral protein Vif is further the antagonist of other APOBEC3 protein members (i.e., APOBEC3D, APOBEC3H, and APOBEC3F) that also have anti-lentiviral activities. Vif is thereby involved in multiple viral-host arms races against several cellular proteins (Desimmié et al. 2014).

Tetherin/BST-2 and the Viral Proteins Vpu, Nef, and Env

Tetherin/BST-2 inhibits viral infection by primarily blocking the release of enveloped viruses. This host transmembrane protein, stimulated by interferon, tethers budding virions to the plasma membrane, thereby blocking their release and inhibiting infection of a new target cell (Sauter et al. 2010). Recent studies have shown that Tetherin is involved more broadly in viral immune sensing and activation of the host innate immune response (Hotter et al. 2013). Lentiviruses have

therefore evolved antagonistic mechanisms to counteract Tetherin activity and allow an efficient spread of viral particles between cells. Primate lentiviruses have evolved different antagonists to inhibit Tetherin. HIV-1 encodes the Vpu accessory protein that targets the transmembrane domain of Tetherin, downregulates it from the cell surface, and allows efficient viral release. On the other hand, most primate lentiviruses antagonize Tetherin by encoding a Nef protein that targets the cytoplasmic tail of Tetherin and impairs its trafficking to the plasma membrane. In contrast, HIV-2 seems to use another viral protein, its envelope protein, to sequester Tetherin away from the plasma membrane (Sauter et al. 2010). Overall, Tetherin is targeted by lentiviral antagonists in several domains of the protein. Consistent with this, Tetherin is evolving under positive selection across primates, and specific sites in both the transmembrane domain and the cytoplasmic domain demonstrate signatures of positive selection (Lim et al. 2010). In addition, a five-amino acid deletion in the transmembrane domain of Tetherin, a genetic innovation not detected by standard tests for positive selection, has further played a role in the virus-host arms race in humans (more below).

SAMHD1 and the Viral Accessory Proteins Vpr and Vpx

SAMHD1 is a deoxynucleotide triphosphohydrolase that notably lowers the dNTP pool in the cytoplasm and blocks the reverse transcription step of lentiviruses in certain cell types (Laguette et al. 2011). As a countermeasure, most lentiviruses encode for an antagonist, Vpr or Vpx, which binds to SAMHD1, recruits it to the Cul4/DCAF1/DDB1 ubiquitin ligase complex, and targets it for degradation. As expected, SAMHD1 has evolved under strong positive selection throughout primate evolution (Laguette et al. 2012; Lim et al. 2012; Spragg and Emerman 2013). The identification of two hot spots of positively selected sites aided in the identification of two distinct virus-host interaction sites, demonstrating the power of an evolutionary approach to understand virus-host antagonism (Fregoso et al. 2013). Of note, HIV-1 does not encode any

direct antagonist to SAMHD1. It is likely that HIV-1 and its ancestors SIVcpz and SIVgor have lost this antagonistic function as a result of another evolutionary selective constraint (Etienne et al. 2013) and have evolved other means, which remain to be discovered, to efficiently infect their hosts.

Host Evolutionary Analyses of Ongoing and/or Recent Virus-Host Genetic Conflicts

On recent time scales, the analysis of the dN/dS ratio to look for evidence of positive selection in host genome is not appropriate as it relies on accumulation of significant numbers of mutations over time. Recent genetic conflicts can be witnessed by the presence of polymorphism within a host species where the amino acid changes functionally impact the virus-host interaction (Table 1). For example, APOBEC3G is polymorphic within African green monkey species and several amino acid changes were found to impact Vif antagonism (Compton et al. 2012). Spragg and Emerman further identified genetic variants of SAMHD1 in the African green monkey populations that resist viral antagonism (Spragg and Emerman 2013). Together, these studies show evidence of ongoing and/or recent genetic conflicts between African green monkeys and lentiviruses, in particular between the restriction factors APOBEC3G and SAMHD1 and the lentiviral antagonists Vif and Vpr, respectively.

To test whether adaptive selection has occurred in recent years within a species, analyses based on allele frequency differences and variation of allele frequencies between populations can be performed. The main statistical methods to detect the type of selection acting on recent genetic conflicts have been reviewed by Quintana-Murci and Clark (2013) and are briefly listed here: F_{ST} statistics to identify allele differences between populations; Tajima's D , Fay and Wu's H test, and others to identify unusual allele frequencies; HKA test to estimate reduction or excess in diversity.

Virus-Host Evolution: Beyond Positive Selection

On both ancient and recent time scales, host proteins can undergo different types of evolution as a result of evolutionary arms races with pathogens.

