Numerous HIV-1 studies examined the relationship between the antibody responses to viral proteins and disease. The responses to HIV-2 viral proteins were studied in 141 HIV-2-infected women from the Dakar cohort followed for up to 11 years (Popper et al. 1998). The absence of antibodies to p26, the virion-associated core protein of HIV-2, was a highly significant predictor of CDC IV category HIV disease ($p < .01$) in multivariate analysis. The antibody response to the virion-associated Vpx protein was also evaluated; while responses did not correlate to antibody responses to p26, they were similarly established early postinfection. In individuals lacking responses to p26 and with responses to Vpx, were six times more likely to be classified as CDC IV category disease ($p < .01$).

In HIV-1 infection some studies have suggested that anti-Tat antibodies may be associated with a better clinical outcome. The prevalence of anti-Tat antibodies was determined in 111 HIV-2 seroprevalent and 33 seroincident Dakar sex workers observed longitudinally between 1985 and 2003 (Rodriguez et al. 2006). Sixty-eight percent of the subjects tested positive for anti-Tat antibodies with reactivity notably established early after seroconversion and stably maintained over the course of infection. The absence of anti-Tat antibodies was significantly associated with progression to CDC IV-defined disease or CD4+ T cell count $< 200/\mu\text{L}$ during the study period, extending the importance of this prognostic marker for HIV-2 disease.

Genetic Determinants in HIV-2 Disease

Since slower disease course appeared to be common in HIV-2 infection, it seems reasonable to consider that certain subsets of the population would possess host characteristics that might predispose them to a more rapid disease course. Some human leukocyte antigen (HLA) class I alleles have been associated with slower or faster rates of HIV-1 disease progression, suggesting

that the presented epitopes or the restricting HLA class I molecule may play a central role in determining the ability to control viral replication.

A case-control study investigated possible associations between HLA and the risk of disease progression in HIV-2 (Diouf et al. 2002). The HLA class I status was molecularly typed in female sex workers from the Dakar cohort; HLA B35 was associated with lack of p26 antibodies ($P < .05$) and higher risk of disease progression. The same association was found for the class I haplotypes B35-Cw4 and A23-Cw7 ($P < .05$), similar to the association with HIV-1. The data showed that certain HLA molecules are associated with risk of disease progression in HIV-2; some of the alleles and haplotypes involved in susceptibility to disease are similar for both HIV-1 and HIV-2. Therefore, certain genetic factors may be shared by HIV-1 and HIV-2 with respect to susceptibility to enhanced disease progression. In addition, the role of the CCR5 delta 32 allele was also evaluated in 139 Dakar sex workers (Kokkotou et al. 1998). This is a known mutation in the CCR5 coreceptor that may reduce susceptibility to CCR5 HIV viruses. The presence of the CCR5delta 32 genotypes was found in 2 PBMC samples (1.44%) and was found to be less susceptible to in vitro infection by an M-tropic HIV-1 primary isolate.

HIV-2 Protection from HIV-1

Demonstrated differences in the infectivity and disease potential of HIV-2 compared to HIV-1 supported the notion that upon interaction, HIV-2 might protect from HIV-1 infection or disease, analogous to an attenuated virus vaccine model. In studies of the Dakar female sex worker cohort, the hypothesis that the attenuated phenotype of HIV-2 infection might protect from subsequent HIV-1 infection was addressed (Travers et al. 1995). HIV-1 infection in previous HIV negatives along with superinfection of HIV-2 infected was documented over the study period with both serology and PCR assays. A Poisson regression model was used to estimate the independent effect of demographic, behavioral, and biologic variables on the risk of HIV-1 infection. Despite higher incidence of other sexually

HIV-2: Lessons from the Dakar Cohort,
Table 2 Natural protection from HIV-1 conferred by HIV-2 in Dakar, Senegal

HIV-1 incidence rate ratio (HIV-2, negative)	Fraction protected (%)	Years of observation	<i>p</i> value
0.23–0.32	68–77	9 years	<.05
0.26–0.36	64–74	11 years	<.05
0.33–0.42	58–67	12 years	<.05
0.34–0.44	56–66	13 years	<.03

transmitted diseases (STDs), HIV-2-infected women had lower incidence of HIV-1 than seronegatives, with an incidence rate ratio (IRR) of 0.32 ($p = 0.008$). When immunosuppression (reduced CD4+ cell count) was accounted for, the IRR associated with HIV-2 was reduced further to 0.23 ($p = 0.02$) (Table 2). This analysis led to the conclusion that HIV-2 infection conferred a significant reduction in the subsequent risk of HIV-1 infection.

The generalizability of these findings was questioned by studies from other West African sites. In Ivory Coast, Guinea-Bissau, and the Gambia, studies originally designed as cross-sectional surveys were analyzed for short periods of longitudinal observation; as a result of their design, they did not possess sufficient statistical power, capable only of detecting an extremely high protected fraction (>99%) of HIV-1 infection due to HIV-2 infection (Kanki and Meloni 2009). Continued analysis of the Dakar cohort extended the observation period from the first published report to over 13 years; HIV-2 protection ranged from 52% to 74% depending on the method of analysis. Notably, in 2012, Esbjornsson et al. reported slower progression to AIDS in individuals with dual infection where HIV-2 infection had preceded HIV-1 in Guinea-Bissau (Esbjornsson et al. 2012), thereby suggesting that HIV-1 disease progression is inhibited by concomitant HIV-2 infection and that dual infection is associated with slower disease progression.

Dieng-Sarr et al. sequenced the HIV viruses from 29 dually infected Dakar sex workers to determine if HIV-1 subtypes differed in dual infection. The majority (14/23) were infected with the prototype West African HIV-1 subtype,

CRF 02_A/G, and 9/23 formed a separate distinct cluster, later determined to be sub-subtype A3 (Meloni et al. 2004a). This was in contrast to what was found in HIV-1 singly infected women where the variant sub-subtype A3 was found in only 13/98 (13.3%). Thus, it seemed possible that the mechanisms of HIV-2 protection may be less efficacious with the sub-subtype A3 compared to the more common CRF 02A/G, resulting in the different proportion of the subtypes based on single or dual infection (Dieng-Sarr et al. 2000).

While numerous viral characteristics of HIV-2 were likely to play a role in its reduced transmission and slower disease protection, the host's immune response to the virus and potential cross-reactivity to HIV-1 was also considered. The neutralizing antibody response against heterologous isolates in HIV-2 infection and their relationship with established clinical markers of progression were examined (Rodriguez et al. 2007). Neutralizing responses against 7 heterologous primary isolates and 1 laboratory strain from 43 untreated HIV-2-infected subjects were analyzed using a pseudotyped reporter virus assay. Positive neutralization against at least 1 heterologous isolate was detected in 42 of 43 (98%) HIV-2-infected individuals tested, and significantly, 33% of chronically infected subjects neutralized all of the heterologous viruses in the panel. The magnitude of the heterologous responses was low overall, with a median IC₅₀ titer against heterologous isolates of 117, compared to 285 in HIV-1 infected subjects. The development of heterologous responses was analyzed in 10 Dakar sex workers assessed longitudinally for up to 14 years of HIV-2 infection. Longitudinal analysis demonstrated that these intratype heterologous responses develop fully after about 2.5 years of infection. Overall, there was a significant positive correlation between IC₅₀ titer and viral load, suggesting heterologous antibodies may be driven by viral replication. Plasma from a subgroup of 24 HIV-2-positive subjects was then tested for intertype neutralization against a panel of 6 HIV-1 reporter viruses. Here, only 10 of 144 (7%) plasma-virus combinations were positive for neutralization. When HIV-1 reporter viruses were pretreated with

sCD4 protein, however, the proportion of plasma–virus combinations positive for neutralization increased to 128 of 144 (88%). It was concluded that the extensive intratype cross-neutralization observed indicated the presence of conserved neutralization determinants among HIV-2 viruses circulating in Senegal. Further, it was demonstrated that HIV-2 infection elicits CD4-induced (CD4i) antibodies able to neutralize a virus as divergent as HIV-1.

T cell activation in HIV-2 infection was studied in the Dakar cohort where CD4⁺ and CD8⁺ T cell populations were independently assessed with the hypothesis that distinct factors mediate immune activation in specific T cell subsets (Hanson et al. 2005). CD8⁺ T cell immune activation has previously been strongly associated with HIV-1 disease progression. CD8⁺ T cell activation was significantly different between HIV-2 and HIV-1 volunteers ($p < 0.0015$), and both groups expressed higher activation levels compared to seronegative individuals ($p = 0.014$ and < 0.001 , respectively). A significant correlation between viral load and T cell activation was observed only in the HIV-1-infected group ($r = 0.57$, $p = 0.01$), but a similar association was not observed in the HIV-2-infected group ($r = 0.23$, $p = 0.47$). Surprisingly, similar levels of CD4⁺ T cell activation were observed in HIV-1- and HIV-2-infected subjects ($p = 0.52$), perhaps reflecting similar in vivo viral pathogenesis. CD4⁺ T cell activation in HIV-1-infected subjects correlated with CD4⁺ cell count ($r = -0.49$, $p = 0.03$) but not with viral load ($r = 0.16$, $p = 0.52$). In contrast, no correlation between CD4⁺ immune activation and CD4⁺ cell count or viral load was demonstrated in HIV-2-infected subjects ($p = 0.76$ and 0.90 , respectively). Thus, HIV-2 demonstrated distinct differences in both CD4⁺ and CD8⁺ activation compared to HIV-1.

The ELISPOT technique and a unique HIV-2 antigen delivery system to further prime and quantify the HIV-2-specific CTL response in HIV-2-infected individuals were described (Dieng Sarr et al. 2001). The frequency of HIV-2-specific gag CTL precursors in uncultured PBMCs from HIV-2-infected women was evaluated using a

modified nontoxic form of the anthrax toxin (*Bacillus anthracis*). The HIV-2 gag (P26) was fused to the terminal domain of the anthrax lethal factor (LFn; 255 aa). The LFn-P26 (HIV-2 gag) recombinant proteins were expressed and used as antigens to stimulate CTLs in an ELISPOT format and compared to the classic antigen delivery system using recombinant vaccinia virus (rVV) expressing HIV-2 gag. A majority of individuals (87.5%) in the study showed a specific gag CTL response using the LFn-P26 expression, far superior to the classic rVV expression. Interestingly, the individuals with strong cellular immune response had no detectable HIV-2 plasma load implicating the role of cellular immunity in the delayed pathogenesis of HIV-2.

In Vitro Evidence for HIV-2 Protection from HIV-1

Studies have described in vitro interactions of HIV-1 and HIV-2 that support the Dakar cohort in vivo observations; these range from virus–virus interactions to potential immune-mediated mechanisms for HIV-2 protection. Arya et al. have reported that HIV-2 inhibits the replication of HIV-1 at the molecular level. This inhibition was selective, dose dependent, and nonreciprocal. Though the exact mechanism remains to be defined, the inhibition appeared to be mainly due to an intracellular molecular event because it could not be explained solely on the basis of cell surface receptor-mediated interference. The results support the notion that the inhibition likely occurred at the level of viral RNA, possibly involving competition between viral RNAs for some transcriptional factor essential for virus replication (Kanki and Meloni 2009).

Using an in vitro HIV-1 challenge system, a significant proportion (60%) of PBMCs derived from HIV-2-infected women from the Dakar sex worker cohort could not support replication of a CCR5-dependent HIV-1 virus compared with CXCR4-dependent virus (Kokkotou et al. 2000). Resistance was transferable and CD8 dependent and strongly correlated with beta-chemokine production in the media. All resistant cultures were rendered susceptible by addition of a cocktail of antibodies to beta chemokines.

HIV-2 infection might dramatically influence beta-chemokine production by enhancing it in magnitude and/or duration, thus enabling HIV-2-infected individuals to cope favorably with subsequent exposure to HIV-1. This is supported by studies demonstrating that binding of the HIV-2 envelope to the alpha chain of CD8 stimulates dramatic levels of beta-chemokine production in comparison to HIV-1 gp120 activity. Further, unstimulated PBMCs from HIV-2-infected Dakar sex workers demonstrated diminished surface CCR5 receptor expression on CD4⁺ T cells (Shea et al. 2004). In vitro upregulation of the CCR5 receptor was readily demonstrated indicating that the receptor was functional. The in vivo downregulation of the receptor was not correlated with activation markers (HLA-DR), beta-chemokine levels, or plasma viral load. It was postulated that the downregulation of the CCR5 receptor in HIV-2 infection contributed to slower disease course, by decreasing susceptibility of target cells for infection in conjunction with HIV-2-specific cellular immune responses. It is also recognized that CTLs are able to lyse infected cells before progeny virions are produced and the production of granzyme particles will elicit beta chemokines therefore providing two mechanisms by which viral replication could be limited or prevented. Not only does this implicate a novel viral suppressive mechanism but one that may be adapted for immunoprophylaxis. Antiretroviral vaccine strategies that incorporate beta-chemokine induction or other receptor-blocking functions raise some encouraging possibilities for vaccine design and development.

Impact of HIV-1 Subtypes

Clinical and immunological differences have also been found between HIV-1 subtypes, and it was well recognized that multiple diverse HIV-1 subtypes are prevalent in West Africa with dynamic changes over time. The epidemiology of HIV infection in the Dakar cohort was further studied with diagnosis of the HIV-1 subtype in 328 HIV-1-infected women. A 385 bp C2-V3 fragment of the envelope gene was sequenced and classified into the following subtypes or recombinant forms: 239 (72%) were subtype

A [of which 180 (55%) were CRF02_AG, and 53 (16%) were A3], 10 (3%) were B, 12 (4%) were C, 11 (4%) were D, 18 (6%) were G, 24 (7%) were CRF06_cpx, and 7 (2%) were CRF09_cpx. An increasing proportion of CRF02_AG was observed over many years, but the more recently described sub-subtype A3 had overtaken CRF02_AG, with the largest proportion of new infections (Meloni et al. 2004a, b). The predominance of existing HIV-1 subtypes did not preclude the emergence and increase of other closely related subtypes or recombinant forms. This 20-year prospective serologic and sequence analysis of HIV viruses revealed a complex and changing HIV epidemic in Senegal and represents a unique long-term description of the epidemiology of these two HIV viruses in high-risk people (Hamel et al. 2007). In addition, women infected with CRF02_AG in the Dakar sex worker cohort had a significantly higher viral load during the early stage of infection than did women not infected with CRF02_AG (Kanki and Meloni 2009). Finally, women infected with CRF02_AG demonstrated slower progression to AIDS compared to women infected with other HIV-1 subtypes (Kanki et al. 1999).

Conclusions and Lessons Learned

HIV-2 was first described in the Dakar sex worker cohort in 1985 and was the dominant virus when HIV-1 was first entering this population. Between 1985 and 2004, HIV-2 prevalence dropped from 8% to 4%, a 50% decrease over 20 years. Concurrently, HIV-1 prevalence increased from 0% to 13% during the same time period. Anderson and May's prediction that HIV-2 would decrease in the face of an increasing HIV-1 prevalence is well supported by the Dakar sex worker cohort data. The attenuated rate of HIV-1 infection in a high-risk group of sex workers would also suggest that the interaction of the HIV viruses in this population may inhibit explosive increases in HIV-1 that have been described in similar HIV-1 studies of sex workers. In addition, the registration and health-care system for these women supported by a strong government HIV/AIDS control, prevention, and treatment program may have

contributed to the decline or stabilization of infection rates for both viruses (Kanki 2009).

HIV's propensity for genetic diversification has resulted in two closely related HIV types, HIV-1 and HIV-2. These viruses have a distinct geographic distribution, with HIV-2 predominating in West Africa. Current epidemiologic trends suggest that HIV-2 is unlikely to result in a global pandemic like HIV-1 and may in fact be decreasing in endemic regions. Major differences in the biologic properties between HIV-1 and HIV-2 suggest a more ancestral history to HIV-2 with adaptation to the human host and relative attenuation. This has resulted in lowered transmission potential and decreased pathogenicity. The diversification of HIV-1 appears to be more recent and less well understood. HIV-1 subtypes, sub-subtypes, and recombinant forms demonstrate a unique geographic distribution, even within the African continent. Current studies suggest that the epidemiology of these variants is dynamic, particularly within Africa. In the future, it will be important to molecularly characterize HIV subtypes in order to accurately map the molecular epidemiologic timeline. This may indicate important differences in the transmission and pathogenic properties of HIV types and subtypes which may inform our understanding of immune protection and disease pathogenesis.

Observational and *in vitro* studies suggest that the attenuated HIV-2 virus infection may provide cross-protective immunity for HIV-1, suggesting that one plausible explanation for the relatively low rates of HIV-1 infection may be due to the coexistence of HIV-2, a unique feature of West Africa. Unbiased, powerful studies, using sensitive and specific classification methods, will effectively address the generalizability of the observation of HIV-2's protective efficacy against subsequent HIV-1 infection described in the Dakar sex worker cohort for over a decade (Kanki and Rowland-Jones 2014). The long person-time of observation with few losses to follow-up and rigorous PCR testing supported these important findings. A potential mechanism could include the expression of beta chemokines from HIV-2-infected lymphocytes that inhibit HIV-1 infection. In addition to HIV-2's

demonstrated robust CTL responses, the accompanying granzyme production would elicit beta chemokines resulting in downregulation of the CCR5 receptor on CD4-bearing cells, rendering the target for HIV-1 and HIV-2 viruses less susceptible to infection. Therefore, HIV-2 infection resulting in active humoral, cellular immunity and beta-chemokine production could inhibit the replication of HIV-1 and ensuing disease progression.

Finally, the discovery and description of HIV-2 infection in Dakar, Senegal, also provided an important model for international and long-term collaboration and partnership. The initial discovery of HIV-2 in registered sex workers in Dakar, Senegal, was conducted through a unique collaboration between Souleymane Mboup and his team, Cheikh Anta Diop University, Francis Barin, University of Tours (France), Francois Denis, University of Limoges, and the Harvard School of Public Health, USA. This interuniversity convention worked together for more than two decades to advance our understanding of the biological and clinical significance of HIV-2 (Kanki 2009). Much of the research was based on studies conducted on registered female sex workers in Dakar Senegal. It is important to also recognize the contribution of these women who consented to participate in the research studies that advanced the HIV research community's understanding of HIV-2 and provided important lessons on HIV-2 infection and its implications.

Definition

HIV-associated cancers are cancers whose incidence is increased in patients with HIV infection and especially those in which the increased incidence is a result of the HIV infection. These include both AIDS-defining cancers (cancers that confer a diagnosis of AIDS when they occur in HIV-infected persons) and non-AIDS-defining cancers (other cancers whose incidence is increased in HIV infection). The AIDS-defining cancers are Kaposi's sarcoma, certain high-grade B-cell lymphomas, and cervical cancer.

Introduction

On June 5, 1981, the Centers for Disease Control reported in *Morbidity and Mortality Weekly Report* a cluster of 5 cases of *Pneumocystis pneumonia* in young homosexual men. A month later, on July 3, they reported on both *Pneumocystis pneumonia* and Kaposi's sarcoma (KS) (see entry on “► [Epidemic Kaposi Sarcoma, Pathogenesis and Presentation](#)”) occurring among homosexual men in New York and California (Centers for Disease Control 1981). These were the first reports of the disease we now call acquired immunodeficiency syndrome (AIDS). KS had previously been a very rare skin cancer

Note: This work was supported by the Intramural Research Program of the NIH, National Cancer Institute.

reported primarily in elderly men in Mediterranean regions, and its occurrence in young men who had sex with men (MSM) and the severity of many of these cases were a distinct departure from previous epidemiologic patterns.

AIDS-Defining and Non-AIDS-Defining Tumors in the AIDS Epidemic

As the AIDS epidemic unfolded over the next several years, it became apparent that AIDS was a complex disease characterized by profound immunodeficiency, especially of CD4+ T cells; immune dysregulation; and unusual opportunistic infections. Also, it became apparent that this syndrome was associated with certain cancers, especially KS (see entry on “► [Epidemic Kaposi Sarcoma, Pathogenesis and Presentation](#)”), central nervous system lymphoma (see entry on “► [AIDS-Related Primary Central Nervous System Lymphoma](#)”), and certain other high-grade B-cell lymphomas (see entry on “► [Presentation and Pathogenesis of B-Cell Lymphoid Cancers Associated with HIV Infection](#)”). As we now know, HIV/AIDS is associated with an increased risk of a number of tumors, some like KS that are rare outside the setting of profound immunodeficiency (Fig. 1) and others that develop in immunologically intact individuals but occur at a higher rate in patients with HIV/AIDS.

As the Centers for Disease Control (CDC) established criteria for this new and complex

syndrome, they considered Kaposi’s sarcoma and certain B-cell lymphomas [Burkitt or equivalent term (see entry on “► [Burkitt and Burkitt-like Lymphoma](#)”), immunoblastic or equivalent term, or primary brain lymphoma] as “AIDS defining” (Table 1) (see entry on “► [Epidemiology of AIDS-Defining Malignancies](#)”). This meant that the development of these tumors in an HIV-infected individual conferred a diagnosis of AIDS. These tumors tended to occur particularly in patients with low CD4 counts. Subsequently, in 1992, invasive cervical carcinoma was added to the list of “AIDS-defining tumors,” although it did not have as clear an association with profound immunodeficiency (see entry on “► [Cervical Cancer and HIV](#)”). It should be noted that the AIDS-defining lymphomas included in the 1985 CDC criteria are based on the classification of lymphomas in use at that time, which has since been superseded. There is some uncertainty as whether certain lymphomas in the current terminology should be considered AIDS defining. Primary effusion lymphoma, for example, was not described as a separate entity in 1992 but is generally considered an AIDS-defining lymphoma (see entry on “► [Primary Effusion Lymphoma](#)”).

These were not the only tumors that are increased in patients with AIDS (or infected with HIV). Epidemiological studies identified a number of other tumors with increased incidence, such as anal carcinoma, lung cancer, and non-Hodgkin’s lymphoma (see entries on “► [Anal Cancer](#),” “► [Lung Cancer](#),” and “► [Hodgkin](#)

HIV-Associated Cancers,

Fig. 1 Two patients with AIDS-associated KS. *Left:* patient with multiple lesions of cutaneous KS on the back. *Right:* lower limb, showing extensive involvement with confluent KS and lymphedema

Lymphoma in Patients with HIV Infection”). These additional HIV-associated cancers are now called “non-AIDS-defining tumors” (see entry on “► **Epidemiology of Non-AIDS-Defining Malignancies**”). This term is sometimes also used to refer to any cancer that arises in an HIV-infected patient (even if it is not HIV associated) and that is not one of the AIDS-defining tumors.

For a number of years, the fact that some tumors were markedly increased in incidence in HIV-infected patients, while others were not, was a puzzle to scientists. Some clues came from epidemiology. For example, KS was particularly common in HIV-infected patients who had had sex with men, while the incidence of lymphoma was relatively equal in all HIV risk groups. The epidemiology of KS suggested that another infectious agent besides HIV was responsible for its pathogenesis, but attempts to identify such an agent failed until 1994, when the husband and wife team of Patrick Moore and Yuan Chang reported sequences of a novel gammaherpesvirus in the KS lesions of AIDS patients using the technique of representational difference analysis (Chang et al. 1994). This virus, which is called Kaposi’s sarcoma-associated herpesvirus (KSHV) or human herpesvirus-8 (HHV-8), is now known to be the cause of KS (see entry on “► **Kaposi Sarcoma-Associated Herpesvirus (KSHV) or Human Herpesvirus 8 (HHV-8)**”). It has also been identified as the etiologic agent of a rare lymphoma called primary effusion lymphoma (PEL) (Cesarman et al. 1995) and of most cases of multicentric Castleman disease (MCD) that arise in HIV-infected individuals (see entry on “► **Multicentric Castleman Disease**”). With the discovery of KSHV, it became evident that most (but not all) HIV-associated tumors were caused by another oncogenic virus (Table 1).

The development of several effective anti-HIV drugs enabled the use of highly active combination regimens, often called highly active antiretroviral therapy (HAART). The use of HAART in the USA and other resource-rich countries started around 1996. In addition to markedly reducing the mortality of HIV, the widespread use of HAART led to a decrease in the incidence of some AIDS-defining cancers, especially those

(such as KS or central nervous system lymphoma) that occur in patients with very low CD4 counts and immunologic impairment (Shiels et al. 2011). There was initially optimism that these tumors would largely become a thing of the past. However, because of several factors, after an initial decrease, the number of cases of AIDS-defining malignancies has remained fairly constant in the USA since about 2002. One reason is that there has been more than a doubling of the number of individuals living with AIDS in the USA, because the rate of new HIV infection has not changed and HIV-infected patients are living longer. Another factor is that some HIV-infected patients do not realize they are infected, or do not engage with medical care, until they become substantially immunosuppressed and develop an AIDS-defining tumor. A third is that some AIDS-defining tumors, such as cervical cancer, develop in patients with relatively high CD4 counts. Finally, the population of HIV-infected patients is becoming older, and age is an additional major risk factor for many tumors.

As noted above, in addition to the AIDS-defining tumors, a number of other tumors develop more often in HIV-infected individuals than the general (age-matched) population (Engels et al. 2006). These include anal carcinoma, Hodgkin’s lymphoma, lung cancer, pharyngeal carcinoma (see entry on “► **Other HPV-Associated Cancers (Oropharyngeal and Penile)**”), and Merkel cell tumor (see entry on “► **Merkel Cell Carcinoma and Other HIV-Associated Skin Cancers**”). In addition, as HIV-infected patients live longer and this population is increasing in age, they are increasingly developing the wide range of tumors seen in the general population. The best evidence is that many of these tumors arise independent of HIV infection, although it is possible that HIV will be found to be a contributory factor as we learn more about the epidemiology and factors contributing to their pathogenesis.

Recent studies have shown that unlike the AIDS-defining tumors, the number of cases of non-AIDS-defining tumors has increased substantially since the introduction of HAART in 1996, and in fact, there are now more non-AIDS-defining tumors than AIDS-defining tumors in

HIV-Associated Cancers, Table 1 Selected malignancies that are more frequent in HIV patients and their associated viruses

Malignancy	AIDS defining	Principal-associated virus or viruses	Comment
Kaposi's sarcoma	Yes	KSHV	
Primary central nervous system lymphoma	Yes	EBV	
Diffuse large B-cell lymphomas (germinal center or activated B-cell subtypes) ^a	Yes	EBV	A substantial percentage of cases are EBV negative
Burkitt lymphoma	Yes	EBV	A substantial percentage of cases are EBV negative
Primary effusion lymphoma	Yes	KSHV	Often also EBV
Hodgkin's lymphoma	No	EBV	Sometimes EBV negative in HIV patients
Multicentric Castleman disease	No	KSHV	
Anal cancer	No	HPV	
Pharyngeal cancer	No	HPV	
Primary hepatocellular carcinoma	No	HBV or HCV	
Plasmablastic lymphoma (oral cavity associated) ^b	No	EBV	Occasionally EBV negative in HIV patients
Merkel cell tumor	No	Merkel cell polyomavirus	Some are negative for Merkel cell polyomavirus
Leiomyosarcoma in children ^c	No	EBV	
Conjunctival carcinoma	No	Unclear; possibly HPV	Reported almost only in Africa
Lung cancer	No	None yet identified	Much of increased risk due to high prevalence of smoking

Abbreviations: *KSHV* Kaposi's sarcoma-associated herpesvirus, *EBV* Epstein-Barr virus, *HPV* human papillomavirus, *HBV* hepatitis B virus, *HCV* hepatitis C virus

HIV patients in the USA (Shiels et al. 2011). Also, with the widespread use of HAART, there are now fewer deaths from uncontrolled HIV infection, complications of profound AIDS immunosuppression, or opportunistic infections, and in some studies, cancer has now become the most common cause of death in patients with HIV/AIDS (Bonnet et al. 2009).

Pathogenesis of Tumors in HIV/AIDS

As noted above, the discovery of KSHV and its identification as the cause of KS (and several other tumors) was crucial, not just for its understanding of KS, but also because it led to an appreciation that most (but not all) tumors that are associated with HIV infection are caused by other oncogenic

viruses (Table 1). Our current understanding is that the immune system plays an important role in suppressing infection with these viruses and also suppressing malignant cells that express foreign epitopes from the viruses. Thus, in the setting of AIDS, the profound immunodeficiency permits an outgrowth of these viruses and cells transformed by them. In some cases, such as KSHV-associated multicentric Castleman's disease (MCD), the tumor is really a hyperproliferative state. In other cases, such as lymphomas caused by Epstein-Barr virus (EBV), our understanding is that a proliferation of virus-infected cells increases the likelihood of mutations that eventually lead to clonal tumors (see entry on “► [Epstein-Barr Virus \(EBV\)](#)”). Even HIV patients who are treated with HAART and have relatively normal CD4 counts have defects in their immune repertoire that over time can

enhance the risk of various tumors. An increased incidence of a tumor in the setting of HIV infection is a clue that this tumor may be caused by a virus. As an example, Merkel cell carcinoma, a rare skin cancer, is more likely to develop in HIV-infected patients, and an investigation of this relationship led to the discovery of Merkel cell polyomavirus as a new oncogenic virus (Feng et al. 2008).

Interestingly, not all tumors are more frequent in HIV-infected patients, and in particular, the incidence of some common tumors such as colon cancer, breast cancer, or cancer of the prostate is not increased. This observation suggests that either the immune system does not play an important role in keeping such tumors in check or time for such tumors to arise is longer than the survival of AIDS patients, at least until HAART was developed. It will be of interest to see if these tumors also become more common in the setting of HIV infection than in the general population as HIV-infected patients live for decades on HAART.

HIV can promote tumorigenesis in other ways as well. HIV infection is associated with immune dysregulation and B-cell hyperactivation, and this can promote the development of B-cell lymphoma and other tumors (such as KS) that respond to cytokine excess. Also, specific proteins of HIV may promote tumor development; for example, the Tat protein can penetrate cells and has been shown to enhance infection of cells with KSHV. Another possible factor is long-term exposure to antiretroviral drugs. Nucleoside reverse transcriptase inhibitors such as zidovudine act as chain terminators, and administration of high doses of certain of these drugs (including AZT) to pregnant mice has been reported to lead to an increased incidence of tumors in the offspring. However, it is important to note that epidemiologic studies of these drugs in humans have not yielded evidence that they contribute to tumorigenesis.

For some of the tumors whose incidence is increased in HIV-infected patients, the cause of the increased incidence may be in part or whole because of increased exposure to other cancer risk factors. For example, such patients have an increased risk of lung cancer that is due, at least in part, to increased cigarette use in the HIV-infected population. Studies trying to

determine if immunodeficiency or HIV infection independently contributes to the increased incidence of lung cancer have yielded conflicting results. Also, HIV-infected patients often have coinfection with hepatitis B virus (HBV) or hepatitis C viruses (HCV), as these viruses, like HIV, are spread through injection drug use, and hepatitis B can be spread sexually. Infection with these viruses can lead to hepatocellular carcinoma, which is also increased in incidence in HIV-infected patients. It appears that most of this increased incidence is due to the increased coinfection with HBV and/or HCV (see entry on “► [Hepatocellular Carcinoma in HIV-Positive Patients](#)”). However, there is reasonable evidence that immunosuppression also plays a role in the increased incidence of hepatocellular carcinoma. Similarly, HIV-infected patients have higher exposure to human papillomavirus than the general population, and this can work in conjunction with immunosuppression to lead to a higher incidence of cancer of the cervix, anus, penis, and oral pharynx (see entry on “► [Human Papillomavirus \(HPV\)](#)”). Thus, each HIV-associated cancer has its own complex story, and while there are some common themes, the pathogenesis of each has to be considered separately.

As the rate of HIV infection does not appear to be changing, at least in the USA, and as HIV-infected patients live for years with HAART, the HIV-infected population overall is increasing in age, and we are seeing an increasing population of HIV-infected patients over the age of 50 or 60 years. Cancer is in general a disease of aging, and some AIDS-defining tumors, such as KS, can occur in elderly patients outside the setting of HIV infection. It is not known exactly how the combination of aging, chronic mild immune defects of HIV and aging, coinfection with other oncogenic viruses, prolonged exposure to antiretroviral drugs, and enhanced exposure to other cancer risk factors such as cigarettes will interact to affect the development of tumors as we see a “graying” of the HIV-infected population. As HIV-infected patients age, they are increasingly susceptible to develop tumors on that basis alone. It is not known at this time how this process may be affected by long-term HIV infection. It will be

important to monitor the development of various tumors in the population living with long-term HIV infection to understand these issues and develop appropriate screening, preventive, and therapeutic strategies.

HIV-Associated Tumors in Resource-Limited Countries

Special attention must be given to HIV-associated cancers in resource-limited countries (see entry on “► [HIV Cancers in Resource-Limited Regions](#)”). In these regions, a higher proportion of cancers overall are due to infectious agents than in the more developed world, and many of these areas have a high prevalence of viruses that cause HIV-associated cancers. In particular, there is a high prevalence of KSHV infection in sub-Saharan Africa (Chokunonga et al. 1999), and in this region, KS is among the most common cancers; in some sub-Saharan countries, it is the most common tumor in males. Even before the spread of HIV, KS was a relatively common tumor in Africa, and KSHV-infected patients in Africa are more likely to develop KS than in other regions. The reasons for this are not clear. Possible explanations include exposure to other diseases, such as malaria, that cause inflammation; an earlier age of infection with KSHV; genetic factors that predispose to KS; or exposure to certain plants or other environmental factors that promote KS. Also, Burkitt lymphoma is relatively common in regions of sub-Saharan Africa even in HIV-uninfected patients. Most endemic cases of Burkitt lymphoma are caused by Epstein-Barr virus, and epidemiologic studies show that coinfection with malaria is an important contributor to tumorigenesis. There are certain HIV-associated tumors reported in Africa, such as carcinoma of the conjunctiva, that are not reported elsewhere, and there is much we need to learn about these unusual tumors (see entry on “► [Conjunctival Carcinoma](#)”).

Research on the epidemiology and pathogenesis of HIV-associated tumors in the developing world, and especially Africa, is hampered by the relatively undeveloped state of the medical and

research infrastructure in these regions. Patients with suspected tumors are often treated without biopsy or in setting with limited pathological expertise, and lymphoma, for example, can be confused with tuberculosis or other common diseases. As an example of this, while KSHV-associated multicentric Castleman disease has been diagnosed in a number of African immigrants to the USA, there are only few reports of this condition in Africa in spite of a very high prevalence of both KSHV and HIV. It is almost certain that many cases of this disease in Africa go unrecognized and are thought to be tuberculosis or a related illness.

The President's Emergency Plan for AIDS Relief (PEPFAR) is an ambitious program of the USA to provide effective therapy to HIV-infected patients in resource-limited settings. This program started in 2003 and has brought AIDS treatment to a substantial number of patients in Africa and other regions. As a result of this, we are starting to see a drop in AIDS-related tumors, especially KS. However, there is some evidence that, like in the resource-rich world, there is now the beginning of an increase in non-AIDS-defining tumors in these areas.

Treatment of Tumors in HIV-Infected Patients

The treatment of specific HIV-associated tumors is discussed in the specific sections on these tumors. However, it is worth presenting some broad principals. While KS has been, until recently, the most common tumor arising in AIDS patients in the USA, it was relatively rare in the USA prior to the AIDS epidemic, and relatively little was known about how to treat it. Thus, treatments for KS, including the use of interferon alpha, the identification of effective cancer chemotherapeutic drugs such as vincristine or paclitaxel, and the development of liposomal anthracyclines, were largely developed in the setting of AIDS (Krown et al. 1983; Welles et al. 1998). As we have learned more about the pathogenesis of this tumor, novel treatments aimed at blocking specific steps in its pathogenesis are now being developed.

With regard to systemic AIDS lymphomas, a challenge was that while these tumors were often curable outside the setting of AIDS with combination chemotherapy regimens, such regimens were initially viewed as too toxic to administer to AIDS patients. As a result, before the widespread use of HAART, low-dose chemotherapy regimens were developed specifically for HIV-associated lymphomas (Kaplan et al. 1997). An additional challenge at that time was that patients often died of their AIDS even if the lymphoma could be effectively treated. This was a problem with essentially all tumors developing in AIDS patients, and in fact, AIDS patients were almost universally excluded from experimental protocols to treat cancers except for studies of specific AIDS-related tumors.

With the development of HAART, this whole picture changed. The immune system of many AIDS patients could be restored to a large degree, they were not as frail, they had a better life expectancy, and they could tolerate toxic regimens better than before HAART. As a result, in a series of incremental clinical studies, it was shown that such patients could generally tolerate full-dose lymphoma regimens. There is recent information that HIV-infected patients can even tolerate allogeneic stem cell transplantation, and this approach is also being explored as a means of eradicating HIV in infected patients (see entry on “► [Stem Cell Transplantation](#)”). At the same time, a number of advances (such as rituximab and infusional regimens) were made in the therapy of various lymphomas (Dunleavy et al. 2010), and the expected survival of patients with certain types of AIDS lymphoma now approaches that of lymphoma patients without HIV.

While AIDS patients on HAART could often tolerate cancer chemotherapy, physicians treating such patients have often been reluctant to use full-dose therapy because of their experience with AIDS patients before the widespread use of HAART, and such patients have often been undertreated. Contributing to this problem has been the relative paucity of published information on the treatment of various tumors in HIV-infected patients as a result of their exclusion from cancer trials. Another concern for physicians

is that many HIV drugs, and especially the protease inhibitors that interact with cytochrome P450, can have substantial pharmacokinetic interactions with other drugs including cancer drugs (see entry on “► [cART and Supportive Care for HIV-Associated Malignancies](#)”). In many cases, there was little published information on these interactions, and this was another cause for caution. In 2008, the US National Cancer Institute determined that in most instances, there was no good reason to exclude HIV-infected patients from cancer trials, and they have made a concerted effort to open trials to such patients when feasible (Persad et al. 2008). Other cancer research agencies have also made an effort to study the treatment of cancer in HIV-infected patients, and as a result, there is an emerging body of information on the optimal treatment of a variety of cancers in the setting of HIV infection. This is an important development, as we see a shift from a few AIDS-defining tumors to a wide variety of AIDS-non-defining tumors arising in patients with HIV/AIDS.

Prevention of Tumors in HIV-Infected Patients

As noted above, a number of HIV-associated tumors are caused by oncogenic infectious agents, and they may thus be amendable to preventive strategies aimed at the underlying virus. Moreover, HIV itself plays an important role in the pathogenesis of the tumors, and strategies to prevent or treat HIV infection can therefore affect the development of these tumors. In fact, the development and widespread use of HAART caused a dramatic decrease in the incidence of AIDS-defining tumors, especially those that are associated with very low CD4 counts. It goes without saying that successful prevention of HIV infection, for example, by public health measures or, if developed, an HIV vaccine, will prevent HIV-associated cancers.

A number of approaches can also be used to prevent or reduce the extent of infection with the viruses responsible for causing many of these tumors. A vaccine against hepatitis B virus

(HBV) has been in use for several decades, and vaccines have recently been developed against strains of HPV responsible for the majority of cases of cervical, anal, and other HPV-associated cancers (Lowy and Schiller 2006). These vaccines must be given prior to infection with HPV, usually before the time of sexual activity. As a result, the population of adults today will generally not be protected by this vaccine, and its effects will be largely seen over the next several decades. Another concern is that, at least in the USA, the uptake of the vaccine in boys is very low, and MSM may remain an unprotected population for some time.

There are currently no vaccines developed against hepatitis C virus (HCV) or KSHV. Antiviral drugs have been developed or shown to be active against both of those viruses, and the use of ganciclovir (for cytomegalovirus retinitis) has been shown to reduce the development of KS (Martin et al. 1999). The spread of HCV, as well as HBV, has been reduced by the development of tests to screen the blood supply and can also be impacted by public health measures. KSHV is known to be secreted in saliva, although there is still much we do not know about the main causes of transmission. Unlike Epstein-Barr virus, KSHV appears to only be effectively transmitted in certain populations, and as we learn more about this, it may be possible to institute public health recommendations to reduce its spread. Strategies to prevent tumors in HIV-infected patients will be an important area of research and development as we move forward.

Conclusion

While it is still unclear whether HIV can be directly oncogenic, HIV infection and its associated immunodeficiency enhance the development of a variety of tumors. Some of these tumors, called "AIDS defining," confer a diagnosis of AIDS when they arise in an HIV-infected individual. The widespread use of HAART has dramatically reduced the incidence of several of these AIDS-defining tumors, especially those associated with very low CD4 counts. A number of

other "non-AIDS-defining" tumors are also more frequent in the setting of HIV infection. In some cases, HIV or HIV-associated immunodeficiency has directly contributed to their development. HIV-infected patients often have increased exposure to a variety of oncogenic agents, such as HCV or cigarette smoke, and this may contribute or even be the cause of the increased frequency of certain tumors. As HIV-infected patients live longer on HAART and as this population becomes older, we are seeing a decrease in AIDS-associated tumors and an increase in others. It is possible that new trends may emerge as patients live for decades with suppressed HIV infection, chronic subtle immune defects, and chronic exposure to antiretroviral drugs.

Most of the AIDS-defining or HIV-associated tumors are caused by oncogenic viruses, and it may be possible to effectively screen, prevent, or treat these tumors by strategies directed at the underlying virus. Substantial progress has already been made in this area, and it promises to be a fruitful area for future progress. At the same time, the trend toward development of a wider range of tumors in HIV patients is increasing the complexity of this field and will require teasing out and understanding the trends as they emerge.

Whether or not it is HIV associated, the treatment of cancer in an HIV-infected individual is often quite complex, as patients have two life-threatening conditions. Immunodeficiency and other manifestations of HIV may complicate the treatment of the tumor, and there is the potential for substantial drug interactions. It will be important to continue to develop improved therapy for those tumors that principally develop in HIV patients. At the same time, it will be important to learn how to optimally manage other cancers, whether or not they are HIV associated, that develop in the setting in HIV infection.

HIV-Associated Immune Exhaustion

Victor Appay, Anna Lissina and
Delphine Sauce

Centre d'Immunologie et des Maladies
Infectieuses (CIMI-Paris), Sorbonne Universités,
UPMC Univ Paris 06, CR7, Paris, France
INSERM, U1135, CIMI-Paris, Paris, France

Definition

The immune systems of HIV-infected patients show evidence of exhaustion. Immune exhaustion occurs at three different levels: (i) functional, (ii) clonal, and (iii) systemic. Firstly, HIV-specific cells present functional alterations, largely related to the overexpression of co-inhibitory receptors, upregulated as a result of chronic antigenic stimulation. Secondly, persistently activated HIV-1-specific CD8⁺ T-cell clones are driven towards a state of replicative senescence, resulting in the loss of cytotoxic T-cell populations important for the control of viral replication. Lastly, HIV-1-infected individuals are characterized by declining lymphocyte renewal capacities or lymphopoiesis, observed at the level of hematopoietic progenitors and reminiscent of old age. Thus, immune exhaustion in chronic HIV infection is multifaceted and affects the immune response in a number of ways, all of which are likely to contribute towards disease progression.