First, selection to maintain polymorphism within a species, also known as *balancing selection*, can be the result of frequency-dependent selection or heterozygote advantage. When a single antiviral protein is facing multiple selective pressures (e.g., from different viruses), different haplotypes can be maintained in the population to “keep up” in the virus-host arms race. Some of the best-known examples of genes evolving under balancing selection are the *MHC* (major histocompatibility complex) genes (Hughes and Yeager 1998), which by maintaining multiple alleles can recognize a wide variety of pathogens. Various haplotypes may also provide a heterozygous advantage to the host where the virus is forced to adapt to multiple alleles with various interfaces to replicate efficiently. Heterozygous African green monkeys that have two alleles of *APOBEC3G* with different virus-host interfaces apply a strong adaptive constrain on the viral antagonist Vif that is “facing two battlegrounds” (Compton et al. 2012). This may ultimately be advantageous to the host during lentiviral challenges (Fig. 2, Box 1).

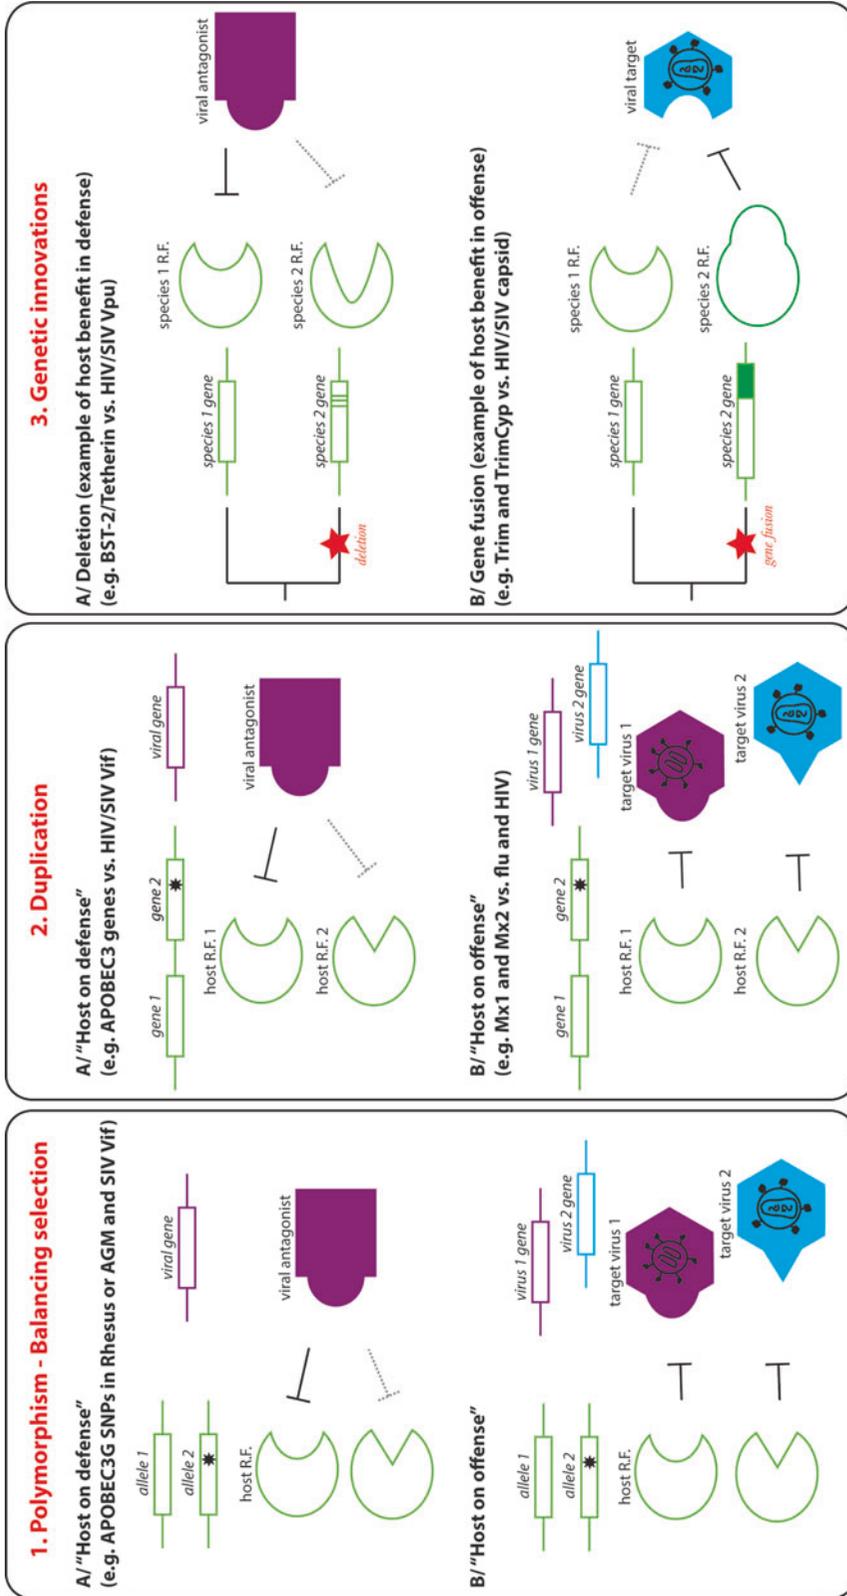

Second, the *duplication* of antiviral genes may be another major evolutionary strategy for the host to remain competitive in the virus-host arms race. Indeed, multiple restriction factors are part of a gene family that results from gene expansion by duplication. *APOBEC3G* is for example one gene of the *APOBEC3* family that comprises seven members in primates. Other examples of antiviral gene duplications come from the *TRIM* family, the *IFITM* genes, or the *Mx* genes. The advantage to maintain several genes for the host may be seen as an extension of the heterozygous advantage (a) to target different type of viruses (i.e., diversification of the offense) and/or (b) to provide multiple virus-host interfaces (i.e., diversification of the defense). (a) For example, the Mx2 restriction factor, thanks to its N-terminal tail, can restrict HIV as opposed to Mx1, which

cannot block HIV but can restrict influenza and other viruses (Busnadiego et al. 2014; Goujon et al. 2014). This gene duplication has = allowed the host to restrict very different viral families (Fig. 2, Box 2B). (b) On the other hand, gene duplication can also benefit the host evasion from a viral antagonist. For example, the different *APOBEC3* proteins with anti-lentiviral activities are targeted by the viral antagonist Vif at different protein interfaces, constraining strongly the viral protein evolution (Desimmie et al. 2014) (Fig. 2, Box 2A).

Third, *genetic innovations*, such as insertions (from insertion of few amino acids to entire gene fusion) and deletions, are other evolutionary strategies observed during viral-host arms race (Fig. 2, Box 3). Because these events include dramatic changes to the host genome, they are often deleterious and are less frequent than single amino acid changes. However, there are few instances where such events were selected during evolution, as they may have provided a strong advantage to the host under a major selective pressure from a pathogen. An example of deletion can be found in the evolution of BST-2/Tetherin, which lost five amino acids in its N-terminal domain in the human lineage specifically, possibly as a result of a viral-host arms race with a lentiviral antagonist like Nef (Sauter et al. 2009; Lim et al. 2010) (Fig. 2, Box 3A). Examples of gene fusion in an antiviral gene can be found in several primate species (e.g., owl monkeys, Asian macaques), where convergent evolution has led to the generation of TRIMcyp fusion proteins. The retrotransposition of *CypA* (cyclophilin A) downstream or within the *TRIM5* gene in several primate lineages has led to various forms of TRIMcyp proteins. These fused restriction factors have gained new antiviral specificities thanks to the capsid-binding properties of CypA (Malfavon-Borja et al. 2013) (Fig. 2, Box 3B).

Beyond Restriction Factors: Arms Races Between Viruses and Other Host Genes

Amongst host genes, few bear signatures of rapid evolution as restriction factors do. However,

Virus-Host Evolution and Positive Selection, Fig. 2 Beyond positive selection: other mechanisms of host evolution in viral-host genetic conflict. Boxes 1, Balancing selection (A, the host is “winning” on defense; B, the host is “winning” on offense). Box 2, Duplication (A, the host is “winning” on defense; B, the host is “winning” on offense). Box 3, Genetic innovations (A, deletion; B, gene fusion). Examples of known genetic conflicts involving lentiviral proteins and host restriction factors are given. R.F. restriction factor. *Black stars* and *triangles* in genes represent amino acid changes. *Dashed lines* represent loss of block