Introduction: Chronic Immune Activation in HIV Infection

The progressive depletion of and eventual deficit in CD4⁺ T cells represent hallmarks of HIV disease progression. However, the phenomenon of immune exhaustion may also play a key role in the decline of immune competence seen during the course of HIV infection. The plasticity of the immune system and its efficacy against pathogens are prodigious. Upon primary viral infection,

virus-specific naïve lymphocytes, that have not previously encountered the virus, become activated and develop into short-lived “effector” cells, capable of mounting a potent antiviral response. Upon viral clearance, a small proportion of these cells remains and acquires a memory state. These relatively long-lived memory lymphocytes will be responsible for orchestrating a rapid and robust recall response against the same pathogen. However, HIV is a persistent virus, which establishes chronic infection in its host, associated with the development of chronic immune activation. Elevated immune activation, which is a clear correlate of HIV disease progression, is believed to be an important determinant of immune exhaustion in HIV-infected patients (Appay and Sauce 2008).

A major contributor to immune activation in HIV-infected individuals is the persistent stimulation of immune cells that directly recognize HIV components, arising from incessant viral replication and elevated antigen loads (see sections “[Functional Exhaustion of HIV-1-Specific Humoral and Cellular Responses](#)” and “[Senescence of HIV-Specific T Cells and Clonal Exhaustion](#)”). Continued exposure of T cells to their cognate antigen can lead to their functional and clonal exhaustion. Systemic inflammation due to the activation of the innate immune response is another major issue in HIV pathogenesis. HIV-mediated depletion of CD4⁺ T cells (and to a lesser extent macrophages and dendritic cells) can disrupt the normal process of immune surveillance in mucosal lymphoid tissues, unleashing an avalanche of microbial products originating from commensal bacteria as well as microbial pathogens residing in the intestinal tract (Brenchley et al. 2006). Microbial products like lipopolysaccharide (LPS), flagellin, and CpG DNA are sensed by innate receptors such as TLRs present on dendritic cells and macrophages, leading to the release of proinflammatory mediators (e.g., tumor necrosis factor (TNF), interleukin 6 (IL-6), IL-1 β , macrophage inflammatory protein (MIP)-1 α , MIP-1 β , and RANTES) within both plasma and tissues. Moreover, the HIV-mediated depletion of CD4⁺ T cells and the creation of an inflammatory environment result in the

reactivation of latently integrated forms of persistent viruses (hepatitis B virus, HBV; hepatitis C virus, HCV; cytomegalovirus, CMV; or Epstein–Barr virus, EBV), which HIV-positive individuals are commonly coinfecting with. In this highly proinflammatory environment, a broad range of immune cell subsets, comprising CD8⁺ and CD4⁺ T cells, NK cells, monocytes, polymorphonuclear (PMN) neutrophils, and B cells, are activated. The release of large amounts of inflammatory mediators and reactive oxygen species (ROS) by these cell subsets propagates systemic immune activation. Heightened immune activation drives viral replication and, with it, the process of global immune exhaustion, affecting primary lymphoid organs and immune resources (see section “[Systemic Exhaustion of Immune Resources in HIV-1 Infection](#)”).

Functional Exhaustion of HIV-1-Specific Humoral and Cellular Responses

Given their important role in controlling HIV replication, many studies have focused on the immune exhaustion of CD8⁺ T cells. Exhausted CD8⁺ T cells cease the production of cytokines like IL-2, TNF, and interferon gamma (IFN γ) and show reduced cytotoxicity (Wherry 2011). Similarly, exhausted CD4⁺ T cells lose certain effector functions during chronic HIV-1 infection. Amongst the functions most affected is their ability to produce the homeostatic cytokines IL-2 and IL-21, which are important for maintaining CD8⁺ T cells alive and stimulating B cells to produce neutralizing antibodies. Chronic HIV-1 infection also interferes with normal B-cell function and differentiation pathways, giving rise to exhausted B cells. Exhausted memory B cells exhibit a CD21^{Low} CD10⁻ CD27⁻ phenotype, reduced ability to migrate to the T-cell-rich areas (sites of T-cell-dependent B-cell maturation) of lymphoid tissues, poor proliferative capacity, and decreased immunoglobulin diversity (Moir and Fauci 2009).

Functional exhaustion is to a great extent related to the expression of co-inhibitory receptors. Upon HIV infection, CD8⁺ T cells are subjected to considerable levels of antigenic

stimulation through the T-cell receptor (TCR). This excessive or chronic triggering of the TCR results in increased expression of immunoregulatory molecules such as programmed death receptor 1 (PD-1). PD-1 belongs to a class of co-inhibitory receptors with important roles in the negative regulation of the immune response. Signaling through PD-1 acts to preserve the delicate balance between immune activation in response to infection and immune contraction essential for maintaining tolerance. In chronically HIV-viremic individuals, high PD-1 levels on CD8⁺ T cells correlate positively with viral load and inversely with CD4⁺ T-cell counts (Day et al. 2006; Petrovas et al. 2006; Trautmann et al. 2006). Collectively, such observations and many others have labeled PD-1 as an important marker of immune exhaustion. It is however important to mention that PD-1 is also expressed on activated, yet fully functional, T cells during the acute phase of infection. Thus, the expression of PD-1 and other co-inhibitory signals on recently activated T cells should be considered as part of a normal mechanism of immune regulation, while sustained expression of these receptors may be an indicator of functional alteration or exhaustion. PD-1 expression is not limited to activated and exhausted CD8⁺ T cells and is found on the surface of many other immune cells, including CD4⁺ T cells, B cells, NK cells, and monocytes. Similar to CD8⁺ T cells, PD-1 expression on CD4⁺ T cells, NK cells, and B cells is related to functional exhaustion and more rapid HIV-1 disease progression.

In addition to the best-characterized immunoregulatory receptor PD-1, a multitude of other co-inhibitory cell-surface molecules, expressed on CD8⁺ and CD4⁺ T cells, have been identified in recent years (Crawford and Wherry 2009). These include cytotoxic T-cell antigen 4 (CTLA-4), T-cell immunoglobulin and mucin protein 3 (Tim-3), B- and T-cell attenuator (BTLA), 2B4 (CD244), lymphocyte-activation gene 3 (LAG-3), and CD160. Similarly, memory B cells can also upregulate co-inhibitory receptors besides PD-1. These tend to be different from T-cell co-inhibitory receptors and include Fc receptor-like 4 (FCRL4), sialic acid-binding Ig-like

6 (SIGLEC6), CD22, CD72, and CD85. Besides the various co-inhibitory cell-surface molecules, immunoregulatory soluble mediators can also contribute to immune exhaustion. During chronic HIV-1 infection, dendritic cells, monocytes, and certain subsets of CD4⁺ T cell produce the immunosuppressive cytokine IL-10. Another immunosuppressive modulator, the transforming growth factor beta (TGF- β), which is expressed by a wide variety of cell types, may also promote immune alteration during chronic HIV-1 infection. In many instances, a close connection exists between the initiation of regulatory signaling pathways through ligation of co-inhibitory receptors and the induction of immunosuppressive mediators. For example, PD-1 upregulation on monocytes following ligation of innate sensors such as TLRs may actually contribute to CD4⁺ T-cell dysfunction through the production of IL-10. Master regulators of these pathways are likely to be type I interferons (Teijaro et al. 2013; Wilson et al. 2013), whose adverse role in chronic HIV infection appears increasingly evident.

Senescence of HIV-Specific T Cells and Clonal Exhaustion

In addition to functional exhaustion, the replicative capacity and survival potential of HIV-specific cells can be affected. Accumulating evidence suggests that the Hayflick limit (which defines the irreversible state of growth arrest indicative of replicative senescence, initially observed in cultured human fibroblasts) applies to all cells of the immune system, meaning that their replicative lifespan *in vivo* is limited. The onset of replicative senescence is primarily related to the number of divisions undergone by a given cell and is associated with the shortening of telomeres (repeated hexameric DNA sequences found at the ends of the chromosomes). A cell experiencing substantial telomere shortening can succumb to chromosome instability, leading to growth arrest and/or apoptosis. During primary viral infection, upregulation of telomerase (the enzyme responsible for the maintenance of telomere length) enables newly activated virus-specific

T cells to retain long telomeres during this period of considerable clonal expansion. However, such capacity to upregulate telomerase decreases on repeated stimulation. As a consequence, continuously replicating memory T cells specific for persistent viruses present increasingly shorter telomere lengths and may rapidly reach a stage of replicative senescence. Such senescent CD8⁺ T-cell populations have been identified in HIV-viremic individuals and display a number of other functional defects such as the reduced capacity to produce IL-2 and lowered proliferative potential. Moreover, these memory T cells are characterized by a lack of CD28 and an increased expression of CD57, a cell-surface marker associated with cellular senescence (Papagno et al. 2004). Of note, reduced telomerase activity and telomere shortening have been directly reported in HIV-specific CD8⁺ T cells derived from infected patients (Lichterfeld et al. 2008). Persistent viral replication and repeated stimulation may therefore gradually drive HIV-specific CD8⁺ T cells towards an irreversible state of exhaustion, resulting in the eventual loss of important anti-HIV T-cell populations.

HIV-specific T-cell populations are heterogeneous and consist of cells displaying varying functional features and levels of antiviral efficacy. While all T cells are endowed with TCRs that determine their specificities for antigen, the term TCR “avidity” describes the combined affinities of these TCRs and provides a measure of the strength of a given T cell–target cell interaction. TCR avidity is thought to be a major determinant of the qualitative attributes of HIV-specific T cells, including their immunodominance, poly-functionality, HIV-suppressive capacity, and ultimately their control of HIV replication (Appay et al. 2008). Due to their superior sensitivity to antigen, high-avidity T cells may be particularly prone to viral antigen-mediated stimulation, resulting in a faster progression towards senescence and eventually the depletion of these clones from the repertoire of HIV-infected patients altogether (Almeida et al. 2007; Lichterfeld et al. 2007). The exhaustion and loss of these important T cells can play a significant role in the onset of HIV disease progression, despite

other functionally active, albeit lower avidity, HIV-specific CD8⁺ T cells remaining in circulation. Clonal exhaustion can also be blamed for the loss of specificity towards certain HIV epitopes. Ultimately, the maintenance of optimal immune pressure and control of HIV replication depends on the capacity of the immune system to continuously recruit new high-avidity T cells targeting a wide range of antigenic specificities.

Systemic Exhaustion of Immune Resources in HIV-1 Infection

In the face of their continuous depletion during HIV infection, the maintenance of adequate levels of CD4⁺ T cells depends not only on the ability to stop viral replication but also on the capacity to renew depleted lymphocyte stocks. However, continuous replacement and recruitment of new lymphocytes in HIV-infected patients is thwarted by the global decline of primary immune resources. It is indeed important to appreciate that activation-driven immune exhaustion in HIV infection may go far beyond the simple loss of virus-specific lymphocytes or cells actively depleted by the virus. HIV disease progression is actually associated with a general lymphopenia. As CD4⁺ and CD8⁺ T-cell counts drop during the chronic phase of HIV infection, the naive T-cell compartment is most strongly affected. NK- and B-cell numbers are also reduced during HIV infection. Similar to the observations made for the T-cell compartment, B-cell populations originating from HIV-infected patients are characterized by an underrepresentation of naive B cells. Collectively, these findings indicate that the integrity of all lymphocyte subsets is affected during the course of HIV disease progression. Given that all the cells that make up our immune system originate from hematopoietic stem cells (HSCs), the capacity to generate new lymphocytes ultimately depends on the availability of functional lymphoid precursors. However, accumulating evidence suggests that like other immune cells, HSCs have a limited replicative lifespan *in vivo*. Thus, it appears that the renewal capacity of the entire immune system has a limit.

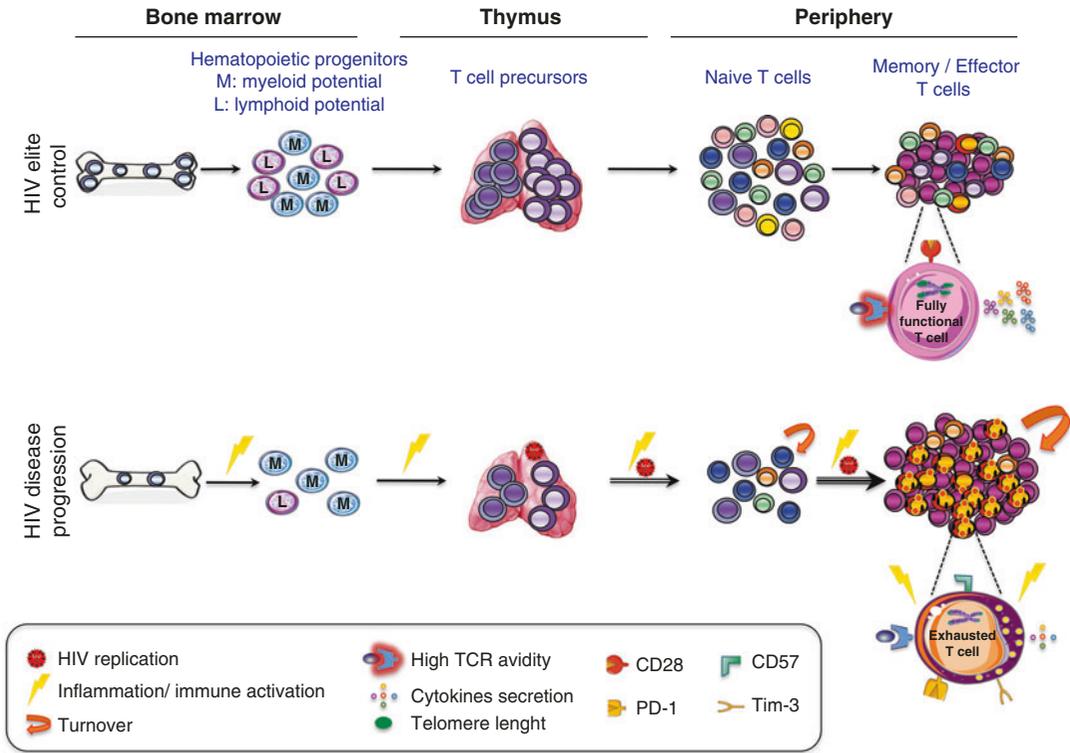

The reduced output of new T cells in HIV-infected patients can be partly caused by impaired thymopoiesis, relating to viral infection of the thymus or thymic involution. However, the general state of lymphopenia observed in chronic HIV infection appears to have a more profound origin, seeing as upstream elements of lymphocyte development are also affected. CD34⁺ hematopoietic progenitor cells (HPCs) represent the source of all blood cells. It was observed that HPCs derived from the bone marrow of HIV-viremic patients were functionally different from those found in healthy individuals, pointing to a case of impaired hematopoiesis in HIV infection (Moses et al. 1998). Recently, the detailed assessment of HPCs extracted directly from blood, allowing for the study of a large number of donors, revealed that patients progressing towards AIDS have decreased numbers of circulating HPCs. Moreover, CD34⁺ cells from these individuals displayed both functional defects and poor lymphoid precursor capacity, compared to healthy donors or HIV-infected nonprogressors (Sauce et al. 2011). These findings are in line with the impairment of T-cell progenitor function observed in chronic HIV infection. Results from fetal thymic organ culture experiments performed on CD34⁺ HPCs from HIV-infected progressors showed that these cells displayed a reduced capacity to generate both CD4⁺ and CD8⁺ T cells. Disrupted lymphopoiesis may thus significantly limit the production of new lymphocytes, including CD4⁺ T cells, and consequently disrupt the maintenance of adequate CD4⁺ T-cell numbers during HIV-1 infection. The onset of HIV disease progression appears therefore to be closely related to the condition of the primary lymphoid resources.

While lymphocytes are produced continuously throughout normal life, exacerbated consumption of cellular resources due to chronic or recurrent immune activation may eventually lead to the progressive decay of immune renewal capacities in HIV-infected subjects. This is reminiscent of the situation observed in the elderly, independently of HIV. Indeed, with age, the renewal capacity of the immune system gradually declines. Specifically, advanced age is

characterized by reduced lymphopoiesis due to dwindling HSC production and reduced egress from the bone marrow, accompanied by thymic involution. The end result is the shrinkage of the naïve lymphocyte pool and a loss of repertoire diversity. This deterioration forms part of the process of immunosenescence and is thought to be the result of successive rounds of immune activation throughout a lifetime. The parallels drawn between the state of primary immune resources in HIV-infected patients and HIV-negative elderly individuals suggest that premature immune aging occurs in chronic HIV infection.

Limiting Immune Exhaustion in HIV Infection

The different factors contributing to immune activation in HIV-infected patients eventually results in the perturbation of normal lymphocyte function, differentiation pathways, regenerative capacity, and ultimately a suboptimal immune control of viral replication. Better understanding of immune regulation has opened up new therapeutic avenues aimed at limiting the development of immune exhaustion during HIV infection. For instance, the functional exhaustion of lymphocytes mediated by co-inhibitory receptor overexpression appears to be a reversible phenomenon. Blockade of the interaction between PD-1 and its principal ligand PD-L1 resulted in improved CD8⁺ T-cell function in experiments performed *in vitro* using HIV⁺ human samples (Day et al. 2006; Petrovas et al. 2006; Trautmann et al. 2006). In the context of simian immunodeficiency virus (SIV) infection of macaques, animals receiving PD-1 antibody blockade showed improved T-cell and B-cell responses, in addition to a better control of viral replication and prolonged survival (Velu et al. 2009). Most recently, the therapeutic benefits of blocking PD-1 have been demonstrated in HIV-infected humanized mice, with a substantial decrease in viral load and a steady rise in CD4⁺ T-cell counts. Although promising, PD-1 blockade alone is not sufficient to fully rescue T cells

HIV-Associated Immune Exhaustion, Fig. 1 Exhaustion of T-cell immunity with HIV disease progression. Persistent HIV replication and chronic immune activation are associated with exhaustion of the T-cell compartment,

which occurs at three different levels: (1) functional, (2) clonal, and (3) systemic, as highlighted by the differences observed between HIV elite controllers and HIV-infected progressors

from exhaustion. One explanation is that the severity of functional exhaustion is influenced by the simultaneous expression of different co-inhibitory receptors on a single cell. Exhausted PD-1⁺ T cells express additional co-inhibitory receptors. The combined blockade of several co-inhibitory molecules can enhance functional restoration more effectively than abrogation of a single signaling pathway alone. Collectively, these observations expose the interesting possibility of different T-cell subsets being regulated by distinct combinations of co-inhibitory molecules, opening up opportunities for therapeutic reversion of immune exhaustion in a population-specific manner. It remains to be seen if these encouraging results can be replicated in humans, taking into account the potential development of immunopathological side effects when interfering with these immunoregulatory pathways.

While blockade of co-inhibitory signaling pathways is being exploited in the reversal of immune exhaustion during chronic HIV-1 infection, another approach involves tackling the problem of immune activation directly. Antiretroviral therapy (ART) represents the most effective antidote to HIV-driven immune activation developed to date. HIV-infected individuals receiving ART display reduced T-cell activation, diminished apoptosis, and lowered proinflammatory cytokine levels and show some reversion of immune exhaustion, with a partial recovery of cellular functions and primary immune resources. Of note, patients who fail to reconstitute their CD4⁺ T-cell compartment upon ART, referred to as immunological failure, present signs of profound and persistent damage to their hematopoietic system, with a fully exhausted capacity to produce lymphocytes (Sauce et al. 2011). Other therapies

aiming at reducing systemic immune activation are also being investigated. Amongst the candidates are inhibitors of T-cell activation (e.g., cyclosporine-A) and microbial product sensors (e.g., TLR antagonists), as well as blocking antibodies designed to target the proinflammatory cytokines themselves (e.g., IL-10 antagonists) (Rajasuriar et al. 2013). In cases of severe immune exhaustion (e.g., immunological failure), where restoration of immune function through decreased immune activation is simply not an option, alternative approaches aimed at endowing the immune system with younger, healthier cells may represent a solution. Examples of this strategy include the use of (i) homeostatic cytokines (IL-2, IL-7) to promote thymic regrowth and T-cell expansion, (ii) hematopoietic growth factors (e.g., growth hormone) to boost lymphopoiesis, and (iii) total reconstitution of the immune system through hematopoietic stem cell (HSC) transplantation.

Conclusions

Immune exhaustion caused by persistent HIV replication and chronic immune activation is likely to play an important role in the control of HIV infection and progression towards AIDS. The term “immune exhaustion” historically refers to the progressive decline of effector functions and proliferative potential observed in CD8⁺ T cells. However, exhaustion of other immune cell populations, including CD4⁺ helper T cells, memory B cells, NK cells, as well as hematopoietic progenitors, has also been reported in chronic HIV infection. Immune exhaustion can happen at three levels: (i) functional exhaustion of antiviral attributes of HIV-specific lymphocytes, (ii) clonal exhaustion of T cells important for the control of HIV replication, and (iii) systemic exhaustion of primary resources resulting in the decline of lymphopoiesis, accompanied by a general aging of the lymphocyte population (as exemplified in the Fig. 1). The development of strategies to limit or even reverse the onset of immune exhaustion is essential for securing the long-term survival of HIV-infected patients.

Hodgkin Lymphoma in Patients with HIV Infection

Michele Spina, Rosanna Ciancia, Accursio Augello, Massimiliano Berretta and Umberto Tirelli
Department of Medical Oncology A, National Cancer Institute, Aviano, PN, Italy

Definition

Hodgkin lymphoma (HL) is a type of lymphoma characterized by Reed-Sternberg cells and often associated with systemic symptoms. In is one of the more common non-AIDS-defining cancers, and it tends to be relatively more aggressive and to more frequently exhibit extranodal involvement. In the era of highly active antiretroviral therapy (HAART) the same regimens employed in HIV-negative patients with HL can be used in HIV setting with similar results.

Introduction

The availability of highly active antiretroviral therapy (HAART) has led to improvements in immune status among HIV-infected persons, reducing AIDS-related morbidity and prolonging survival. However, despite the impact of HAART on HIV-related mortality, malignancies remain an important cause of death (Bonnet et al. 2009). The use of HAART was also associated with reduced incidence of the two major AIDS-associated malignancies – ► [Kaposi's sarcoma \(KS\)](#) and high-grade non-Hodgkin lymphoma (NHL). However, among non-AIDS-defining cancers, an increased risk of Hodgkin lymphoma (HL), ► [anal cancer](#), ► [lung cancer](#), and hepatocarcinoma has been observed since the widespread use of HAART (Biggar et al. 2006).

Although HL is included in the World Health Organization's categorization of HIV-associated lymphomas, a number of questions remain regarding the relationship between HIV infection and HL. HIV-associated HL (HIV-HL) displays several peculiarities when compared with HL of the general population. First, HIV-HL exhibits an unusually aggressive clinical behavior, which mandates the use of specific therapeutic strategies and is associated with a poor prognosis. Second, the pathologic spectrum of HIV-HL differs markedly from that of HL in the general population (Tirelli et al. 1995). In particular, the aggressive histological subtypes of classic HL (cHL), namely mixed cellularity (MC) and lymphocyte depletion (LD), predominate among HIV-HL and pathologically, the tumor is characterized by an unusually large number of neoplastic cells, termed Reed-Sternberg (RS) cells. Finally, despite the great improvement in chemotherapy and supportive care, optimal staging and treatment is still a matter of controversy.

Epidemiology

In the HIV-negative population of western countries, HL is one of the commonest malignancies diagnosed in young adults, with 6 cases of HL observed per 100,000 inhabitants under 45 years

of. The epidemiology of HL is characterized by a peculiar age distribution pattern – a bimodal incidence curve with a first peak around the age of 30 and the second peak around the age of 50 years – that has been taken as suggestive of an infectious etiology. In immunosuppressed patients, HL occurs more frequently than in the general population of the same age and gender. In part because of the relative high frequency of HL in the population groups at high risk for HIV infection, a marked change in risk of HL was not initially appreciated in HIV-infected individuals, and HL was not included in the spectrum of HIV-defining cancers. However, with the spread of the epidemic and longer survival of infected people, the impact of HL was better recognized. A number of studies (Biggar et al. 2006; Serraino et al. 1997; Dal Maso et al. 2003; Clifford et al. 2005) strongly support the evidence that HIV-infected persons have, overall, a 10-fold higher risk of developing HL than HIV-negative persons. Such an excess risk is more pronounced in HIV-infected individuals with moderate immunosuppression; this is a different pattern than that observed for KS or certain other types of NHL such as ► [primary central nervous system lymphoma \(PCNSL\)](#) (Serraino et al. 1997). Thus, the epidemiological pattern of HL in HAART era substantially differs from those observed for KS or NHL – two neoplasms which drastically decreased after the introduction of HAART – and this pattern raises several new questions with regard of the relationship between degree of immunodeficiency, persistent viral infections, and cancer.

Of some interest is the recent observation of Powles et al. that have investigated the occurrence of cancers in a prospective cohort of 11,112 HIV-positive individuals, with 71,687 patient-years of follow-up (Powles et al. 2009). Standardized incidence ratios (SIRs) were calculated using general population incidence data. The incidence of HL in the HIV cohort was higher than in the general population (SIR 13.85; 95% CI, 9.64 to 19.26). There was a significant increase in the SIRs across the three study periods (1983 to 1995: 4.5; 1996 to 2001: 11.1 and 2002 to 2007: 32.4). Multivariate analysis demonstrated that

HAART was associated with an increased risk of disease (SIR 2.67; 95% CI, 1.19 to 6.02). Further multivariate modeling by class of antiretroviral agent showed that of the three classes of antiretroviral therapy, only the nonnucleoside reverse transcriptase inhibitors were associated with a significant increase in the incidence of HIV-HL (HR 2.20; 95% CI, 1.03 to 4.69); the reason for this association is not understood. The increased risk of HL with HAART might be explained because the risk of HL peaks when CD4 counts range from 150 to 199 CD4 cells/ μ L (Serraino et al. 1997). As the overall effect of HAART is to increase the CD4 count level, it paradoxically may increase HL incidence, leading to speculate that, with severe immune suppression, the cellular background surrounding the RS cells may be altered. A potential mechanism emphasizes the role of the RS cells producing several growth factors that increased the influx of CD4 cell and inflammatory cells, which, in turn, provide proliferation signals for the RS neoplastic cells. One can imagine that in the case of severe immune suppression, there are insufficient CD4 cells to maintain this feedback loop and there is less growth of the RS neoplastic cells (Gloghini and Carbone 2007). In addition, HIV-HL is associated with ► [Epstein-Barr virus \(EBV\)](#) in almost all cases, in contrast to the general population, in which this association is only observed in 20–50% according to histological type and age at diagnosis (Dolcetti et al. 2001). In summary, the use of HAART has improved the immunity of HIV-infected persons, diminishing the risks of developing other cancers or other opportunistic infections and paradoxically increasing the risk of HL.

Pathological Features

HIV-HL displays a number of different pathological features in comparison HL in HIV-negative patients. In fact, HIV-HL is characterized by the high incidence of unfavorable histological subtypes (i.e., MC and LD) (Tirelli et al. 1995). In the pre-HAART era, among HIV-infected persons, MC was the most frequent HL subtype and nodular sclerosis (NS) was less frequent than in

HIV-uninfected persons. For each HL subtype, incidence decreased with declining CD4 counts, but NS subtype decreased more precipitously than MC subtype, thereby increasing the proportion of MC subtype of HL seen in persons with AIDS. Thus, the greater proportion of MC and LD subtypes appears specifically related to severe immunocompromise in AIDS. By contrast, in the HAART era, HIV-infected patients with modest immunocompromise are more at risk for the development of the NS subtype (Biggar et al. 2006).

HIV-HL exhibits special features related to the cellular background (presence of fibrohistiocytoid stromal cell proliferation) and the high number of neoplastic cells, and both these features may pose relevant difficulties in diagnosing and classifying the disease. This finding contrasts with the rather low population of neoplastic cells usually found in HIV-unrelated HL. Moreover, a high frequency of EBV association has been shown in HL (80–100%) tissues from HIV-HL (Carbone et al. 1999). The EBV genomes in such cases have been reported to be episomal and clonal, even when detected in multiple independent lesions. The elevated frequency of EBV association with HIV-HL indicates that EBV probably does represent a relevant factor involved in the pathogenesis of HIV-HL. An etiologic role of EBV in the pathogenesis of HIV-HL is further supported by data showing that LMP-1 is expressed in virtually all HIV-HL cases (Carbone et al. 1999). On this basis, HL in HIV-infected persons appears to be an EBV-related lymphoma expressing LMP1.

It should be noted that RS cells of classical HL in HIV-negative patients represent transformed B-cells that originate from pre-apoptotic germinal center (GC) B-cells (Klein and Dalla-Favera 2008). By contrast, most HIV-related HL cases express LMP1 and display the BCL6-/CD138+/MUM1 IRF4+ (for multiple myeloma-1 interferon regulatory factor-4), phenotype, thus reflecting post-GC B cells (Carbone et al. 1999; Klein and Dalla-Favera 2008). The possible contribution of LMP1 to the loss of BCL6 expression seems plausible given that LMP1 can down-regulate many B-cell specific genes. Loss of

B-cell identity occurs during the normal differentiation of a GC B-cell into a plasma cell or memory B-cell.

Clinical Aspects and Treatment

As in HIV-NHL, one of the most characteristic features of HIV-HL is the widespread extent of the disease at presentation and the frequency of systemic “B” symptoms, including fever, night sweats and/or weight loss >10% of the normal body weight. At the time of diagnosis 70–96% of the patients with HIV-HL have “B” symptoms and 74–92% have advanced stages of disease with frequent involvement of extranodal sites, the most common being bone marrow (40–50%), liver (15–40%) and spleen (around 20%) (Tirelli et al. 1995). HIV-HL tends to develop relatively early in the course of HIV infection with a median CD4+ cell count ranging from 275 to 306/ μ L (Tirelli et al. 1995). The widespread use of HAART has resulted in substantial improvement in the survival of patients with HIV infection and lymphomas, due to the reduction of the incidence of opportunistic infections, to the opportunity to allow more aggressive chemotherapy and to the less aggressive presentation of lymphoma in patients in HAART in comparison with those lymphomas diagnosed in patients who never received HAART (Tirelli et al. 1995; Vaccher et al. 2003).

The Italian Cooperative Group on AIDS and Tumors (GICAT) has collected data on 290 patients with HIV-HL (Chimienti et al. 2008). Two hundred and eighty-one patients (87%) were males and the median age was 34 years (range 19–72 years). 69% of patients were intravenous drug users. The median CD4 cell count was 240/ μ L (range 4–1, 100/ μ L) and 57% of patients had a detectable HIV viral load. MC was diagnosed in 53% of cases, followed by NS in 24% and LD in 14%. Advanced stages of disease were observed in 79% of patients and 76% had B symptoms. The overall extranodal involvement was 59% with bone marrow, spleen and liver involved in 38, 30 and 17%, respectively. The authors split the series into two subgroups: the

first group was comprised of patients who received HAART throughout the 6 months before the onset of HL (84 patients); the second group was comprised of those patients who never received HAART before the diagnosis of HL or for less than 6 months (206 patients). Briefly, in comparison to patients who never received HAART, patients who received HAART before the onset of HL were older, had less B symptoms, and had a higher leukocyte count, neutrophils count and hemoglobin level. The following parameters were associated with a better overall survival (OS): MC subtype, the absence of extranodal involvement, the absence of B symptoms and a prior use of HAART. Interestingly, three parameters were associated with a longer time to treatment failure: a normal value of alkaline phosphatase, a prior exposure to HAART and an international prognostic score less than 3 (Chimienti et al. 2008).

A similar study was carried out within the Spanish group GESIDA where the authors compared the clinical characteristics and outcome of 104 patients with HIV-HL, treated (83 patients) or not (21 patients) with HAART (Berenguer et al. 2008). No differences were found between the groups at baseline, but the complete remission (CR) rate was significantly higher in HAART group (91% vs 70%, $p = 0.023$). The median overall survival was not reached in HAART group and was 39 months in no-HAART group ($p = 0.0089$); the median disease free survival (DFS) was not reached in HAART group and was 85 months in no-HAART group ($p = 0.129$). Factors independently associated with CR were a CD4 cell count >100 cells/ μL and the use of HAART; CR was the only factor independently associated with OS (Berenguer et al. 2008).

The optimal therapy for HIV-HL has not yet been defined. Because most patients have advanced stages of disease, they have generally been treated with combination chemotherapy regimens. Even so, the CR rate remains lower than that attained in HL of the general population with the OS being approximately 1.5 years (Tirelli et al. 1995). Due to the low incidence of HIV-HL, no randomized controlled trials have

been conducted. However, several phase II studies have evaluated the feasibility and activity of different regimens. In a prospective trial, conducted within the GICAT between March 1989 and March 1992, 17 previously untreated patients with HIV-HL were treated with epirubicin, vinblastine, and bleomycin (EVB). Overall, CR was achieved in 53% of the group, lasting a median of 20 months. The median OS for the group as a whole was 11 months and the 2-year DFS was 55% (Errante et al. 1994). In an attempt to improve upon these results, from 1993 to 1997, a second prospective trial consisting of full dose EVB plus prednisone (EVB/P) and concomitant antiretroviral therapy (zidovudine or didanosine) was conducted. The results of this trial in which 35 patients were enrolled, showed a CR rate of 74% and a 3-year OS and DFS of 32 and 53% respectively (Errante et al. 1999). The AIDS Clinical Trials Group (ACTG) reported the results of a phase II study in 21 patients treated with adriamycin, bleomycin, vinblastine, and dacarbazine (ABVD) for 4–6 cycles and primary use of G-CSF. Antiretroviral therapy was not used. The CR rate, on an intent-to-treat analysis, was 43% with an overall objective response rate of 62%. Median survival for all patients was 18 months (Levine et al. 2000). The widespread use of HAART allows the use of more aggressive chemotherapeutic regimens. Within the European Intergroup Study 59 consecutive HL-HIV patients were treated with Stanford V regimen, consisting of short term chemotherapy (12 weeks) with adjuvant radiotherapy. This regimen was well tolerated and 69% of the patients completed treatment with no dose reduction or delayed chemotherapy administration. The most important dose-limiting side effects were bone marrow toxicity and neurotoxicity. Eighty-one percent of the patients achieved CR, and after a median follow-up of 17 months 33/59 (56%) patients are alive and disease-free. The estimated 5-year OS, DFS and freedom from progression (FFP) were 59, 68 and 60%, respectively. Probability of FFP was significantly higher ($p = 0.002$) among patients with an international prognostic score (IPS) of <2 than in those with IPS >2 , and the percentage of FFP at 2 years were 83 and 41% respectively. Similarly,

Hodgkin Lymphoma in Patients with HIV Infection, Table 1 Results of prospective studies in HIV-HL

Regimen / reference	# of patients	Stage III-IV (%)	Response rate (%)	Complete remission rate (%)	Overall survival
EBV (Errante et al. 1994)	17	88	82	53	11 months
EBVP (Errante et al. 1999)	35	83	91	74	16 months
ABVD (Levine et al. 2000)	21	81	62	43	18 months
Stanford V (Spina et al. 2002)	59	71	89	81	59% at 5 years
BEACOPP (Hartmann et al. 2003)	12	92	100	100	75% at 3 years
ABVD (Xicoy et al. 2007)	62	100	87	87	76% at 5 years
VEBEP (Spina et al. 2008)	71	70	78	67	69% at 2 years

probability of OS was significantly different ($p = 0.0004$), and the percent survival at 3 years was 76 and 33% respectively for IPS <2 and IPS >2 (Spina et al. 2002).

Within the German group, the very intensive bleomycin, etoposide, adriamycin, cyclophosphamide, oncovin, procarbazine, prednisone (BEACOPP) regimen has been tested in 12 untreated patients with a 100% of CR rate but a high incidence of opportunistic infections (Hartmann et al. 2003). Recently, the results of a large prospective phase II study with ABVD have been published. Within a cooperative network in Spain, 62 patients with HIV-HL received the standard ABVD plus HAART. The scheduled six to eight ABVD cycles were completed in 82% of cases. Six patients died during induction, 54 (87%) achieved a CR, and two were resistant. The 5-year OS and event-free survival (EFS) probabilities were 76 and 71%, respectively. The immunological response to HAART appeared to have a positive impact on OS ($p = 0.002$) and EFS ($p = 0.001$) (Xicoy et al. 2007). Finally, the GICAT has concluded the accrual of 71 patients in a prospective phase II study aiming to evaluate feasibility and activity of a novel regimen including epirubicin, bleomycin, vinorelbine, cyclophosphamide, and prednisone (VEBEP regimen). Seventy percent of patients had advanced stages of disease and 45% had an IPS >2 . The CR was 67% and 2-year OS, DFS,

TTF and EFS were 69, 86, 59 and 52%, respectively (Spina et al. 2008). The results of the largest prospective studies are shown in Table 1.

Recently, a stage-adapted approach has been reported on 112 patients with an excellent outcome similar to that of HIV negative patients (Hentrich et al. 2012). Moreover, a comparison between patients with HIV-HL and patients with HL without HIV infection showed that HIV patients have more advanced stages of disease with more adverse prognostic factors; however, when these patients were treated with ABVD, HIV infection does appear to not adversely affect OS or EFS (Montoto et al. 2012). Because a large proportion of patients with HIV-HL progress and relapse, the use of high dose chemotherapy and autologous stem cell transplantation (ASCT), which is considered the gold standard for salvage therapy, has been tested in this setting. Several data from different groups, including the GICAT, have demonstrated the feasibility of this (Re et al. 2009). Different conditioning regimens, varying in their inclusion of total body irradiation, have been tested. Recently, the AIDS Malignancy Consortium demonstrated in a multinstitutional trial that a regimen of dose-reduced high-dose chemotherapy, including cyclophosphamide and busulfan and ASCT, is well tolerated and is associated with favorable DFS and OS probabilities for selected patients with HIV associated NHL and HL.

PET Scanning

Positron emission tomography using [^{18}F]-Fluoro-2-Deoxy-D-Glucose (FDG-PET) was first introduced in the management of lymphomas in the early 1990s. It is now recognized as an important tool for staging and treatment response assessment in HL and NHL. In HIV-negative patients, residual FDG PET avidity after two cycles of ABVD has been shown to predict poor prognosis and therefore, has been proposed to guide future therapy (Gallamini et al. 2006). A negative PET scan after two cycles of ABVD predicted a 96% 2-year progression free survival (PFS). Nearly 80% of the HL patients show a complete normalization of PET scan after two courses of ABVD. This phenomenon, called “metabolic CR,” can be explained by the peculiar architecture and organization of the neoplastic tissue, where only few, scattered neoplastic cells (accounting for less than 1% of the total cellular population) are surrounded by a population of nonneoplastic mononuclear bystander cells. The latter cells are probably responsible for the immortalization of RS cells in HD by stimulating cytokine production by other CD4+ lymphoid cells (paracrine loop) or by inducing cytokine production by the RS cells (autocrine loop). In cases presenting with bulky lesions at diagnosis, a negative early PET is often associated with a persisting bulky lesion of more or less unchanged size. The explanation might be that chemotherapy switches off the production of chemokines by the activated lymphoid cells, as described for TARC (thymus and activation-related chemokine). The latter can be measured in the serum of HL patients and its level is correlated to the quality of treatment response: for patients in CR TARC levels are much lower than in patients with stable or progressing disease.

PET scanning within the HIV framework can be problematic. Some preliminary reports suggested that FDG activity may correlate with detectable lymphoma. Although initial staging may not alter the treatment plan, it can provide additional information, assess areas of possible, and help foresee and possibly avoid further complications. However, PET scanning in the HIV-HL

needs to be further studied. If PET is to be utilized, a baseline study is mandatory, since early PET interpretation is based on a site-to-site comparison of FDG uptake both before and after chemotherapy. Pitfalls are numerous in these patients in whom HIV-associated immunodeficiency predisposes to infection, as does the use of aggressive immunosuppressive chemotherapy regimens. PET imaging requires cautious reading and pertinent clinical correlation to avoid misdiagnosing benign disease as malignant. This can pose a problem, for example, when hypermetabolic foci seen in the lung or esophagus, which are common sites of HIV-and/or chemotherapy-promoted infections. Nodal FDG uptake can be observed in lymphoma, various infections (e.g., *Mycobacterium avium* intracellular, *Mycobacterium tuberculosis*, Herpes simplex virus, among others) and other AIDS-related malignancies such as Kaposi sarcoma. In addition, stimulation of bone marrow following treatment with granulocyte colony stimulating factors induces a striking increase in FDG uptake in bone marrow. To take into account the possibility of minimal residual uptake, a semi-quantitative approach has recently been proposed for interim PET interpretation in the context of an international protocol for advanced-stage HL.

Finally, PET is useful for an accurate initial staging and it should be recommended to monitoring treatment response. PET scans have prognostic value, and a negative scan is frequently associated with a favorable outcome. Significance of residual uptake at sites of disease needs further evaluation (e.g., biopsy). However, the use of FDG in the follow-up of HIV-HL patients who achieved CR cannot be routinely recommended and further studies are warranted to assess the possible value of such scans.

Conclusions

The outcome of patients with HIV-HL has improved in recent years with better combined antineoplastic and antiretroviral approaches. The main important challenges for the next years are: (a) to better understand the pathogenesis of HD and the ways that HIV interacts with this process;

(b) assess in a randomized trial whether ABVD is the standard regimen in HIV setting; (c) to validate the role of PET scan both in the staging and in the evaluation of response; (d) to better understand the interactions between chemotherapy and antiretroviral therapy in order to reduce the toxicity of both approaches; (e) to evaluate the use of new drugs (i.e., bortezomib) in this setting; (f) to evaluate the long-term toxicity of the treatment in cured patients.

Host Genetics and Genomics

 Switzerland

Definition

HIV host genetic research seeks to comprehensively describe human genetic influences on HIV/AIDS. The rationale behind host genetic and genomic analyses, the different study designs, and the proven associations between DNA polymorphism and HIV infection outcomes are discussed in this section.

Heritability of Susceptibility to HIV

Susceptibility to HIV infection varies considerably between individuals, owing in part to the virus itself and to other environmental influences. It has long been known, however, that differences in HIV control are also partially heritable. The strongest evidence comes from in vitro studies of

immortalized B lymphocytes from extended families, which demonstrated that more than half of the observed difference in cell susceptibility to HIV-1 is due to the individual genetic background (Loeuillet et al. 2008). Heritability is also demonstrated by rare case studies involving related individuals: for example, identical twins concomitantly infected with the same retroviral strain had very comparable clinical histories, while a third brother, contaminated with a different HIV-1, had a markedly different disease course (Draenert et al. 2006).

Genetic Analysis

Overview

Studies of the host genetic factors contributing to HIV susceptibility and disease progression have generally focused on either quantitative measurements of disease progression (e.g., set point viral load, CD4+ T cell decline, or time to AIDS) or a binary classification usually involving extreme phenotypes (e.g., elite control of viremia or exceptional resistance against HIV acquisition in highly exposed individuals). The goal of such investigations is to uncover genetic variants (either individually, combined on haplotypes, or interacting) whose presence significantly correlates with the quantitative phenotype or, in the case of a binary phenotype, is found at significantly different frequencies between cases and controls. Such genetic studies have uncovered strong influences on disease outcome mediated by the class I HLA genes (in particular *HLA-B*) and *CCR5* (discussed in detail below). However, many other reported associations in numerous genes have either failed replication in subsequent studies or have not undergone sufficient investigation so as to be considered bona fide genetic influences on HIV control.