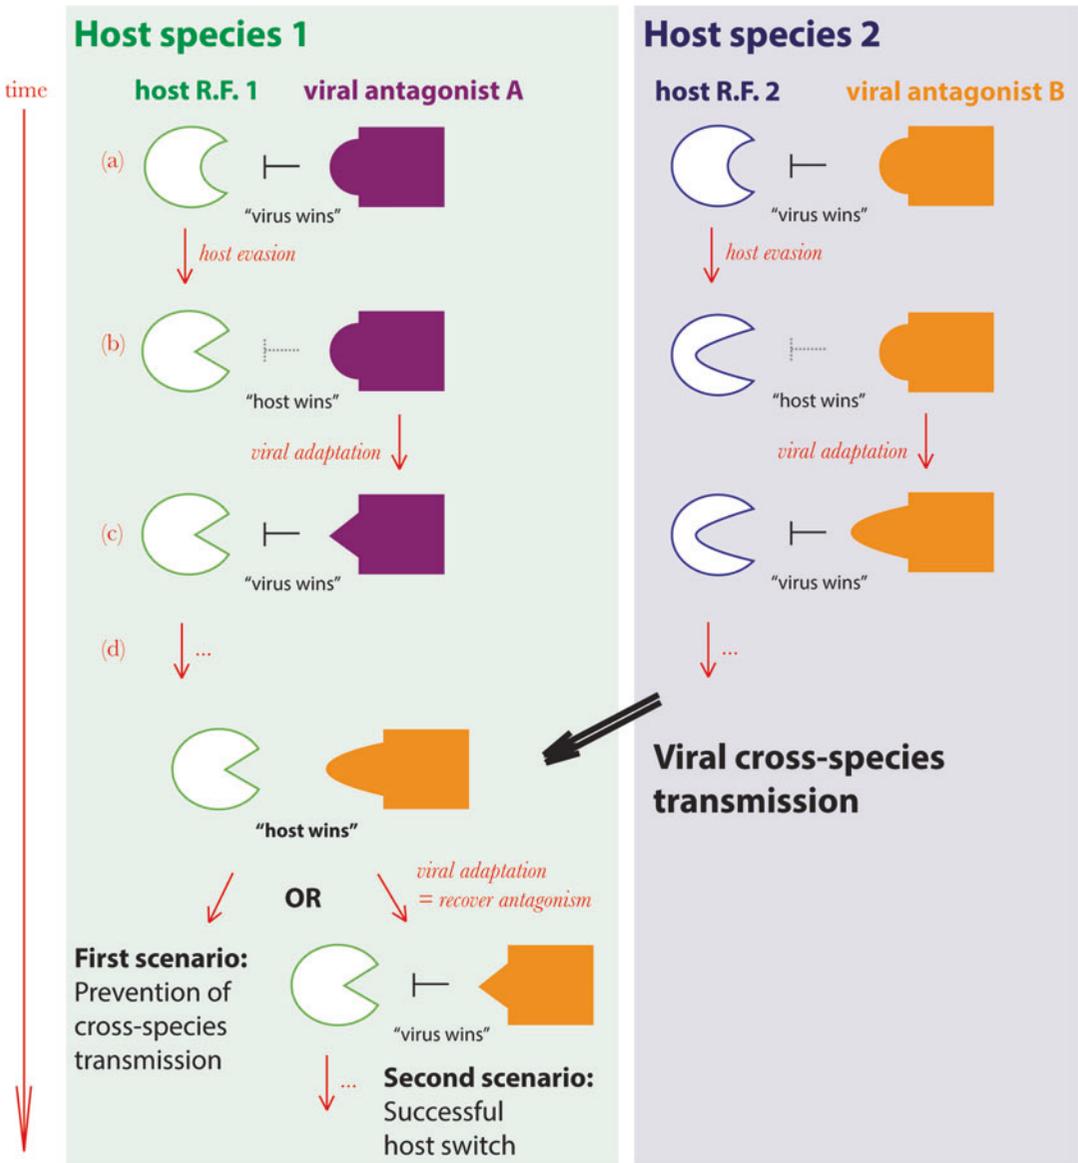

because the virus interacts with numerous other host proteins, it has been recently proposed that host cofactors may also be evolving under positive selection as a result of viral pressure. Unlike restriction factors that are “specialized intrinsic immune genes,” host factors that are usurped by the virus for replication also perform essential cellular functions. Therefore, like most host proteins that are important for cellular physiology processes, they are expected to be mostly conserved throughout evolution (i.e., evolve under purifying selection). However, recent studies have highlighted that, despite this evolutionary constrain, host factors that are necessary for virus replication may also be evolving under recurrent positive selection as a result of “host evasion” mechanisms. This was first shown in an elegant study for Tfr1, which is a receptor for multiple viruses (Demogines et al. 2013), and it was recently shown that some HIV cofactors may also be under positive selection (Meyerson et al. 2014). For example, the HIV receptor CD4 is found under strong positive selection in primates and a site that is bearing a strong signature of positive selection is implicated in the specificity of HIV entry (Meyerson et al. 2014). Therefore, even though most host cofactors of HIV seem to be generally conserved, a subset of them may evolve under positive selection driven by virus-host interactions that have played out over evolutionary time. More evolutionary studies of HIV cofactors associated with functional analyses will help in the characterization of these “unusual” viral-host arms-races and increase our understanding of the biology and evolution of these cellular cofactors that could be potential anti-HIV drug targets.

Consequences of Ancient and Ongoing Virus-Host Arms Races on the Cross-Species Transmission Potential of Modern-Day Lentiviruses

Ancient and ongoing virus-host arms races have therefore shaped modern-day host species and in particular have driven the specificities of interactions between the host restriction factors and

viruses. As viruses can adapt very rapidly to their host, modern-day viruses efficiently counteract the antiviral genes of the host species they infect. However, differences in restriction factors between species may be sufficient to create a barrier to viruses and may shape the host species spectrum of viruses (i.e., species-specificities). These differences between orthologous antiviral genes have mainly been shaped by ancient virus-host genetic conflicts (Daugherty and Malik 2012; Duggal and Emerman 2012) and current selective pressures continue to shape our antiviral repertoire. Therefore, the evolutionary history of virus-host interactions may in part explain the susceptibility and resistance of modern-day species to viral cross-species transmissions (Fig. 3). In particular, the differential susceptibility of host species to lentiviral cross-species transmissions may lie in the capacity of restriction factors to block SIV emergence (Fig. 3, first scenario). Furthermore, the evolutionary potential of a virus to adapt to the new restrictive cellular environment may determine the ease at which cross-species transmissions can occur (Fig. 3, second scenario).

Lentiviruses have infected primates over millions of years. However, the global picture today is that each primate species is infected by its own lentiviral lineage and few cross-species transmissions have been identified. This lentiviral species-specificity may be driven by the inability of lentiviruses to antagonize or escape from the restriction factors encountered in a new species (Fig. 3, first scenario). Although the influence of host restriction factors on viral cross-species transmission has not been well studied, in particular in natural settings, some *in vitro* and *in vivo* experimental studies have tackled this question. Both APOBEC3G and TRIM5 may represent natural selective barriers to lentiviral cross-species transmissions and only viruses that have the capacity to adapt rapidly to counteract or escape from the antiviral proteins will successfully emerge (Fig. 3, second scenario). Indeed, although the role of APOBEC3G as a species barrier has been mainly investigated in experimental cross-species transmissions, it has been shown that its evolution and its variability between and within primate

Virus-Host Evolution and Positive Selection, Fig. 3 Model for the consequences of long-term viral-host arms race on the potential of viral cross-species transmission. Steps: (a) The viral protein A is able to antagonize the restriction factor 1. This puts a selective pressure on the host that will evolve to evade the antagonist, leading to (b) where the “host is winning.” Such selective pressure will induce a rapid viral evolution. (c) Only viruses able to block the new host protein will

be selected. (d) This virus-host interaction sets an evolutionary “arms-race” in the host species 1. Similarly, another evolutionary “arms-race” is in place in the host species 2 infected by a virus B. So that, when a virus crosses from species 2 to species 1, the host will most likely “win” and this will, in most cases, prevent the cross-species transmission (first scenario). However, if the virus is able to rapidly adapt to the new species, it will successfully jump the species barriers (second scenario)

species have been implicated in the species-specificity of lentiviruses (Johnson 2013). Studies on the origin of the HIV-1/SIVcpz lineage in hominoids also suggest that APOBEC3G has

been a selective barrier for SIVs, and only lentiviruses with some capacity to antagonize the new host APOBEC3G may have the potential to jump efficiently in the new species (Etienne et al. 2013)

(Etienne et al. unpub). Genetic variations in TRIM5 may also influence in some primates the outcome of cross-species transmissions. Indeed, TRIM5 has played a role of selective barrier at the origin of SIVmac during the species-jump of SIVsmm from sooty mangabeys to macaques (Johnson 2013). Future studies on the role of other restriction factors as selective barriers and their potential hierarchy are likely to uncover more examples of host barriers to transmission of lentiviruses among primates.

Conclusion

Over evolutionary time, primate species have been under the selective pressure of many pathogens, including lentiviruses. The adversarial interactions between the cellular restriction factors, principal component of the host intrinsic immune system, and the viral antagonists have set the two entities in a “Red Queen” competition where the host gene imposes a selective pressure on viral replication and the virus exerts pressure on the host for survival. These antagonistic virus-host interactions and evolutions have therefore mainly evolved under positive selection, although other evolutionary strategies have been identified. In conclusion, both ancient and recent virus-host genetic conflicts have shaped our modern-day intrinsic immune genes, largely determining our current sensitivity and resistance to pathogenic and emerging viruses.

Definition

Women worldwide bear a substantial burden of human immunodeficiency virus (HIV) infection, the majority attributed to heterosexual transmission. A woman's risk of HIV acquisition results from a complex intersection of biological, behavioral, social, and structural factors. Timely diagnosis and linkage to care and treatment can reduce morbidity and mortality as well as perinatal transmission of HIV. Effective HIV prevention efforts among women will require a synthesis of biomedical, behavioral, and structural approaches which address the underlying social structures (e.g., gender inequality) which promote vulnerability to HIV infection among women.