Candidate Gene Genotyping

Among the most common approaches for detecting genetic associations with polygenic traits in the pre-genomic era were candidate gene studies. As suggested by the term “candidate gene,” this approach involves some a priori knowledge of gene function and a presumed

importance to the trait of interest. Such studies are attractive since they require very little in terms of technology and investment (targeted genotyping or sequencing), once patient cohorts have been built and characterized. In HIV infection, commonly interrogated classes of candidate genes include innate and adaptive immune mediators (such as cytokines, chemokines, and their receptors), HIV dependency factors (i.e., host genes required for viral replication), and factors that restrict either HIV or other related viruses in vitro or in vivo (e.g., *APOBEC3G* and *TRIM5*).

One of the earliest examples was the description of the impact on HIV disease of a 32-base pair deletion in the *CCR5* gene (*CCR5Δ32*), a receptor for the chemokines CCL3, CCL4, and CCL5, acting as the main HIV co-receptor on CD4+ T cells. *CCR5Δ32* is overrepresented in its homozygous form among exposed uninfected individuals and associates with delayed disease progression in heterozygous individuals (Dean et al. 1996). However, despite this early success, few other genetic variants identified through candidate gene studies have stood up to multiple rounds of replication by subsequent investigations.

The main failures of this method are the generally small sample sizes, the lack of correction for multiple testing, and in particular the inability to account for non-phenotypic factors associating with genotype that can be misinterpreted as true associations (such as differences in ethnic background between cases and controls or cryptic relatedness between study participants). An example of such a spurious association is the reported link between the $-46C/C$ genotype in the Duffy antigen receptor for chemokines (*DARC*) gene (known to influence susceptibility to *Plasmodium vivax* malaria) and HIV resistance (He et al. 2008). Subsequent investigations into this gene demonstrated that the frequency differences observed in the initial study were likely due to differing proportions of African and European ancestries between cases and controls (the $-46C/C$ variant has been driven to fixation in multiple African populations) rather than to a true association with HIV resistance (Julg et al. 2009; Walley et al. 2009). Ultimately, targeted candidate gene studies have given way to genome-wide

approaches where methods have been developed to account for such confounders.

Genome-Wide Association Analysis

Facilitated by the complete sequence of the human genome, extensive catalogues of human variation and laboratory and statistical techniques to produce and analyze massively dimensional data sets, genome-wide association studies (GWAS) have become the leading tool for interrogating the genetic underpinnings of complex traits. These studies aim at testing all common variants (defined as those present in the population at $>5\%$ frequency) for association with a trait of interest by assuming that all common variants, even if not directly tested, are captured through linkage disequilibrium (LD). Success of GWAS requires large cohorts of well-characterized individuals in order to have sufficient statistical power to detect the often-modest effect sizes of disease-associated variants. Since the publication of the first GWAS in 2005, more than 1,000 associations have been reported with hundreds of traits (a catalogue of which can be found at www.genome.gov/gwastudies). In practice, GWAS use microarrays to genotype patient samples and controls (or populations with a measured quantitative trait) at hundreds of thousands to millions of single nucleotide polymorphisms (SNPs). Tests for association are most commonly performed individually for each variant by regressing phenotype (binary or quantitative) on SNP dosage (i.e., the number of variant alleles present) plus covariates. The linear (quantitative) and logistic (binary) regression approaches have been widely adopted as these models can flexibly include covariates to correct for confounders. These covariates generally include principal components calculated from the genome-wide SNP data to control for population stratification (Price et al. 2006). Due to the large number of tests being performed (approximately 1×10^6 independent tests), the community has adopted a statistical threshold of p-values below 5×10^{-8} (referred to as genome-wide significance) in order to claim discovery. In almost all cases, independent replication in a separate sample (either through direct genotyping or meta-analysis) is also required.

There have been multiple GWAS performed in cohorts with HIV phenotypes, primarily in individuals of European ancestry, and mostly focusing on HIV viral load or disease progression (CD4 decline or time to AIDS). Almost all of them have described the same signals located in the major histocompatibility complex (MHC) region, identifying it as the major genetic determinant of disease outcome in the genome-wide context (Fellay et al. 2007; The International HIV Controllers Study 2010). Similar results have been observed in the MHC region of African American populations, although the precise SNPs identified differ from Europeans (due to differential LD between tag SNPs and causal variants between ethnic groups) (Pelak et al. 2010; McLaren et al. 2012). Additionally, a small number of GWAS have been performed on cohorts of HIV-exposed uninfected individuals. None of these have identified genetic signals that pass the statistical thresholds required to claim genetic discovery (Petrovski et al. 2011; Lingappa et al. 2011). Of note, the sample sizes of the GWAS performed to date in the HIV field are small in comparison to other complex traits. Thus, only very strong effect sizes have been detected. Meta-analyses of existing GWAS data sets will be required to determine if further common genetic variants with smaller effect sizes contribute to susceptibility to HIV acquisition and/or disease progression.

Exome and Whole Genome Sequencing

Moving beyond GWAS, which are limited to testing relatively common variants, advances in sequencing technologies and reduction in costs now make it possible to interrogate all classes of genetic variants in a single experiment. Currently, the favored study design involves sequencing the approximately 2% of the human genome that is known to code for genes, i.e., exome sequencing. In addition to providing genotypes on common variants located in genes (also provided by GWAS), low frequency polymorphisms and some forms of structural variation (e.g., small insertion/deletions) are also obtained. Several genes underlying Mendelian diseases have been identified using this approach, and it is now being applied to

common traits. In general, these studies focus on analysis of rare, coding mutations that are presumed to have larger effects on phenotype than more common variants (as severely deleterious mutations are selected against reaching high frequency by evolutionary pressure). However, to detect individual rare variants as associated with a particular phenotype would require sample sizes that are much larger than those currently available. Thus, techniques to increase power for detection of signals in exome data are receiving much attention. These include using extreme phenotypes (i.e., individuals presumed to be highly enriched for causal mutations), variant collapsing methods (i.e., combining all variants in a gene rather than testing them individually), and empirical weighting based on functional impact or evolutionary context. Use of these methods in combination has been successful in increasing power of variant detection (Emond et al. 2012).

As sequencing costs continue to decline, the focus will move from exome to whole genome sequencing. The advantage of this approach over exome sequencing is that it provides complete characterization of variation in all genetic regions in a sample. However, the drawbacks include increased cost and computational load, as well as multiple testing burden. Additionally, strategies to enhance power through collapsing variants in noncoding regions of the genome are less clear than in exome data sets and will require further development. Although there are no published studies to date, both exome and whole genome sequencing approaches are currently being applied to cohorts with HIV phenotypes to address the role of rare genetic variants on influencing HIV outcome.

Phenotypes and Cohorts for Genomic Analysis

Genetics of Resistance Against HIV Infection

An understanding of host genetic resistance against HIV infection is of key importance to identifying novel prophylactic drug targets or correlates of protection for rational vaccine design. Individuals that were repeatedly exposed to HIV

but remained seronegative have been compared to HIV-infected cohorts or to large numbers of samples collected from the general population, in an attempt to detect significant differences in allelic frequency of genetic variants, suggesting a protective or deleterious role in HIV acquisition. Exposed uninfected subjects have been described in various high-risk populations: examples include hemophiliacs exposed to contaminated batches of factor VIII concentrates in the early days of the pandemic, men who have sex with men reporting high-risk behavior, and highly exposed female sex workers (Telenti and McLaren 2010).

Genetics of Control of Viral Replication

Viral load during primary infection and when a patient has reached the set point are strong predictors of disease progression. Set point viral load (spVL), the stage of infection where viral load is relatively stable prior to progression to AIDS, shows substantial variation in the population. Genetic studies of viral load have used both spVL (\log_{10} transformed) (Fellay et al. 2007) and an extreme phenotype approach comparing HIV controllers to progressors (The International HIV Controllers Study 2010). Controllers are a subset of HIV long-term non-progressors that maintain low virus load in the absence of therapy (Deeks and Walker 2007). This group can be further subdivided into viremic controllers, those with spVL < 2,000 copies per mL of plasma, and elite controllers, those with spVL < 50 copies/mL. Although it has been hypothesized that the genetic influences mediating extreme viral control may differ from those that impact set point in the general population, this has not been observed. In fact, for those genetic variants that are reproducibly associated with HIV progression (Table 1), a strong correlation between the magnitudes of effect on spVL and controller/progressor status is observed (Fellay et al. 2009). This suggests that at least the common genetic influences are shared between these phenotypic measurements. Whether there are further modifying genetic influences that contribute to viremic/elite control in addition to these known effects is a topic of ongoing investigations.

Genetics of Disease Progression and AIDS

In addition to viral load, other laboratory or clinically measurable outcomes have been used as phenotypes in genomic analyses of the natural history of HIV disease, most notably the speed of disease progression as measured by the rate of CD4+ T cell decline or the time from seroconversion to an AIDS-defining illness. Here again, extreme phenotype study designs have been applied: individuals with sustained levels of CD4+ T cells despite years of infection (long-term non-progressors) and, inversely, patients presenting a very rapid immune deterioration and progression to AIDS (rapid progressors) were carefully selected from large clinical cohorts for GWAS or sequencing analyses.

Host Genetics in HIV Vaccine Trials

The tools of human genetics can also be used to explore the interindividual differences in response to immunogens, particularly in the context of randomized vaccine trials. In the HIV field, a GWAS assessed the host genetic determinants of HIV-specific responses to the T-cell vaccine tested in the Step trial (Fellay et al. 2011). Even if no polymorphism reached genome-wide significance, single nucleotide variants located in the MHC showed the strongest association with response to the HIV-1 Gag protein. These SNPs were markers for HLA-B alleles already known to associate with differences in HIV control, indicating that the host immunogenetic background plays a role in the host immune response to T-cell vaccines and confirming the existence of a connection between natural viral control and vaccine response.

Confirmed Human Genetic Determinants of HIV Control

As mentioned above, several variants previously identified by candidate gene studies and GWAS have failed to be widely replicated. In the two largest GWAS of viral control, the authors attempted to replicate >100 variants with reported effects on HIV disease outcome (The International HIV Controllers Study 2010; Fellay

Host Genetics and Genomics, Table 1 Single nucleotide polymorphisms reproducibly associated with HIV disease outcome

Variant	Gene class	Implicated gene	Description	Impact	References
rs333	Chemokine receptor	CCR5	32-base pair deletion in exon 4 resulting in the loss of expression on cell surface	HIV resistance (homozygous) delayed progression (heterozygous)	(Dean et al. 1996)
rs1800024			C > T transition mutation in the promoter region of CCR5. In high LD with rs1799864		Delayed progression
rs1799864		CCR2	Valine to isoleucine amino acid change at position 64 (V64I). In high LD with rs1800024 in CCR5		(Smith et al. 1997)
rs2395029	HLA	HLA-B	G allele is a near-perfect proxy for classical HLA-B*57:01 allele	Low viral load/ delayed progression	(Fellay et al. 2007)
rs4418214			C allele lies on haplotypes containing either HLA-B*57:01 or 27:05		(The International HIV Controllers Study 2010)
rs2523608			G allele is in high LD with HLA-B*57:03 and other protective alleles in African Americans		(Pelak et al. 2010; McLaren et al. 2012)
rs9264942		HLA-B/C	C allele tags haplotypes carrying multiple protective HLA-B alleles and a microRNA binding site (rs67384697) that modulates HLA-C expression level		(Fellay et al. 2007; Fellay et al. 2009)
rs67384697		HLA-C	Insertion/deletion polymorphism that disrupts a miRNA binding site in the 3' UTR of HLA-C, modulating expression level		(Kulkarni et al. 2011)

H

et al. 2009). With the exception of a small number of variants in the MHC region, in *CCR5* and in *CCR2*, all failed to be replicated. Although differences in study phenotypes, in ethnic background of study participants, or in circulating viral subtype may be proposed to explain some of this lack of replication, it is most likely that the majority of reported associations were falsely positive. Similarly, several large-scale studies of exposed uninfected individuals have failed to discover or replicate variants associated with resistance to infection, with the exception of *CCR5*Δ32 (Telenti and McLaren 2010). Thus, the number of variants that have been reproducibly associated with resistance to HIV infection or various disease

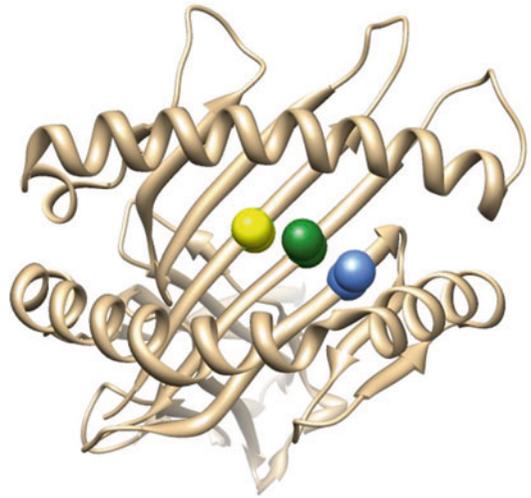

outcomes is small (a list of these is provided in Table 1).

In addition to *CCR5*Δ32 (discussed above in the “Candidate Gene Genotyping” section), two variants have been consistently replicated in the *CCR5/CCR2* region. The *CCR2* V64I variant (rs1799864) causes a valine to isoleucine amino acid change in the *CCR2* protein (thought to be a minor co-receptor for HIV entry) and associates with better viral control (Smith et al. 1997). A promoter variant in the *CCR5* gene (*CCR5* C927T or rs1800024) has also been shown to associate with delayed HIV disease progression. However, strong linkage disequilibrium exists between *CCR2* V64I and *CCR5* C927T in

Europeans (the predominant population in which they have been studied), preventing inference as to which is actually driving the observed impact on disease outcome.

Variants in genes of the MHC have the strongest effects on HIV control, likely mediated through binding and presentation of HIV peptides to the host immune system. Multiple classical HLA alleles with positive and negative influences on disease progression have been identified in several ethnic groups (discussed in detail in a separate entry: “► [MHC Locus Variation](#)”). GWAS have also identified multiple unlinked SNPs in this region that are strongly associated with disease outcome (Table 1) (The International HIV Controllers Study 2010; Fellay et al. 2009). The two most commonly described SNPs are rs2395029, a near-perfect proxy for the classical *HLA-B* allele 57:01, and rs9264942, located 35 kilobases upstream of *HLA-C* (often called *HLA-C* -35). The latter SNP has been identified as an expression quantitative trait locus influencing *HLA-C* mRNA levels. Further investigation has suggested that this *HLA-C* expression effect is mediated through an insertion/deletion polymorphism (rs67384697) in the 3' UTR of *HLA-C*, which is highly correlated with rs9264942 (Kulkarni et al. 2011). Additionally, strong evidence for association at rs4418214 in individuals of European ancestry and rs2523608 in African Americans has also been reported (Pelak et al. 2010).

Recently, attempts have been made to map specific amino acid residues carried by protective and non-protective classical *HLA-B* alleles (the gene that most strongly influences HIV control). These studies have shown the strongest associations map to amino acid residues in the peptide-binding groove, the domain of the protein responsible for selecting peptide epitopes to present to cytotoxic T lymphocytes (The International HIV Controllers Study 2010; McLaren et al. 2012; Kløverpris et al. 2012). Interestingly, three of the top amino acid residues are adjacent to one another and located in the beta sheets lining the bottom of the peptide-binding groove, suggesting an important functional role for this domain in particular (Fig. 1). These and other amino acid positions in the binding groove of HLA-B have

Host Genetics and Genomics, Fig. 1 Ribbon diagram looking into the peptide-binding groove of HLA-B showing spatial arrangement of top amino acid residues associated with modulating HIV outcome. Variations at positions 9 (yellow), 97 (green), and 116 (blue) lying at the bottom of the peptide-binding groove have been identified as key mediators controlling viral load in African (position 9 (Kløverpris et al. 2012)), African American (positions 97 and 116 (McLaren et al. 2012)), and European (position 97 (The International HIV Controllers Study 2010)) populations (Figure was modified from PDB entry 2BVP and prepared with UCSC Chimera)

been shown to explain the majority of the signal at the SNPs described above (The International HIV Controllers Study 2010).

Although variation in *CCR5/CCR2* and in HLA genes are reproducibly associated with HIV outcome, it remains to be determined if they account for the entirety of the host genetic influence. Meta-analyses of GWAS and large-scale sequencing studies are now seeking to detect common polymorphisms of more modest effect as well as rare variants, which are more likely to play a direct causal role. The combination of these approaches should finally delineate the impact of human genetic diversity on HIV control.

Clinical Implications of Host Genetic Determinants

The recent advances in the human genomics of HIV infection have improved understanding of

the natural history of the disease and opened new avenues in translational science. The inclusion of human genetic variation in the design of vaccine trials and of population-based in vitro experiments will allow for more informed analyses, stratified by genotypes of interest. More directly relevant to clinical care, personalized medicine based on genetic knowledge has the potential to benefit patients by allowing doctors to individually adjust diagnostic procedures and treatments. It will be essential, however, to explain the nature and the relevance of the genetic findings to the public and to healthcare providers: a limited number of variants have excellent predictive values (a clear example from the HIV pharmacogenetic field is the causal link between HLA-B*57:01 and hypersensitivity to abacavir), but most of them are poorly predictive for any given individual, even when they have significant effects at the population level. Genetic scores will be developed to help clinical decision-making, but they will never replace a global clinical assessment.

Conclusion

Recent developments in genomics have changed the way information about human DNA variation is used to understand and treat disease. The identification of associations between human genetic variants and HIV-related outcomes has the potential to benefit individuals and populations worldwide: a better comprehension of basic pathogenic processes can lead to the development of new drugs or vaccine strategies, and knowledge of individual genetic variation will pave the way toward more personalized medical care.

Housing as HIV Prevention

Diana Hernández¹, Mallika Bhandarkar² and Angela Aidala³

Definition: Housing as HIV Prevention

The co-occurrence of homelessness and HIV infection has long been recognized. However, evidence is beginning to show that housing status is not simply a correlate, but is strongly implicated

in multiple causal levels of risk for infection and continued transmission of HIV. Effectively addressing HIV risk requires attention to contextual or structural factors that shape or constrain individual behavior, which directly or indirectly affects an individual's ability to avoid exposure to HIV, or for HIV-positive individuals to avail of health-promoting and risk-reducing resources. A growing evidence base identifies housing status as a key structural factor influencing HIV vulnerability, risk, and health outcomes. Housing occupies a strategic position as an intermediate structural factor, linking broader societal processes of economic, social, and cultural exclusion to the more immediate physical and social environments within which individuals carry out day-to-day life (Aidala and Sumartojo 2007). The pressure of daily survival needs, limited opportunities to form stable partner relationships, high rates of transactional sex, exposure to violence, substance use as a way to cope with stress or mental health issues, and other conditions of homelessness make homeless and unstably housed persons especially vulnerable to HIV infection. Homelessness or inadequate housing itself appears to place persons at risk of HIV infection, and among persons already disproportionately impacted by HIV/AIDS (e.g., men who have sex with men (► [HIV Prevention for MSM](#)), persons of color, homeless youth, injection drug users, and victimized women (► [HIV Prevention and Women](#))), the lack of stable housing greatly amplifies their vulnerability for HIV and transmission to others. Research has also demonstrated that receipt of housing assistance has an independent, direct impact on reduction of drug and sexual risk behaviors as well as improving access to treatment (Access to Care) for HIV-positive persons and viral suppression which results in an additional prevention impact by reducing HIV transmission. The evidence on housing as prevention indicates that housing interventions improve the health and quality of life of people living with HIV/AIDS and also reduce new HIV infections, thereby contributing to both primary and secondary HIV prevention. As a strategic target for intervention, housing addresses the more proximal consequences of a multitude of broader social

and economic factors that affect HIV prevention and health care.

Housing and HIV Epidemiology

Since the beginning of the epidemic, lack of housing has been significantly associated with the risk for HIV exposure and transmission. Multiple studies have documented the dramatically higher prevalence of HIV/AIDS among homeless people compared to the general population. Among homeless persons in the USA, an estimated 3 to 20% are living with HIV (Robertson et al. 2004). The prevalence of HIV/AIDS is three to more than ten times higher among persons who are homeless or unstably housed (Housing and Homelessness) compared with persons with stable and adequate housing, though results vary by the population and geographic area studied (Culhane et al. 2001; Wolitski et al. 2007). A recent review of studies primarily in other developed nations found lower rates than in the USA, but prevalence ratios nonetheless indicate that HIV is much more common among the homeless in other nations as well (Beijer et al. 2012).

HIV/AIDS contributes substantially to excess mortality among homeless persons. For example, the rate of new HIV diagnoses among users of the New York City's homeless shelter system is over 16 times the rate compared to the general New York City population, and the death rate due to AIDS-related causes is seven times higher (Kerker et al. 2005; see also Chueng and Hwang 2004).

Housing and Risk for HIV Infection

Evidence has demonstrated that housing status is strongly associated with HIV-risk behaviors. Persons who are homeless or unstably housed are more likely to use drugs, use needles, share needles, have unprotected sex and multiple partners, and engage sex for money, drugs, or a place to stay (Survival Sex). The people most at risk of HIV – men who have sex with men, persons of color, unattached youth, injection drug users

(Injecting Drug Users (IDUs), Epidemiology of HIV/AIDS), and impoverished women – are significantly more likely to become HIV infected if they lack stable housing (Bruneau et al. 2011). A surveillance study of HIV infection among heterosexuals in 24 US cities found that the odds of testing positive for HIV are almost twice as high for residents of high-risk neighborhoods who experience homelessness compared to persons in the same neighborhoods with more stable housing (CDC 2011). Proven HIV-risk reduction interventions – including counseling, needle exchange, and other behavioral interventions (► [Behavior Aspects of HIV Treatment as Prevention](#)) – are considerably less effective for participants who are struggling with housing issues (Des Jarlais et al. 2007). Housing instability creates layers of chaos and unpredictability in the daily lives, environments, and habits of the homeless that creates multiple contexts of risk and limits access to risk reduction resources. Studies have confirmed a “dose relationship” such that homeless individuals are at increased risk for HIV compared to the unstably housed, and both homeless and unstably housed individuals have greater risk for HIV than those with stable secure housing (Aidala et al. 2005).

Housing Is HIV Prevention

Stable housing is an effective strategy for reducing an individual's risk for HIV and continued transmission of HIV to others. Longitudinal studies show a clear association between change in housing status and risk behavior change (Behavior Change). Formerly homeless persons who improve their housing status reduce risk behaviors by as much as half, while persons whose housing status worsens have higher rates of risky behavior (Aidala et al. 2005). Change in housing status is associated with risk reduction controlling for substance use, mental health issues, and receipt of health, behavioral health, and supportive services.

Housing assistance is a promising secondary prevention intervention. “Prevention for positives” is critical for protecting the health of people

living with HIV/AIDS (PLWHA) and reducing the continued spread of HIV. HIV infection increases risk for housing loss. An estimated 50% of all PLWHA will experience homelessness or housing instability during the course of their illness (HUD 2012). The HIV epidemic is increasingly concentrated among low income, racial/ethnic, and sexual minority communities and/or transient populations who may face limited housing options. However, regardless of prior housing resources, medical conditions and medical costs often lead to housing problems for persons with chronic illness. Illness limits employment and income drops, while housing costs continue to rise. Stigma (Stigma and Stigmatization) and discrimination associated with HIV can also limit housing options. For many, mental illness and substance abuse further challenge the ability to secure and maintain housing.

The lack of stable housing is associated with lack of treatment success. Homeless PLWHA compared to those who are stably housed are more likely to delay entry into care and to remain outside or marginal to HIV medical care. They are less adherent to treatment regimens and less likely to achieve viral suppression. Homeless/unstably housed PLWHA whose housing status improves over time are more likely to report continuous care and care that meets clinical practice standards than those who continue to experience housing instability. They are more likely to return to care after dropping out (Aidala et al. 2007; Kidder et al. 2007). Those who receive housing assistance are more likely to reduce risk behaviors, to engage in medical care, and to enjoy better health (Kidder et al. 2007, Buchanan et al. 2009). Access to housing improves access and adherence to antiretroviral medications, which lowers viral load and reduces the risk of transmission to uninfected persons (Leaver et al. 2007). Housing status is a more consistent predictor of health-care access and treatment outcomes than individual characteristics, insurance status, substance abuse and mental health comorbidities (Mental Health or Substance Abuse), or behavioral health service utilization. A systematic review of the literature identified 102 studies published between 1996 and 2012 that examined the effects of housing

status on health-related outcomes in PLWHA. Overall, findings from the included studies show that homelessness and unstable housing consistently contribute to poorer access to health services, ART adherence (► [Antiretroviral therapy \(ART\), Prevention of HIV](#)), and health outcomes and to increased HIV-risk behaviors. Almost all studies (87%) that investigated health outcomes among PLWHA found a negative association with homelessness or unstable housing, although some studies were underpowered to show statistical significance (Aidala et al. 2012). A more comprehensive review including later publications to 2014 reports the same pattern of findings regarding the association of unstable or inadequate housing and worse HIV engagement with care and health outcomes (Aidala et al. 2016).

Several local demonstration projects (e.g., Schwarcz et al. for San Francisco) and two large random assignment studies – the Chicago Housing for Health Partnership (Buchanan et al. 2009) and the HUD-CDC Prevention’s three-city Housing and Health Study (Wolitski et al. 2010) – provide the strongest evidence that providing housing assistance improves access and adherence to HIV care, reduces viral load, and reduces high-risk behavior associated with HIV transmission. These were both “housing first” models, providing PLWHA direct access to permanent housing without prior or ongoing demonstration of sobriety or commitment treatment, although services were available.

Housing Interventions Work and Are Cost-Effective

The Housing and Health (H&H) Study assessed the impact of immediate access to rental assistance vouchers on the medical care, health, and risk outcomes of homeless or unstably housed adults living with HIV/AIDS. The H&H Study included 630 HIV-positive participants in three cities (Baltimore, Chicago, and Los Angeles), half of whom were randomly assigned to receive a rental assistance voucher. The comparison group was referred to existing community resources in the attempt to secure housing. At the end of the

18-month study period, the majority of the intervention group achieved housing stability including those with long histories of chronic homelessness. Health outcomes improved dramatically with housing stability – including a 35% reduction in emergency room visits, a 57% reduction in the number of hospitalizations, and significantly improved mental health status. Even stronger differences were found in analyses that compared study participants who experienced homelessness during the follow-up period with those who did not. After controlling for socio-demographic variables, substance use, and physical and mental health status, those who continued to experience homelessness were 2.5 times more likely to use an emergency room, were 2.8 times more likely to have a detectable viral load at follow-up, reported significantly higher levels of perceived stress, and were more likely to report unprotected sex with a negative/unknown status partner (Wolitski et al. 2010).

The Chicago Housing for Health Partnership (CHHP) program provided housing and supportive service to persons with chronic medical illnesses including HIV who were homeless at discharge from hospitalization. The study examined medical care and health outcomes among formerly homeless patients randomly assigned to receive supportive housing compared to patients who were discharged to usual care in the community (most often emergency shelters). Among the one-third of CHHP study participants living with HIV/AIDS, those who received housing upon discharge from the hospital were almost twice as likely at 12 months to have an undetectable HIV viral load compared to HIV-positive participants who did not receive CHHP housing assistance (Buchanan et al. 2009). Overall, CHHP participants were three times more likely to achieve stable housing at 18 months than the usual care group and stability translated into significantly improved health outcomes. Controlling for a range of individual and service variables, housed participants had 29% fewer hospitalizations, 29% fewer hospital days, and 24% fewer emergency department visits than their counterparts (Sadowski et al. 2009).

Providing housing assistance for people living with HIV/AIDS both improved treatment

effectiveness and reduced costs associated with inappropriate care. Compared to usual care, the CHHP housing program generated average annual net public cost savings of over \$6000 per person (Basu et al. 2011). H&H Study cost analyses determined the cost utility of housing as an HIV-risk reduction and health-care intervention, considering the cost of the rent and services provided, HIV transmissions averted, medical costs saved, and quality-adjusted life years saved. Findings indicate that housing interventions are cost-effective if one out of every 64 HIV-positive persons receiving housing avoided HIV transmission to an HIV-seronegative partner. Considering comparative cost-effectiveness, with a cost per quality-adjusted life year (QALY) of \$35,000 to \$62,000, housing is a cost-effective HIV health-care intervention in the same range as widely accepted health-care interventions such as kidney dialysis (\$52,000 to \$129,000 per QALY) and screening mammography (\$57,000 per QALY) – and far less expensive than HIV pre-exposure prophylaxis (PrEP) (\$298,000 per QALY) (Holtgrave et al. 2007, 2013). The cost-effectiveness of housing as a platform to improve health outcomes and reduce health disparities has provided increasing justification for investing in housing interventions, which have been linked to reduced hospitalizations, emergency room visits, and other medical expenditures as well as improved quality of life for PLWHA. This is particularly relevant given that one in four homeless adults is hospitalized at least once in a year for largely preventable conditions. Forty percent of these adults are re-hospitalized within 14 months for the same condition, when they would have been better served by attention from outpatient services or ambulatory preventative care (Levinson and Ross 2007). Persons living in poverty without insurance and access to regular medical treatment tend to use costly emergency services more often.

Additional “housing first” randomized control trials provide clear evidence on the stabilizing effects of housing among homeless individuals with co-occurring substance use and mental health disorders, whereby providing safe housing spaces served to reduce risk behavior in substance

abuse and treatment nonadherence compared to “treatment first” options based on drug treatment, substance use counseling, and ambulatory medical service utilization (Burt 2002; Padgett et al. 2006). Housing first (HF) models developed in the USA are increasingly implemented in other national settings as well. See for example the *At Home/Chez Soi* national housing first program implemented by the Canadian Mental Health Commission whose evaluation concluded that HF rapidly ends homelessness, is associated with other positive outcomes, and is a sound public investment (Goering et al. 2014).

Conclusion: Policy Implications and Global Context

Accumulating evidence on the role of housing and other supportive services for people living with and at high risk of HIV/AIDS has influenced the policy landscape in the USA, resulting in several federal-level mandates issued by the White House, the Center for Disease Control (CDC), and the US Department of Housing and Urban Development (HUD) among other key governing entities and funders. The National HIV/AIDS Strategy (NHAS) for the USA released in 2010 set out three main goals: (1) to reduce new HIV infections, (2) to increase access to care, and (3) to improve health outcomes for PLWHA and to reduce health disparities related to HIV. NHAS calls specifically for increased housing support as a means by which to improve health outcomes and reduce health disparities for PLWHA (White House Office of National AIDS Policy 2010). HUD has committed to using housing as a platform to improve health in general and improve HIV outcomes in particular by expanding the reach of the Housing Opportunity for People Living with AIDS (HOPWA) program. HOPWA is a federal program that supports states, municipalities, and nonprofit organizations to develop and manage housing units and provide rental assistance and/or short-term payments in order to prevent homelessness among PLWHA (HUD 2012).

Internationally, the HIV and housing service sectors have increasingly worked together to

address the complex relationships between housing conditions, housing rights, and HIV/AIDS. The human settlement challenges in overcrowded slums with inadequate water, sanitation, and basic services are intensified by the impact of HIV. Risk of HIV infection is especially higher in settings where women have limited housing rights. Research has shown that women who have secure access to land and housing are better able to avoid relationships that increase their risk for HIV infection and to better manage their HIV if infected. Gender norms (Gender Roles) and traditional practices in nations that limit women’s access to housing both generate and sustain women’s disproportionate susceptibility to HIV infection (COHRE 2013).

The World Health Organization has included housing as one of the fundamental determinants of health. The right to adequate housing is defined as human right by the Office of the United Nations High Commissioner for Human Rights. UN-HABITAT has an initiative to incorporate programs to address AIDS in rights and development programs particularly in urban areas around the world. Another source of resources, research, and advocacy is the Centre on Housing Rights and Evictions (COHRE), an international human rights organization whose mission is to ensure the full enjoyment of the human right to adequate housing among all populations. COHRE has a program specifically to address women’s housing rights in the context of HIV/AIDS (COHRE 2013). The Interagency Coalition on AIDS and Development (ICAD) and Rooftops Canada (ICAD 2010) provide further resources and references on housing issues as they intersect with HIV/AIDS in developing nations.

Human Papillomavirus (HPV)

Zhi-Ming Zheng

Tumor Virus RNA Biology Section, Gene Regulation and Chromosome Biology Laboratory, Center for Cancer Research, National Cancer Institute, National Institutes of Health, Frederick, MD, USA

Definition

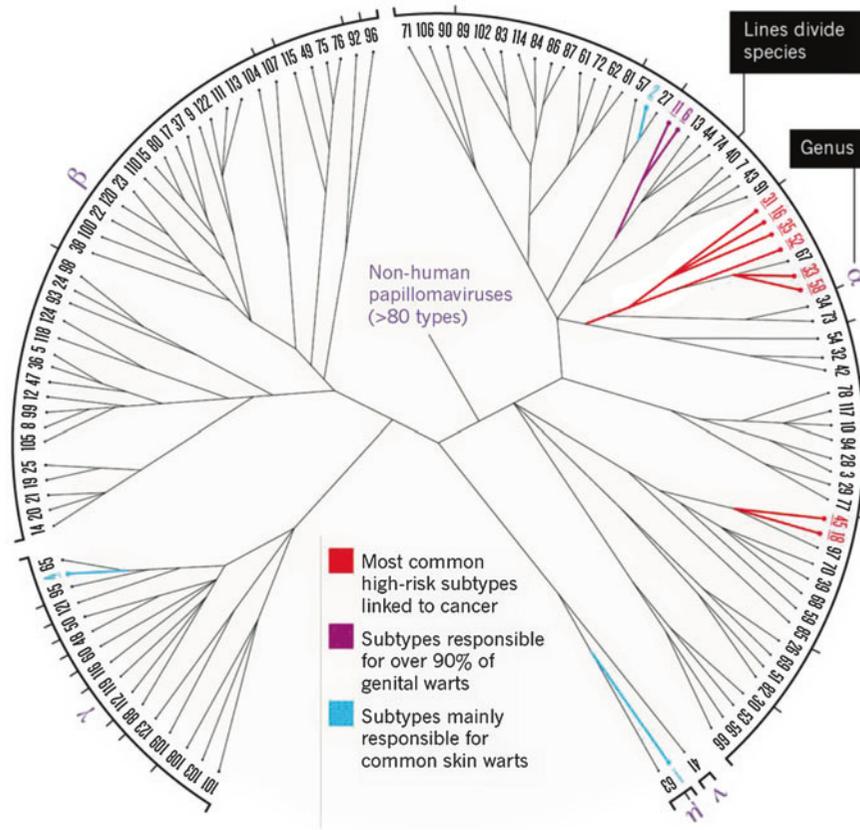

Human papillomaviruses (HPV) are a family of small DNA tumor viruses with a size of ~52–55 nm. The family consists of ~200 different genotypes; many of the types cause benign warts or papilloma, while a small fraction of oncogenic or “high-risk” types can cause invasive cervical cancer or other tumors. HPV infects keratinocytes in the basal layer of stratified squamous epithelia and replicates in the nucleus of infected keratinocytes along with keratinocyte differentiation. The viral genome in size of ~7.9 kb encodes six early,

nonstructural regulatory proteins (E1, E2, E4, E5, E6, and E7) and two late structural proteins (L1 and L2). E6 and E7 are two oncoproteins responsible for the viral oncogenesis of high-risk HPVs, including HPV16, HPV18, HPV31, HPV33, HPV35, HPV39, HPV45, HPV51, HPV52, HPV56, HPV58, HPV59, HPV68, HPV73, and HPV82. L1 is a major structural component of viral capsid, and its self-assembly in vitro into a viral-like particle (VLP) provides the basis of prophylactic vaccines against infections of several HPV types. In addition to cervical cancer, high-risk HPVs are associated with the development of various anogenital cancers and certain head and neck cancers.

Classification of Human Papillomaviruses

HPVs are a family of ~200 different genotypes, with 155 genotypes being completely sequenced. Papillomaviruses were originally classified as members of the family *Papovaviridae*, but reclassified in 2002 as an independent family, *Papillomaviridae*. The family *Papillomaviridae* currently contains at least 29 genera, and human papillomaviruses are grouped into five (alpha, beta, gamma, mu, and nu) genera (Fig. 1). The classification of papillomaviruses depends on the most conserved L1 open reading frame (ORF) by genotyping. Different genera share less than 60% nucleotide sequence identity in the L1 ORF. A new type of papillomavirus is given when its DNA sequence of L1 ORF differs by more than 10% from the closest known HPV type. Otherwise, a subtype indicates the difference between 2% and 10% and a variant less than 2%. HPV types are numbered in the order of their discovery. HPVs in the alpha genus cause mucosal and a fraction of cutaneous HPV lesions, while HPVs in the beta, gamma, mu, and nu genera cause cutaneous lesions.

HPVs are also grouped clinically as high-risk (oncogenic) types, which are frequently associated with invasive cervical cancer, and low-risk (non-oncogenic) types, which are found mainly in genital warts. Fifteen HPV types (types 16, 18,

H

Human Papillomavirus (HPV), Fig. 1 Classification of papillomaviruses (Adapted with permission from *Nature* (Crow 2012))

31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 68, 73, and 82) are high risk. Twelve HPV types (types 6, 11, 40, 42, 43, 44, 54, 61, 70, 72, 81, and 89) are low risk (Munoz et al. 2003). Among the high-risk HPVs, HPV16 and HPV18 are the principal causes of cervical cancer, with a combined, worldwide relative contribution of ~70% of invasive cervical cancer.

General Properties of Human Papillomaviruses

HPV Virions and Genome Structure

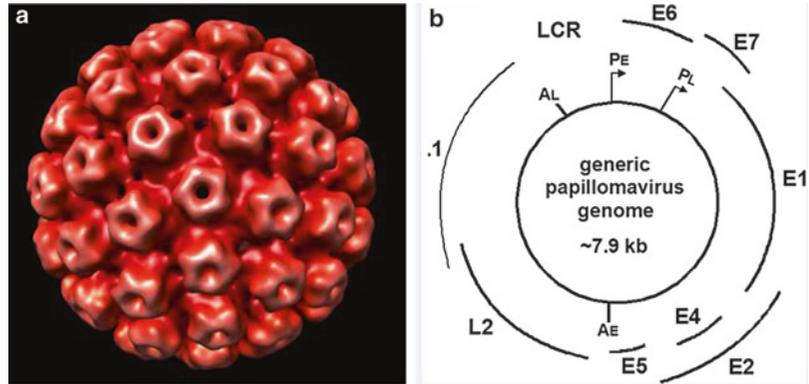

A mature HPV particle or virion contains a double-stranded, circular genome in the size of ~7.9 kb covered by a shell or capsid. HPV particles do not have an envelope or a lipid membrane outside of its capsid and thus is resistant to ether

treatment. An HPV capsid is composed of 72 pentamers, of which 60 are hexavalent and 12 are pentavalent (Fig. 2a). These pentamers are made up by two viral structural proteins, L1 and L2. Viral L1 (~55 kDa) is the major capsid protein and represents approximately 80% of the total viral protein. Viral L2 (~70 kDa) is a minor capsid protein. Each viral pentamer is comprised of five copies of L1 attached by one L2 from the inside of the pentamer. This is particularly true for the pentamers on the L2 vertices of icosahedral capsid shell. HPV virions are extremely stable and tolerate high temperature, low pH, proteases, and desiccation.

The HPV genome can be divided into three major regions: early, late, and a long control region (LCR), also called the noncoding region (NCR). The three regions are separated by two polyadenylation (pA) sites: an early pA (AE) site and a

Human Papillomavirus (HPV), Fig. 2

HPV genome structure and virion particles. (a) HPV11 VLP visualization of cryoEM reconstruction (<http://nramm.scripps.edu/?p=1042>). (b) HPV genome in a circular episomal form, with relative positions of viral early (*PE*) and late (*PL*) promoters and early (*AE*) and late (*AL*) polyadenylation signals

late pA (AL) site (Fig. 2b). The early region encodes six ORFs (E1, E2, E1[^]E4, E5, E6, and E7) and this region of HPV16, HPV18, and HPV31 also encodes an E2[^]E8. The late region lies downstream of the early region and encodes L1 and L2 ORFs. The LCR region (~850 bp) has no protein-coding function, but bears the origin of DNA replication and transcription factor-binding sites important for RNA transcription (Zheng and Baker 2006).

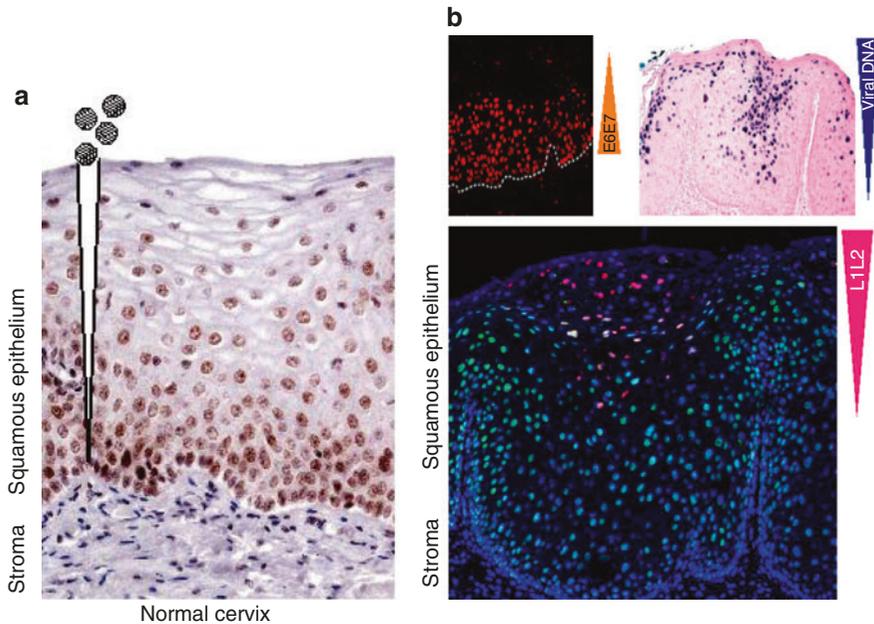

HPV Life Cycle

HPV depends on keratinocyte differentiation to complete its life cycle (Fig. 3). HPV infection is cell type-specific and requires the access of viral particles to human basal cells on the basal lamina through micro-wounding induced by scratching, sexual intercourse, etc. Initial attachment of HPV virions to the host cells takes place by the interaction of viral major capsid protein L1 with the host receptor, heparan sulfate proteoglycan. This interaction leads to a conformational change and exposes viral minor capsid protein L2 for furin/proprotein convertase digestion. Subsequently, exposed L2 (aa 108–120) interacts with the S100A10 subunit of annexin A2, a secondary cell receptor, followed by viral entry of the infected cells by endocytosis (Raff et al. 2013). L1 dissociation from the L2-viral genome, which is facilitated by cyclophilin B, results in viral particle uncoating and leaves the L2-associated viral genome in the endosome to interact with the retromer complex and to be transported to the nucleus via the trans-Golgi network. Once in the nucleus, L2 localizes the

viral genome to PML bodies for the transcription of early genes and establishment of infection.