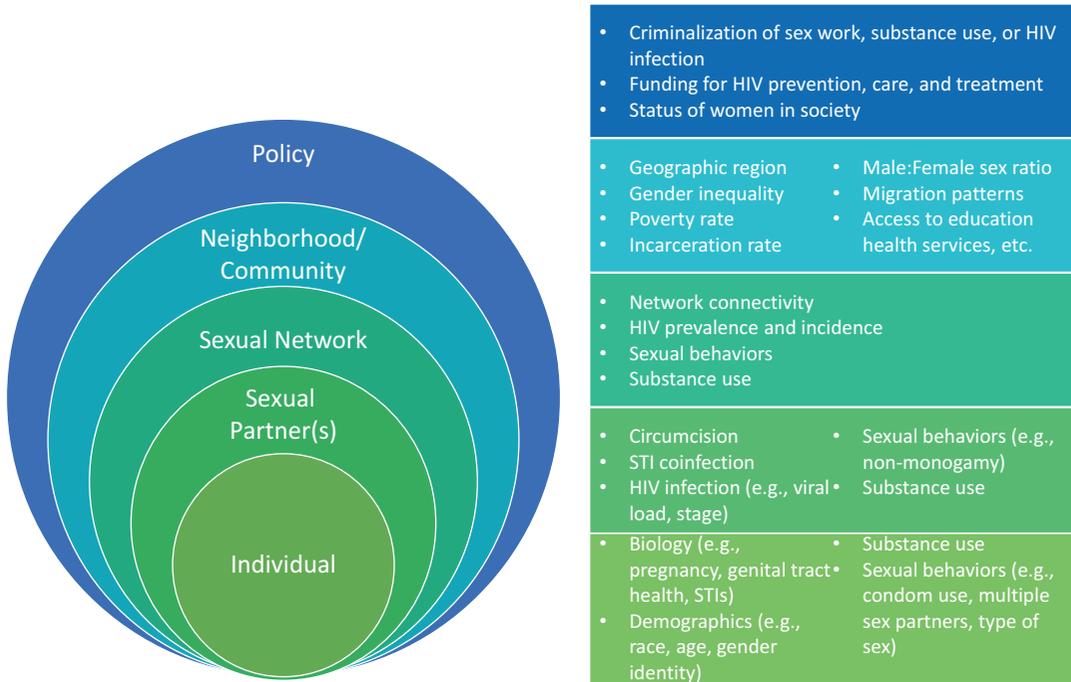

HIV/AIDS in Women

Globally, over 50% of all adults aged 15 years and older living with HIV are women, an estimated

total of 17.8 million women in 2015 (UNAIDS 2017). The burden of HIV among women varies by geographic region of the world. The majority of HIV-infected women live in sub-Saharan Africa, which constitutes roughly 80% of the epidemic among women (UNAIDS 2017).

Risk Factors for HIV Acquisition Among Women

The vast majority of women (>80%) acquire HIV through sex with an HIV-infected male partner. A number of biological, behavioral, social, and structural factors shape women's risk of HIV acquisition (Fig. 1). The probability of HIV transmission per sex act depends on the susceptibility of the female partner (e.g., coinfection with other sexually transmitted infections [STIs], pregnancy status, integrity of the genital tract), the infectiousness of the male partner (e.g., circumcision status, stage of HIV disease, HIV viral load), the mode of sex (i.e., oral, vaginal, or anal), and frequency of exposure. For example, having an STI increases the probability of HIV infection more than 17-fold per vaginal sex act, and the probability of HIV acquisition per anal sex act is more than five-fold the probability of HIV acquisition per vaginal sex act (Boily et al. 2009). The presence of multiple factors may further increase the probability of transmission. Individual behaviors, such as vaginal or anal sex without a condom, substance use, having multiple male sex partners, and

Women, Epidemiology of HIV/AIDS, Fig. 1 Multilevel factors shaping women’s risk of HIV acquisition

exchanging sex for money, drugs, or other commodities, are associated with increased risk of HIV acquisition among women. In addition, characteristics of sexual partners (e.g., non-monogamy) or corresponding sexual networks (e.g., network connectivity and HIV prevalence) may create susceptibility to HIV infection by connecting otherwise low-risk women to higher-risk sexual networks. There is a growing appreciation of how social phenomena, such as gender inequality and poverty, create vulnerability to disease among women. A disproportionate number of women live in poverty globally. Limited economic and educational opportunities may increase women’s reliance on male partners, promote sex exchange, and undermine a woman’s ability to negotiate safer sex practices. Notably, 50% of women living with HIV also report experiencing gender-based violence during their lifetime (UNAIDS 2013). Similarly, social and built characteristics of the places where women live may engender higher-risk environments. For example, high incarceration rates or out-migration of men

for labor may result in a shortage of men relative to the number of women in a community. Imbalanced sex ratios may support multiple sexual partnerships and reduce the ability of women to negotiate monogamy or safer sex practices. Policies may further promote risk. Notably, laws which criminalize behaviors associated with HIV acquisition (e.g., drug use, commercial sex work) may discourage access to healthcare and effective HIV prevention, care, and treatment.

Within the epidemic, certain subgroups of women who represent a substantial or disproportionate share of the HIV epidemic are considered priority populations. These groups include:

Commercial Sex Workers

The majority of commercial sex workers (CSW) are women. Female sex workers are 13.5 times as likely to be HIV infected as their female counterparts (Baral et al. 2012). HIV risk factors associated with commercial sex work include behavioral characteristics, such as high number of sexual partners, illicit drug use, and concurrent

infection with sexually transmitted infection (STIs) as well as social factors such as the power differential inherent in a transactional relationship that may result in high rates of sexual violence, lower condom use, and risky sexual practices. Importantly, structural factors such as policies that criminalize commercial sex work or carrying condoms, stigma, and inadequate access to condoms and healthcare contribute to increased HIV risk among CSW (Baral et al. 2012; UNAIDS 2013).

Women Who Inject Drugs

Central and Eastern Europe and Central Asia, in particular, have well-documented HIV epidemics within populations that inject drugs. The HIV prevalence among people who inject drugs is estimated to be as high as 20% (Jolley et al. 2012). Although the majority of people who inject drugs are men, women who inject drugs are also vulnerable to HIV infection. This risk is in part attributable to the efficiency of HIV infection through the use of intravenous needles contaminated with HIV virus, challenges negotiating safer sex and injection practices, violence experienced by women who inject drugs, commercial sex work, and the criminalization and stigma associated with injecting drug use (Jolley et al. 2012).

Young Women in Sub-Saharan Africa

Although 15% of all women living with HIV aged 15 years and older are young women 15–24 years old, of these, 80% live in sub-Saharan Africa (UNAIDS 2014). The HIV prevalence among young women in sub-Saharan Africa is twice as high as the prevalence in young men, and women acquire HIV infection at least 5–7 years earlier than men (UNAIDS 2014). This imbalance reflects several factors contributing to these women's vulnerability to HIV, including gender inequality, older male sexual partners, high population level HIV prevalence (e.g., male partners are more likely to be HIV infected), fertility desire and decreased use of condoms, low rates of male circumcision, migratory labor and resulting concurrency, and, in some regions, “dry sex” practices which result in increased genital trauma.

African American Women in the United States

Significant racial disparities exist for newly reported cases among women in the United States. HIV incidence is more than 15 times higher among African American (AA) women than among White women (Prejean et al. 2011). Sexual behaviors alone do not explain the dramatic differences in HIV infection by race and ethnicity in the United States. A number of studies have found comparable sexual risk behavior among AA as compared to other racial and ethnic groups, and some demonstrated that Whites engaged in higher-risk behaviors than their White counterparts. Characteristics of sexual networks (e.g., indirect concurrency, prevalence of HIV within network) and of the places where people live (e.g., neighborhood poverty, ratio of men to women) are thought to be powerful drivers of the epidemic among AA women in the United States (Cooper et al. 2014).

Transgender Women

Transgender women, defined as persons born biologically male who identify themselves as female, shoulder a disproportionate burden of the HIV epidemic. A 2013 review of available literature from Europe, Central and South America, Asia-Pacific, and the United States found that the odds of HIV infection among transgender women were consistently 20–90 times the odds of HIV infection among adults living in the same country (Baral et al. 2013). Transgender women are at enhanced risk of HIV infection in part due to the high prevalence of receptive anal sex and high prevalence of HIV within sexual networks but also frequently face social exclusion, economic marginalization, and unmet healthcare needs (Baral et al. 2013).

Incarcerated Women

More men are incarcerated than women worldwide. However, the incarceration rate of women has grown substantially in the United States, a country that incarcerates a larger proportion of the population than other countries in the world. The prevalence of HIV is higher among incarcerated females than among incarcerated males in the

United States. Data on HIV prevalence among incarcerated women in low- to middle-income countries is limited but has been estimated to be as high as 20% (Dolan et al. 2007). Commercial sex workers, substance users, transgender women, and, in the United States, AA women are more likely to be incarcerated than women in the general population; incarcerated women represent an intersection of several high-risk groups and the complex behavioral, social, and structural factors which enhance HIV acquisition.

HIV Testing, Antiretroviral Treatment, and Linkage to Care

Globally, HIV/AIDS is the leading cause of death among women of reproductive age (UNAIDS 2014). Antiretroviral therapy (ART) reduces mortality attributable to HIV, improves quality of life of HIV-infected individuals, and reduces HIV transmission. Timely initiation of ART depends on HIV testing, linkage to HIV care, and access to treatment. Globally, only 48% of persons living with HIV are aware of their HIV status (UNAIDS 2014). Women are more likely to have been tested than men in most regions, which is most likely a result of the integration of HIV testing in many antenatal and reproductive health settings. Treatment guidelines and access vary by region (UNAIDS 2013; World Health Organization 2013; UNAIDS 2017). Women living in high-income countries, such as the United States, in theory, have better access to ART but may not be successfully connected to care; the Centers for Disease Control (CDC) estimates that among HIV-infected women, 88% are aware of their HIV infection, 45% are linked to care, 41% are prescribed ART, and 32% that are virally suppressed are linked to HIV care and taking ART (CDC 2011).