HPV DNA replication requires the A + T-rich origin of DNA replication in the LCR and two viral DNA-binding proteins, E1 as a DNA helicase and E2 as an accessory factor to E1 (McBride 2008). It occurs bidirectionally in the nuclear replication foci during two different stages of the viral life cycle. The initial DNA replication takes place in an average of once per cell cycle in the G2 phase in the infected basal cells and allows the cells to maintain 50–100 copies of virus genome per cell. DNA repair plays a role in the promotion of HPV DNA amplification. The interaction of E1 with a cellular protein p80/UAF1 is required for efficient maintenance of the viral episome in undifferentiated keratinocytes. E2 binds to the viral genome and tethers it to mitotic chromosomes through mitosis by interaction with Brd4 on mitotic chromosomes to ensure partitioning of replicated viral episomes to the nuclei of both daughter cells (McBride 2008).

Viral vegetative DNA replication takes place in highly differentiated, upper layer spinous keratinocytes no longer undergoing cellular DNA synthesis. This stage of viral DNA replication is robust and presumably undertaken by a rolling circle replication mechanism, leading to amplification from a low, stable copy number to several thousands of viral genome copies per cell to be packaged into progeny virions. Viral DNA amplification is required for HPV late gene expression. Virions assemble into paracrystalline

Human Papillomavirus (HPV), Fig. 3 Keratinocyte differentiation-dependent HPV life cycle. **(a)** Infection of the cervical basal keratinocytes by viruses (*circles, top left*) is initiated through a microtrauma usually during sexual intercourse. The panel is modified with permission (Jia et al. 2009). **(b)** Expression of viral E6 and E7 is initiated in the infected basal cells (*orange color on the top left* for MCM7 as a surrogate for viral E6 and E7). Viral DNA

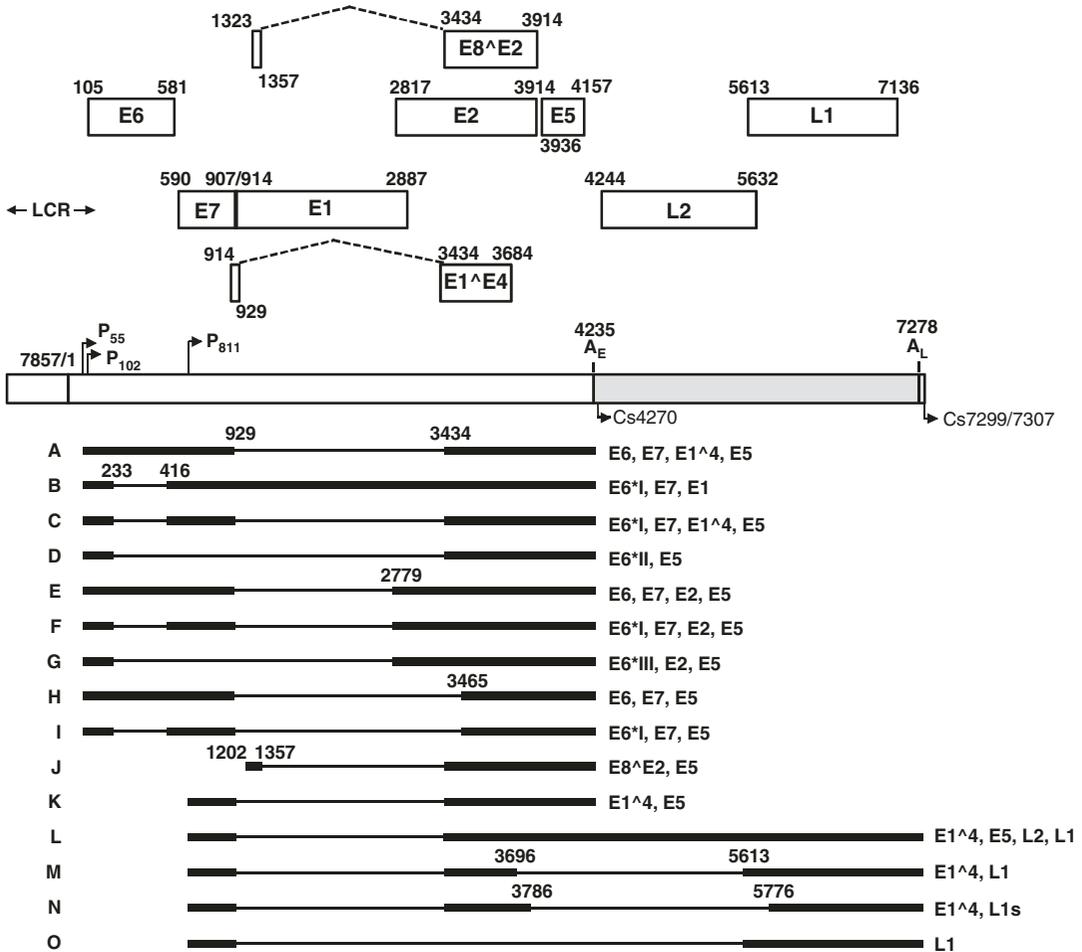

replication takes place in the spinous and granular keratinocytes under intermediate or high differentiation (*navy blue color on the top right* for viral DNA). However, viral L1 and L2 (*red color for L1 in the bottom*) become detectable only in the granular and cornified keratinocytes under terminal differentiation (This panel is adapted with permission (Zheng and Wang 2011))

arrays in the granular layer and egress from the cornified layers of the epithelium.

HPV Genome Expression

HPV transcribes its RNAs from one strand of its genome in one direction and starts from two major promoters named by their transcription start site position in the virus genome. A viral early promoter upstream of the E6 ORF and a viral late promoter residing in the E7 ORF are responsible for the expression of viral early and late ORFs, respectively. The viral early promoters P97 in HPV16, P99 in HPV31, and P55/P102 (previously named as P105) in HPV18 are three most studied early promoters. Their activities are tightly controlled by *cis*-elements in the LC-R. These *cis*-elements, including consensus E2-binding sites, interact with cellular transcription factors and the viral transactivator/repressor E2 protein and regulate the transcription from

each viral early promoter in undifferentiated keratinocytes. The resulting early primary transcripts (pre-mRNAs) carry all the early ORFs, which span three exons and two introns and undergo alternative RNA splicing and polyadenylation using an early pA signal (Fig. 4). The viral late promoters P670 in HPV16, P811 in HPV18, and P742 in HPV31 are three studied late promoters. Their activities can be induced only in differentiated keratinocytes during vegetative virus replication. Because a viral late promoter is positioned in the E7 coding region (Fig. 4), transcription from the late promoter has to bypass the early pA site to allow expression of the late region. As a result, a true late pre-mRNA is a chimeric transcript of the early and late regions, with the early region in its 5' half and the late region in its 3' half. This late pre-mRNA can be processed either into an early region transcript which is cleaved and polyadenylated at the

Human Papillomavirus (HPV), Fig. 4 Genome structure and transcription map of HPV18. The *bracket line* in the *middle* of the panel represents a linear form of the virus genome for better presentation of head-to-tail junctions, promoters (*arrows*), early (A_E) and late (A_L) pA sites, and mapped cleavage sites (CS). The ORFs (*open boxes*) are diagrammed above the *bracket*, and the numbers above each ORF (E6, E7, E1, E2, E5, L2, and L1) are the positions of the first nucleotide (nt) of the start codon and the last nt of the stop codon assigned to the HPV18 genome. The E1^ΔE4 and E8^ΔE2 ORFs span two exons with the nt positions

indicated. Because the first AUG of E1^ΔE4 and E8^ΔE2 is positioned in the first exon, formation of an intact E1^ΔE4 or E8^ΔE2 ORF requires RNA splicing (*dashed lines*). LCR is a long control region. Below the *bracket line* are the RNA species derived from alternative promoter usage and alternative RNA splicing. Exons (*heavy lines*) and introns (*thin lines*) are illustrated for each species of RNA, with the mapped splice site positions being numbered by nt positions in the virus genome. Coding potentials for each RNA species are shown on the right (Adapted with permission (Wang et al. 2011))

early pA site (transcript K) or a late region transcript which is cleaved and polyadenylated at the late pA site (transcript L–O) (Fig. 4). The alternative splicing of HPV early and late transcripts produces various species and sizes of mRNA transcripts with multiple coding potentials (Fig. 4 transcripts A–O). Thus, any given HPV transcript, no matter whether it is an early or late

transcript, could be bicistronic, tricistronic, or polycistronic and contains two or more ORFs (Zheng and Baker 2006; Wang et al. 2011). Conversely, a particular ORF can be a part of multiple mRNA species. Thus, to determine which transcript encodes which viral proteins has been a challenge, and we know very little about which protein is translated from which transcript.

Because E6, E1, and L2 ORFs span over an intron region, the expression of these three proteins requires the retention of its corresponding intron. RNA splicing promotes expression of E7 from viral early transcripts in high-risk HPVs and E4 from viral late transcripts.

Viral Proteins

The HPV genome encodes eight major viral proteins: E1, E2, E4, E5, E6, E7, L1, and L2. L1 and L2 are structural proteins for virus capsid formation. The other six viral proteins are nonstructural and are responsible for virus replication and pathogenesis. E6 and E7 are viral oncoproteins responsible for cell transformation and tumorigenesis.

E1

E1 (~68 kDa) is a site-specific DNA-binding protein for the viral origin of DNA replication. Although relatively little is known about how E1 protein is produced in HPV-infected tissues, E1 is biochemically a well-studied protein. E1 can be subdivided into three functional regions: a C-terminal helicase/ATPase domain, a central origin-binding domain, and an N-terminal regulatory region. E1 serves as a DNA helicase and opens the DNA duplex to initiate viral DNA replication. E1 by itself has low binding affinity for the viral origin of replication, which contains specific, palindromic E1-binding sites. However, binding of E2 protein to specific sites adjacent to the E1-binding sites helps recruit E1 in a cooperative manner. When loaded onto the origin, the E1/E2 protein complex recruits host replication factors such as topoisomerase I, DNA polymerase alpha/primase, replication protein A, and Brd4 to initiate viral DNA replication (McBride 2008). E1 protein is dispensable for maintenance of replication, but is essential for the initial and productive replication of HPV16 DNA. Overexpression of E1 blocks S-phase progression and triggers an ATM-dependent DNA damage response in viral DNA replication foci during the initial viral DNA amplification.

E2

E2 (~42 kDa) is a viral transcription factor in addition to its role in viral DNA replication. E2

contains two defined functional domains. The N-terminal domain is crucial for transcriptional activation, whereas the C-terminal domain possesses the DNA/RNA binding and dimerization properties of the protein. These two domains are linked by a hinge region. E2 interacts with E1 and enhances the binding affinity of E1 to the origin of replication. E2 functions as a transcriptional activator or repressor to regulate viral early promoter activity through the consensus E2-binding sites, upstream of the viral early promoter. However, E2's transcriptional repression occurs only in cells harboring integrated, but not episomal HPV16 DNA. E2 binding to the viral genome is important for tethering viral genome to mitotic chromosomes throughout mitosis (McBride 2008). E2 also plays roles in apoptosis, ubiquitination, and intracellular trafficking. E2 regulates RNA processing including RNA splicing and RNA polyadenylation.

E4

E4 (~10 kDa) is the most abundantly expressed HPV late protein and accumulates in the cytoplasm of differentiating cells in the upper epithelial layers. E4 is expressed as an E1^{E4} protein in which the N-terminal 5-amino acid (aa) residues are derived from the E1 ORF spliced to the E4 ORF. HPV16 E4 expression and cleavage of its N-terminal 17-aa residues by calpain lead E4 to multimerization, formation of amyloid-like fibers, and disruption of the normal dynamics of the cyokeratin networks. E4 mediates cell cycle arrest in G2 by sequestering Cdk1/cyclin B1 onto the cyokeratin network to prevent the accumulation of active Cdk1/cyclin B1 complexes in the nucleus. The E1^{E4} protein of HPV16 may also regulate gene expression at the posttranscriptional level by interacting with a DEAD box containing RNA helicase and SR protein kinase 1 (SRPK1).

E5

E5 is a small (~10 kDa), hydrophobic, oligomeric channel-forming membrane protein, which is localized in the endoplasmic reticulum (ER) and the nuclear envelope. Assembled hexameric E5 channels in membranous environments have a

defined luminal diameter and stoichiometry. The N terminus of E5 is restricted to the ER lumen, while its C terminus is exposed in the cytoplasm to mediate interactions with cytoplasmic and ER proteins. The C terminus of E5 also induces koilocytosis, the structural cellular changes that are characteristic of papillomavirus infection. HPV16 E5 is also an oncoprotein. High levels of E5 expression in the mouse skin in the presence of persistently provided exogenous estrogen induce epithelial hyperproliferation, resulting in spontaneous tumor formation and increased dysplastic disease in the cervical epithelium. E5 induces anchorage-independent growth, enhances immortalization of human primary keratinocytes by E6 and E7, and causes cell-cell fusion. E5 activates epidermal growth factor receptor (EGFR) signaling pathways and enhances mitogen-activated protein kinase (MAPK) activity, but attenuates TGF β 1/Smad signaling and downregulates the expression of MHC class I.

E6

E6 is an ~18 kDa nuclear oncoprotein that interacts with hundreds of cellular proteins. E6 inactivates cellular p53 family proteins (p53, p63, and p73) essential for cell cycle control, DNA repair, and cell adhesion (Moody and Laimins 2010). The complex of E6 with E6-associated protein (E6-AP) functions as a ubiquitin-protein ligase in the ubiquitination of p53. E6 contains two hypothetical zinc fingers involved in zinc binding and three nuclear localization signals (NLS) as well as a PDZ-binding site in the N terminus. E6 dimerizes through its N-terminal domain and this self-association promotes polyubiquitination of p53 by E6-AP. The basic-hydrophobic pocket of E6, which composes of two zinc domains and a linker helix, interacts with an acidic LxxLL motif of host proteins to exercise E6 transformation and degradation activities (Zanier et al. 2013). Besides its ability to immortalize and transform cells, E6 regulates gene expression at transcriptional and posttranscriptional levels through interaction with other transcription factors/coactivators and splicing factors, as well as its direct interaction with DNA and RNA. High-risk E6 enhances telomerase activity and activates several signaling

pathways, including Akt, Wnt, Notch, and mTOC1, but inhibits apoptosis, keratinocyte differentiation, and the interferon response. High-risk E6 regulates the expression of a subset of cellular miRNAs (Zheng and Wang 2011). In E6 transgenic mice, E6 oncoprotein, in the absence of E7, synergizes with estrogen to induce cervical cancer after 9 months.

E7

E7 is a ~16 kDa nuclear protein. The N-terminal half of E7 contains conserved regions (CR) that have sequence similarity to other viruses. These conserved regions have sequence similarity to a portion of the CR1 and the entire CR2 in adenovirus E1A and SV40 T antigen. E7 contributes to the binding and degradation of pRB and its related pocket proteins p107 and p130 through cullin 2 ubiquitin ligase complex associated with ZER1. A conserved Leu-X-Cys-X-Glu (LXCXE) motif in CR2 is sufficient for the association of E7 protein with pRB. The C-terminal half of E7 contains a CR3 region with a zinc-binding domain; this region contributes to the degradation of pRB and to E7 dimerization and transformation activities. E7 interacts with many cellular transcription factors/coactivators and participates in epigenetic reprogramming. In addition to its cellular transformation activities, oncogenic E7 also plays a role in the viral life cycle and deregulates the cell cycle by stabilizing p21 and upregulating p16 expression. Oncogenic E7 interacts with the centrosomal regulator gamma-tubulin and induces mitotic defects and aneuploidy, leading to centrosome abnormalities and chromosomal instability. In transgenic mice, the continuous expression of E7 is required for the maintenance of cervical cancers and precancerous lesions even in the presence of viral E6 (Jabbar et al. 2012). E7 downregulates the expression of MHC class I and prevents the recognition of HPV-induced lesions by cytotoxic CD8 T cells.

L1

L1 (~55 kDa) is a major structural component of viral capsid. Both HPV16 and HPV18 L1 mRNAs initiate their translation from an initiation codon right at the splice junction of exon 2 and exon 3 of

the viral late mRNAs and encode corresponding 506-aa HPV16 L1 and 508-aa HPV18 L1 (Fig. 4), both of which are shorter than the one originally predicted in the GenBank database (Wang et al. 2011). L1 self-assembles into pentameric capsomers with a hollow channel at the center through a five-fold central axis when five L1 monomers come together and assemble in a symmetrical manner. Thus, its tendency to form a pentavalent structure is directly reflected in the star-shaped motif visible as a result of each capsomer. Purified capsomers can form capsids, which are stabilized by disulfide bonds between neighboring L1 molecules through their C termini. The C-terminal half of L1 also contains activities for HPV DNA binding and nuclear localization. The N-terminal half of L1 interacts with L2. L1 capsids assembled *in vitro* are the basis of prophylactic vaccines against infections of several HPV types (Schiller et al. 2012). Although most portions of L1 are well conserved between types, the surface loops of L1 can differ substantially, probably reflecting a mechanism for evasion of neutralizing antibody responses elicited by previous papillomavirus infections.

L2

L2 (~70 kDa) is a minor capsid protein which exists in an oxidized state within the papillomavirus virion, with the two conserved cysteine residues forming an intramolecular disulfide bond. A single molecule of L2 interacts with an L1 pentamer via a C-terminal L1-binding domain. L2 is not required for capsid formation, but participates in the encapsidation of the viral genome. Up to 72 molecules of L2 can be incorporated per capsid, one beneath the axial lumen of each L1 capsomer. Both C- and N-terminal NLSs of L2 bind to viral DNA during capsid formation and are important for nuclear localization of the DNA particle. L2 also interacts with cellular proteins during the infectious entry process. After the initial binding of the virion to the cell, the N terminus of L2 containing a consensus furin cleavage site (RxKR) is cleaved by a cellular protease, furin. The N-terminal L2 has a conserved transmembrane domain with three GxxxG motifs to facilitate homotypic and heterotypic interactions

between transmembrane helices for vDNA translocation across the endo-/lysosomal membrane. Disruption of some of these GxxxG motifs has been shown to result in noninfectious viruses. L2 interacts with members of the T-box family, TBX2 and TBX3, and represses transcription from the long control region of HPVs. A small N-terminal portion of L2 is well conserved between different papillomavirus types. Experimental vaccines targeting these regions may offer protection against a broad range of HPV types.

HPV Infections and Transmission

HPVs can cause benign and malignant tumors in persistently infected skin and mucosal tissues anywhere in the human body. Benign tumors induced by low-risk HPVs are also called papilloma or warts, and these are in general harmless. However, when such a papilloma occurs in the larynx or upper airway, it could be life threatening as exemplified by recurrent respiratory papillomatosis (RRP), a juvenile disease predominantly caused by HPV6 and HPV11 infection. RRP tends to recur and has the potential to spread throughout the respiratory tract. Benign tumors in the genital area are called condyloma acuminatum or genital warts, of which around 96–100% are caused by low-risk HPV6 or HPV11 infection. Although sexual contact as a risk factor in the development of cervical cancer was described in 1842 by Domenico Rigoni-Stern and the infectious nature of human warts was established in 1907 by Giuseppe Ciuffo's self-inoculation experiments with a cell-free extract of common warts, a landmark breakthrough on HPV cervical infection as a cause of cervical cancer was not achieved until 1983 when HPV16 DNA was discovered in ~60% of cervical cancer samples by Harald zur Hausen and colleagues in Germany. Since then, the role of various HPV genotypes in cervical cancer has been extensively studied, with HPV16, HPV18, HPV31, HPV33, HPV35, HPV45, HPV52, and HPV58 together contributing up to 91% of invasive cervical cancer and HPV16, HPV18, and HPV45 contributing up to

94% of cervical adenocarcinomas. Cervical cancer (see ► [Cervical Cancer and HIV](#)) is the second most common cancer among women worldwide. Approximately 500,000 incident cases and 320,000 cases of attributable deaths are predicted each year. More than 80% of cases arise in developing countries.

In addition to the cervix, high-risk HPVs also infect other anogenital areas and can lead to the development of anal, vaginal, vulvar, and penile cancers. Most anal cancers (~84%) are caused by HPV infection (see ► [Anal Cancer](#)). High-risk HPV infection of the oropharynx (the tonsils and the back of the tongue) may lead to the development of oropharyngeal cancer (see ► [Other HPV-Associated Cancers \(Oropharyngeal and Penile\)](#)). Oropharyngeal cancer is more common in men than women. The prevalence of HPV in oropharyngeal cancer is increasing, rising from 16.3% during 1984–1989 to 71.7% during 2000–2004. Epidermodysplasia verruciformis (EV) is an extremely rare autosomal recessive genetic hereditary skin disorder associated with a high risk of skin carcinoma and is characterized by high susceptibility to HPV5 and HPV8 of the skin. The role of human papillomavirus (HPV) in cutaneous squamous cell carcinoma (SCC) is elusive.

HPV infection is transmitted through skin abrasions (skin warts), by sexual intercourse, during passage through an infected birth canal (juvenile RRP), and probably in other ways. Women with multiple sex partners or a history of prostitution have an increased risk of infection with HPVs and an increased risk of cervical cancer. Women with history of cervical cancer (or precancer) also have an increased risk of anal cancer (see ► [Anal Cancer](#)). Receptive anal intercourse increases the risk of anal cancer in both men and women. Oral HPV infection is related to oral sex behavior. Most HPV infections are transient and have either no viremia or only a minimal viremic phase. Thus, HPVs are not disseminated in general to other sites by blood in the course of HPV infections. However, detection of HPV DNA in human peripheral blood mononuclear cells and the findings of papillomavirus productive infection in the lymphocytes, placenta, and bovine fetal tissues

indicate that hematogenous and vertical spread of HPV should be carefully investigated.

Pathogenesis and Immune Responses of HPV Infections

After HPV enters epithelial cells in the wound basal layer, virus infection is established by the initiation of viral gene expression and then DNA replication. The HPV life cycle is tightly linked to cell differentiation, and the time from infection to release of virus can be approximately 3 weeks. Viral early gene expression and initial viral DNA replication happen in undifferentiated cells in the lower layers of the infected skin or cervix, while late gene expression and vegetative DNA replication occur in highly differentiated cells in the upper layers of the infected skin or cervix (Fig. 3). Although HPVs do not induce a lytic virus infection or cytolysis/cell death, viral early gene expression causes cell cycle interruption, apoptosis, keratin network collapse, DNA damage, genome instability, viral genome integration into the host genome, and cell immortalization and transformation. The viral late gene expression leads to the maturation of virus particles which appear as aggregates in the infected cell nuclei.

Even though most HPV infections are asymptomatic and cause no clinical problems, chronic or persistent cervical or anal HPV infection may result in histologic changes, with the infected cells displaying koilocytosis and nuclear inclusion bodies. The presence of koilocytes is a characteristic of HPV infection in all precancerous lesions and can be found in cervical smears. The period between infection and first appearance of lesions is highly variable and can range from weeks to months. HPV-induced histologic changes are classified as cervical intraepithelial neoplasia (CIN) grade 1, 2, or 3 on the basis of increasing degree of abnormality of cell growth in the cervical epithelium (see ► [Cervical Cancer and HIV](#)). The likelihood of spontaneous clearance versus progression to cancer in the absence of treatment varies for CIN1, CIN2, and CIN3. Histologic CIN1 or cytologic low-grade squamous intraepithelial lesion (LSIL) indicates

abnormal cell growth that is confined to the basal 1/3 of the epithelium, usually clears spontaneously (80% of cases), and rarely (<1%) progresses to cancer. About 10–20% of women with CIN1 progress to CIN2 or CIN3, which corresponds to cytologic high-grade squamous intraepithelial lesion (HSIL). CIN2 and CIN3 have a lower percentage (~40%) of spontaneous clearance and a higher (~10%) percentage rate of progression to cancer if not treated (Schiffman et al. 2007). CIN2 and CIN3 are distinguished by the extent of neoplasia, which is confined to the basal 2/3 of the epithelium in CIN2 and more than 2/3 in CIN3. CIN3 may involve the full thickness of the epithelium and is sometimes referred to as “cervical carcinoma in situ.” Expression of viral E6 and E7 in the infected epithelial cells inhibits cell differentiation and induces cell immortalization and transformation, resulting in disruption of virus productive life cycle and leading to viral genome integration into the host genome. Although the integration of host genome is random in general, the circular HPV genome is commonly disrupted at the E1 or E2 region for the integration. Thus, the degree of E1 or E2 integrity would reflect HPV genome status in cervical cancer tissues.

Because HPVs cause infections that are largely if not exclusively limited to the epithelium, they are largely shielded from the host immune response. To date, the correlates of immunity to HPV infection remain elusive. The majority of HPV infections are transient and cause no clinical problems. Most of new HPV infections clear within 1–2 years. The median duration of new infections is 6–18 months (Schiffman et al. 2007). However, the women with HIV/AIDS or immunosuppression take longer time to clear their HPV infections. Not all infected persons have antibodies. Approximately 60% of women with incident HPV infections may have antibodies. The median time to seroconversion after a new infection is approximately 8 months. Among serum antibodies against many different viral products, the best characterized and most type-specific antibodies are those directed against conformational epitopes of the L1 protein.

HPV inhibits innate immunity and evades the host immune system. HPV infection suppresses interferon (IFN) synthesis and signaling and the expression of MHC class I in the infected cells, resulting in reduced recognition of the infected cells by CD8⁺ T cells or exclusion of CD8⁺ T cells from the dysplastic epithelium of HPV16-associated cervical lesions. HPV-specific CD4 T cells isolated from lymph node biopsies of cervical cancer patients also suppress proliferation and cytokine (IFN-gamma, IL-2) production by responder T cells. However, T cells do play a role in preventing persistent HPV infection and inducing wart regression. Healthy individuals with HPV infections display E6-specific memory T-helper cells in their blood. The majority of subjects clearing HPV16 display an HPV16 E6-specific cytotoxic T-lymphocyte (CTL) response. Failure of this response is associated with the development of cervical cancer. A significant CD8⁺ T-cell tumor infiltration with a higher CD8⁺/CD4⁺ and/or CD8⁺/regulatory T-cell ratio prevents the tumor cells from metastasizing to the tumor-draining lymph node. Moreover, T-cell defects due to a mutation in a *ras* homologue gene family member H (RHOH) gene and MST1, EVER1, and EVER2 deficiencies also lead to persistent HPV infections.

Diagnosis of HPV Infections

Exfoliated Cell Cytology and Tissue Biopsy

Pap smear, also called a cervical smear or smear test, is a screening test to check for changes in the cervical cells from the outer opening of the cervix; it is done to identify individuals who can benefit from procedures to prevent progress to cervical cancer (see ► [Cervical Cancer and HIV](#)). The cytologic changes that can be observed include atypical squamous cells of undetermined significance (ASC-US); atypical squamous cells, cannot exclude HSIL (ASC-H); low-grade squamous intraepithelial lesion (LGSIL or LSIL); high-grade squamous intraepithelial lesion (HGSIL or HSIL); squamous cell carcinoma; and atypical glandular cells not otherwise specified (AGC or AGC-NOS). Dysplasia seen on a biopsy of the

cervix is grouped histologically into three categories: CIN1, mild dysplasia; CIN2, moderate to marked dysplasia; and CIN3, severe dysplasia to carcinoma in situ.

Electron Microscopy

HPVs cannot be grown by conventional tissue culture methods. HPV infection can be diagnosed by electron microscopy, in which virus particles in clinical specimens can be visualized either by negative staining or thin-sectioning techniques. In thin sections of human skin warts, papillomavirus particles can be found in aggregates in an infected nucleus.

Viral Antigen Detection

HPV infection can also be diagnosed by detection of HPV proteins in infected tissues or exfoliated cells. In general, HPV L1 is detectable in cervical smears in most high-risk HPV-associated LSIL, but becomes undetectable in most of HSIL cases.

Viral E2, E4, and E7 proteins have been detected from formalin-fixed paraffin-embedded cervical cancer tissues or cervical smears. Type-specific HPV E4 and E7 antibodies are particularly useful in distinguishing HPV type-specific infection of HPV16, HPV18, HPV58, and other genotypes by immunohistochemistry, ELISA, or Western blot.

Viral DNA and RNA Detection

Qualitative or semiquantitative DNA or RNA tests for the diagnosis of HPV infection have been developed that are based on the sequence conservation and variation of viral L1-coding regions. To date, four FDA-approved HPV DNA tests, one FDA-approved RNA test, and two Europe-approved HPV DNA tests are commercially available. These include (1) Hybrid Capture 2 (HC2) HPV DNA Test (Digene Corp., Gaithersburg, MD), (2) Cervista HPV HR test (Hologic, Bedford, MA), (3) Cervista HPV 16/18 test (Hologic, Bedford, MA), (4) cobas 4800 HPV Test (Roche, Pleasanton, CA), (5) APTIMA HPV assay (Gen-Probe, San Diego, CA), (6) LINEAR ARRAY HPV Genotyping Test (Roche Molecular Systems Inc, Alameda, CA), and

(7) INNO-LiPA HPV Genotyping Extra (Innogenetics, Ghent, Belgium).

The HC2 is an in vitro nucleic acid hybridization assay with signal amplification using microplate chemiluminescence for the qualitative detection of 13 high-risk types of HPV (16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 68) and 5 low-risk types of HPV (6, 11, 42, 43, 44). This DNA assay was the first FDA-approved HPV DNA test and has become the standard in many countries and widely used in clinical studies. The HC2 distinguishes between the low-risk and high-risk groups, with the detection limits of ~5,000 genome copies, but cannot determine the specific HPV genotype.

The Cervista HPV HR test and the Cervista HPV 16/18 test are two HPV DNA tests for high-risk HPV infections, but have no genotyping capability. The Cervista HPV HR test is an in vitro diagnostic test for detection of 14 high-risk HPV types (16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 66, 68) in cervical specimens. The Cervista HPV HR test uses the Invader chemistry and is a signal amplification method for detecting specific nucleic acid sequences.

The cobas 4800 high-risk HPV Test uses fluorescence signal to detect nucleic acids amplified by using real-time PCR methodology and detects 14 high-risk HPV types (16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 66, 68). The cobas 4800 system, consisting of two separate instruments, integrates sample preparation, amplification and detection, and result management. It has high throughput (designed to process up to 280 samples per day) and is automated.

The APTIMA HPV assay detects viral E6/E7 mRNA transcripts of 14 high-risk HPVs (16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 66, 68), but has no genotyping capability. The APTIMA HPV assay is a transcription-mediated amplification-based assay, and the amplicons are then detected by hybridization protection with chemiluminescent-labeled single-stranded nucleic acid probes that are complementary to the amplicons.

The LINEAR ARRAY HPV Genotyping Test is used in the European Union for detection and genotyping of 37 high- and low-risk HPVs (6, 11,

16, 18, 26, 31, 33, 35, 39, 40, 42, 45, 51, 52, 53, 54, 55, 56, 58, 59, 61, 62, 64, 66, 67, 68, 69, 70, 71, 72, 73 (MM9), 81, 82 (MM4), 83 (MM7), 84 (MM8), IS39, and CP6108). The test utilizes the amplification of target DNA by PCR with PGMY09/11 primers and then hybridizes the amplicons to multiple HPV genotype-specific probes fixed on a membrane strip.

INNO-LiPA HPV Genotyping Extra uses the principles of reverse line blot hybridization. The test amplifies HPV DNA with SPF10 primers at the L1 region and then hybridizes the amplicons to the probes fixed on membrane strips in sequence-specific lines. The INNO-LiPA test detects and distinguishes 28 low- and high-risk HPVs including 18 high-risk-HPVs (16, 18, 26, 31, 33, 35, 39, 45, 51, 52, 53, 56, 58, 59, 66, 68, 73, 82), 7 low-risk HPVs (6, 11, 40, 43, 44, 54, 70), and 3 additional genotypes (69, 71, 74).

Serology

HPV serology is a valuable tool to study immune status prior to and after HPV vaccination. Although most HPV infections are cleared spontaneously within 2 years, the majority of infected subjects develop and maintain serum antibodies to viral L1 for up to 5 subsequent years. Serology is not commonly used for clinical diagnosis because more than 40% of women do not seroconvert after HPV infection. The standard methods are VLP ELISA and pseudovirion neutralization assays. Both methods have similar sensitivity and specificity in the detection of serum L1 antibodies in the majority of infected subjects. There is recent evidence that antibody to HPV16 E6 can be predictive of subsequent development of oropharyngeal or anal cancer with a high degree of specificity, and this will be an important area for future research.

Detection of Cellular Surrogates of High-Risk E6 and E7 in Infected Tissues

A few cellular biomarkers of high-risk HPV E6 and E7 expression have been used to indicate viral oncoprotein expression in precancer lesions or cancers. These include cell cycle inhibitors (p16Ink4a and p18Ink4c), MCM7

(minichromosome maintenance protein 7), cyclin E2, and a subset of miRNAs (Zheng and Wang 2011).

Epidemiology and Prevention of HPV Infections

The global prevalence of HPV infection among women with normal cervical cytology is around 11–12%. The prevalence of any HPV is about 26.8% in females aged 14–59 and 44.8% among women aged 20–24 years in the United States. The majority of HPV infections are transient and asymptomatic; 70% of new HPV infections clear within 1 year, and approximately 90% clear within 2 years. The median duration of new infections is 8 months. Up to 50% of young women with one type of HPV infection may acquire another type of HPV infection within a few years. Although coinfection with multiple high-risk HPVs may lead to an increased risk of CIN2/CIN3, persistent infection with any high-risk HPV is the most important risk factor for cervical lesions and cervical cancer. The risk of cancer development varies by HPV type, with HPV16 being more oncogenic than other high-risk HPV types. Factors associated with cervical cancer (see ► [Cervical Cancer and HIV](#)) also include an increased number of lifetime sexual partners, increased age, other sexually transmitted infections, immune suppression, and other host factors. There are also epidemiology reports of smoking being associated with increased cervical cancer, although it is not clear if this may be due to association with other risk factors. The time between initial HPV infection and development of cervical cancer is usually decades. Many aspects of the natural history of HPV remain to be understood, including the role and duration of naturally acquired immunity after HPV infection.

Because HPV is the most common sexually transmitted infectious agent, condom use and circumcision are two common practices to prevent sexual partners from HPV transmission. Pap smear screening is widely used in developed countries to check for changes in the cervical cells from the outer opening of the cervix and to

prevent progress to cervical cancer by treatment of these lesions. While likely, it is not known if screening for and treatment of anal HSIL will similarly prevent anal cancer, the US National Cancer Institute has recently initiated a large randomized clinical trial to study this issue. Two FDA-licensed prophylactic HPV vaccines, Gardasil from Merck (USA) and Cervarix from GlaxoSmithKline (UK), are very safe and effective in preventing new or persistent HPV infections and reducing HPV infection-induced cervical, vulvar, vaginal, anal, and penile lesions. Their use will be an important public health measure to prevent HPV-associated cancers (Schiller et al. 2012). Both vaccines are comprised of viral DNA-free, L1 VLP. Cervarix contains L1 VLP from HPV16 and 18 produced in insect cells, while Gardasil is comprised of L1 VLP from HPV6, 11, 16, and 18 produced in yeast. Because it contains L1 from HPV6 and 11, Gardasil immunization also provides protection against genital warts. In the presence of adjuvant aluminates, both the quadrivalent Gardasil and the bivalent Cervarix are highly immunogenic and excellent HPV type-specific protection is provided to girls and boys at age 11 or 12 who receive all three vaccine doses (0, 1, and 6 months). Catch-up vaccination with either one of HPV vaccines is approved by the US FDA for young women through age 26 or young men through age 21 (see ► [Cervical Cancer and HIV](#)).

Due to the limited inclusion of HPV types, the current vaccines do not provide cross-immune protection against other types of high-risk mucosal HPVs. However, there is evidence to suggest that HPV L2 might work as a pan-HPV vaccine against different HPVs. A small N-terminal portion of L2 is well conserved among different HPVs, and experimental vaccines targeting these conserved domains offer protection against a broad range of HPV types (Jagu et al. 2013).

Most of therapeutic vaccine approaches target high-risk HPV E6, E7, or both to control disease progression in preexisting HPV infections and lesions. To date, these studies have provided only a gleam of success. An experimental HPV16 E6 and E7 synthetic long peptide vaccine can increase the number and activity of HPV16-

specific CD4⁺ and CD8⁺ T cells in patients with vulvar intraepithelial neoplasia or cervical cancer. HPV VLP entry into NK cells triggers cytotoxic activity and cytokine secretion, although VLP does not activate Langerhans cells. A therapeutic HPV16/HPV18 DNA vaccine with optimized E6 and E7 codons stimulates high titers of anti-E6/E7 antibodies and high levels of cellular immunity by both CD8⁺ and CD4⁺ T cells (Bagarazzi et al. 2012).

Conclusion

HPVs have been well recognized as a group of small DNA tumor viruses that are highly transmissible through sexual or close contact. In the past decades, HPV infection has been found in association with the development of various human cancers, including cervical, anogenital, oropharyngeal, and even some skin cancers. Although there is more to be learned about the basic biology of HPV, the translational research on HPVs has remarkably advanced our understanding of HPV epidemiology, disease progression, clinical diagnosis, and cervical cancer prevention. Today, L1-based HPV vaccination has become a general practice and has been mandated in many countries to protect girls and boys from HPV infections and HPV-related precancerous lesions and cancer.

Identification and Validation of HIV Cofactors

Oliver Taltynov¹, Jan De Rijck¹ and Zeger Debyser²

¹Laboratory for Molecular Virology and Gene Therapy, KU Leuven, Leuven, Flanders, Belgium

²Laboratory for Molecular Virology & Gene Therapy, Center for Molecular Medicine - Faculty of Medicine - KU Leuven, Leuven, Flanders, Belgium

Definition

Viruses in general and HIV in particular have a limited genetic content. To accomplish their life cycle, lentiviruses make therefore use of host proteins, the so-called cellular cofactors, to complement the limited set of viral proteins carried in the viral particle. Interactions between host cell and viral proteins during different stages of lentiviral infection can provide attractive new antiviral targets (see entry ► [Cellular Cofactors of HIV as Drug Targets](#)). The interaction between HIV envelope proteins and the CD4 receptor and either CXCR4 or CCR5 coreceptor is the best known virus-host interaction (see entries ► [CXCR4, Coreceptors](#) and ► [Attachment/Binding](#)). This interaction resulted in the development of the HIV fusion inhibitors enfuvirtide (targeting GP41) and maraviroc (targeting CCR5-GP120 interaction). Other host proteins that have been put forward as

potential drug targets are DDX3 (see entry ► [DDX3, Cofactors, and RNA Export](#)) and cofactors of HIV integration and nuclear import. Since these last cofactors were identified and validated by a systematic approach, those will be described in more detail as to make general recommendations about cofactor identification and validation. Validated cofactors will be prioritized in terms of their potential to serve as new drug targets.

The insertion of lentiviral cDNA in a host cell chromosome is a step of no return in the replication cycle, after which the host cell becomes a permanent carrier of the viral genome and a producer of lentiviral progeny. Integration is carried out by integrase (IN), an enzyme playing also an important role during nuclear import. Plenty of cellular cofactors of HIV-1 IN have been proposed. To date the lens epithelium-derived growth factor (LEDGF/p75) is the best studied cofactor of HIV-1 IN (see entry ► [Role of LEDGF/p75 in Cell Biology and Disease Pathogenesis](#)) (Cherepanov et al. 2003). Moreover, small molecules that block the LEDGF/p75-IN interaction have recently been developed for the treatment of HIV infection (Christ et al. 2010). The nuclear import factor transportin-SR2 (TRN-SR2) has been proposed as another cofactor of HIV IN-mediating nuclear import of the virus (see entry ► [Role of Transportin-SR2 \(Transportin-3, TRN-SR2, TNPO3\) in HIV Replication](#)) (Christ et al. 2008). Using both IN cofactors as examples, the approaches to be taken to identify and validate novel cofactors as new antiviral targets will be

described. Similar approaches may be undertaken for other HIV proteins such as reverse transcriptase (RT) or protease. In fact high-throughput screens based on yeast two-hybrid screening (Rain et al. 2009) or co-immunoprecipitation (Jager et al. 2012) have been undertaken to identify novel cofactors of HIV. For each of the candidate hits, a thorough validation has to be undertaken to verify if the host protein is important for HIV replication to understand its role in the replication cycle and to determine whether the interaction between the viral protein and the cofactor can be considered a potential new antiviral target. It follows that identification without validation provides only a small step forward in the better understanding of the disease.

Identification and Validation of Integrase Cofactors as Novel Antiviral Targets

Farnet and Bushman noticed that a factor important for integration activity *in vitro* was removed upon gel filtration of HIV-1 PICs in the presence of high salt (Farnet and Bushman 1997). The activity could be restored by addition of protein extracts from uninfected human SupT1 cells. This observation opened a new field in retrovirology focused on so-called cellular cofactors of retroviral integration. Purified proteins from diverse sources could rescue the intermolecular integration activity of retroviral PICs isolated from infected cells and salt stripped of associated host factors. The factor was identified as the high mobility group chromosomal protein A1 (HMGA1; HMG I(Y) protein). HMGA1 is a nonhistone DNA-binding protein involved in the regulation of inducible gene transcription and microRNA expression in both benign and malignant neoplasias. The same complementation method led to the discovery of another cellular cofactor of HIV, barrier-to-autointegration factor (BAF) (Lee and Craigie 1998). By combining antibodies against known viral and cellular PIC components (MA, Vpr, Ku-80) with anti-BAF antibodies, human BAF was proven to be a component of the PIC (Lin and Engelman 2003). The functional co-immunoprecipitation strategy was

based on examining different fractions obtained from HIV-1-infected C8166 T cells for the presence of integration activity, viral IN, and endogenous BAF (Lin and Engelman 2003). Although BAF was suggested to protect retroviral DNA from auto-integration and also to promote the association of PICs with target DNA, knockdown of BAF by siRNA in HeLaP4 cells was later found not to affect HIV-1 replication. Validation of the role of cellular cofactors in lentiviral infection thus requires multiple independent experimental approaches.

The initial discoveries of HMGA1 and BAF were followed by a systematic search for cellular cofactors of lentiviral integration. The increasing interest in the interactomics of HIV integration and replication resulted in algorithms for the identification and proper validation of cofactors (Fig. 1). The discovery of novel HIV-1 cofactors as potential antiviral targets can be accomplished by different techniques and is often based on the search for specific and direct protein interaction partners by yeast two-hybrid (Y2H) screen or high-throughput co-immunoprecipitation (co-IP) followed by mass spectroscopy. Alternatively, full-genome RNA interference (RNAi) screens can be used to identify genes/proteins involved in HIV integration/replication.

Physical protein-protein interactions between viral protein and cofactor (Y2H and co-IP) need validation in a phenotypic assay. After specific RNAi-mediated depletion of the specific host factor, the impact on HIV replication is determined. If depletion of the candidate cofactor, verified by RT-QPCR and Western blotting, has no deleterious effect on HIV replication, the cofactor can be dismissed as an important cofactor of HIV replication. If depletion results in a stimulation of HIV replication, the binding partner may represent a restriction factor. In parallel colocalization of viral protein (IN) and host protein in the cell can be verified by microscopy. Phenotypic assays measure single and multiple rounds of infection in both laboratory-immortalized cell lines (e.g., HeLaP4) and primary CD4⁺ T cells and macrophages. In the authors' expertise multiple-round replication represents the best assay system to validate cofactors. The use of multiple siRNAs

interactor 1 (INI1)/hSNF5 and transportin-SR2 (TRN-SR2) were identified as IN cofactors (Christ et al. 2008; Kalpana et al. 1994).

Three RNAi-based whole-genome screens for HIV infection in mammalian cells were reported in 2008 (Brass et al. 2008; Konig et al. 2008; Zhou et al. 2008). Drawbacks of these screens are the use of HeLa or HEK293T cells that are not natural host cells of HIV-1 infection. VSV-G pseudotyping of HIV may confound interactions with natural host factors during early steps of the replication. The use of mutated or cell line adapted viruses in the screens can be another source for false-negatives and positives. The necessity of proper validation of potential cofactors derived from siRNA screens is underlined by comparison of the results of two large siRNA screens performed for HIV. Brass et al. (Brass et al. 2008) identified 284 genes, whereas Zhou et al. (2008) picked up 232 genes. Only 15 genes overlapped between both studies (Zhou et al. 2008). LEDGF/p75 was not identified in either of them.

Nuclear import is an important step in lentiviral infection. The classical technique to study nuclear import of cellular proteins with recombinant import factors is based on digitonin-permeabilized cells. The method was also adapted to study nuclear import of snRNA and DNA. This technique is of limited use for the study of lentiviral nuclear import since NLSs of individual viral proteins can be masked within the PIC, and the data obtained for isolated proteins do not need to fit the real situation during viral infection. There are now better approaches available for studies of lentiviral nuclear import (and early postentry steps in general) based on advances in fluorescence microscopy: real-time *in vivo* tracking (Arhel et al. 2006) and the so-called PIC import assay (Christ et al. 2008; Albanese et al. 2008). The PIC import assay is based on fluorescently labeled viral particles containing IN fused to eGFP (HIV-IN-eGFP) *trans*-incorporated in the particle through a fusion with HIV-1 Vpr. In 2008, transportin-SR2 (TRN-SR2, TNPO3) was independently identified as a cellular cofactor of HIV-1 replication in two siRNA screens (Brass et al. 2008; Konig et al. 2008) and as an HIV-1 IN

binding partner by Y2H screening (Christ et al. 2008) (see entry ► [Role of Transportin-SR2 \(Transportin-3, TRN-SR2, TNPO3\) in HIV Replication](#)). Although its exact role in HIV-1 infection has not been fully clarified, several independent studies confirmed TRN-SR2 as a genuine cellular cofactor to the extent that it is now being used as a positive control in HIV-1 interaction studies.

After validation of the interaction between host factor and viral protein, drug discovery can be initiated, facilitated by high-throughput screening (HTS) and high-content screening (HCS) technologies developed since the 1990s, as, for example, amplified luminescent proximity homogeneous assay (AlphaScreen[®]) technology, high-throughput FLIM for protein-protein interaction screening, enhanced chemiluminescence, fluorometric microvolume assay technology (FMAT[™]), LEADSeeker[™], scintillation proximity assays (SPA), etc. These screening technologies allow screens to be performed efficiently, cost-effectively, and with low amounts of material. Nowadays there is a trend to move from labeled reporter assays toward label-free assays. If structural biology approaches (crystallography, NMR, SAXS, etc.) can reveal the interface of the PPI aided by site-directed mutagenesis to corroborate the hot spots of the interaction, structure-based drug design can be embarked upon. For the discovery of LEDGINS, AlphaScreen[®] technology and structure-based drug design were used.

Conclusion

This review highlights the importance of research on cellular cofactors of HIV replication as potential targets for anti-HIV drugs. The interaction between LEDGF/p75 and IN is crucial for HIV replication, and the rational design of LEDGINS as novel antivirals represents an important achievement in translational research. Efficient targeting of host-virus PPIs expands the possible arsenal of targets beyond HIV-encoded enzymes. This novel paradigm can be extended to other viral diseases. Increased understanding of the

virus-host interactome can be the basis for plenty of future antivirals. Since PPIs have pivotal roles in virtually all physiological and disease-related intracellular macromolecular complexes, development of SMIPPIs can benefit many therapeutic areas. While the example described here is particularly relevant to the field of virology, applications of SMIPPI technology to other fields will increase as knowledge on the role of PPIs in human diseases expands.

Since the nuclear import of PICs still represents a black box in the knowledge of HIV infection and since IN plays an active role at this stage, study of the IN interactome may also shed light on this process. The discovery that the importin TRN-SR2 is a binding partner of integrase can provide the lever to open this box. Research on HIV nuclear import not only provides insights in basic virology but has also great potential for drug discovery especially since nuclear import is a bottleneck in HIV replication. There is increasing evidence that lentiviral chromosomal target site selection for integration is linked to nuclear import of PICs. Moreover, proper illumination of the lentiviral route to the nucleus and of the impact on integration site selection will aid the design of safer gene therapy approaches.

Definition

HIV-1 transmission is both inefficient and heterogeneous, and host factors that prevent and/or facilitate viral acquisition in HIV-uninfected individuals hold the key to better biomedical prevention. This review will highlight some of the factors influencing HIV transmission via the female genital tract.

Background to the Problem

HIV is predominantly transmitted during sexual intercourse (► [HIV-1 Sexual Transmission](#)), with young women having the highest risk of HIV infection in parts of the world that are severely impacted by the pandemic (Abdool Karim et al. 2011b). Despite the size of the current HIV pandemic, HIV is relatively inefficient at infecting susceptible target cells across the genital mucosa of women, with estimated per-coital transmission rates as low as 1 per 1,000 contacts (Powers et al. 2008). This suggests that natural barriers to HIV infection within the mucosal surfaces of the female genital tract are generally effective. To gain entry via mucosal surfaces, HIV must first transverse several layers of hostile territory prior to finding enough suitable target cells for it to eventually establish a lifelong infection.

While HIV transmission via mucosal surfaces is generally inefficient (HIV-1 Transmission Dynamics), specific failures of mucosal defenses must nevertheless occur to account for the more than two million successful HIV transmission events that take place annually. Various cofactors for HIV transmission, such as other coincident sexually transmitted infections, undermine mucosal defenses and consequently amplify the per-contact risks of HIV acquisition. This review focuses on what is known about male-to-female HIV transmission, the reasons why most potential transmission events are “normally” blocked, and how biomedical augmentation of natural mucosal defenses against HIV might offer women protective immunity from infection via their genital tracts.

While this review will focus primarily on factors that influence HIV acquisition in women, it is clear that the concentration of HIV in blood of their HIV-infected sexual partners is the best-described predictor of HIV transmission risk. This has been defined in prospective studies of HIV serodiscordant couples where higher virus loads in blood and in genital secretions from the HIV-infected partner predicted similarly higher risk of HIV acquisition in the uninfected partner (Baeten et al. 2011). Further compelling support for this relationship has come from several studies which showed that antiretroviral drug treatment of HIV-infected partners almost completely protected their HIV-negative partners from infection (Cohen et al. 2012; ► [Antiretroviral Therapy \(ART\), Prevention of HIV](#)). Despite the reported efficacy of such a prevention strategy, several operational barriers to the widespread use and timing of antiretroviral drug therapies exist in HIV-infected individuals such that there remains a need for continued commitment to the development of alternative strategies to protect HIV-uninfected individuals.

Although the anatomical features of mucosal surfaces that influence the risk of HIV acquisition or the precise behavioral factors that impact the health and integrity of these surfaces are not completely understood, both of these approaches

represent critical targets for the development of better vaccines and biomedical prevention strategies.

Preventing HIV Exposure

All the most effective methods to completely block HIV infection involve avoiding exposure. These methods include having only one faithful HIV-uninfected partner, consistent and correct condom use, and/or remaining sexually abstinent. Because sustainably modifying sexual behavior has proven difficult (Behavior Change), the development of new and/or refined biomedical approaches to minimize HIV exposure is urgently needed. Many of these interventions (such as medical male circumcision, topical or oral pre-exposure prophylaxis, early treatment of HIV-infected partners in discordant relationships, and HIV vaccines) have shown partial efficacy in preventing HIV infection in randomized clinical trials. Although partial efficacy may suggest imperfect protection, an alternative interpretation is that some individuals are more difficult to protect than others, either due to higher levels of HIV exposure or the presence/absence of host immune factors that modulate HIV risk. While the extent of HIV exposure is partially partner dependent (e.g., higher partner HIV viral loads, the frequency of unprotected sexual intercourse, or number of different partners), the risks of HIV infection once a person is exposed are likely to also be determined by a complex combination of host factors (including an individual's genetic makeup, their immune status, genital health, and a range of other factors). Understanding the heterogeneity in HIV risk at an individual level may hold the key to understanding how transmission can be successfully blocked.

How Does HIV Gain Entry?

When a woman is exposed to HIV during heterosexual intercourse, initial contact between HIV and the female genital mucosa will usually occur

in the presence of semen (► [HIV Prevention and Women](#)). HIV in semen is a heterogeneous combination of cell-free viral particles and HIV-infected target cells from the male partner (such as CD4+ T cells that are present in semen) (► [HIV-1 Transmission; Influence of Bodily Secretions](#)). While the proportionate role of cell-free versus cell-associated HIV contributing to male-to-female transmission is unclear, it is likely that both mechanisms are involved. Plasma viral loads in male partners accurately predict the concentrations of cell-free HIV present in semen, and conditions such as urethritis in males (inflammation of the urethra) increase both the concentration of immune cells contained in semen and HIV transmission risks to sexual partners. Despite semen having well-described anti- and pro-inflammatory effects on cells of the immune system (many of which are aimed at facilitating fertilization of female partners), most studies of HIV transmission have ignored the role of semen in determining transmission rates. Improved systems to study cell-to-cell HIV transmission are needed to dissect its role in genital HIV transmission and pathogenesis (Abela et al. 2012), and the design of strategies to block HIV transmission should consider both the cell-free and cell-associated viruses that are contained within the semen.

The female reproductive tract can broadly be divided into (1) the upper reproductive tract which consists of the uterus, fallopian tubes, and ovaries; (2) the lower reproductive tract which consists of the vagina and ectocervix; and (3) the transformation zone between the ectocervix and endocervix which signifies the intersection of the upper and lower reproductive tracts. Among the best defenses against HIV infection within the female genital tract are the extracellular components of the innate immune system, which include the physical barrier presented by the vaginal mucous layer, the antimicrobial molecules within this layer, and the relatively acidic pH within the vaginal lumen (which is regulated by healthy commensal microflora). Secretory cells in the endocervical canal, which are arranged in the gland-like crypts, produce this mucous. The mucous barrier is made up of

glycoproteins that constitute a structural framework that not only prevents contact between the cervicovaginal epithelium and pathogens from the vaginal vault (by steric hindrance) but also physically binds to growth factors and immunological proteins such as protective antibodies. Vaginal mucous is composed of commensal and other bacteria present in the vault, host cells that have been shed, inflammatory cells and their secreted products, and serum transudate.

The majority of HIV exposures are effectively blocked or neutralized by these innate defenses, which provide an impermeable barrier to the virus. When HIV breaches the initial mucous barrier, an important unresolved question is how the virus is then able to breach the underlying epithelial cell barrier. The importance of the epithelial barrier in defense against HIV infection is evidenced by the increased risk for HIV transmission when this barrier is disturbed (e.g., genital ulcers, bacterial vaginosis, or abrasions in the vaginal and cervical epithelial layers).

The cervical transformation zone between the ectocervix and endocervix has been identified as the main portal of HIV entry during successful transmission because it is lined with only a single layer of columnar epithelial cells – a barrier that is presumably less formidable than the multilayered stratified epithelia found in the vagina and ectocervix. The transformation zone also contains higher concentrations of HIV target cells than the vagina and ectocervix. The importance of the transformation zone during HIV transmission is further supported by the fact that women with cervical ectopy (immature formation of the ectocervix with columnar cells from the endocervix appearing at the ectocervix) are more susceptible to HIV infection than healthy women. Despite the relatively increased susceptibility of the transformation zone to HIV infection, it is important to note that it is certainly not the only route by which male-to-female HIV transmission occurs. The surface area of the vaginal lumen is substantially larger than that of the cervix and micro-abrasions in the multilayered vaginal epithelial barrier are likely to also account for a portion of

HIV entries. It is also worth noting that women who have had hysterectomies (who do not have uteruses) can become HIV infected and that cervical barrier methods such as diaphragms have failed to prevent HIV acquisition.

Once HIV has breached the epithelial and mucosal barriers of the genital mucosa (► [Mucosal Immunity to HIV-1](#)), it must successfully infect particular target cell types in order to establish an infection. Since there are a couple of likely target cell types that HIV is capable of infecting, it is currently uncertain which of its potential target cell types are the most important in this regard. HIV can infect a variety of immune cells that express the primary entry receptor CD4 and the chemokine coreceptors CCR5 and CXCR4. Such cells include CD4+ T cells, dendritic cells, macrophages, and monocytes. Within the genital mucosa, such cells are typically located in the submucosal layer beneath the epithelium. In addition to becoming productively infected (which means that infected cells have replicating virions within them), it has also been demonstrated that HIV can be “captured” by dendritic cells that do not themselves become infected during this process but can facilitate the infection of other cells of the immune system (► [Dendritic Cell Interaction with HIV-1 Envelope Glycoprotein – Implications for Prevention of Transmission](#)).

Studies performed in vitro and in primate models of vaginal transmission suggest that CCR5+ CD4+ T cells are the major initial target of HIV (Hladik et al. 2007). Although these cells are present in the submucosa to protect against potential invaders, HIV directly infects these cells and uses them to gain direct access to draining lymph nodes that in turn contain very high concentrations of HIV-susceptible target cells. Movement of HIV from the genital mucosa to draining lymph nodes occurs within 1 week of an initial mucosal surface breach and marks the point at which the irreversible establishment of latently infected cell populations occurs (Li et al. 2009). Any additional natural or medically medicated barriers to HIV infection must therefore act prior to HIV becoming fully established in the mucosa and spreading to the draining lymph nodes.

Factors That Influence Mucosal HIV Transmission

For the sake of understanding how the establishment of HIV-infected cell populations might be effectively blocked during transmission events, it is worthwhile considering the many factors that could influence this process. For example, in order to migrate into tissues such as the genital mucosa, immune cells need to specifically exit blood vessels that penetrate the high endothelial tissues – a process known as extravasation. Extravasation is achieved when immune cells circulating in blood (in high endothelial venules) recognize specific chemical signals (such as inflammatory or chemotactic cytokines) within blood plasma or receptor molecules on the surfaces of blood vessel epithelial cells that allow the immune cell to move out of the endothelial venule into tissue. The specific movement of T cells to mucosal surfaces occurs mostly in response to inflammatory cytokine gradients. High concentrations of inflammatory cytokines at mucosal sites (such as those produced in response to sexually transmitted infections or physical trauma during sex) create a gradient that allow the migration of high numbers of activated CD4+ CCR5+ immune cells into the genital mucosal tissue. The initiation of a productive HIV infection requires the presence within the genital submucosa of adequate numbers of susceptible CD4+ target cells (► [CD4+ T Cell Depletion](#)). Since genital tract inflammation is associated with increased rates of T-cell recruitment to the genital mucosa, it is perhaps unsurprising that such inflammation is associated with an increased risk of HIV transmission.

In addition to specifically recruiting HIV-targeted cells to the genital mucosa, genital inflammation may also interfere with the innate barrier function of the mucosa (► [Immune activation and HIV transmission](#)). Specifically, by inducing alterations in the epithelial cell layer, the mucous layer, and the composition of the genital microbiome, inflammation can directly impact the ease with which HIV is able to penetrate into the submucosal layers of the genital tract. A better general understanding of the causes and consequences of genital inflammation could

therefore yield crucial insights into how to best preserve the effective natural barriers against HIV incursion of healthy mucosal surfaces.

Sexual Transmission Usually Involves Only a Single HIV Variant

The difficulty HIV faces in breaching mucosal barriers during transmission is perhaps highlighted by the finding that as many as ~80% of HIV infections are initiated by a single-virus variant implying that many infections might be initiated by just a single-virus particle (Keele et al. 2008). Since individuals who are chronically infected with HIV typically harbor thousands of distinct HIV variants, it is particularly noteworthy that they will generally only transmit a single variant. Such an observation is consistent with both the low transmission probabilities implied in HIV-1M epidemiological studies and the small genital tissue infection foci seen in primate studies during the first few days of infection. It remains unknown both why ~20% of HIV transmission events involve the transmission of multiple HIV variants (i.e., multiple distinct virions) and whether there are particular genetic features of the virus variants that make it through the transmission bottleneck that predispose them to establishing a new infection.

Blocks to Transmission

Medical interventions aiming at HIV prevention might seek to either preserve or promote the integrity of the natural mucosal barriers or treating the medical conditions that have caused the damage in the first place (Preventing HIV-1 Transmission Through Novel Strategies).

Promoting the Integrity of the Natural Mucosal Barrier

Although ongoing infections with sexually transmitted microbes including Herpes simplex virus-2 (HSV-2) (► [Risk of Sexual HIV-1 Transmission](#):

Co-infections Associated with Risk), *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, and *Trichomonas vaginalis* and disruptions of natural commensal flora such as bacterial vaginosis are known to increase HIV transmission risks, several well-conducted clinical trials aimed at treating such infections and promoting overall genital health have failed to convincingly reduce rates of HIV transmission. The reasons for this remain unclear, but it may be that damage caused to the genital mucosa and other immunological effects of sexually transmitted infections persist for long after these infections are resolved.

While certain sexually transmitted infections and bacterial vaginosis are known to increase risk for HIV transmission, defining characteristics of the genital mucosa that are associated with better protection is important. The international definition for a healthy female genital tract is one harboring predominantly *Lactobacillus* species, having a pH between 3.5 and 4.5, and having no bacterial vaginosis, candida, or STI. Lactobacilli species have been shown to lower vaginal pH by the production of lactic acid and H₂O₂, resulting in a low and protective pH. Furthermore, lactic acid is more effective than acidity alone as a microbicide against HIV or against pathogens such as *Neisseria gonorrhoeae*. When these species of *Lactobacillus* are displaced by a diverse mix of anaerobic bacteria, the vaginal pH increases (above the optimal range which is ≤ 4.5) and bacterial vaginosis results.

There are several modes of action by which Lactobacilli could alter the vaginal microenvironment and reduce risk of inflammation and HIV susceptibility. These include: (i) antagonism of pathogens by competition for binding or nutrients, (ii) stimulating the production of antimicrobial factors, (iii) modulation of epithelial barrier integrity, (iv) epithelial or immune cell function via production of cytokines and other stromal factors, and (v) generation of tolerizing DCs and regulatory T cells. While antibiotic treatment of sexually transmitted infections and bacterial vaginosis is commonly implemented to improve vaginal health, alternative approaches that have been considered include probiotics. Convincing clinical efficacy of probiotic applications has been

documented for various conditions, including prevention of antibiotic-associated diarrhea, necrotizing enterocolitis, irritable bowel syndrome, and reduction of respiratory tract infections. Since the vaginal microbiota of women with bacterial vaginosis has been found to contain a reduced number of lactobacilli, lactobacilli administered orally or intravaginally have been tested for their effectiveness in colonizing the vagina and curing women with bacterial vaginosis or at least preventing its recurrence. Probiotics delivered topically do alter the vaginal flora by suppressing the overgrowth of pathogenic phyla and reestablishing vaginal homeostasis. Topical application decreases culture-positive bacterial vaginosis in pregnant women, and oral probiotics given alone or in combination with oral antibiotics fair better than antibiotics alone in decreasing culture-confirmed bacterial vaginosis and associated bacteria.

Treating STIs or Dampening Genital Tract Inflammation to Reduce HIV Risk

Several large randomized control trials have shown that neither the prevention nor aggressive treatment of sexually transmitted infections was effective in reducing HIV incidence. Unfortunately these trials did not also directly test whether direct management of genital tract inflammation had any impact on HIV transmission. Since inflammation is a critical initial stage during the initiation of immune responses at mucosal sites, an important consideration in HIV prevention strategies should be the safest and most effective approaches to modulating inflammatory responses in the genital tract.

The rationale for the management of genital inflammation in the context of reducing HIV transmission risks has perhaps been best illustrated in a nonhuman primate study (Li et al. 2009). It was found that topical application of glycerol monolaurate during vaginal exposure to SIV decreased concentrations of important chemokines in genital secretions. This led to reduced degrees of target cell recruitment in treated animals, which in turn was associated

with enhanced protection from SIV infection. While glycerol monolaurate is a relatively non-specific anti-inflammatory molecule, other anti-inflammatories that are safe for use on mucosal tissues are in early phases of preclinical development. Anti-inflammatory molecules that specifically block only the components of normal immune responses that are exploited by HIV to access and infect suitable target cells will likely be the best candidates for inclusion within anti-inflammatory formulations specifically geared to reducing HIV transmission risks (► [HIV Infection, Immune-Based Interventions](#) for).

Passive or Vaccine-Induced Antibodies to Protect Against HIV Entry

Taking lessons from other viral infections for which effective vaccines are available (human papillomavirus and hepatitis B virus), the best-established correlates of vaccine-induced protection are neutralizing antibodies (► [Preventing HIV-1 Transmission Through Vaccine-Induced Immune Responses](#)). Neutralizing antibodies generally bind to the outside of an invading pathogen and prevent its entry into host cells. In the case of HIV, there is evidence from nonhuman primate studies that both neutralizing antibodies and T cells can protect against high-dose vaginal virus challenges. Neutralizing antibodies that are able to neutralize a broad array of HIV strains only develop in ~20% of HIV-infected individuals and usually only after years of chronic antigenic stimulation. There is concerted effort to characterize what these antibodies recognize, how they develop, and where they originate from as this will give important insight into how the epitopes of HIV vaccines should be designed so as to achieve similarly broadly neutralizing vaccine antibody specificities.

Certain well-characterized HIV-specific broadly neutralizing antibodies isolated from HIV-infected individuals have been tested for their ability to protect primates against SIV infection after passive immunization (Hessell et al. 2009; BrNAb Responses; HIV-1 Transmission and Effects of). Even when administered

intravenously, no SIV infection was noted within vaginal tissues, suggesting that antibodies were able to reach mucosal sites in sufficient numbers to provide protection.

The RV 144 “Thai” trial recently demonstrated 31% protection against HIV infection and was the first partially protective vaccine tested in humans. Although being protective, RV 144 did not elicit neutralizing antibody responses either systemically or at the genital mucosa. Despite this, the best correlate of vaccine efficacy in this trial was shown to be the ability to stimulate HIV-specific immunoglobulin G antibodies that bound to a specific part of the HIV envelope (the variable loops 1 and 2 or V1V2 region of HIV envelope). This specific V1V2 part of the HIV envelope is biologically important since it is involved in attachment of HIV to target cells (Haynes et al. 2012). This suggests that the V1V2 region of the HIV envelope that was bound by these antibodies might be a crucially important target for future vaccines. Despite being unable to block cell entry, non-neutralizing antibodies, such as those induced during the RV 144 Thai trial, were effective at binding to HIV and clearing HIV-infected cells. Because no mucosal samples were collected from individuals vaccinated during the RV 144 Thai trial, it is unknown whether HIV-specific antibodies identified in blood were also present at mucosal surfaces and/or in genital secretions.

Harnessing T Cells to Protect Against HIV Infection

While T cells that are reactive against HIV-derived epitopes (small 8–12 amino acid long fragments of viral proteins) are thought to reduce disease severity (► [HIV & SIV, CD8+ T Cell Responses](#) to), their role in preventing new HIV infections is less clear. Such cells facilitate viral clearance either directly by killing virus-infected cells or indirectly by producing soluble cytokines that enhance the ability of virally infected cells to destroy intracellular virions. For nonpersistent viral infections (such as influenza), vaccine-elicited T cell responses are believed to provide protection even in the absence of appropriate

antibodies. Several vaccine vectors aimed specifically at eliciting HIV- or SIV-specific T cell responses have been developed and tested in pre-clinical and clinical trials. Preclinical studies have shown that these T cell-based vaccines are able to decrease SIV viremia postinfection. However, no solely T cell-based vaccine has been shown to prevent SIV or HIV infection in preclinical or clinical trials. In fact, the only vaccine that has recently shown to provide complete protection of nonhuman primates from SIV challenge was the one utilizing the live, replicating cytomegalovirus-based delivery vector, which elicited lifelong anti-SIV effector memory mucosal T cells in all animals receiving the vaccine (Hansen et al. 2009).

Advances in the understanding of T-cell memory have revealed additional T-cell subsets such as tissue-resident memory T cells that may be crucially important components of any fully protective vaccine-induced anti-HIV cytotoxic T lymphocyte response. It may be that the imperfect protection provided by first-generation anti-SIV cytotoxic T lymphocytes eliciting vaccines is attributable to their failure to induce sufficient numbers of memory T cells at mucosal sites of initial infection foci so that these can be controlled prior to the occurrence of systemic viral dissemination.

One of the most effective vaccine strategies yet tested in nonhuman primates has employed the use of live attenuated SIV variants (► [HIV-1 Prevention Using Live-Attenuated Vaccines](#)). These studies have provided valuable data on the relative benefits of vaccine-induced anti-HIV T-cell and antibody responses. Specifically, a recent study evaluated 11 different potential correlates of protection following vaccination with a live attenuated SIV variant and surprisingly found that only SIV-specific T-cell responses in lymph nodes were protective against vaginal SIV challenge (Hansen et al. 2013). Interestingly, as is the case with “wild-type” HIV variants, this vaccine strain preferentially infected T follicular helper cells within lymph nodes. Unfortunately further studies focusing on cytotoxic T lymphocyte responses at

mucosal surfaces are required to determine exactly how such live attenuated SIV vaccines are capable of providing sterilizing immunity against vaginal SIV challenges.

Despite the successes of certain anti-SIV cytotoxic T lymphocyte-inducing vaccines that have been tested in nonhuman primates, it is important to point out here that far fewer vaccine candidates have so far been tested in humans. Also, the results of clinical trials evaluating these vaccine candidates have been altogether both less compelling and less predictable than those tested in primates (McElrath et al. 2008). Finally, the successes of many promising anti-SIV vaccines, such as those based on attenuated virus variants, will likely never be translated into humans due to legitimate concerns that attenuated HIV variants could potentially revert to pathogenic variants that cause AIDS-like illnesses in vaccinated individuals.

Antiretroviral Therapy Can Prevent HIV Infection

The precedent for using antiretroviral drugs in HIV-negative individuals to prevent them from acquiring HIV comes from several very successful mother-to-child transmission trials in HIV + pregnant women (► [Pre-Exposure Prophylaxis \(PrEP\)](#)). Clinical trials have clearly demonstrated the plausibility of using antiretroviral drugs to protect women from HIV infection when taken either orally or in a topical microbicide formulation (Abdool Karim et al. 2010).

It is noteworthy, however, that certain other trials have failed to demonstrate that preemptive antiretroviral treatments provide HIV-negative women with any protective benefits. Although it is currently unclear why some trials have indicated protection and others not, it is likely that differences between the trials with respect to overall treatment adherence, routes of drug delivery, and antiretroviral concentrations achieved at mucosal surfaces could in part account for the differences in their outcomes. For example, overall protection in the 1% tenofovir microbicide trial

(CAPRISA 004) was 39% across all treated women, although a sub-analysis of women who were regular gel users and had >1,000 ng/ml tenofovir in their cervical secretions showed 79% protection (Abdool Karim et al. 2011a). The major conclusion of successful trials is that they are able to prevent HIV infections when antiretroviral drugs reliably reach the sites of HIV exposure.

Since these trials all showed only partial efficacy, it is clear that HIV transmission events can occur even in the face of what would normally be considered protective antiretroviral drug concentrations. It is hoped that a better understanding of the infections that occurred in HIV-negative women treated with antiretrovirals will both inform the design of better drug formulations and delivery mechanisms and illuminate the reasons why, even when present at high concentrations at the correct anatomical sites, antiretrovirals are only sometimes protective.

The Value of Knowing Your Epidemic

Information about the prevailing conditions within the genital milieu in which HIV transmissions are occurring is invaluable when deciding on what prevention modalities would work best.

Conclusion

HIV prevention remains a major public health priority that will likely only be effectively addressed by novel biomedical developments. Detailed analyses of the early stages of HIV and SIV infections have revealed that within healthy genital tracts, there exist various highly effective natural barriers to HIV transmission. Despite this, the pandemic persists and millions of new infections continue to occur annually. Thorough understanding of how the natural barriers to HIV infection result in per-contact transmission rates being lower than 1% and biomedical augmentation of these barriers so as to further reduce these

rates have started to show promise. Further work is, however, clearly needed to translate promising prevention strategies into practically viable treatments. Determining the best ways to combine and synergistically deploy multiple partially protective pharmaceuticals so as to decrease per-contact transmission rates by an order of magnitude or more will likely be a major research priority over the coming decade.

Definition

Transmission of HIV is dependent upon target availability at the portal of entry. Activated T cells are the preferential targets for HIV. The interaction between host immune system and viral invader triggers a cascade of inflammation that fuels the infection. Factors influencing T cell recruitment and activation at mucosal sites affect HIV acquisition. Low basal levels of immune activation have been observed among HIV-exposed seronegative (HESN) individuals. These individuals show reduced susceptibility to HIV infection, and the study of their natural correlates of protection has highlighted the importance of immune activation in HIV transmission.

Immune Activation Drives HIV Replication

The immune system is conditioned to respond to “danger” signals from foreign pathogens and inflammatory stimuli. In response to the signals, an activation cascade is triggered and several factors from the innate and adaptive immune systems begin their journey. This cascade of signaling events governs CD4+ T-helper cell fate and function and plays an important role in tailoring the immune response. By targeting CD4+ T cells, the human immunodeficiency virus (HIV) has

evolved one of the most efficient strategies to hijack immune defense. Mainly transmitted through unprotected sexual contact, HIV infects local populations of CD4⁺ T cells at the site of mucosal entry, before becoming rapidly disseminated to the lymphoid organs. The rapid CD4⁺ T depletion in mucosal sites, hallmark of HIV infection, contributes to disorganizing the immune system and causes a progressive loss of immune functions. Given that HIV preferentially targets and replicates in activated CD4⁺ T cells (Card et al. 2013), immune activation fuels the infection rather than contributing to its elimination. Hence, immune activation not only drives progression to AIDS (Miedema et al. 2013) but also impacts individual susceptibility to acquire HIV.

The activation program of T cells is triggered upon antigen recognition by the T cell receptor (TCR). Mature antigen-presenting cells (APC) present antigens to naïve or recirculating antigen-experienced T cells and provide proper co-stimulatory signals. This is followed by a remodeling of the metabolic program resulting in proliferation and expression of activation markers, effector molecules, and factors involved in energy production. Once activated, T cells offer the ideal cellular environment for massive production of HIV virions. HIV integrates into transcriptionally active units of the cell chromosome and pirates several host factors, including transcription factor NF- κ B, to promote its own replication. Host inflammatory response also directly encourages the replication process by triggering signaling pathways involved in NF- κ B nuclear translocation and initiate HIV long terminal repeat (LTR) transcription (► [Cellular Cofactors for HIV Transcription](#)).

Activation status governs cell susceptibility to HIV infection. Expression of early and late activation markers on the cell surface can be monitored and reflects HIV capacity to establish a productive infection. In peripheral blood mononuclear cells (PBMC), expression of high levels of HLA-DR, CD25, CD69, or CCR5 by CD4⁺ T cells correlates with higher infection and replication rate *in vitro* (Card et al. 2013). HLA-DR and CD25 are late activation markers expressed by memory cells with antigenic activity, while

CD69 is an early activation marker expressed after TCR engagement. Thus, antigen-experienced cells are preferentially targeted by HIV. *In vivo*, effector memory T cells (T_{EM}) are the first cells depleted during the course infection. Sexual transmission of HIV is the result of a single virus using CCR5 to mediate its entry into the cell and initiate productive infection. Similar genetic bottleneck has also been observed during HIV transmission from the mother to the infants. Most T_{EM} cells express HIV co-receptor CCR5 and reside in mucosal sites under constant microbial pressure where they secrete immune effectors and offer the perfect phenotype for HIV infection and replication (selection of CCR5 using viruses; transmission; overview 385719).

Unlike T_{EM} cells, antigen-experienced central memory T cells (T_{CM}) reside in lymphoid organs and harbor a resting or quiescent phenotype. This nondividing subset is refractory to HIV production and is consequently latently infected (Zack et al. 2013). Low transcriptional and metabolic activity, low or absent expression of CCR5, and presence of host restriction factors render the cellular environment hostile to viral production and contribute to the formation of a viral reservoir (Zack et al. 2013). Like T_{CM}, naïve T cells express low levels of CCR5 and harbor low metabolic and transcriptional program consistent with latent infection. Hence, HIV primarily targets activated CD4⁺ T cells with antigenic activity for replicative purposes but also takes advantage of the resting pool to keep dormant copies of its genetic material ready to be replicated upon activation signals.

Role of Activation in Early Transmission Events

Initial Cascade of Activation

Cell activation not only plays a major role in disease progression but also greatly affects the early events of HIV acquisition. CD4⁺ T cells with prior history of activation are the fuel of HIV infection and their presence at the portal of entry is a prerequisite for the rapid expansion of the local founder population that promotes viral

dissemination to lymphoid organs (Haase 2010). Our understanding of the key early events involved in the establishment of infection has been greatly improved by the study of the simian immunodeficiency virus (SIV) in macaque models of sexual transmission. The virus first gains entry through the epithelial layers of the female genital tract (FGT) by crossing the thick and hostile mucus layer. Epithelial cells recognize the “danger” signals contained in the infected inoculum and secrete immune mediators. The release of macrophage inflammatory protein-3 (MIP-3a/CCL20) at the entry site calls for the first wave of respondents. Plasmacytoid DCs respond to this chemical invitation by migrating to the genital epithelium where they also recruit T cells. By increasing the number of available targets, this inflammatory chain reaction initiated by innate mediators provides the favorable conditions for the growth of a local founder population. Once the founder population has reached a critical mass, the infection is spread systemically and crosses the point of no return (Haase 2010). Reservoirs are established and the overwhelmed immune system cannot contain the massive viral replication that takes place in the secondary lymphoid tissues.

In humans, the study of the genital mucosa, male and female, also points toward a similar sequence of early events. In the FGT, HIV can penetrate both the squamous stratified epithelium of the vagina and ectocervix and the single-layered columnar epithelium of the endocervix and upper tract. Cervical and foreskin ex vivo explant models have shown that HIV induces the expression of T cell attractant molecules that can recruit activated target cells at the portal of entry (Ganor et al. 2010). Although dendritic cells (DCs) and Langerhans cells (LC) were reported to be the first subsets to encounter and capture HIV (Ferreira et al. 2014), activated CD4+ T cells appeared to be better candidates for viral replication and establishment of a founder population (Haase 2010). Mucosae of the FGT and inner foreskin are a milieu rich in HIV-target cells. Compared to blood populations, cervical and foreskin T cells manifest the predominant inflammatory T_{EM} phenotype. They express high levels

of CCR5, activation marker CD69, and cytokines interleukin (IL)-17 and IL-22 (Prodger et al. 2011; McKinnon et al. 2011) which correspond to the cell phenotype preferentially depleted during acute HIV infection (Miedema et al. 2013) (HIV-1 sexual transmission; overview 385727). This milieu enriched in target cells only requires the right igniter to set in motion the cascade of inflammatory events that promote HIV infection.

Targets Availability

Hence, the targets availability is a key concept for HIV transmission. Infection is highly dependent on the availability of targets at the time of exposure and several evidences support this concept. Local application of an inhibitor of T cell activation, the glycerol monolaurate, prevents acquisition of SIV by decreasing activation and recruitment of target cells in the vaginal mucosa of macaques. On the other hand, the use of nonoxinol-9 in the first microbicide trials showed the opposite effect. Nonoxinol-9 induces an inflammatory response in the FGT and increased transmission rate instead of offering the expected protection (Card et al. 2013) (► [HIV Transmission Blocking Microbicides](#)). In men, HIV incidence rate positively correlates with foreskin’s size and removing this target-rich tissue by circumcision reduced the risk of acquiring HIV by 50–60% (Ganor and Bomsel 2010).

Sexually transmitted infections (STI) have also been under the spotlight of HIV transmission studies because they result in the disruption of the protective mucosal lining and induce an inflammatory response in the genital mucosa. Several epidemiological observations have highlighted the role of STI in increasing the risk of HIV acquisition two- to fivefold, through both vaginal and anal intercourse. The synergy between HIV acquisition and STI operates with several bacterial and viral pathogens, causing both ulcerative and non-ulcerative genital lesions, including genital herpes, *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *Trichomonas vaginalis*, infectious syphilis, and human papillomavirus (HPV). Deciphering the temporal relationship between STI and HIV acquisition has been challenging because STI and HIV share the same risks

factors. However, biological mechanisms such as disruption of the mucosal barrier by genital ulcers, induction of local inflammation, and recruitment of highly inflammatory leucocytes support a role for STI in facilitating HIV infection by recruiting and activating target cells at the portal of entry (Ferreira et al. 2014). Thus, factors that influence presence and activation of target cells at entry site seem to be critical to ensure the full sequence of events leading to HIV infection.

Acquisition of HIV and Immune Activation: Lessons Learned from HESN Individuals

Heterogeneity in HIV Susceptibility

Not all individuals are equally susceptible to HIV infection. Epidemiological observations have demonstrated the existence of a spectrum of susceptibility with a handful of individuals, about 10–15% of those exposed, harboring a surprising capacity to escape HIV infection despite multiple exposures (Fowke et al. 1996). These HESN individuals comprise individuals exposed through sexual behaviors such as female sex workers (FSWs) from high HIV prevalence areas, men who have sex with men, and serodiscordant couples, as well as individuals exposed through the bloodstream like drug-injecting users, hemophiliacs, and care workers with an accidental needle-stick exposure. Uninfected infants born from HIV-infected mothers are also considered as HESN and are exposed through the placenta during pregnancy or through intestinal mucosa when swallowing infected secretions, blood, and milk (Kaul et al. 2011). Mechanisms of protection are multifactorial and vary according to the route of exposure; however, several interesting lines of evidence indicate a similar pattern of reduced immune activation as one of the underlying mechanisms for HESN protection.

Reduced susceptibility to HIV infection has been associated by reduced systemic levels of T cells activation (lower frequency of CCR5, HLA-DR, and CD38 CD4⁺ and CD8⁺ T cells) in sexually and parenterally exposed individuals (Kaul et al. 2011; Card et al. 2013). In addition to

reduced T cell activation, dampened expression of inflammatory mediators or upregulation of factors involved in the control of immune activation has been observed in the blood and mucosal compartments of HESN individuals. A lower amount of TNF- α and reduced proportion of Th17 target cells was observed in the foreskin of men from discordant couples (Prodger et al. 2013), and cytokine gradient in Beninese FSWs suggests a T cell migration pattern from the FGT to the blood instead of a T cell recruitment pattern toward the FGT (Lajoie et al. 2013). Increased expression of factors involved in the control of immune activation such as Vitamin D receptor and IL-10 transcripts was also observed in plasmatic and vaginal compartments of serodiscordant couples (Aguilar-Jiménez et al. 2013). A similar observation was made for mother-to-child transmission. Higher levels of anti-inflammatory IL-10 protected against transmission, while elevated concentration of proinflammatory cytokines, especially interferon- γ (IFN- γ)-induced protein 10 (IP-10) in the placenta, was associated with HIV transmission during pregnancy (► [MTCT HIV-1 Transmission Routes and Mechanisms](#)). In addition, individuals with a polymorphism in the IL-10 promoter that increased IL-10 expression were less likely to acquire HIV (Boettler et al. 2012). Thus, low inflammatory signal in systemic and mucosal compartments along with lower T cell activation is a recurrent observation among individuals that remain uninfected despite frequent exposure.

However, immune activation could also be deemed essential to mount an immune response, and some studies have observed an opposite tendency looking at T and NK cell activation and Toll-like receptor (TLR) engagement (► [Natural Killer and Their Role in Preventing HIV Transmission](#)). HIV-specific T cell and B cell responses have been correlated with HESN protection through sexual, parenteral, oral, and placental routes (Piacentini et al. 2008). Yet, it is still unknown to what extent this response is involved in the protection against HIV acquisition. HIV-specific response is sporadic and may merely reflect exposure to HIV rather than a protective mechanism. Furthermore, waning of the HIV-specific

response in absence of ongoing exposure has been reported (Piacentini et al. 2008).

In summary, several observations from HESN's cohorts with various routes of exposure suggest that a combination of low baseline levels of T cell activation and dampened immune environment may be beneficial to protect individuals against HIV acquisition. Discrepancies exist among the results and reflect the important difference in HESN models and ethnicity as geographic localization was shown to influence the baseline levels of immune activation (Kaul et al. 2011). Looking at individuals prior to their seroconversion has helped reconcile these findings.

Immune Activation Prior to Seroconversion

Immune activation is a key driver of HIV disease progression and organ damage (Miedema et al. 2013). The pre-seroconversion immune activation was found to predict post-seroconversion disease progression in a prospective study from Amsterdam. This study of 102 individuals with well-documented seroconversion dates showed that the presence of pre-seroconversion low CD4+ T cell numbers or elevated levels of CD4+ T cell activation predicted the development of AIDS after acquisition of infection (Hazenberg et al. 2003). The role of pre-seroconversion inflammatory milieu in setting the stage for HIV acquisition has been supported by indirect evidence, with several studies establishing the role of STIs in augmenting HIV transmission.

Results from preexposure prophylaxis (PrEP) studies using both oral and topical formulations of antiretroviral drugs generated great enthusiasm for the prospect of HIV prevention with efficacy ranging between 39% and 74%. The analysis of CAPRISA 004 showed that women who acquired HIV had significantly higher systemic innate immune activation prior to infection, when compared to those who remained uninfected. Those that acquired HIV had a combination of systemically elevated levels of proinflammatory cytokines, platelets, activated NK cells, as well as more spontaneous cytotoxic T cell degranulation

in the blood (Naranbhai et al. 2012). It remains to be determined whether the heightened immune activation has any association with migration of lymphocytes to mucosal sites, thus presenting more targets at the site of mucosal entry.