Timely HIV diagnosis, prevention of unwanted pregnancy, and access to ART are especially critical for HIV-infected women, who may transmit HIV to infants during pregnancy, in childbirth, or through breast milk (mother-to-child transmission, MTCT). MTCT has been virtually eliminated in high-income countries such as the United States and Europe due to ART. Although low- and middle-

income countries experienced a 52% decline in new HIV infections among children between 2001 and 2013, significant gaps remain (UNAIDS 2013). In many low- and middle-income countries, pregnant women living with HIV are less likely to receive antiretroviral therapy than other HIV-infected treatment-eligible adults (UNAIDS 2013). In 2012, 62% of pregnant women in low- and middle-income countries living with HIV received antiretrovirals. In contrast, 49% received ART during the breastfeeding period. Estimates suggest that nearly half of all cases of HIV transmission period occur during the breastfeeding period (UNAIDS 2013). As a result, breastfeeding recommendations for HIV-infected women vary by country, replacement feeding alternatives, and access to clean water, sanitation, and health services (World Health Organization 2013).

HIV Prevention in Women

The substantial burden of HIV among women globally and the complex behavioral, social, and structural factors which contribute to HIV acquisition necessitate strategies which combine behavioral, biomedical, and structural approaches to reducing HIV acquisition and increasing diagnosis and treatment among HIV-infected women (UNAIDS 2013).

Some successful biomedical approaches, including treatment as prevention and male circumcision, have emerged as effective HIV prevention tools in recent years and have contributed to a decline in new HIV infections among women in some parts of the world. The treatment of an HIV-infected person with ART may reduce the risk of HIV transmission to his/her HIV-uninfected partner by up to 96% (Cohen et al. 2011). Voluntary adult medical male circumcision reduces HIV infection in men by approximately 60% and may result in population-level reductions in the rate of male-to-female HIV transmission by up to 46% (Hallett et al. 2011). Condoms can also be considered effective biomedical devices for HIV prevention. When used correctly and consistently, condoms are 80% effective in reducing HIV transmission (Weller and Davis 2002). Increases in condom use, which occurred

in parallel with an increase in condom distribution, are credited with declines in new HIV infections in South Africa between 2000 and 2008. However, access to condoms may be limited in a variety of settings. In 2013, only eight male condoms were available per year for each sexually active individual in sub-Saharan Africa (UNAIDS 2014). In addition, there a number of reasons why women may elect not to use condoms, including desire for children and perceived HIV-negative status of sexual partner(s) and partner monogamy.

Condom use, voluntary medical male circumcision, and sexual partner HIV testing and treatment require buy-in by male partners, which may not be feasible in many settings. There is a need for highly effective, female controlled biomedical prevention. Preexposure prophylaxis (PrEP), which involves the topical or oral use of an antiretroviral drug before, during, or after sex, may also be a promising prevention tool for women. However, the evidence supporting PrEP use in women is inconclusive (Baeten et al. 2013). One clinical trial of tenofovir vaginal gel showed a 39% reduction in HIV acquisition and 51% reduction in herpes simplex 2 virus acquisition when used by study participants before and after sex. However, subsequent trials testing tenofovir gel or oral PrEP were halted because HIV acquisition in the participants using the study product was not significantly different than the participants using the placebo product (a gel or pill which looks like the study product but is made with inactive ingredients, also known as “sugar pill”). However, further investigation of these clinical trials suggested that study participants did not use products as prescribed and further research is needed to understand PrEP acceptability and use among women (Baeten et al. 2013).

There are a number of existing evidence-based interventions (EBIs) for individuals, couples, and groups that are designed to reduce risk behaviors associated with HIV acquisition (e.g., unprotected sex) and to promote healthy sexual norms (e.g., partner communication). These interventions have been tested in clinical trial settings and have demonstrated efficacy in changing the target

behaviors relative to the control group (the group that did not get the intervention). Although behavior change is a critical component of HIV prevention, behavior change alone may not reduce the risk of HIV acquisition in women.

Structural approaches, which seek to address the underlying social and structural factors which create vulnerability in women (e.g., gender norms, poverty), may also reduce new HIV infections among women. Approaches currently being explored include cash transfers (e.g., providing financial support to families who keep their young girls enrolled in school), vouchers, and food and nutrition support. Implementing successful structural interventions on a community-wide level is complex, costly, and requires political support. Notably, needle exchange programs, which distribute clean needles and injecting equipment to people who use drugs, have been shown to be effective in reducing HIV transmission, but the implementation of these programs is often stymied by policies that criminalize the distribution of drug-related paraphernalia. Policy change may be an essential component of interventions seeking to change the social and structural determinants of HIV acquisition among women.

Conclusion

In summary, women represent a substantial portion of the HIV/AIDS epidemic globally. Although biomedical approaches offer exciting opportunities to reduce HIV transmission among women, the failure of condoms to control the HIV epidemic, nonadherence to PrEP in recent clinic trials, and incomplete HIV testing and access to treatment highlight the complex behavioral, social, and structural factors which shape women’s HIV risk and necessitate strategies which harmonize behavioral, biomedical, and structural approaches designed to increase access to medical care and reduce HIV acquisition in women and their male partners (UNAIDS 2013). Such approaches will not only improve the health of women but benefit their families and communities.