Immune Quiescence: Lessons from the Female Sex Workers from Nairobi

Studying HESN individuals and seroconverters has brought convincing evidence that immune activation plays a significant role in HIV transmission. Some of the strongest indications come from the Pumwani cohort of female sex workers (FSWs), from Nairobi, Kenya. The Pumwani cohort was established in 1984 and has enrolled more than 4,000 women. Defying the odds imposed by the high HIV pressure of Nairobi's slums, the FSWs who remained seronegative (5–10%) were more likely to exhibit a true phenotype of resistance (Fowke et al. 1996). In the early years, HIV pressure was so strong that being engaged in sex work for 3 years or more would already imply a natural resistance to HIV infection for the ones remaining negative (Fowke et al. 1996). Now, successful prevention programs have considerably decreased HIV incidence in Nairobi's slums, and 7 years of commercial sexual activity is necessary to reach a similar level of pressure. Women who do not meet these criteria of exposure duration are considered to be at high risk of acquiring HIV and are often used as HIV-susceptible controls. Emerging lines of evidence collected by dozens of studies from the well-described Pumwani cohort point toward a central role of immune activation in HIV transmission. Low levels of immune activation, identified as immune quiescence, have been observed among resistant women and may be instrumental to limit targets availability and prevent HIV infection and dissemination.

Systemic Immune Quiescence

Systemic immune quiescence in HESN FSWs from the Pumwani cohort was observed on multiple strata, from the molecular signature to the cell phenotype. Reduced *ex vivo* frequency of

CD69+, CD4+, and CD8+ T cell was first reported in HESN individuals when compared to their HIV-susceptible counterparts. Along with lower T cell activation, HESN FSWs harbored higher frequency of CD4+ regulatory T cells (Tregs) expressing the forkhead box P3 (FOXP3) transcription factor that are involved in the control of immune activation. Higher Treg proportion and lower frequency of activated T cells correlate with HIV-reduced capacity to establish infection *in vitro*. Further evidence was provided when immune functions were compared between HESN and HIV-susceptible FSWs. Baseline cytokine production (TNF- α , IL-6, IL-1b, IL-10) was significantly lower in HESN individuals. Similar to what was observed among discordant couples from Abidjan, cell capacity to respond to mitogen stimulation was not affected in HESN individuals, suggesting that HESN individuals' immune system is not impaired in its capacity to respond to external threats (Card et al. 2013).

Further studies looking at the molecular signature by microarray analysis of peripheral immune cells confirmed the metabolic state of immune quiescence in HESN individuals. Several pathways involved in metabolism and immune functions are downmodulated in HESN individuals. Genes involved in TCR engagement, proteasomes, and glycolysis pathways are highly underexpressed in PBMC and CD4+ T cells from HESN individuals, while the mitochondrial oxidative phosphorylation pathway (OXPHOS) is the only pathway overexpressed (Card et al. 2013). Quiescent cells maintain low rates of glycolysis and predominantly oxidize glucose-derived pyruvate via OXPHOS pathway (Pearce et al. 2013). Low metabolic and transcriptional activity compromised the expression of factors essential for viral replication and render quiescent cells refractory to viral replication (Zack et al. 2013). The genetic expression profile of the blood immune cells indeed confirmed this quiescent phenotype observed in HESN individuals that may prevent productive infection of target cells.

Immune Quiescence in the FGT

The immune environment of the FGT also shows signs of immune quiescence among those FSWs

who remain uninfected. Significantly lower expression of NK and T cell recruitment factors IL-1 α , RANTES, monokine induced by IFN- γ (MIG), and IP-10 are observed in the FGT of HESN individuals along with lower frequency of HLA-DR expressing CD8+ T cells. Cytokine secretion capacities are also reduced in HESN individuals, and lower baseline levels of TNF- α and IL-10 as well as blunted production of IL-17, IL-22, IL-6, and IFN- γ transcripts upon superantigen stimulation are detected in cervical cells from HESN individuals. IL-17- and IL-22-producing cells are found in the FGT and are the preferential targets for HIV infection (Miedema et al. 2013; Card et al. 2013). Their reduced frequency corroborates a limited number of target cells in the FGT of HESN FSWs from the Pumwani cohort.

Immune quiescence also extends to innate functions in the FGT. Expression of various pattern recognition receptors (PPR) was measured in cervical mononuclear cells from HESN and HIV-susceptible FSWs. PPR include numerous receptors from different families (TLR, retinoic acid-inducible gene-1 (RIG-I)-like receptors (RLRs), C-type lectin receptors, Nod-like receptors, and DNA-dependent activator of interferon (IFN)-regulatory factors) and sense microbial products from the environment to activate the inflammatory response. Expression of TLR2, TLR7, TLR8, RIG-I, and MDA-5 was significantly reduced in cervical cells from HESN individuals. In addition, downmodulation of UNC93B in HESN individuals may blunt TLR trafficking within the cell. Nevertheless, HESN individuals' capability to respond to TLR stimulation is not impaired, and vigorous response to TLR7/TLR78 agonist stimulation is observed (Card et al. 2013).

In summary, baseline mucosal and systemic immune quiescence are observed among women that are protected against HIV acquisition despite years of sexual exposure. Accumulated evidence from the Pumwani cohort supports this phenotype on systemic and mucosal levels. Despite a lower baseline level of immune activation, HESN individuals possess potent immune capacity and are not immune compromised. A balance between

quiescence that prevents recruitment of target cells and immune responsiveness may be crucial for protection. But what exactly drives this phenotype in HESN individuals? Multiple genetic and environmental factors have been suggested.

To Be or Not to Be Activated: Factors Governing Immune Quiescence

Genetic Polymorphism in Interferon Signaling Pathway

Genetic polymorphism in interferon regulatory factor-1 (IRF1) correlates with reduced susceptibility to HIV infection in HESN individuals from the Pumwani cohort. IRF1 is a transcriptional activator and repressor involved in multiple biological processes, including regulation of innate and adaptive immune response. Three protective polymorphisms in the IRF1 gene have been identified and correlate with a ~60% reduction of basal and IFN-induced production of IRF1 protein and transient responsiveness to IFN- γ stimulation. Protective IRF1 genotypes also correlate with reduced ability to transactivate HIV LTR, suggesting reduced capacity to promote viral transcription. Transient kinetics and rapid silencing of the IRF1 response in PBMC have also been observed among HESN individuals who did not harbor protective IRF1 variants suggesting that more factors, still to be identified, are present in HESN individuals that may govern the kinetics of interferon response (Card et al. 2013). The down-modulation of IFN- γ responsive factors MIG and IP-10 in the cervix suggests that dampened interferon responsiveness can also be observed in the FGT (Card et al. 2013). Genetic polymorphism in these chemokines, however, was not shown to predict protection in a study combining data collected from 25 cohorts including over 6,000 patients and controls, suggesting that these genetic effects may be rare, of small magnitude, or specific for the different cohorts (McLaren et al. 2013).

Overexpression of Antiproteases

Overexpression of antiproteases with anti-inflammatory properties at the FGT could also

drive the low basal expression of inflammatory markers observed in the FGT of HESN individuals. Members of the serpin A family, cystatin B, Elafin, and A2ML1 were found to be overexpressed by proteomics approach in HESN individuals' cervical lavage, and Elafin has been identified as a correlate of protection in HESN individuals. Expression of antiproteases is usually induced by inflammatory cytokines and chemokines, and rapid expression of antiproteases in response to cytokine secretion may alleviate the inflammatory response in HESN individuals. Indeed, correlation between cytokines and antiproteases expression was strictly observed in HESN individuals, however, not in susceptible or positive FSWs. By preventing inflammation of the FGT, antiproteases probably also contribute to maintaining the integrity of the mucosal barrier, protecting against inflammation and disruption of the tight junctions (Kaul et al. 2011; Card et al. 2013).

Hormonal and Sexual Activity

Immune activation of the FGT can also be influenced by multiple factors. Hormonal cycle, microbiological environment, and sex work all have a recognized influence on the fluctuation of immune activation at the FGT. Human epidemiological studies showed that women using injectable contraception had doubling of the risk of acquiring HIV from their infected partners compared to those who used nonhormonal (Ferreira et al. 2014). The progesterone phase of the menstrual cycle or progesterone-based contraceptives have been suggested to create a window of opportunity for HIV infection by influencing cell susceptibility. Ex vivo HIV infection of biopsy explants has shown that tissues are more susceptible to productive infection when collected in the luteal (high progesterone) phase of the menstrual cycle and higher susceptibility to HIV infection correlated with progesterone levels (Ferreira et al. 2014).

Sexual activity also influences the level of T cell activation and the distribution and phenotype of the immune populations in the FGT. Contact between seminal fluid and cells at the FGT triggers a cascade of events involved in the

clearance of seminal debris, selection of fertilizing sperm, and induction and maintenance of immunological tolerance toward paternal antigens. Microbial and cellular products contained in the semen can trigger an antigenic response against bacterial, viral, or alloantigens. Sexual intercourse induced the secretion of proinflammatory cytokines that correlates with the recruitment of activated neutrophils, macrophages, DCs, and lymphocytes in the epithelial and stromal layers of the cervix. Continuous exposure to semen of several clients through sex work has been associated with alteration of the chemokines and cytokine profiles in the blood and the FGT of FSWs. T cell and monocyte attractant chemokine (MIP-3a; ITAC; MCP-1; IL-1, IL-6, and IL-8; TNF- α ; IP-10; MCP-1; MIP-1a and MIP-1b) were underexpressed in the FGT of FSWs when compared to low-risk non-sex worker populations. These alterations appear as early as 1 year after initiation of sex work and were more pronounced with accumulating years of sex work (Lajoie et al. 2013). Moreover, late seroconversion among HESN individuals from the Pumwani cohort has been correlated with reduction of commercial sexual activity. The high immune pressure maintained on the genital immune system may contribute to the induction of a tolerogenic mechanism that heightens the T cell activation threshold at the FGT.

A similar tolerogenic effect of sex work was observed among FSWs from Ivory Coast. Upon allo-stimulation, CD4⁺ and CD8⁺ T cells from FSWs expressed less CD69 on memory subsets compared to controls. Intrinsic capacity to respond to stimulation was not impaired among these HESN FSWs as stimulation with mitogen resulted in increased expression of CD69. In support of the effect of allo exposure, condom use was shown to impact the observed levels of systemic immune activation. Higher degree of condom use inversely correlated with expression of CD38 on CD4⁺ T cells of serodiscordant couples (Card et al. 2013; Lajoie et al. 2013). Induction of an active tolerogenic response by constant exposure to sexual antigens may contribute to keep on a leash immune activation at the FGT.

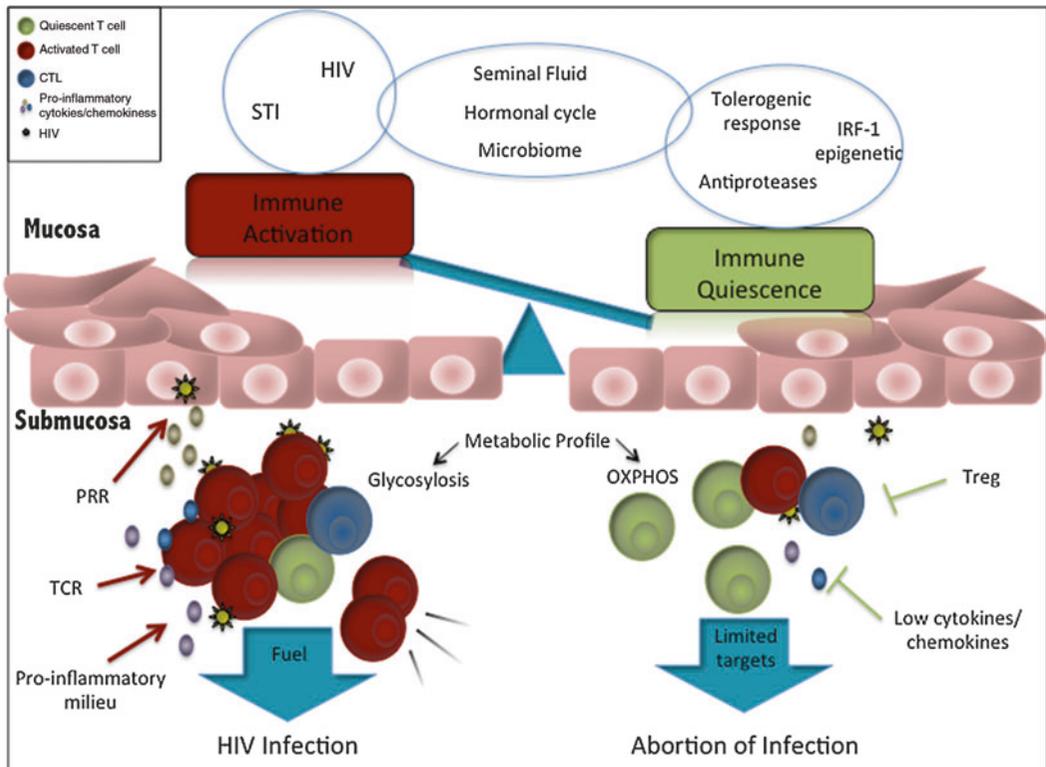

Regulatory T Cells

Tregs are well renowned for their implication in peripheral tolerance to self-antigen but also in induced tolerance to microbiome. Treg's role in HIV infection remains controversial. On one side, they inhibit HIV-specific T cell response and fuel the infection being targeted by HIV. On the other hand, Treg suppresses immune activation by direct contact with activated cells or through anti-inflammatory cytokine production. Tregs can also negatively impact HIV replication through cyclic adenosine monophosphate (cAMP) activity or by repressing HIV LTR transcription through Treg transcription factor FOXP3 (Card et al. 2013). Treg's role in HIV transmission has not been fully elucidated yet, but higher proportions of Treg that correlate with lower systemic T cell activation were observed in HESN individuals from the Pumwani cohort and in exposed-uninfected neonates (Card et al. 2013). Several gaps in knowledge remain in relation to the protective nature of Treg in HESN individuals. The nature of their antigenic specificity and their functional capacity has yet to be explored.

Vaccinate to Limit Immune Activation and Prevent HIV Transmission: Proof of Concept in the Monkey Model

Inducing immune quiescence at the portal of entry without impairing the cell capacity to mount an immune response seems to be an attractive strategy to prevent HIV acquisition among HESN individuals. The lesson learned from this group of individuals is now translated into preventive interventions. Induction of quiescence by tolerogenic vaccine has shown to be protective in monkey models.

In a first study, macaques were vaccinated with a live-attenuated simian/human immunodeficiency virus (SHIV) lentiviral vector producing continual low doses of virions and diminishing immune activation. Following an SIV challenge, FOXP3⁺ Treg populations expanded in the vaginal tract of immunized monkeys and this expansion correlated with lower immune activation at the genital tract. It was suggested that the quick resolution of the innate response collectively with

Immune Activation and HIV Transmission, Fig. 1 Immune activation and immune quiescence in HIV acquisition. HIV preferentially establishes infection in activated T cells. In the genital mucosa, factors triggering an inflammatory response such as sexually transmitted infections (STI) or HIV fuel the infection by activating and recruiting HIV targets cells at the portal of entry. Conversely, factors, genetic or environmental, favoring a quiescent phenotype at the genital mucosa may limit cell activation. Quiescent CD4⁺ T cells are susceptible to HIV infection but their low metabolic and transcriptional activity result in low level of viral replication. The absence of

inflammatory signals prevents the recruitment of targets cells. Low levels of productive infection in a quiescent environment may allow a sufficient opportunity to HIV-specific cytotoxic T cells (CTL) to clear the few infected cells leading to the abortion of infection. Some factors can favor the balance in both ways, according to inter-individual response to antigens (tolerogenic vs. inflammatory response) or cyclic expression of sexual hormones. PRR, pattern recognition receptor; TCR, T cell receptor; CTL, cytotoxic T cell; IRF-1, interferon regulatory factor-1; OXPHOS, oxidative phosphorylation pathway; Treg, regulatory T cells

the modest antiviral effector CD8⁺ T cell response elicited by SHIV immunization could eliminate the few HIV-infected cells at mucosal sites (Lajoie et al. 2013).

Similarly, protection against intrarectal SIV challenge was also achieved in macaques after oral immunization with a combination of heat-inactivated SIV and a digestive tract commensal bacterium that is known to induce immune tolerance (*Lactobacillus plantarum*). Induction of SIV-specific, histocompatibility complex (MHC)-Ib/E restricted CD8⁺ regulatory T cells potent at suppressing CD4⁺ T cell activation and viral

replication in SIV infected CD4⁺ T cells resulted in the protection of the immunized monkeys (Lajoie et al. 2013).

Thus, induction of a potent immunoregulatory mechanism through constant exposure to viral antigen or vaccination with a tolerogenic agent can protect against SIV infection by limiting T cell activation. Interestingly, even a modest CTL response, insufficient to control viral replication in other immunization models, in the context of controlled mucosal immune activation, was able to suppress viral replication. The best opportunity for the immune system to stop HIV is

to take advantage of its vulnerability, before the founder population is established. It was suggested that sufficient amounts of HIV-specific CTL that are able to kill infected cells when the first burst of local replication is not augmented by immune activation would lead to an aborted infection (Haase 2010). These studies support the observations made in HESN individuals and highlight the importance of controlling local immune activation without impairing immune response to prevent HIV transmission.

Conclusion

All together, the sequence of events involved in HIV acquisition is dictated by a fine equilibrium between immune activation and potent mechanisms of immune control (Fig. 1). Low levels of basal immune activation may prevent establishment of a founder population disseminating systemically, but sufficiently activated cells would ensure cells capacity to respond to the threat with a rapid control of inflammation. This judicious combination would warrant a sufficient number of HIV-specific CTL at the site of entry to prevent a burst in the initial replication. Uncontrolled immune activation would fuel the cascade of transmission events resulting in HIV acquisition, while maintaining a tight balance between basal quiescence and transient responsiveness with a quick return to basal state would favor a microenvironment refractory to HIV replication and prevent acquisition. Efforts should now be directed into translating what we know about immune quiescence and control of immune activation for developing new prevention strategies. The first attempts to develop tolerogenic vaccine in monkeys have so far been promising. Now it is time to see how we can translate that to humans.

Definition

Immunogenetics is the study of pathogen and host genetic factors that affect immunological responses leading to abnormal health conditions. The term also encompasses studies of the mechanisms of transmission of those factors from generation to generation in both pathogen and host. Over the past two decades, immunogenetics of infectious diseases has rapidly developed into a diverse field exploiting a range of methodologies to discover new genes and antigens that affect host immune responses. However, despite significant progress in the field and the use of new genetic tools (e.g., next generation sequencing) and study designs (e.g., genome-wide analyses) to tackle the ever-increasing burden of infectious diseases such as the Acquired Immunodeficiency Syndrome (AIDS) caused by the Human Immunodeficiency Virus (HIV), several important questions remain unanswered. For example, what are the immunogenetic variations in humans and in the virus that affect the differential susceptibility to infection? Which host genetic factors are involved in the heterogeneity of disease progression observed in humans? The latter is particularly important in HIV-2 infection because, while many remain healthy for decades, some people fail to control

viral replication and rapidly develop an immunodeficiency state similar to that seen in HIV-1. In this section we will consider the host genetic variations that influence susceptibility to HIV-2 and rate of progression of disease.

HIV-2

The second human immunodeficiency syndrome virus (HIV type 2) is structurally and genetically similar to HIV-1 with up to 60% homology in some genes (Guyader et al. 1987), is spread through same route as HIV-1, and can cause significant mortality and morbidity (Gilbert et al. 2003). However, HIV-2 is restricted to certain geographical areas (mainly West Africa and few European and Asian countries) for reasons that are not fully understood. One possible explanation could be the existence of host gene variants that favor or inhibit the spread of HIV-2 in affected individuals. The identification of new gene variants that modulate immune responses to HIV-2 could lead to identification of molecules or pathways that would serve as target for immunomodulatory or pharmacological interventions to curb the spread of the more virulent HIV-1 virus.

Genes That Affect HIV Infection and Disease Progression

A number of viral and host immune regulatory genes have been implicated in the control of HIV at different stages of infection and progression to AIDS (Table 1). These genes have been extensively examined in HIV-1 field but only a few studies have been performed in populations affected by HIV-2 (Diouf et al. 2002; Yindom et al. 2010).

HLA Studies

The human leukocyte antigens form a set of highly polymorphic genes located on chromosome 6 (6p21.31). HLA genes encode cell surface molecules which present short peptides derived

Immunogenetics of HIV-2 Infection, Table 1 Key genes affecting innate and acquired immune responses to HIV in humans

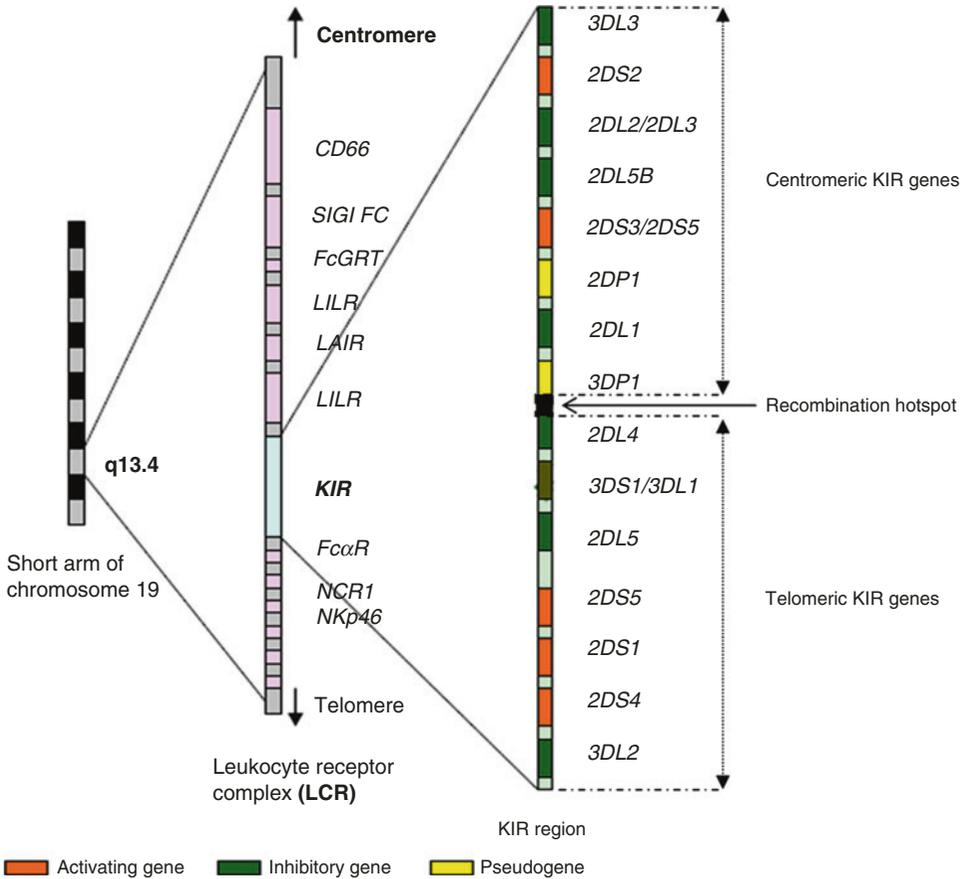

Gene	Allele	Mode	Effect		Mechanism of action
			HIV-1	HIV-2	
<i>HLA</i>	<i>A, B, C</i>	Homozygous	Accelerate AIDS	Not known	Decrease epitope recognition
	<i>B*27</i>	Co-dominant	Delay AIDS	Not known	Delay viral escape
	<i>B*57</i>	Co-dominant	Delay AIDS	Not known	Delay viral escape
	<i>B*35-PX</i>	Co-dominant	Accelerate AIDS	Not known	Not clear
	<i>B*1503</i>	Co-dominant	Not known	Accelerate progression to AIDS	Not clear
<i>KIR</i>	<i>3DS1</i>	Epistatic with <i>HLA-Bw4</i>	Delay AIDS	Not known	Not clear
	<i>2DL2/2DS2</i>	Co-dominant	Not known	Protect against infection	Not clear

from intracellular proteins to T cells for recognition. This antigen presentation results in initiation of an adaptive type of immune response. Several studies have demonstrated the importance of certain HLA molecules in immune responses to viral infections (Carrington and O’Brien 2003; Trachtenberg et al. 2003). Immunological evidence from HIV-2 studies in West Africa suggests that specific immune responses to HIV-2 can occur in vivo (Rowland-Jones et al. 1995; Leligidowicz et al. 2007), but only two studies have investigated the role of *HLA* in HIV-2 infection (Diouf et al. 2002; Yindom et al. 2010). In one of these studies, HLA typing was performed using low-resolution genotyping techniques, and the authors reported that *HLA-B*35* was significantly associated with lack of p26 antibodies and higher risk of disease progression in 62 female sex workers. In the same study, *HLA-B*53* showed some beneficial effect in slowing progression to AIDS. The second study was carried out in a different population in another West African country using much more sensitive molecular techniques in a larger sample (n = 513 individuals). The authors found that a different set of *HLA* alleles were associated with susceptibility to HIV-2 infection and to disease progression. They reported a positive association between *HLA-B*0801* and HIV-2 acquisition. In the same study, analysis of 4–6 digits *HLA* alleles together with more than 20 years longitudinal data on CD4⁺ T cell counts and viral loads collected

from 136 chronic HIV-2 patients belonging to the same ethnic group revealed that specific *HLA* class I alleles could predict HIV-2 disease outcome. Individuals with *HLA-B*1503* allele had an overall lower CD4⁺ T cell counts and higher HIV-2 viral loads compared to people infected with HIV-2 over the same length of time but lacking this allele. The reason(s) behind this poor prognosis in people carrying *HLA-B*1503* is not known, and future studies are needed to unravel the functional mechanism behind this association.

KIR Studies

The killer cell immunoglobulin-like receptor (KIR) cluster is a family of 16 genes located within the leukocyte receptor complex (LRC) on human chromosome 19q13.4 (Suto et al. 1996) (Fig. 1). These genes encode receptors (type I glycoproteins) that specifically recognize HLA class I on the surfaces of other cells (targets). KIR molecules are expressed mainly by natural killer (NK) cells and some memory T lymphocytes (γδT cells). The function of these NK cell receptors is to help in the identification of abnormal body cells (also known as “non-self”) that could have been infected with intracellular pathogens or are in the process of undergoing transformation (tumorigenesis) (Naumova et al. 2007). KIR molecules do this by interacting with their ligands

Immunogenetics of HIV-2 Infection, Fig. 1 The genomic organization of KIR locus on human chromosome 19. KIR genes are tightly organized in a head-to-tail fashion within the leukocyte receptor complex (LCR) and occupy approximately 150 kb of genomic space. Inhibitory KIR genes are shown in *green boxes*; activating genes are

shown as *orange boxes*; pseudogenes are shown as *yellow boxes*; the recombination hotspot is shown as a *black box*; KIR genes vary in sizes and range between 10 and 16 kb and are mostly separated by a 2 kb intergenic space except for the 14 kb recombination zone upstream of KIR2DL4 and separating the telomeric KIR genes from centromeric KIR genes

(HLA class I molecules) and transducing signals to NK cells to either trigger inhibition of cytotoxicity or promote NK cell activation leading to the destruction of the target. The interactions between KIR and HLA class I molecules contribute to the modulation of immune responses against viruses, autoimmunity, and reproduction (Carrington and Martin 2006).

Like the *HLA* system, the *KIR* family shows extensive variation in gene content and allelic polymorphism, thereby distinguishing between individuals and populations (Yawata et al. 2002). KIR molecules are structurally similar to each other and have been classified based on the number of

extracellular domains (D0, D1, and D2) and the length of their cytoplasmic tail (long [2DL or 3DL] or short [2DS or 3DS]). Those with a long tail are “inhibitory” meaning that under normal circumstances, they prohibit NK cells from killing the target cells carrying the intact ligand, while those with a short tail are “activatory,” i.e., they instruct NK cells to lyse the target particularly when the intact ligand(s) for the inhibitory KIRs has(ve) not been found on the target cell. Lysis of any target therefore is tightly regulated by a fine balance between both the inhibitory and activatory signals.

On the basis of gene content, all *KIR* haplotypes have been classified in two groups, namely,

A and B. Group A haplotypes have a fixed gene content (*KIR3LD3*, *2DL3*, *2DP1*, *2DL1*, *2DL4*, *3DL1*, *2DS4*, and *3DL2*) with the only activating gene being *KIR2SD4*. In addition to having only 7–8 genes on the haplotype, group A genes are highly diversified at the allelic level. In contrast, group B haplotypes have variable gene content comprising both inhibitory and activating genes (4–16 genes) but with moderate or low allelic polymorphisms. Adding to the complexity is the fact that both A and B haplotypes can be divided into centromeric and telomeric parts based on the number of genes present upstream and downstream of the recombination hotspot located between two framework genes *KIR3DP1* and *2DL4* (Yawata et al. 2002).

Several epidemiological studies mostly from Western populations have demonstrated the importance of KIRs and NK cells in innate immunity of infectious diseases including HIV. These studies have implicated certain *KIR/HLA* compound genotypes with HIV outcomes. Only one of those studies was designed to look at the role of *KIR* genes on HIV-2 infection and disease progression in a community cohort of HIV-2 infected individuals in West Africa (Yindom et al. 2010). The study showed that *KIR* genes do not individually affect HIV-2 outcomes. Their effect was only noticeable in the presence of their ligands (HLA class I). The study reported that having *KIR2DS2/KIR2LD2* and at least one copy of HLA-C group 1 (C1) was beneficial or protective against HIV-2 infection. The authors found that in a community cohort of more than 500 participants from the same ethnic group (Manjaco in north western coast of Guinea Bissau), individuals with the compound genotypes *2DS2:HLA-C1/x* or *2DL2:HLA-C1/x* (where x is either C1 or C2) were more likely to be free of HIV-2. However, this finding needs to be confirmed in future studies in other HIV-2 cohorts.

Conclusion

Despite the interesting research opportunity offered to the scientific community by the nature of HIV-2 infection model which could offer

important insights into HIV-1 pathogenesis, only a few immunogenetic studies have been carried out thus far. There is a paucity of information on non-HLA-related genes in the field of HIV-2 immunogenetics. Several other genes are likely to be important including those affecting cell surface proteins involved in viral attachment and entry to cells and antigen processing; however, these genes have not yet been investigated. Funding opportunities for HIV-2 research are limited, but efforts to design and carry out good hypothesis-based immunogenetic studies in HIV-2 should be encouraged since this offers a natural model in humans where a potentially highly pathogenic immunodeficiency virus is normally well controlled by the host immune response.

Immunological Responses to Antiretroviral Therapy

Martyn A. French

School of Pathology and Laboratory Medicine,
University of Western Australia, Perth, WA,
Australia

Department of Clinical Immunology, Royal Perth
Hospital and PathWest Laboratory Medicine,
Perth, Australia

Definition

Maintenance or restoration of immune function is a major goal of treating HIV infection with antiretroviral therapy (ART). Patients who achieve a normal CD4⁺ T cell count of >500/ μ L are unlikely to experience opportunistic infections and can expect a near-normal life expectancy, whereas patients whose CD4⁺ T cell count does not increase above 200/ μ L have substantially increased long-term mortality. Up to 36% of patients receiving ART never achieve a normal CD4⁺ T cell count and immune dysfunction may persist in those that do. Furthermore, immune reconstitution may, paradoxically, result in patients being more susceptible to some immunological disorders. Here, mechanisms of immune reconstitution and the causes, consequences, and management of persistent immune dysfunction and immune reconstitution disorders will be discussed.

Reconstitution of the Immune System Following Suppression of HIV Replication by ART

Depletion of blood CD4⁺ T cells is the most characteristic immune defect caused by HIV infection, and the CD4⁺ T cell count has been

used for many years to assess the severity of HIV disease and monitor immune reconstitution after commencement of ART. However, HIV infection affects many components of the immune system, and a greater understanding of the multiplicity of HIV-induced immune defects, and how these change on ART, provides a more comprehensive picture of immune reconstitution.

Bone Marrow, Thymus, and Lymphoid Tissue

Cells of the immune system are generated in the bone marrow and thymus, whereas immune responses against pathogens are generated in lymphoid tissue present in the spleen; lymph nodes and mucosal immune system, which includes pharyngeal lymphoid tissue (tonsils and adenoids); gut-associated lymphoid tissue (GALT); and bronchial-associated lymphoid tissue (BALT). Lymph nodes and GALT are prominent sites of HIV replication and both the bone marrow and thymus are also adversely affected by HIV infection. Replication of HIV in lymph nodes and GALT causes inflammation and fibrosis, which results in a persistent proinflammatory milieu and abnormal lymphoid tissue architecture that adversely affect mechanisms that normally maintain T cell numbers, T and B cell interactions and the maturation of B cell responses and antibody production (Estes 2013). Proinflammatory cytokines, such as IL-1 β , and interferon-alpha appear to play a prominent role in this process. These abnormalities improve when HIV replication is suppressed by ART but often do not resolve completely (Cha et al. 2014; Lederman et al. 2013). This may reflect persistence of low-level HIV replication consequent upon low penetrance of antiretroviral drugs into lymphoid tissues.

T Cell Numbers and Function

During early HIV infection, massive depletion of effector memory CD4⁺ T cells (expressing the CD4 and CCR5 molecules) occurs in the blood and lymphoid tissue, particularly the GALT, caused directly by HIV replication. Immune activation also contributes to CD4⁺ T cell depletion and becomes the dominant cause during chronic HIV infection. Plasma biomarkers of immune activation associated with CD4⁺ T cell depletion

include the proinflammatory cytokine TNF- α and the chemokine CXCL10 (also known as interferon-inducible protein 10 [IP-10]). Increased production of these molecules probably reflects immune activation and inflammation in response to HIV replication in lymphoid tissues (see “► [Chronic Immune Activation in HIV](#)”). Of the several subpopulations of CD4+ T cells that mediate immune responses against different types of pathogen, the type 1 helper T cell (Th1) subpopulation (characterized by IFN-gamma production) and the Th17 subpopulation (characterized by IL-17 production) are particularly affected by HIV infection (see “► [Th17 Cells](#)”). Depletion and dysfunction of Th1 CD4+ T cells is the major cause of increased susceptibility to systemic infections by opportunistic pathogens, whereas depletion and dysfunction of Th17 CD4+ T cells contributes to impaired immune responses against mucosal infections, including *Candida* sp. infection, and is a cause of increased translocation of microbial products from the gut, which also contributes to immune activation (Brenchley et al. 2006) (see “► [Microbial Translocation](#)”).

Depletion of CD4+ T cells from the blood and lymphoid tissues in HIV infection results from decreased production of naïve (antigen inexperienced) T cells in the thymus, decreased homeostatic proliferation of naïve and memory T cells in lymphoid tissue, and increased apoptosis and turnover of CD4+ T cells (see “► [Thymic Function](#)” and “► [T-Cell Homeostasis](#)”). After ART is commenced, numbers of CD4+ T cells in the blood and lymphoid tissues increase as a result of decreased immune activation, increased production of naïve T cells in the thymus (thymopoiesis), and improved homeostatic proliferation of naïve and memory CD4+ T cells, but all occur to a variable degree. Increased thymopoiesis reflects thymus regeneration during the first year of ART (Franco et al. 2002), which may persist on long-term ART, but is very variable and least likely to occur in older patients. Homeostatic proliferation of naïve and memory CD4+ T cells, regulated by interleukin (IL)-7, is impaired by ongoing immune activation, which is associated with decreased IL-7 receptor (R)

expression and abnormalities of the intracellular IL-7R signaling pathway. Proinflammatory cytokines, including IL-1 β , and IFN- α contribute to the defects of IL-7R signaling in patients receiving ART.

Up to 36% of HIV patients receiving effective ART exhibit persistent CD4+ T cell deficiency (CD4+ T cell count <500/ μ L) after 5 years of ART. Several factors are associated with poor recovery of CD4+ T cells on ART including coinfections with hepatitis B virus, hepatitis C virus, and cytomegalovirus (CMV), which probably contribute to immune activation; an age of greater than 50, which probably limits thymus regeneration; and a low nadir (lowest ever) CD4+ T cell count. About 40% of patients who commence ART with a CD4+ T cell count of <200/ μ L do not achieve a normal CD4+ T cell count, even after 10 years of ART (Kelley et al. 2009). The association of a low nadir CD4+ T cell count with poor CD4+ T cell recovery probably reflects irreversible damage to lymphoid tissues associated with advanced HIV infection.

Persistent CD4+ T cell deficiency is associated with an increased risk of infections, poor responses to vaccinations, and an increased risk of atherosclerotic vascular disease, cancer, and osteoporosis and fractures. While some of these conditions may be a direct result of the CD4+ T cell deficiency, it seems likely that others are a consequence of associated immune defects such as memory B cell deficiency or monocyte activation (see below).

B Cell Numbers and Function

B cells recognize microbial antigens via surface immunoglobulin (the B cell antigen receptor) and then present antigens to T cells via class II HLA molecules. Activated T cells express costimulatory molecules and secrete cytokines that induce B cells to differentiate into plasma cells and produce antibodies, or into memory B cells, which are crucial for recognizing antigens during subsequent infections with that microbe. Memory B cells are also generated after vaccination. Memory B cells and plasma cells are mainly produced in the germinal centers of lymphoid follicles in lymphoid tissue, including tonsils, lymph nodes,

and the GALT. This process is regulated by follicular helper T cells (T_{fh} cells), which are a subpopulation of CD4⁺ T cells that produce cytokines and expresses co-stimulatory molecules required for generating plasma cells and memory B cells (see “► [T Follicular Helper Cells in HIV Infection](#)”).

HIV infection induces B cell activation and the accumulation of “exhausted” subpopulations of B cells while reducing numbers of resting memory B cells (Moir et al. 2009). In addition, HIV infection of T_{fh} cells causes an increased number of dysfunctional T_{fh} cells. These abnormalities may reflect the adverse effects of lymphoid tissue inflammation and fibrosis on germinal center responses. The composite effect of these immune defects is increased production of immunoglobulins, particularly IgG, but a decreased magnitude and isotype diversity of IgG antibody responses. The latter defect manifests as serum IgG2 deficiency, which occurs in over 60% of HIV patients, and probably contributes to low opsonophagocytic antibody responses that increase the susceptibility of HIV patients to infections by encapsulated bacteria.

ART improves many aspects of B cell function, especially when commenced early in the course of the infection, but defects often persist, particularly in patients who were very immunodeficient before ART was commenced. Thus, numbers of circulating memory B cells may be persistently low, and antibody responses after vaccination with pneumococcal polysaccharides and influenza virus envelope antigens are subnormal. Evidence that persistent defects of opsonophagocytic antibody responses in HIV patients receiving ART are clinically significant is provided by the persistently higher rates of community-acquired pneumonia compared with the general population.

Vaccines recommended for patients with HIV infection induce neutralizing antibody responses against viruses (e.g., influenza virus, hepatitis B virus, human papillomavirus) or an opsonophagocytic antibody response against encapsulated bacteria (e.g., *Streptococcus pneumoniae*). Their efficacy can be optimized by vaccinating patients when they are receiving ART and by the use of modified dosing schedules, as exemplified by HBV vaccine.

NK Cell Numbers and Function

NK cells are lymphocytes with the specialized function of lysing virus-infected cells or cancer cells (cytotoxicity), though they are also capable of producing cytokines, such as IFN-gamma, that activate other cells. Activation of NK cells occurs by two mechanisms: firstly, as part of an innate immune response through the recognition of virus or tumor cell components on the surface of cells by an array of activatory or inhibitory molecules and secondly, as accessory cells in an antibody response by binding of antibodies to CD16 (FcγRIII) on the surface of NK cells. Interferon-alpha-dependant activation of NK cells contributes to natural control of HIV infection. Activation of NK cells by antibodies may also contribute to the control of HIV replication, as demonstrated by the findings of the RV144 HIV vaccine study.

NK cell numbers and function are decreased by HIV, and while these defects improve on ART, they may not return to normal (see “► [NKT Cells: Bridging Innate and Adaptive Immunity](#)”). Furthermore, activation of NK cells may persist in patients receiving ART. Persistent defects of NK cell responses might impair cancer immunosurveillance mechanisms and contribute to the increased risk of non-AIDS cancers in HIV patients receiving ART (Yanik et al. 2013).

Monocytes and Macrophages

Circulating monocytes and tissue macrophages primarily contribute to antimicrobial immune responses by phagocytosis and killing of microbes. This may occur as part of an innate immune response via various cell-surface and intracellular pathogen recognition molecules, or as accessory cells in adaptive immune responses resulting from activation by IFN-gamma produced by T cells via IFN-gamma receptors, or antibodies via Fc receptors.

Monocyte phagocytosis is decreased by HIV infection and improves on ART. HIV infection also causes monocyte activation, which can be assessed by assaying plasma levels of soluble (s) CD14 or sCD163 (see below). Monocyte activation may persist in patients receiving ART and contributes to the pathogenesis of atherosclerotic vascular disease and probably other serious non-AIDS events.

Dendritic Cells

The numerous types of dendritic cell (DC) recognize, process, and present microbial antigens to T cells. Plasmacytoid dendritic cells (pDC) form a distinct DC population that plays a dominant role in viral infections because they are equipped with pathogen receptor molecules for viruses and also produce large amounts of IFN- α . Blood pDC are depleted by HIV infection, in part because they migrate to sites of HIV replication, such as the GALT, where IFN- α production may contribute to immune activation as well as to control of HIV replication. Circulating pDC numbers increase after ART is commenced.

Additional Therapy to ART for Correction of Suboptimal Immune Reconstitution

Resolution of immune activation and inflammation in lymphoid tissue should maintain the architecture and cell function needed for the differentiation and interaction of lymphocytes. While suppression of HIV replication by ART alone has a beneficial effect, that effect is often incomplete. Therefore, additional therapies may be required to suppress immune activation and inflammation (Rajasuriar et al. 2013). Therapy for HBV or HCV infection, if present, may improve CD4+ T cell deficiency, but therapy for CMV infection, while effective, results in minor CD4+ T cell gains and is expensive. Atorvastatin and possibly other statins decrease monocyte activation, and preliminary evidence suggests that recovery of CD4+ T cells is better when statins are added to ART. Hydroxychloroquine also decreases immune activation in patients receiving ART but has not yet been shown to increase CD4+ T cell counts.

Recombinant (r) growth hormone increases thymus function and increases production of naïve CD4+ T cells but is very expensive and may cause adverse effects that include diabetes. Recombinant IL-2 therapy increases CD4+ T cell counts when added to ART, but this is not associated with a decreased incidence of infections, probably because the expansion of CD4+ T cells mainly affects a subpopulation of CD4+ T cells with a regulatory phenotype. Furthermore, adverse effects of rIL-2 therapy limit its value.

Preliminary data suggest that rIL-7 may be more effective and tolerable than rIL-2 therapy.

Other than vaccination, there are currently no therapies for increasing B cell function in HIV patients receiving ART. A small number of patients have a persistent defect of B cell differentiation that is usually associated with impaired production of IgG2 antibodies and may need immunoglobulin replacement therapy if they experience recurrent invasive infections with bacteria, usually pneumococci.

Effects of ART on Plasma and Cellular Markers of Immune Activation

HIV-induced activation of lymphocyte subpopulations and monocytes/macrophages often persists on ART (Lederman et al. 2013) and can be assessed by enumerating cells expressing activation markers in blood or tissues and by assaying plasma levels of molecules secreted by, or that have been cleaved from the surface of, those cells (Table 1) (see “► [Lymphocyte Apoptosis](#)”). Co-expression of CD38 and HLA-DR on T cells, particularly CD8+ T cells, is the most commonly used marker of T cell activation. Additional markers can be assessed to obtain information on T cell proliferation and turnover (Ki67),

Immunological Responses to Antiretroviral Therapy, Table 1 Cellular and plasma markers of immune activation most commonly used to assess HIV-induced immune activation and the effects of therapy on this

CD4+ and CD8+ T cells
Proportion of blood T cells co-expressing CD38 and HLA-DR
Proportion of blood T cells expressing Ki67, CD57, or PD-1
B cells and plasma cells
Serum levels of immunoglobulins or immunoglobulin free light chains
Monocytes and macrophages
Proportions of blood monocytes expressing CD16
Plasma levels of sCD163 or sCD14
Plasma levels of D-dimers
Proinflammatory cytokines and their receptors
Plasma levels of IL-6 (or CRP as a correlate) or sTNFR _{II}
Interferon-induced chemokines
CXCL10

senescence (CD57), and exhaustion (PD-1). Activation of B cells and plasma cells is most readily assessed by assaying serum immunoglobulins or free light chains. Monocyte activation may be assessed by enumerating the proportion of blood monocytes expressing CD16 or assaying plasma levels of sCD163 (a scavenger receptor) or sCD14 (a lipopolysaccharide receptor). Increased expression of tissue factor on activated monocytes and macrophages leads to activation of the coagulation system and increased plasma D-dimer levels, which has been associated with the occurrence of serious non-AIDS events, such as osteonecrosis. The activity of proinflammatory cytokines and chemokines is most readily assessed by assaying plasma levels of IL-6, CRP, TNFR2, and CXCL10. The use of ART will improve many markers of immune activation, but persistent abnormalities may persist and correlate with an increased risk of serious non-AIDS events and death (Lederman et al. 2013).

Immune Reconstitution Disorders

Reconstitution of the immune system after ART may, paradoxically, increase the susceptibility of HIV patients to particular immunological disorders. These disorders mainly occur in patients who were very immunodeficient prior to commencing ART. Three main categories of immune reconstitution disorder are encountered (Table 2).

Immune Reconstitution Inflammatory Syndromes and Related Disorders

Virtually any pathogen that can cause an opportunistic infection may be associated with an immune reconstitution inflammatory syndrome (IRIS) when immune responses against the pathogen are restored by ART (Table 3). An IRIS occurs in up to 40% of patients commencing ART, particularly those patients with a pretreatment CD4+ T cell count of <50/μL, and usually presents during the first 3 months of ART, mostly during the first few weeks. The infection by the pathogen may not be apparent before ART is commenced and is “unmasked” by the immune response against it (unmasking IRIS). In other patients, an

Immunological Responses to Antiretroviral Therapy, Table 2

Immune reconstitution disorders that may occur in HIV patients on antiretroviral therapy

Immunopathology resulting from the restoration of immune responses against opportunistic pathogens that presents as:

An immune reconstitution inflammatory syndrome (IRIS), in which the inflammation generated by the immune response is exaggerated and/or atypical and often causes significant morbidity and sometimes mortality

Disease that is indistinguishable from that usually caused by the pathogen, such as tuberculosis, herpes zoster, herpes simplex, or flares of hepatitis caused by HBV or HCV infection, during the first 3 months of ART

Autoimmune disease, mainly Graves' disease

Immune-mediated inflammatory disease, mainly sarcoidosis

IRIS occurs in patients who are receiving treatment, or have recently received treatment, for an opportunistic infection, which appears to paradoxically worsen when ART is commenced (paradoxical IRIS). An IRIS of the central nervous system is most likely to cause severe morbidity and death.

The hallmark of an IRIS is exaggerated or atypical inflammation associated with restoration of immune responses against a pathogen. While a high pathogen load is a common risk factor for all types of IRIS, the immune responses initiating the aberrant inflammation appear to differ with the type of pathogen. Inflammatory infiltrates containing CD8+ T cells are found in an IRIS associated with virus infections, such as JC polyomavirus (Fig. 1), whereas granulomatous inflammation or suppuration is typical of an IRIS associated with mycobacterial or fungal infections (Meintjes et al. 2008; Boulware et al. 2010). Antigen-specific Th1 responses have been associated with TB-IRIS, though their relationship with disease pathogenesis is unclear, but it has been difficult to demonstrate antigen-specific Th1 responses in patients with cryptococcal-IRIS (C-IRIS). There is, however, increasing evidence that innate immune responses and pro-inflammatory cytokines, particularly IL-6 and TNF-alpha, are produced in excess in TB-IRIS, MAC-IRIS, and C-IRIS and also data suggesting that chemokines might affect the trafficking of

Immunological Responses to Antiretroviral Therapy, Table 3 Opportunistic pathogens most commonly associated with an IRIS or associated disorders after commencing ART

Pathogen	Nomenclature or disease presentation
Mycobacteria	
<i>M. avium</i> complex	MAC-IRIS
<i>M. tuberculosis</i>	TB-IRIS
<i>M. leprae</i>	Leprosy reversal reaction after commencing ART
Bacille Calmette-Guérin	BCG-IRIS
Other nontuberculous mycobacteria	
Fungi and yeasts	
<i>Cryptococcus</i> spp.	Cryptococcal-IRIS (mainly meningitis)
<i>Pneumocystis jirovecii</i>	Pneumocystis-IRIS
Protozoans	
<i>Toxoplasma gondii</i>	Exacerbation or presentation of cerebral toxoplasmosis after ART
<i>Leishmania</i> spp.	
Viruses	
Cytomegalovirus (CMV)	CMV retinitis after ART CMV immune recovery uveitis
Varicella-zoster virus (VZV)	Cutaneous zoster after ART VZV-IRIS (usually CNS disease)
Herpes simplex virus (HSV) 1 and 2	Mucocutaneous herpes after ART (sometimes necrotizing or hemorrhagic) HSV-IRIS (mainly CNS disease)
Kaposi's sarcoma (KS) herpesvirus	KS-IRIS
JC polyomavirus	PML-IRIS
Hepatitis B virus	Hepatitis flare after ART
Hepatitis C virus	Hepatitis flare after ART
HIV	Exacerbation of HIV encephalitis after ART
Helminths	
<i>Strongyloides</i>	
Bacteria	
<i>Bartonella henselae</i>	

lymphocytes and myeloid cells to sites of inflammation (Chang et al. 2013). An animal model of MAC-IRIS has provided evidence of aberrant interactions between innate immune cells and T cells when ART is commenced in the context

of severe CD4+ T cell depletion and a high pathogen load, which leads to an exaggerated inflammatory response (Barber et al. 2012).

A severe IRIS can be life-threatening and may require the addition of immunomodulatory therapy to ART. Corticosteroid therapy is usually used but efficacy has only been demonstrated in a randomized controlled trial for TB-IRIS. Therapeutic inhibition of those proinflammatory cytokines or chemokines associated with disease pathogenesis (see above) is logical but not yet of proven benefit.

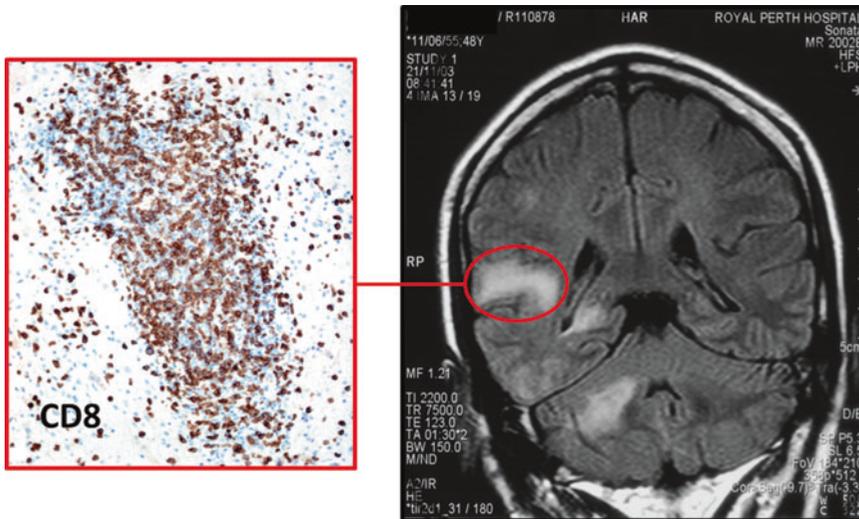

Autoimmune Disease Following Immune Reconstitution in HIV Patients

Several types of autoimmune disease have been reported in HIV patients who have experienced immune reconstitution on ART. Graves' disease of the thyroid is by far the most common (Crum et al. 2006) and often causes very severe thyrotoxicosis, which is commonly associated with severe extra-thyroidal manifestations, such as ophthalmopathy. Graves' disease occurs predominantly in patients who had a very low CD4+ T cell count at the time of commencing ART and who experience a substantial increase of the count on ART. Unlike the various types of IRIS, Graves' disease in HIV patients receiving ART presents at a median time of about 2 years after commencing ART and the immunopathogenesis therefore appears to be different. An acquired defect of central immune tolerance associated with higher numbers of circulating recent thymic emigrant naïve T cells may be one factor.

Systemic or cutaneous lupus has also been reported to present in HIV patients on ART. Those cases presenting during the first 3 months of ART have had serologic evidence of lupus before treatment, and it appears that the immunologic changes immediately after ART unmask subclinical disease. The other cases have presented after 9 months of ART, and the lupus may have resulted from an acquired disorder of immune tolerance during immune reconstitution.

Immune-Mediated Inflammatory Disease During Immune Reconstitution in HIV Patients

Immune-mediated inflammatory disease (IMID) results from immune responses that are apparently

Immunological Responses to Antiretroviral Therapy, Fig. 1 PML-IRIS of the brain after commencing ART for HIV infection. A biopsy of a brain lesion (*circled*) demonstrated large numbers of CD8+ T cells

not precipitated by an infection or the result of autoimmunity. Sarcoidosis is the most common type of IMID presenting as an immune reconstitution disorder in HIV patients (Foulon et al. 2004). It may present up to 3 years after commencement of ART. In some cases, the use of IL-2 or interferon-alpha (IFN- α) therapy appears to have been a precipitating factor. The immunopathogenesis of sarcoidosis in HIV patients receiving ART is unclear, but it is most likely to reflect an increased susceptibility to dysregulation of Th1 immune responses in the reconstituted immune system, which may be exacerbated by cytokine therapy that enhances Th1 immune responses, such as recombinant IL-2 or IFN- α therapy.

Conclusions

ART has substantially improved the health and longevity of people with HIV infection, but it does not completely resolve HIV-induced immune activation and immune dysfunction, particularly when commenced late in the course of HIV disease. Persistent deficiency and/or dysfunction of CD4+ T cells, memory B cells, NK cells, and monocytes and the associated abnormalities of cellular or plasma markers of immune

activation in patients receiving ART are associated with an increased susceptibility to infections and cancers and to serious non-AIDS events. Those patients who experience immune reconstitution from a state of severe immunodeficiency are also susceptible to immune reconstitution disorders, which include various types of IRIS and some autoimmune diseases and IMID. Most of these problems would be avoided by commencing ART before severe immunodeficiency develops. Additional therapies may be needed in patients who develop an IRIS or experience ongoing immune activation on ART. Research is required to elucidate the immunopathogenesis of these conditions so that treatments can be improved.

target CD4⁺ T cells are eliminated by the immune system or as a result of viral infection after releasing progeny virus that propagates the infection. However, as a consequence of normal T cell memory, a subset of HIV-1 cells become infected and revert back to a resting, quiescent state. These cells contain an integrated HIV-1 provirus but are transcriptionally silent and represent the major barrier to HIV-1 eradication. The establishment of latency, the ability of latently infected cells to evade the immune response, and the reactivation and subsequent immune clearance of latently infected CD4⁺ T cells are all major immunological components of latent HIV-1 infection.

Introduction

Understanding latent HIV infection requires both an understanding of T cell-based immune memory in addition to the HIV-1 replication cycle. Latently infected cells contain a stably integrated HIV-1 provirus, are quiescent, and produce little to no detectable viral proteins, thus representing a huge hurdle for immune-based eradication strategies. Understanding the complex interactive between the host immune system and latent infection is likely necessary for complete clearance of HIV-1. Herein, the immunologic principles dictating the establishment, maintenance, and immune-based targeting of latently infected cells will be discussed.

Immunology of Latent HIV Infection

²Division of Infectious Diseases, Department of Medicine, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Definition

Due to restrictions predicated by receptor and coreceptor binding, HIV-1 preferentially infects activated CD4⁺ T cells. Typically, HIV-1 infected

Establishment of the Latent Reservoir

Tropism constraints imposed by the surface glycoprotein gp120 dictate the infection of CD4⁺ T cells in HIV-1 infection. Consequently, the production of latent, HIV-1-infected cells is thought to be an inadvertent result of normal, T cell memory generation (Fig. 1). Typically, naïve CD4⁺ T cells encounter antigen that is presented by an antigen-presenting cell. This naïve T cell then undergoes clonal blast transformation which results in the generation of a pool of clonal effector cells in response to the original antigen. Once antigen has been cleared, the majority of these cells die, but a small fraction persist and revert to

Immunology of Latent HIV Infection, Fig. 1 Generation and maintenance of HIV-1 latency in CD4⁺ T cells. HIV-1 latency is a consequence of normal CD4⁺ T cell memory. Physiologically, naïve CD4⁺ T cells (*blue* cells) encounter antigen in the presence of APC cells and undergo blast transformation and clonal amplification as activated CD4⁺ T cells (*orange* cells). Once antigen has been cleared from the system, contraction occurs and the majority of active CD4⁺ T cells undergo death by apoptosis (†). A minority persist as memory CD4⁺ T cells

(*green* cells), in a long-lived pool of cells that can rapidly respond if exposed to the same stimulatory antigen. In the context of HIV-1 infection, HIV-1 preferentially infects activated CD4⁺ T cells. The majority of infected cells die via normal apoptosis or viral cytopathic effects, but a minority of infected cells revert back to a resting, memory state. These cells are long-lived, quiescent cells with a stably integrated provirus (*black bar*). If these cells reencounter antigen, they reactivate, thus allowing productive HIV-1 viral replication

a resting, quiescent state. A hallmark of the acquired immune response, these cells are primed to potently respond if restimulated with the same antigen (Dooms and Abbas 2006). While HIV-1 preferentially infects activated CD4⁺ T cells, resting CD4⁺ T cells can also be directly infected.

Because productive HIV-1 infection requires active proliferation of the target cell, HIV-1 reverse transcription and integration are not completed in most of these cells. Thus, the HIV-1 genome persists as an extrachromosomal form that retains the ability to integrate upon cellular

activation. These unintegrated genomes form the labile pre-integration latent reservoir (Bukrinsky et al. 1991; Zack et al. 1990) that is found in viremic patients. In contrast, infection of activated CD4⁺ T cells results in productive viral infection, and infected activated CD4⁺ T cells typically perish as a result of HIV-specific immune responses and/or viral cytopathic effects. However, it is possible that a small number of partially activated CD4⁺ T cells become infected and subsequently revert back to a fully resting, memory state. This process results in a stably integrated provirus, contained within a transcriptionally silent, long-lived memory CD4⁺ T cell (Han et al. 2007). These cells form the post-integration latent reservoir and are phenotypically similar to other resting CD4⁺ T cells.

The latent reservoir is established very early in the course of HIV-1 infection. Primary HIV-1 infection is typically characterized by high HIV-1 RNA levels, which decline to a stable set point at the onset of the acquired immune response. Over the course of years, CD4⁺ T cell counts progressively decline in the absence of antiretroviral therapy. AIDS is clinically defined when CD4⁺ T cell counts fall to less than 200 cells per microliter of blood, which occurs concomitant with the appearance of opportunistic infection due to immune system dysfunction. Effective therapy with combination antiretroviral therapy is thought to halt ongoing viral replication, and the implementation of therapy results in a dramatic decay of residual viremia to undetectable levels and a stabilization of CD4⁺ T cell counts (Perelson et al. 1997). With the advent of combination antiretroviral therapy, there was hope that HIV-1 infection could be eradicated. However, the establishment and persistence of the latent reservoir continues to be a barrier for HIV-1 eradication from infected individuals because treatment interruption rapidly leads to viral rebound. Current estimates, based on the half-life of infected, resting CD4⁺ T cells, predict that this stable reservoir will persist for greater than 70 years, thus mandating lifelong antiretroviral therapy (Siliciano et al. 2003).

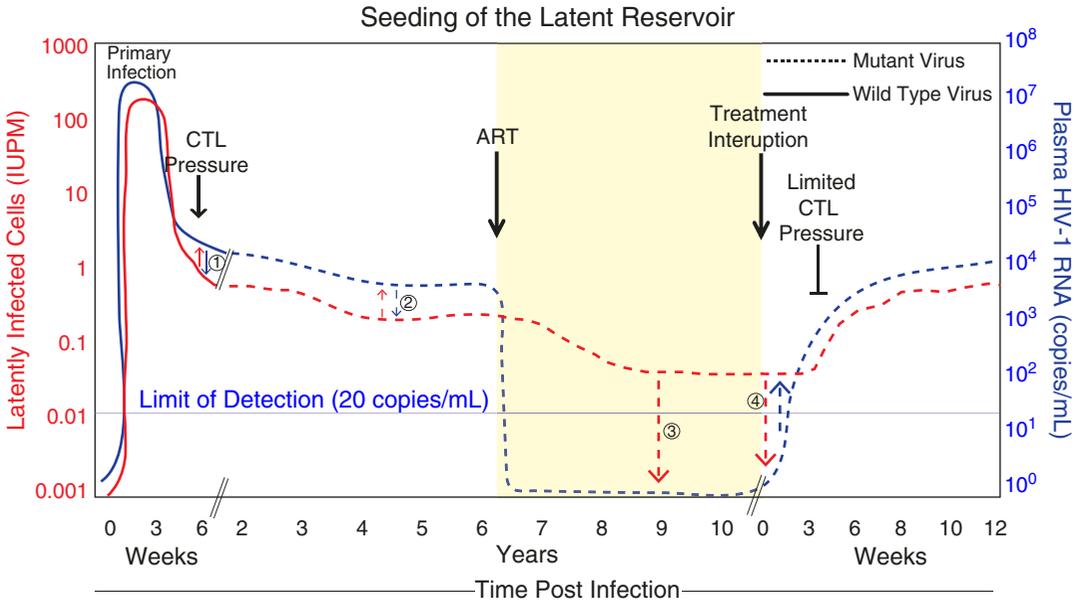

Seeding of the latent reservoir occurs early during viral infection (Chun et al. 1998). During acute infection, plasma HIV-1 RNA levels reach their peak, and the latent reservoir size is thought to be determined by the magnitude and duration of uninterrupted viral replication. Peak viral loads are reduced at the onset of the acquired immune response. The viral set point is a dynamic equilibrium that reflects viral fitness and suppressive activity of the immune system. Even in the face of immune pressure, high levels of viral replication allow the virus to escape both the cellular and humoral immune responses leading to the emergence of immune escape variants (Fig. 2). Early treatment with antiretroviral therapy has been demonstrated to reduce the overall latent viral burden (Jain et al. 2013), and potent immune responses early in viral infection have been hypothesized to reduce the initial seeding of the latent reservoir (Buckheit et al. 2013a).

Current antiretroviral therapies allow the reduction of HIV-1 replication to undetectable levels. However, due to latently infected cells, any cessation of antiretroviral therapy quickly results in a rebound in HIV-1 RNA levels, indicating that antiretroviral therapy alone is not sufficient to eradicate the latent reservoir.

Evasion from the Immune Response

Typically, HIV-1 elicits a strong antiviral humeral and cellular immune response. However, there is a lag between the initial infection event and the development of an acquired immune response and seeding of the latent reservoir occurs during this period. Thus, while there is strong evidence of selective immune pressure exerted on HIV-1, as evidenced by the development of escape mutation in both antibody and CD8⁺ T cell-restricted epitopes, the acquired immune response does not prevent the establishment of the HIV-1 latent reservoir early in viral infection (reviewed in Bailey et al. 2004).

From an immunologic standpoint, the latent reservoir presents a challenging barrier to HIV-1 eradication. Physiologically, the recognition of intracellular bacterial and viral infection requires

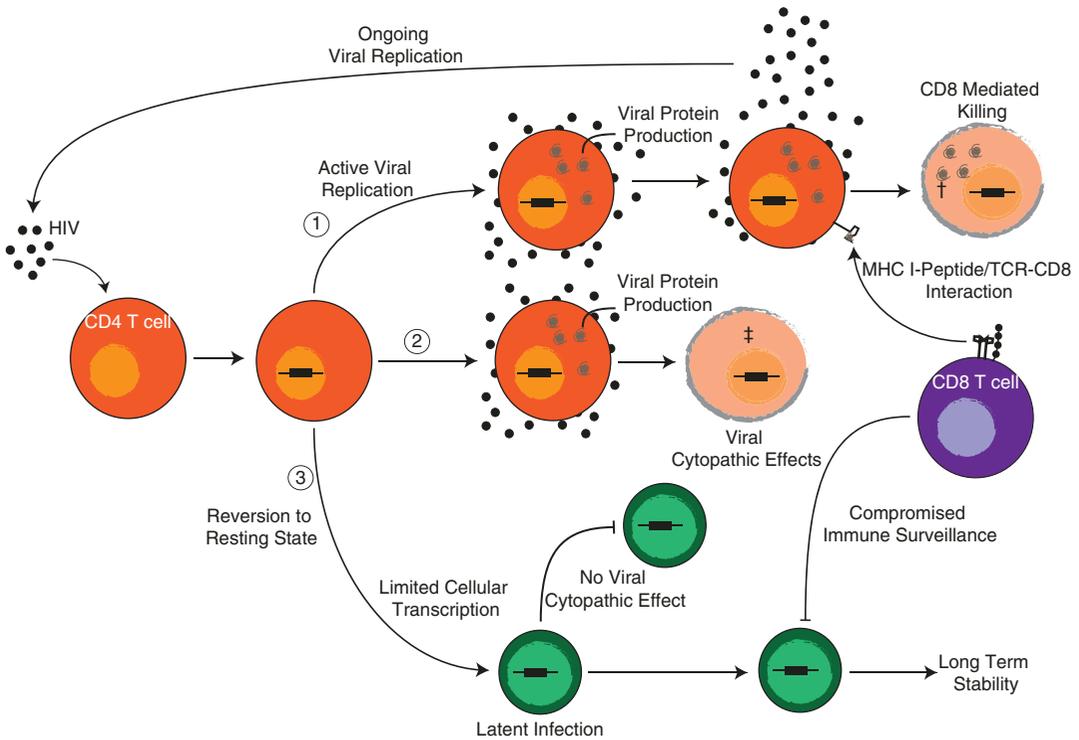

Immunology of Latent HIV Infection, Fig. 2 Immune pressure and seeding of the HIV-1 latent reservoir. The latent reservoir is seeded early in the course of HIV-1 infection. During primary infection, HIV-1 plasma RNA levels (blue line) peak, leading to the initial seeding of the latent reservoir (red line, measured in infectious units per million CD4⁺ T cells or IUPM). The number of latently infected cells, as measured on the Y axis, includes pre- and post-integration latency. The majority of latently infected cells measured during periods of high viremia are comprised of pre-integration, latently infected cells. Viremia is reduced by the emergence of the acquired immune response, and HIV-1 plasma RNA levels reach a dynamic set point level in the absence of antiretroviral therapy. Immune pressure results in the selection of immune escape variants (dotted lines), which ultimately circulate in the

periphery and seed the latent reservoir. During uncontrolled viral replication, there are exchange and mixing of the HIV-1 quasispecies between circulating and latent viral isolates (red and blue arrows, 1 and 2). Initiation of antiretroviral therapy (ART) reduced plasma HIV-1 RNA levels to undetectable levels (less than 20 copies per mL of blood). During the period of ART (yellow shading) ultralow-level circulating residual viremia is probably comprised of escape mutation variants released from the latent reservoir into the plasma (red arrow, 3). If treatment is interrupted, viral rebound occurs rapidly and free exchange between the replicating and latent pools is likely to continue (red and blue arrows, 4). Rebounded virus is comprised predominately of immune escape variants, resulting in reduced or eliminated cytotoxic CD8⁺ T cell responses (CTL)

the recognition of unique viral proteins. In some cases, this recognition occurs through the identification of unique viral RNA or DNA moieties, which activate intracellular pattern recognition sensors and downstream inflammatory effectors. Classically, virally infected cells are eliminated from the body by cytotoxic CD8⁺ T cells (Fig. 3). Viral proteins are degraded by the immunoproteasome, thus generating a series of cleaved viral proteins that are delivered to the assembling MHC class I complex. Processed peptides are then presented on the surface of the infected cell, and the cognate TCR-CD8 complex on cytotoxic CD8⁺ T cells recognizes

the peptide-MHC complex. Importantly, this surveillance mechanism requires the presence of viral antigens within infected cells (reviewed in (Janeway 2005)).

In contrast to activated CD4⁺ T cells, latently infected CD4⁺ T cells are quiescent and have dramatically reduced protein production. Transcription at the HIV-1 LTR requires the production of host transcription factors that are either reduced in resting CD4⁺ T cells or kept sequestered in the cytoplasm. For example, NF- κ B is kept inactive in the cytoplasm due to its interaction with I κ B. Upon cellular activation, I κ B is phosphorylated and degraded, thus allowing the translocation of

Immunology of Latent HIV Infection, Fig. 3 Cytotoxic CD8⁺ T cell response in latent and active HIV-1 infection. HIV preferentially infects activated CD4⁺ T cells (orange cells). Upon infection, HIV-1 integrates stably within the genome (black bar). The cell follows one of three distinct paths. 1 Active viral replication begins, resulting in high levels of virus production and intracellular viral proteins. These viral proteins are processed and presented extracellularly in an MHC-I peptide complex. This complex can be recognized by the TCR-CD8 complex of CD8⁺ T cells (purple cell), resulting in CD8⁺ T cell-mediated killing of these viral infected

cells (‡). Virus produced prior to killing can reinfect other susceptible CD4⁺ T cells. 2 Active viral replication begins, resulting in the production of high levels of viral proteins. The cell is killed as a result of viral cytopathic effects (‡). 3 The infected CD4⁺ T cell reverts to a resting, memory state (green cell) with limited host and viral cell transcription. Due to the lack of viral proteins, there is no cell death as a result of viral cytopathic effects. Additionally, the lack of viral proteins prevents detection by CD8⁺ T cells. Thus, these cells persist long term without productive immune surveillance

NF-κB to the nucleus. Additionally, the HIV-1 genome is kept silent due to the lack of tat and tat-associated factors that are similarly required for productive viral replication. These restrictions do not allow productive transcription of the HIV genome, and without viral protein production immune surveillance is compromised and infected cells are able to persist within the body without detection or elimination. Additionally, reduced viral protein transcription within latently infected cells will also reduce or eliminate cell death due to viral cytopathic effects (Fig. 3).

Furthermore, many circulating HIV-1 quasi-species are archived in the latent reservoir. As discussed previously, high levels of viral replication in the presence of a strong acquired immune response result in rapid escape from the immune system and consequentially the seeding of the latent reservoir with escape variant HIV-1 isolates (Queen et al. 2011). Thus, upon cessation of anti-retroviral therapy, the resulting rebound virus could already harbor immune escape mutations and could prevent a fully effective immune response (Fig. 2).

Targeting the Latent Reservoir

Given these immune evasion strategies, the question now becomes, can the immune response clear latently infected cells from the body? Without proper immune clearance, eradication of HIV-1 infection is likely impossible given the current antiretroviral therapies. Targeting the latent reservoir can occur at two points in the life cycle of HIV-1 infection.

The first would be targeting HIV-1 infection prior to productive integration in resting CD4⁺ T cells. This approach would require vaccination to induce a maximal immune response that limits the size of the latent reservoir early in viral infection. Recently, some lines of evidence suggest this may be possible. Vaccination strategies that elicit an effector memory phenotype in a monkey model of SIV infection prior to challenge were shown to be partially protective and were hypothesized to have reduced or eliminated the seeding of the latent reservoir in protected animals (Hansen et al. 2011). Targeting of non-productively infected CD4⁺ T cells could limit the initial seeding of the latent reservoir, as hypothesized recently in the human model of HIV-1 control (Buckheit et al. 2013b). Thus, a boosted immune response early during infection could lead to a reduced latent reservoir burden early in viral infection.

Secondly, latent HIV-1 infection could be targeted during the chronic phase of infection, thus leading to eradication. Recent efforts to eradicate HIV-1 infection have focused on a “shock and kill” methodology. Briefly, this method dictates the reactivation of HIV-1 latently infected cells using specific small molecule activators while continuing antiretroviral therapy to prevent new round of HIV-1 infection. Reactivation would lead to the production of viral proteins, and the elimination of these infected cells by either viral cytopathic effects or immune-mediated clearance and the presence of antiretroviral drugs will prevent new rounds of viral infection. Recently, clearance of reactivated cells was shown using an *in vitro* primary cell model, after maximal pre-stimulation of effector CD8⁺ T cells. CD8⁺ T cells from

chronically infected individual express higher levels of exhaustion/inhibitory markers, and *in vivo* many of the reactivated viruses may contain immune escape variants. This proof of concept study suggests that immune therapy to boost the CD8⁺ T cell response in chronically infected individuals may be required to clear reactive latently infected cells (Shan et al. 2012). Interestingly, a rare group of patients known as elite controllers have been shown to maintain undetectable viral loads without antiretroviral therapy for years despite the presence of low frequencies of latently infected CD4⁺ T cells (Buckheit et al. 2013a). This suggests that in some cases, the immune system is capable of eliminating reactivated latently infected CD4⁺ T cells, thereby preventing virologic breakthrough.

Conclusions

Overall, HIV-1 latency represents a unique epiphenomenon due to the stable integration of HIV-1 in CD4⁺ T cells. Classically, immune memory allows the maintenance of potent immune responses to a variety of antigens that have been previously encountered by the host. Whether by evolutionary design or by happenstance, HIV-1 has co-opted these processes to persist within the host, even in the face of strong immune pressure and the advent of suppressive antiretroviral therapy, representing a sizable barrier to HIV-1 eradication. The archiving of escape containing isolates within the latent reservoir and the transcriptional quiescent of long-lived memory CD4⁺ T cells represent the two main functional barrier to the immune clearance of HIV-1 infection, although efforts are underway to perturb this balance and potentially achieve eradication.

Definition

HIV-infected patients, particularly those with advanced immunodeficiency, are frequently coinfecting with other common and opportunistic infections. Here, we discuss the immunopathogenesis of six common infections that cause significant morbidity in HIV-infected patients globally. These include coinfection with cytomegalovirus (CMV), *Mycobacterium tuberculosis*, *Cryptococcus neoformans*, hepatitis B virus (HBV), hepatitis C virus (HCV), and *Plasmodium falciparum*. We summarize the epidemiology and global burden of each coinfection; highlight the immune response, pathogenesis, and natural history; and discuss the immune interplay between HIV and the co-pathogen and also the effect of cART in the setting of HIV

coinfections, including the pathogenesis of immune restoration disease (IRD).

Introduction

While AIDS-related deaths have declined globally with the availability of combination antiretroviral therapy (cART), coinfections remain a significant global burden, particularly in HIV-infected individuals who initiate cART late. Coinfections can have a significant impact on the natural history of HIV, and HIV can have a significant effect on the natural history of the specific coinfection, often characterized by unusual clinical presentations and/or increased severity.

Coinfections can directly enhance HIV viral replication through a number of mechanisms including upregulation of chemokines and cytokines, systemic or local immune activation that increases the number of target cells including activated CD4⁺ T cells, and enhancement of HIV transcription through transactivation of the HIV long terminal repeat (LTR) (Lisco et al. 2009). Conversely, HIV can have a direct impact on the innate and adaptive immune response to the specific coinfection leading to a change in natural history and altered response to treatment.

Immune restoration disease (IRD) or immune reconstitution inflammatory syndrome (IRIS) is an additional complication seen in the setting of HIV coinfections. Following cART initiation, restoration of immunity to the specific coinfection can be aberrant, and in some situations, the manifestations of the coinfection can worsen, further complicating the clinical presentation. This is associated with significant morbidity and mortality.

In this chapter, we will discuss the immunopathogenesis of six common and important infections that cause significant morbidity in HIV-infected patients globally. These include coinfection with cytomegalovirus (CMV), *Mycobacterium tuberculosis* (Mtb), *Cryptococcus neoformans*, hepatitis B virus (HBV), hepatitis C virus (HCV), and malaria. Specifically, we review the natural history of each coinfection in the setting of HIV, the specific immune defects

induced by HIV, the effects of cART on the immune response to the coinfection, the pathogenesis of IRD, and how the coinfection has a specific impact on immunopathogenesis of HIV and long-term persistence of virus on cART.

Cytomegalovirus (CMV)

Epidemiology and Global Burden of Disease

CMV is a common pathogen that infects more than half of the human population (nearly 100% in developing countries) and can range from mild or subclinical disease in immunocompetent individuals to severe disseminated disease in immunodeficient patients and severe neonatal congenital disease. CMV is the most common viral opportunistic infection in patients with AIDS.

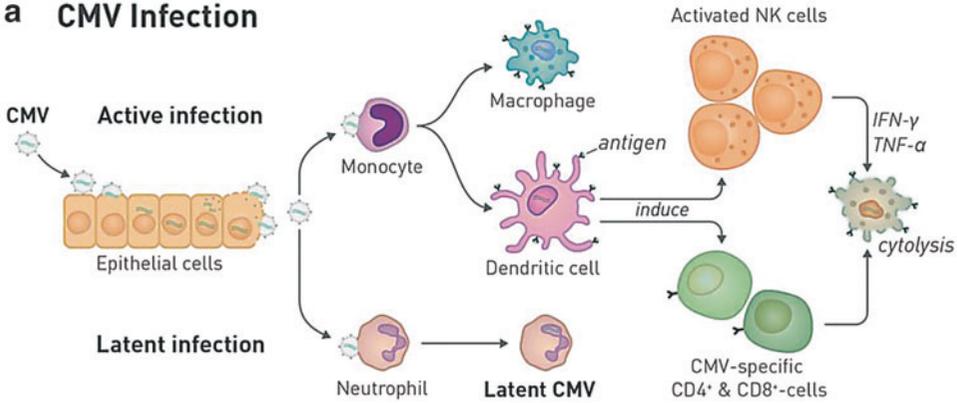

Natural History of CMV Infection

As with many other viruses, CMV can actively replicate and also remain latent. In most immunocompetent individuals, latent CMV causes no adverse effects; however, in the setting of immunosuppression such as advanced HIV infection, latent CMV can reactivate and cause significant end-organ disease such as retinitis, colitis, or pneumonitis. CMV can persist in a variety of cells and tissues and induces CMV-specific CD8⁺ T cells, even in the absence of active replication. With aging, there is a profound expansion of CMV-specific CD8⁺ T cells.

Immune Response to CMV and Pathogenesis

Both innate and adaptive immunities are important in the host control of CMV. Primary CMV infection in immunocompetent patients usually involves CMV replication in the mucosal epithelium, after which CMV disseminates to monocytic cells where it establishes latency. Restricted gene expression limits recognition by immune effector cells. The differentiation of monocytes to macrophages can produce productive CMV infection. CMV particles can be processed by antigen-presenting cells which then stimulate antigen-specific T cells and natural killer (NK) cells, both of which may directly lyse virus-infected cells by cytolysis or block replication

a CMV Infection

b

	CMV	+HIV	+ART
Immune response	CMV-specific CD4 ⁺ & CD8 ⁺ T-cells	↑	↓↓
	CMV-specific IFN-γ release	↑	↓↓
Clinical response	CMV reactivation	rare	↑↑↑
	Disseminated CMV disease	rare	↑↑↑
	End-organ damage	rare	↑↑↑
	Chronic immune activation	↑ (elderly)	↑↑

Immunopathogenesis of HIV Coinfections, Fig. 1 Pathogenesis of CMV infection and impact of HIV and cART. (a) CMV primarily replicates in the mucosal epithelium and then establishes latent infection in mononuclear cells. The differentiation of monocytes to macrophages can produce productive infection. DCs

present CMV antigens and can induce CMV-specific T cells and NK cells, which can both directly lyse virus-infected cells by cytolysis and block replication through secretion of IFN-gamma or TNF-alpha. (b) Impact of HIV and cART on the immune response and clinical manifestations of CMV

through secretion of interferon (IFN)-gamma or tumor necrosis factor (TNF)-alpha (Fig. 1a; Crough and Khanna 2009). The recruitment and activation of immune cells further increase local IFN-gamma concentrations. CMV-specific CD8⁺ T cells are critical for clearance of CMV-infected cells, although IFN-gamma secreting CD4⁺ T cells are also important for recovery from primary CMV infection.

To escape the host response, CMV encodes for a multitude of inhibitors of major histocompatibility complex (MHC) presentation, thereby reducing peptide presentation and avoiding T-cell recognition. CMV also encodes for inhibitors of IFN downstream signaling (Crough and Khanna 2009). The reactivation of CMV from latency is thought to be mediated through TNF-alpha (Crough and Khanna 2009).

Impact of HIV on CMV

Defects in cell-mediated immunity (CMI) seen in HIV infection result in an increased severity of CMV end-organ disease and increased risk for CMV reactivation and replication (Fig. 1b). Asymptomatic excretion of CMV in urine can often be detected in HIV-infected patients with low CD4+ T-cell counts, and transient CMV viremia may be noted (Crough and Khanna 2009). In vitro, there is enhancement of productive CMV infection by coinfection with HIV and of HIV replication by coinfection with CMV. Increasing CMV viremia during HIV disease progression has been described.

Impact of CMV on HIV

Evidence of past infection with CMV is almost universally present in sexually active adults, particularly in men who have sex with men (MSM). Even in the absence of active replication, latent CMV infection has been implicated as a contributing factor to chronic immune activation (► [Chronic Immune Activation in HIV](#)) in HIV-infected patients. In some studies, CMV-specific CD8+ T cells account for over half the total CD8+ T cells. High CMV-specific immune responses are strongly associated with the level of atherosclerosis in HIV-infected, CMV-seropositive individuals and accelerated immunosenescence as well as reduced number of total CD4+ T cells, particularly naïve CD4+ T cells.

Impact of cART on CMV, Including IRD

The availability of cART has dramatically reduced the incidence of CMV disease in HIV-infected patients and CMV viremia. However, HIV-infected patients on cART maintain strong CMV-specific CD8+ T cells (Naeger et al. 2010; Fig. 1b). A randomized placebo-controlled study suggested that daily valganciclovir of 900 mg – an antiviral agent active against CMV – reduced CD8 T-cell activation and CMV viral load (Hunt et al. 2011).

There have been numerous reports of CMV-related IRD, particularly involving ocular CMV disease – immune recovery vitritis and immune recovery uveitis. However, formal studies of CMV-IRD immunopathogenesis are lacking. A lower CD4+ T-cell count is a risk factor for CMV-IRD.

***Mycobacterium tuberculosis* Coinfection**

Epidemiology and Global Burden of Disease

Approximately 14 million people worldwide have HIV and *Mycobacterium tuberculosis* coinfection, and TB is the most common opportunistic infection in individuals with HIV infection, accounting for about 26% of AIDS-related deaths (Opportunistic Infections of Global Significance).

Natural History of *M. tuberculosis* Infection

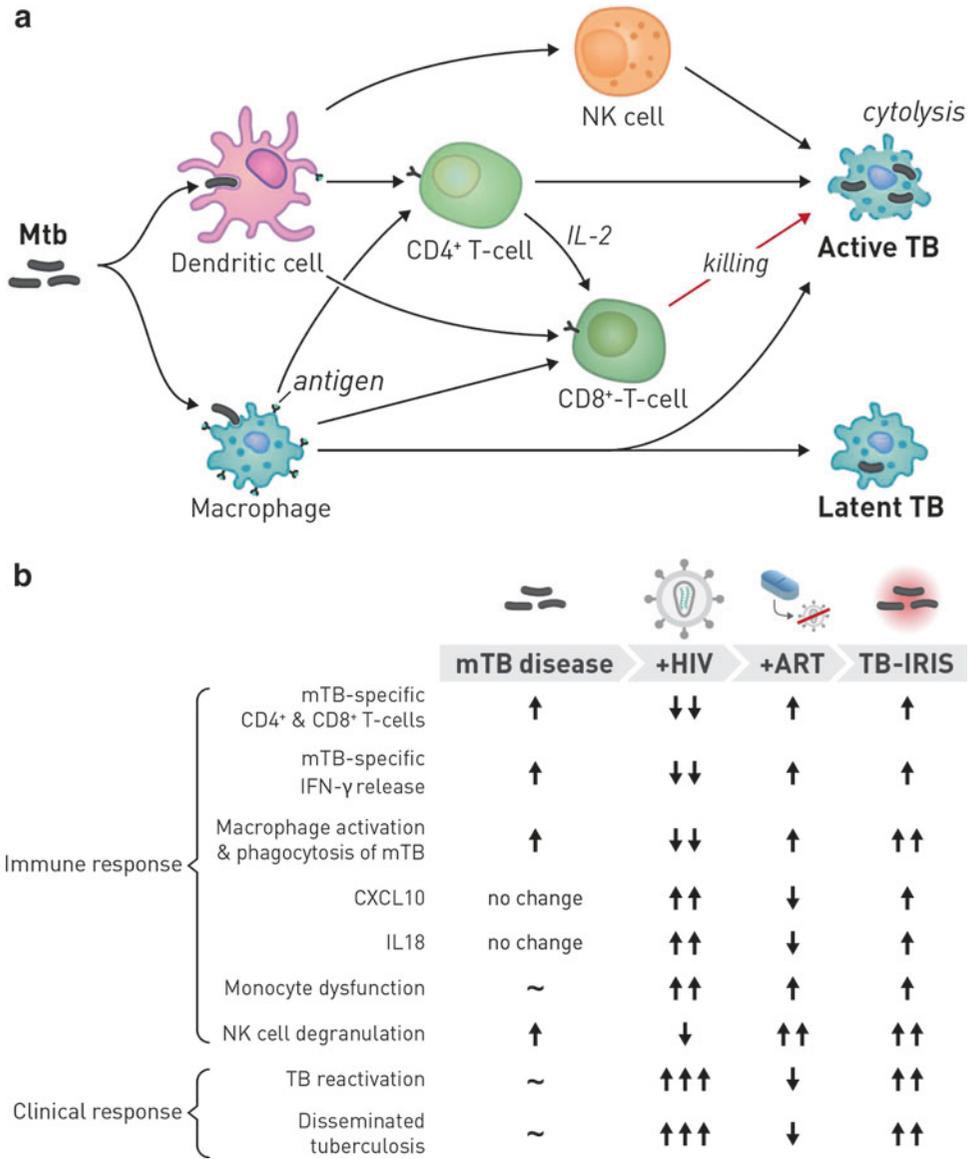

The majority of infected individuals achieve long-term control of *M. tuberculosis* (*Mtb*) infection resulting in latent tuberculosis infection (LTBI), which is associated with a 5–10% lifetime risk of reactivation, triggered usually by immunosuppression. In HIV-infected individuals however, this risk of reactivation increases by about 20-fold, and the risk of acquiring primary *M. tuberculosis* infection increases by 2.2–5.5-fold.

Immune Response to *M. tuberculosis* and Pathogenesis

M. tuberculosis is an obligate intracellular pathogen and is primarily controlled by CMI. Acquired through inhalation, alveolar macrophages and dendritic cells are the first cells that respond to *Mtb* (Fig. 2a). Immune control of *Mtb* infection is mediated by the concerted effects of multiple cell types, including CD4+ and CD8+ T cells, CD1-restricted T cells, B cells, macrophages, neutrophils, fibroblasts, and multinucleated giant cells that all contribute to granuloma formation to contain the infection. The inflammatory process that kills or “walls off” the mycobacterial infection involves chemokines and cytokines that promote a response from type 1 T helper (Th1) cells and monocytes, production of granulysin and other cytotoxic molecules by CD8+ T cells, and macrophage products such as nitric oxide synthase-2 and TNF-alpha.

Impact of HIV on *M. tuberculosis* Infection

CD4+ T-cell depletion seen in HIV infection results in the loss of cellular immune response to *Mtb*, due to a decline in memory CD4+ T cells and antigen-specific CD4+ T cells and a relative

Immunopathogenesis of HIV Coinfections, Fig. 2 Pathogenesis of *Mtb* infection and impact of HIV and cART. (a) Phagocytosis of *Mtb* by DCs leads to recruitment of MTB-specific CD4+ T cells which in turn activates NK cells and MTB-specific CD8+ T cells. Activated CD8+ T cells mediate killing of macrophages infected with *Mtb*. IFN-gamma enhances phagocytosis

and antigen presentation of free mycobacteria. *Mtb* can also establish latent infection that can persist indefinitely and can reactivate at any time despite the presence of MTB-specific CD4+ and CD8+ T cells. (b) Impact of HIV and cART on the immune response and clinical manifestations of *Mtb*

increase in IFN-gamma + CD8+ T cells and dysfunctional monocytes (discussed in Chang et al. 2013). This is associated with an increased rate of reactivation disease and disseminated disease (Fig. 2b). Suppression of cellular immune

responses by regulatory T cells (Treg) and impairment of TNF-alpha-mediated apoptotic responses also play a role. HIV infection is also associated with depletion of CD4+ T cells in granulomas, and both lymph nodes and other tissues infected by

Mtb demonstrate large numbers of neutrophils and necrosis.

Impact of *M. tuberculosis* on HIV

When mononuclear phagocyte cell lines are infected by *Mtb* or interact with *Mtb*-derived molecules, a number of signal transduction cascades are triggered, some of which result in the activation of transcription of the HIV LTR. Indeed, different phylogenetic strains of *Mtb* induce different degrees of HIV replication and may account for the diverse host immune response seen in HIV-TB coinfection.

Impact of cART Including ART-Associated TB and TB-IRIS

The improvement of CMI seen in response to cART reduces the rate of primary TB and reactivation of LTBI by at least 65%, irrespective of the CD4+ T-cell count at which cART is commenced (Suthar et al. 2012). However, the incidence of TB disease increases during the first 3 months of cART before subsequently declining, predominantly in patients with CD4+ T-cell counts of <50/μl. It appears that the *Mtb* infection is unmasked by restoration of immune responses against *Mtb*. In some patients, this presents as typical TB (ART-associated TB) whereas in others it presents as an IRIS with inflammation that is exaggerated or atypical (unmasking TB-IRIS). ART-associated TB is characterized by increased Th1 responses to the RD1 antigens of *M. tuberculosis* with increased production of IFN-gamma, the IFN-gamma-inducible chemokines CXCL10 and CXCL9, and interleukin (IL)-18 (discussed in Chang et al. (2013)).

Commencement of cART in HIV-infected patients who have recently received treatment for TB may also result in an IRIS in 20–25% of patients, termed paradoxical TB-IRIS in which there is worsening of TB clinical disease characterized by a pronounced and/or atypical inflammatory response. TB-IRIS occurs most commonly in patients with high pathogen load such as those with disseminated TB or drug-resistant TB and those with severe CD4+ T-cell deficiency (discussed in Chang et al. (2014)).

Th1 responses against *Mtb* antigens are also prominent in paradoxical TB-IRIS, characterized

by increased IFN-gamma + T-cell responses against tuberculin, ESAT-6 and CFP-10. However, there is also evidence that abnormalities of innate immune responses contribute to the immunopathogenesis of paradoxical TB-IRIS, including lower production of CCL2 (Oliver et al. 2010) and increased NK cell degranulation capacity (Pean et al. 2012) before cART is commenced, and increased production of CXCL10 (Oliver et al. 2010) and pro-inflammatory cytokines (Tadokera et al. 2011) after cART is commenced (Fig. 2b).

Barber et al. have proposed a model of TB-IRIS in which CD4+ T-cell depletion results in the failure of macrophage activation and accumulation of mycobacteria-laden macrophages. These cells become activated after cART is commenced due to an increase in IFN-gamma-producing CD4+ T cells, leading to the excessive production of IL-6 and TNF-alpha (Barber et al. 2012). When HIV infection is suppressed by cART, the recovery of adaptive and innate immune responses may occur in an uncoordinated manner with increased production of IL-18 and CXCL10 driving Th1 responses and increased production of IL-6 and TNF-alpha driving inflammation (Chang et al. 2013; Fig. 2b).

Cryptococcus Coinfection

Epidemiology and Global Burden of Disease

Globally, nearly a million cases of cryptococcal meningitis (CM) are estimated to occur each year, resulting in an estimated 624,700 deaths within 3 months of infection, with more than 80% of deaths occurring in sub-Saharan Africa (Park et al. 2009).

Natural History of *Cryptococcus* Infection

Cryptococcosis is most often due to reactivation of latent infection and can have a variety of clinical manifestations – in particular meningoencephalitis or cerebral cryptococcoma. Immunosuppression and particularly HIV infection are major risk factors for reactivation and disease.

Immune Response to *Cryptococcus* and Pathogenesis

Host defense against cryptococcosis has largely been thought to be mediated by CMI, though evidence for a role for innate and humoral immunity also exists. Protective CMI is based primarily on cryptococcal-specific Th1-type CD4+ T cells which produce IL-12, IL-2, IFN-gamma, and TNF-alpha (Hole and Wormley 2012) with IFN-gamma playing a particularly critical role. NK cells and monocytes have also been found to preferentially track into the CNS in the setting of CM.

Cryptococcus invasion of the CNS is the key to its pathogenesis and can occur via transcellular, paracellular, or vomocytosis in a host macrophage (Fig. 3a). The polysaccharide capsule is continually shed and interferes with macrophage phagocytosis, depletes complement, and impairs leukocytosis. The production of degradative enzymes enables cryptococci to degrade membranes, thereby compromising intra- and intercellular integrity leading to dissemination into the brain.

Impact of HIV on CM

The prominent CD4+ T-cell depletion seen in HIV infection significantly impairs the adaptive immune response to *Cryptococcus* spp. (Fig. 3b). Effective killing of *Cryptococcus* by alveolar macrophages is also impeded by HIV infection. HIV proteins can alter blood-brain barrier (BBB) integrity. The HIV viral protein, tat, can disrupt tight junctions and cross the BBB, contributing to BBB degradation, and may act as a chemoattractant for monocytes (Strazza et al. 2011). Gp120 binds to CXCR4 or CCR5, and the changes in brain microvascular endothelial cell cause tight junction dysfunction and an increase in BBB permeability (Strazza et al. 2011). Nef has been associated with increased secretion of CCL2 (Strazza et al. 2011). Further, expression of CCR5 (the predominant HIV coreceptor) found in the brain increases BBB permeability.

HIV-infected monocytes cross the BBB more readily and can repopulate CSF-resident macrophages. Thus, the presence of HIV in the CNS likely facilitates entry of a wide range of leukocytes into the perivascular space and

Cryptococcus spp. into the brain compartment, together leading to ongoing inflammation and BBB breakdown.

Impact of *Cryptococcus* spp. on HIV

The CNS is a known anatomical reservoir of HIV. The impact of cryptococcal CNS invasion and cryptococemia on HIV transmission and HIV replication and reservoir has not been formally investigated.

Impact of cART on CM, Including IRD

The preventative effect of cART on reactivation of *Cryptococcus* infection in HIV-infected patients has not been investigated, but *Cryptococcus* is rarely observed in HIV-infected patients with a CD4+ T-cell count of more than 100 cells/ml.

A proportion of HIV-infected patients with acute CM who commenced cART very early during antifungal treatment may develop cryptococcosis-associated immune reconstitution inflammatory syndrome (C-IRIS). Predictors of C-IRIS include a lower baseline CD4+ T-cell count, poor CD4+ T-cell recovery post-cART initiation, reduced CSF inflammation, a persistently positive culture of cryptococci from CSF at time of cART initiation, and lower IFN-gamma responses to cryptococcal mannoprotein (CMP) (discussed in Chang et al. 2014; Fig. 3b). Cytokine profiles of CCL2, CCL3, and CXCL10 measured in the CSF may assist in assessing risk for C-IRIS.

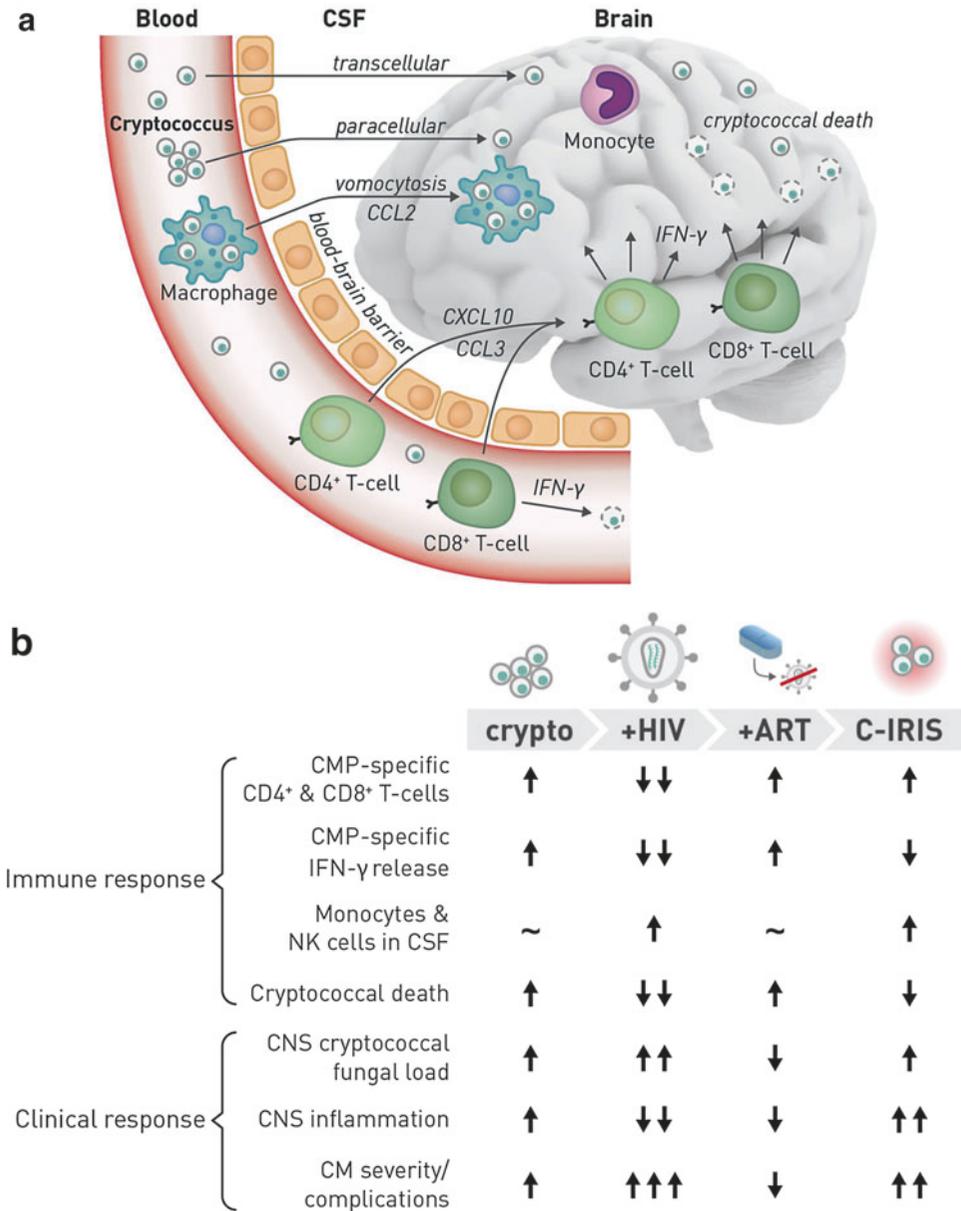

Hepatitis B Virus (HBV) Coinfection

Epidemiology and Global Burden of Disease

Despite the widespread availability of an effective vaccine, there are currently 300 million people with chronic HBV infection. Approximately 10–25% of HIV-infected patients are coinfecting with HBV. Liver-related mortality is a common cause of non-AIDS-related death in HIV-infected individuals on cART.

Natural History of HBV

Following infection with HBV, the initial hepatitis may or may not be symptomatic. Successful

Immunopathogenesis of HIV Coinfections, Fig. 3 Pathogenesis of cryptococcal meningitis and impact of HIV and cART. (a) *Cryptococcus* spp. is able to cross the BBB by paracellular, transcellular, or vomocytosis, using macrophages as a Trojan horse.

Antigen-specific CD4⁺ T cells release IFN-gamma which is critical for host protection. (b) Impact of HIV and cART on the immune response and clinical manifestations of CMV

clearance and resolution of infection is reduced in young infants and in the setting of immunosuppression. Chronic HBV infection is characterized by fluctuations in both hepatic enzymes and HBV viral load, which may eventually lead to liver

fibrosis and hepatocellular carcinoma in a subset of patients. Immune clearance is associated with development of antibodies to the HBV protein e antigen (HBeAg) and occasionally to the HBV protein s antigen (HBsAg). Hepatic

flares – more than twofold rise in alanine transferase (ALT) – often precedes development of these antibodies, or what is commonly referred to as “seroconversion.”

Immune Response to HBV and Pathogenesis

In patients with chronic HBV infection (CHB), HBV-specific CD4⁺ and CD8⁺ T-cell responses are significantly diminished; there are generalized CD4⁺ T-cell and dendritic cell (DC) hypo-responsiveness and dysregulation, altered ratios of total T cells to Treg cells, and impaired NK cell response to TLR9 stimulation (discussed in Chang et al. 2013). A strong positive correlation was recently demonstrated between activated T cells, monocytes, and NK cells and the IFN-stimulated genes (ISG), CXCL10, and abnormal liver function tests in CHB (Bayard et al. 2012). CXCL10 is produced by hepatocytes within the HBV-infected liver and has been associated with intrahepatic immune activity and liver damage (Fig. 4a). CHB is also associated with hypo-responsiveness of the TLR2 and TLR4 pathways. The importance of NK cells in HBV control may be limited to the intrahepatic compartment.

Impact of HIV on HBV

Patients with HIV-HBV coinfection have higher HBV DNA, lower rates of seroconversion, and faster progression to liver disease compared to HBV-mono-infected patients. This is accompanied by impaired HBV-specific T-cell response and increased intrahepatic apoptosis with an increase in liver-infiltrating IL-10-producing CD8⁺ T cells.

HIV significantly depletes CD4⁺ T cells in the gastrointestinal (GI) tract leading to increased microbial translocation (► [Microbial Translocation](#)), measured by elevated levels of lipopolysaccharide (LPS), part of the cell wall from gram-negative bacteria (Fig. 4b). HIV-HBV-coinfecting patients have significantly increased levels of circulating LPS and soluble (s)CD14 and inflammatory chemokines such as CXCL10 compared to HBV-mono-infected patients (Crane et al. 2014). LPS can directly stimulate Kupffer cells and hepatic stellate cells, contributing to liver fibrogenesis. This

pro-inflammatory environment with production of CXCL10 promotes chronic immune activation by recruitment of activated T cells, monocytes, and NK cells into the liver.

Impact of HBV on HIV

HIV has limited impact on the natural history of HIV infection. However, several nucleoside reverse transcriptase inhibitors (NRTI) that inhibit HIV reverse transcriptase (RT) also inhibit the HBV RT. Although HBV is a DNA virus, its replication occurs through an RNA intermediate which requires RT activity by the HBV polymerase. Therefore, HIV and HBV are often treated together using NRTI such as tenofovir and lamivudine that act against HIV and HBV, called HBV-active cART. Whether the liver is a potential anatomical reservoir for latent HIV is uncertain.

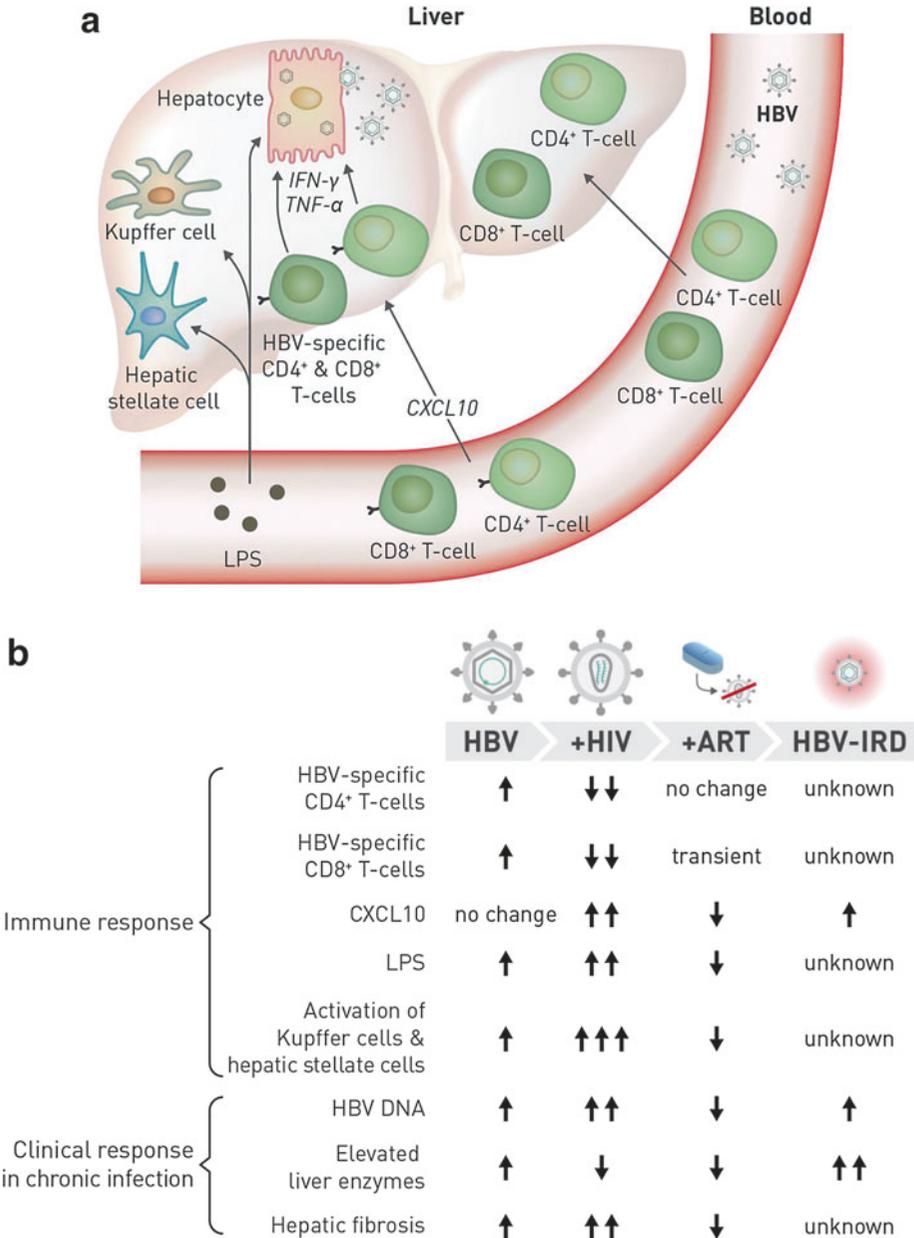

Impact of cART on CHB, Including IRD

HBV-active cART has substantially reduced liver-related mortality and improved rates of HBeAg and HBsAg seroconversion. HBV-active cART has been shown to lead to transient recovery of HBV-specific and mitogen-responsive CD8⁺ T cells. As with other coinfections, HBV-IRD has been described and can manifest as worsening liver function (or hepatic flare) which is often asymptomatic, but occasional deaths have been reported in this setting. Patients with low CD4⁺ T-cell counts and high HBV DNA prior to initiation of HBV-active cART are at highest risk of HBV-related IRD. The elevated CXCL10 seen in HIV-HBV coinfection does not decline despite initiation of HBV-active cART, and this may drive ongoing recruitment of inflammatory T cells into the liver contributing to hepatic destruction (Crane et al. 2009; Fig. 4b).

Hepatitis C Virus Coinfection

Epidemiology and Global Burden of Disease

Approximately 30% of HIV-infected individuals in high-income countries are coinfecting with hepatitis C virus (HCV) – likely acquired via the parenteral route (► [Comorbidity: Hepatitis C](#)).

Immunopathogenesis of HIV Coinfections, Fig. 4 Pathogenesis of chronic hepatitis B infection and impact of HIV and cART. (a) HBV primarily infects hepatocytes and is non-cytopathic. HBV antigens are presented by classical antigen-presenting cells as well as hepatocytes and induce both HBV-specific CD4⁺ and CD8⁺ T cells. HBV-infected hepatocytes can be cleared by HBV-specific T cells with the production of IFN-gamma and TNF-alpha or by direct cytotoxicity. In chronic HBV infection, there is a low frequency of exhausted HBV-specific T cells which are unable to

effectively clear infected hepatocytes. In chronic HBV infection, both HBV-specific and non-HBV-specific T cells are recruited to the liver by chemokines such as CXCL10, leading to hepatotoxicity and chronic liver inflammation. Finally, lipopolysaccharide (LPS) can contribute to HBV pathogenesis by direct activation of hepatocytes, Kupffer cells, and hepatic stellate cells (HSC). Stimulation of HSC by LPS increases production of pro-inflammatory cytokines leading to fibrosis. (b) Impact of HIV and cART on the immune response and clinical manifestations of chronic HBV

Natural History of HCV

Acute HCV infection is usually asymptomatic, but 75% of cases progress to chronic persistent infection. Approximately 5–10% of patients with chronic HCV will develop liver cirrhosis and/or hepatocellular carcinoma (HCC) per decade of infection. Treatments for HCV are rapidly improving, and cure is now possible for many patients.

Immune Response to HCV and Pathogenesis

Acute HCV Mono-infection

An early innate immune response is followed by an adaptive immune response to HCV. This leads to expression of ISGs, NK cell activation, and presentation of HCV antigens by immature dendritic cells to initiate adaptive immune responses, involving both CD4+ and CD8+ T cells (reviewed in Dustin et al. (2014)). HCV-specific CD4+ and CD8+ T cells are critical. An early, vigorous, and sustained CD4+ T-cell proliferative response against multiple HCV proteins and development of neutralizing antibody responses have been associated with an increased likelihood of immune clearance.

Chronic HCV Mono-infection

Hepatocellular injury and death occur as a result of host immune response rather than virus-mediated damage (Dustin et al. 2014). The severity of hepatic necro-inflammation is a key predictor of the rate of fibrosis and hence progression to cirrhosis and late-stage complications. Increased CD4+ T-cell activation in the parenchyma is associated with more severe hepatitis, and increased HCV-specific CD8+ T-cell in liver-derived T cells is associated with worsened hepatic necro-inflammatory activity (discussed in Chang et al. 2013). The leukocyte subsets that infiltrate the portal tracts and lobules differ – CD4+ and CD8+ T cells and B cells accumulate in the former, while CD8+ T cells predominate in the latter. Microvesicular fat accumulation (steatosis) is common. The recruitment of inflammatory cells into the liver is facilitated by expression of the IFN-inducible chemokines CXCL10 and CCL3, CCL4, and CCL5 that are ligands for CXCR3 and CCR5, respectively. These chemokines have been

shown to be increased in HCV-infected liver – in particular, circulating plasma CXCL10 levels have been shown to correlate with intrahepatic mRNA expression in chronic HCV infection (Askarieh et al. 2010).

Hepatic Fibrosis

Activated Kupffer cells produce pro-inflammatory and pro-fibrogenic cytokines, such as TNF-alpha and transforming growth factor (TGF)-beta (reviewed in Boltjes et al. (2014)). These activated hepatic stellate cells mediate liver fibrosis. Insulin resistance has also been implicated in promoting hepatic fibrosis.

Impact of HIV on HCV

Acute HCV

HIV-HCV coinfection leads to an increased HCV viral load, a lower rate of HCV clearance, a higher and faster risk of progression to chronic hepatitis and hepatic fibrosis, and hence higher rates of cirrhosis, liver failure, and hepatocellular carcinoma. HIV-HCV coinfection is associated with reduced HCV-specific T cells, thereby reducing the rates of spontaneous clearance. Higher rates of HCV persistence after primary infection have been shown in patients with lower CD4+ T-cell counts.

Chronic HCV

Studies of individuals with existing chronic HCV, before and after HIV seroconversion, have shown that HCV viral loads increase following HIV infection. Patients with lower CD4+ T-cell counts have higher HCV viremia, lower HCV-specific antibody responses, and a decline in functional HCV-specific CD8+ T-cell responses in the peripheral blood, while the HCV-specific CD8+ T-cell responses in the liver are maintained. A direct interaction between HIV and HCV may be relevant given that envelope protein of HIV (gp120) has been shown to increase HCV replication *in vitro*.

Hepatic Fibrosis

Using *in vitro* models, HIV has been shown to potentially have a direct role in liver disease

progression. HIV infection of both hepatic stellate cell (HSC) lines and primary cells has been demonstrated in vitro and has been associated with elevated levels of markers of HSC activation such as alpha smooth muscle actin and the monocyte chemoattractant CCL2. HIV may also have an indirect role via depletion of CD4+ T cells in the GI tract leading to elevated circulating LPS which can also directly activate HSC and Kupffer cells and therefore can potentially promote fibrosis.

Impact of HCV on HIV

Hepatitis C infection also results in continuous immune activation and thus may accelerate progression to AIDS. The role of the liver as an anatomical reservoir for HIV is unclear.

Impact of cART, Including IRD

Hepatic flares are common in HIV-HCV-coinfected patients initiating cART, but these are usually mild and self-limited, although they can rarely result in hepatic decompensation. These episodes have been associated with an increased Th1 response and higher levels of anti-HCV antibodies (Cameron et al. 2011).

Malaria Coinfection

Epidemiology and Global Burden of Disease

Malaria is caused by parasites of the genus *Plasmodium* spp., of which *P. vivax* is more geographically widespread, but *P. falciparum* is most deadly with more than 1 million deaths each year and thus will be the focus of the discussion here. There is considerable geographical overlap with areas of high HIV prevalence.

Natural History of Malaria

Severe anemia, cerebral malaria, metabolic acidosis, and acute respiratory distress syndrome are the major causes of death. Malaria infections begin with the injection of parasite sporozoites by infected mosquitoes, which then invade hepatocytes and undergo massive proliferation to form merozoites which are released into the blood to

invade erythrocytes. These infected red blood cells (iRBCs) express malaria antigens, some of which (such as pfEMP1) cause attachment of the iRBC to endothelial surfaces. Sequestration of iRBC in capillaries may disrupt blood flow, causing tissue hypoxia and lactic acidosis, as well as induce inflammatory responses, resulting in end-organ damage.

In malaria endemic areas, humans usually acquire protective natural immunity to severe clinical disease after one or two episodes of infection, whereas immunity to mild disease accumulates very slowly. Pregnancy-associated malaria results in morbidity to both the mother and baby.

Immune Response to Malaria and Pathogenesis

Immunity to malaria is primarily mediated by humoral immunity, and protection is mediated by acquisition of antibodies to malaria-associated neo-antigens expressed on the surface of the infected erythrocyte. Preerythrocytic antibodies may prevent sporozoite invasion of hepatocytes. The sporozoites can drain to the lymph nodes where they are able to prime T and B cells (Riley and Stewart 2013). IFN-gamma-producing CD4+ and CD8+ T cells are able to inhibit parasite development into merozoites, and merozoite-specific antibodies can agglutinate and opsonize the parasite and can inhibit the invasion of red blood cells through receptor blockade (Riley and Stewart 2013). Antibodies to variant surface antigens (VSA) expressed on iRBCs may also opsonize and agglutinate iRBCs and prevent their sequestration in the microvasculature (Riley and Stewart 2013).

Parasites and iRBCs activate DCs through pattern recognition receptors and are phagocytosed, and their antigens are presented to T cells (Riley and Stewart 2013). Th1 cells promote B-cell differentiation and antibody secretion and also secrete IFN-gamma which activates macrophages which in turn phagocytose and kill opsonized merozoites and iRBCs (Riley and Stewart 2013) by also secreting pro-inflammatory cytokines in response. Elevated plasma pro-inflammatory cytokines such as TNF-alpha and IL-6 are seen

in severe malarial disease and cerebral malaria in patients infected with *P. falciparum*. In pregnancy, this pro-inflammatory state is not only seen in the blood but also in placenta.

Impact of HIV on Malaria

HIV-infected patients have increased incidence and severity of malaria and repeated malaria infections (Chang et al. 2013). Cohort studies suggest HIV infection was associated with increased peripheral parasitemia and increased placental parasite densities (Hochman and Kim 2009).

In vitro, HIV-infected human macrophages exhibit lower opsonic phagocytosis activity, and HIV-infected pregnant women develop fewer antibodies to VSAs (Hochman and Kim 2009). HIV-related inflammation upregulates adhesion molecules on endothelial cells which may compound the adherence and sequestration seen in malaria (Hochman and Kim 2009).

Impact of *P. falciparum* on HIV

HIV-infected patients with malaria have a more rapid decline in CD4 T cells and have an increased, albeit transient viremia, at the time of increased parasitemia (Hochman and Kim 2009). Binding of recombinant *P. falciparum* adhesin to chondroitin sulfate A on human placental cells is associated with increased HIV replication (Gonzalez et al. 2012). Placental HIV viral RNA is increased, and CCR5 receptor expression is upregulated in women with placental malaria which may increase mother-to-child HIV transmission (Gonzalez et al. 2012).

Impact of cART Including IRD

There are few studies on the efficacy of cART in preventing severe malaria in children or adults. There are no reported cases of malaria-associated IRD possibly because protective immune responses are humoral rather than cellular.

Conclusions

Coinfections remain a major threat to HIV-infected patients globally, particularly in

resource-limited settings where access to cART is limited and diagnostic methods and treatment for coinfections are scarce. Coinfections in HIV not only increase patient morbidity and mortality but can impact directly on HIV viral replication, microbial translocation, and overall systemic immune activation. A deeper understanding of the interactions between HIV, host deficiency, and exogenous pathogens is necessary to develop immunotherapy, novel molecules, and vaccine strategies to adequately manage and/or prevent coinfections in HIV-infected patients.

Inflammasome and HIV

Fabien P. Blanchet

Centre d'études d'agents Pathogènes et Biotechnologies pour la Santé (CPBS), CNRS–UMR, Montpellier, France

Definition

Inflammation is meant to be a transient and non-specific process dedicated to exert a physical and chemical barrier against an incoming injurious stimulus. This process is ignited in the challenged tissues by injured or infected cells which release some alarmins prone to rapidly warn and attract resident immune cells at the challenged site. Some of these cells will then capture the threat and recognize some danger-associated molecular patterns (DAMPs) or pathogen-associated molecular patterns (PAMPs) via their interaction with specific pattern recognition receptors (PRRs). Some of these PRRs are able to associate with other cellular factors and the caspase-1 to form specific multiprotein complexes, called inflammasomes. Formation of these platforms allows a rapid amplification of the inflammatory cascade upon caspase-1 activation, thereby leading to the maturation and release of the active IL-1 β pro-inflammatory cytokine. Recently, a plausible explanation for the massive CD4⁺ T-cell depletion observed during HIV infection relied on the activation of specific inflammasomes in abortively infected CD4⁺ T cells leading to an inflammation-associated form of cell death called pyroptosis. Although still in its early stages, this hypothesis raises hope for potential therapeutic approaches in the field of HIV pathogenesis.

HIV and Chronic Inflammation: Proof of Statement

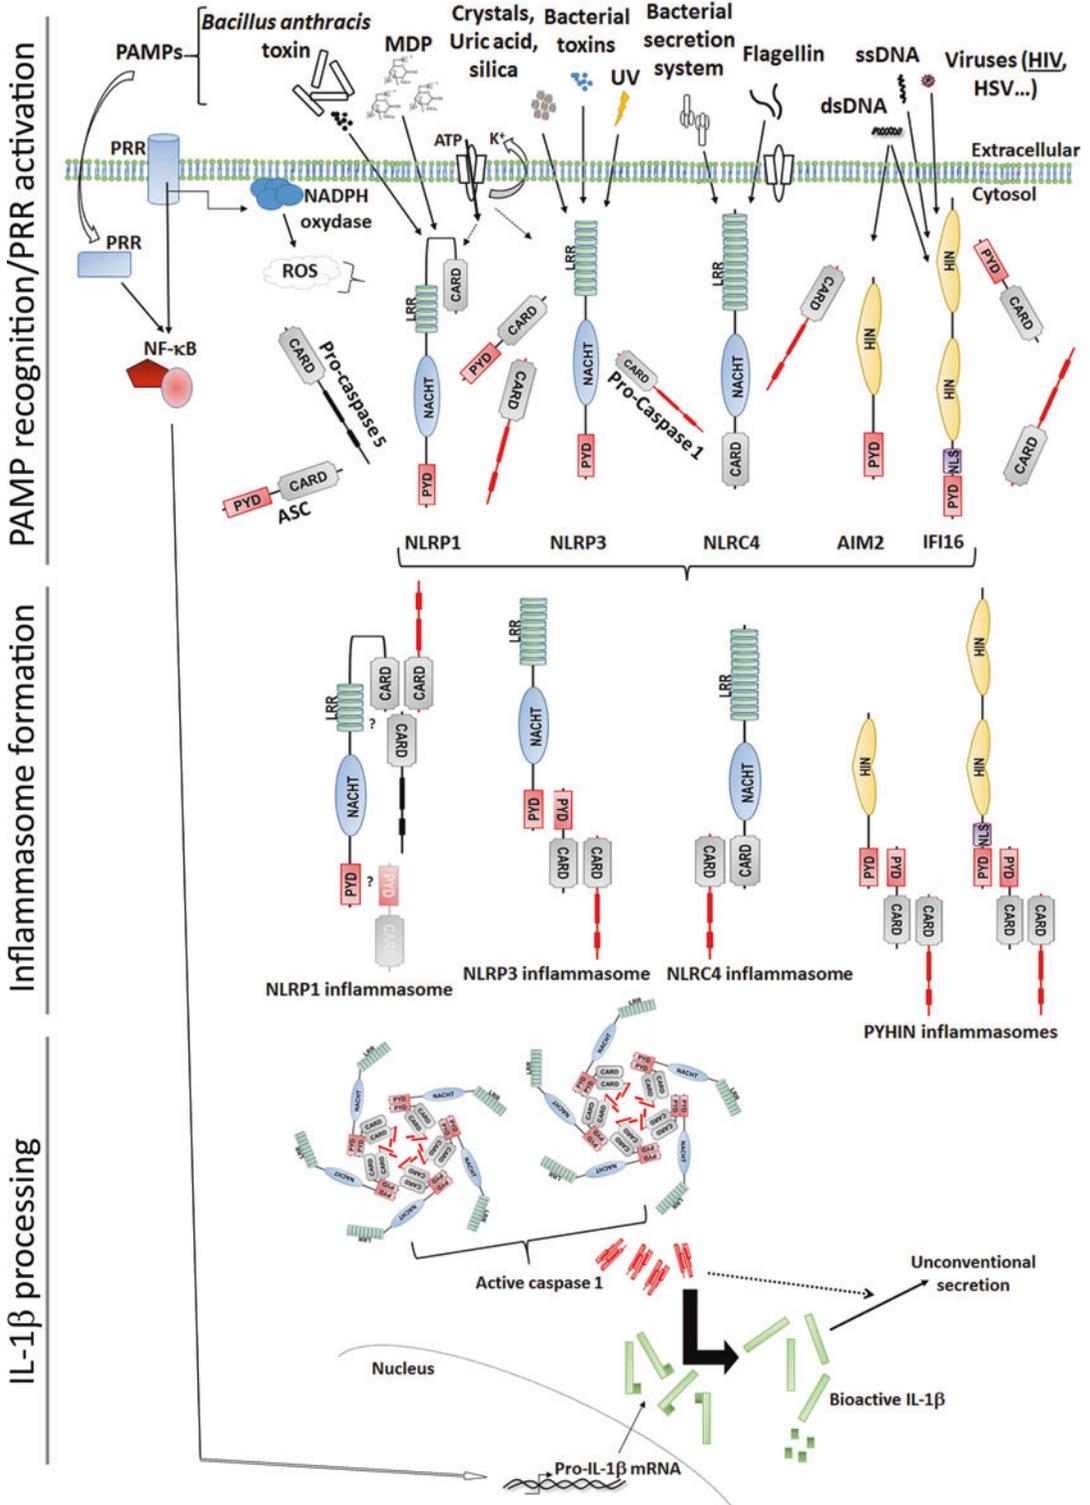

While the prevalence of acquired immunodeficiency syndrome (AIDS) has engaged in a decreasing curve, mainly due to combinations of

antiretroviral therapy (ART) in the last three decades, the HIV-mediated pathogenesis could be now referred to as a chronic disease associated with non-AIDS-related illness and morbidity. Indeed, non-AIDS disorders appear to be higher than expected in HIV-infected adults under ART with a particularly alarming situation regarding cardiovascular diseases, kidney disease, osteoporosis, cancer, and some neurological diseases. There is now a growing line of evidence that most of these complications come from a systemic immune activation linked to an uncontrolled chronic inflammation (“► [Chronic immune activation in HIV](#)”). In fact, the link between HIV-mediated pathogenesis and persistent inflammation was already strongly evidenced in initial reports showing an increase of inflammatory markers in sera from untreated HIV-infected patients at all stages of the disease. Nevertheless, this trend was also described for infected patients under ART regimen suggesting that, although viral replication was controlled and immune functions were almost fully restored, there was still an evident uncontrolled and sustained inflammatory state with a consequent shift toward non-AIDS-related disorders (Deeks et al. 2013). Although traditional risk factors (obesity, alcohol, smoking, etc.) and antiretroviral drug toxicity (insulin resistance, diabetes, hyperlipidemia, etc.) could contribute to such advert effects, they do not entirely recapitulate and explain the symptoms preceding non-AIDS morbidity. There are many other different events and factors thought to contribute to the persistent inflammatory state among which a chronic activation of some T-cell subsets and cells of the monocyte/macrophage lineage; breakdown and leakage of the gut mucosa leading to chronic translocation and exposure to gut microbial products; prominent coinfections by other pathogens like cytomegalovirus (CMV), Epstein-Barr virus (EBV), or herpesviruses (HSVs); and altered functions of T regulatory cells (Treg) and immune regulatory cytokines might be the most plausible reasons. However, while most of these conditions should be largely attenuated in appropriately treated patients, the inflammatory state still persists. There is an intense research activity aiming at further elucidating the reasons for the remaining

CD4⁺ T-cell loss and HIV-associated chronic inflammation occurring in ART-treated patients, and recent studies suggest that a residual HIV replication in tissues could persistently fuel abortive infection of resident CD4⁺ T cells, thus leading to viral DNA accumulation which could be sensed by a specific PRR contributing to inflammasome activation and pyroptotic cell death.

Inflammasome Assembly

The inflammasome is a high molecular weight multiprotein complex (~700 kDa) whose assembly ultimately leads to the clustering and activation of caspase-1, involved in the processing of the pro-inflammatory cytokines IL-1 β and IL-18 and their release via an unconventional secretion pathway (Schroder and Tschopp 2010). Caspase-1 belongs to the family of cysteine proteases and reported to be key mediators of apoptotic and inflammatory processes. They are usually synthesized as inactive proenzymes or zymogens which contain three domains subsequently processed into large and small subunits that associate to form the active enzyme. While most caspases share a common structure, they could be divided based on their known roles in apoptosis (caspase-3, caspase-6, caspase-7, caspase-8, and caspase-9 in mammals) or in inflammation (caspase-1, caspase-4, caspase-5, and caspase-12 in humans). For instance, inflammatory caspases were firmly established as critical mediators of innate immune responses rather than being proapoptotic factors, although they could also promote a non-homeostatic and lytic mode of cell death called pyroptosis in parallel to the release of the pro-inflammatory cytokines IL-1 β and IL-18. Caspase-1 (also named ICE for IL-1 β -converting enzyme) is the prototypic member of this family of inflammatory caspases (including human caspase-4/11 and caspase-5) which all contain an N-terminal caspase recruitment domain (CARD) (Fig. 1). However, the reason why these caspases are more prone to regulate inflammatory processes is still poorly understood, but a possible explanation would rely on the secretion of caspase-1, also described for caspase-5, upon

Inflammasome and HIV, Fig. 1 (continued)

inflammasome activation. Indeed, this secretion is not firmly established for the other proapoptotic caspases, and it is therefore tempting to speculate that a parallel secretion of caspase-1 could favor the survival of activated cells. In agreement with this, a recent study reported that secretion of an oligomeric NLRP3 inflammasome stimulated further activation of caspase-1 extracellularly, therefore amplifying the inflammatory response.

Interestingly, different types of inflammasome have been identified to date, mainly based on the sensor involved in its assembly (Fig. 1). At least four canonical and one noncanonical inflammasomes have been reported until now:

1. The founding inflammasome coined **NALP1 inflammasome** was reported to contain NLRP1 (Nod-like receptor protein 1 and also named NALP1 for NACHT-, LRR-, and PYD-containing protein), the adaptor protein ASC (apoptosis-associated speck-like protein containing a C-terminal caspase recruitment domain), caspase-1, and caspase-5 (Martinon et al. 2002) and was mainly involved in the production of IL-1 β upon TLR-mediated recognition of bacterial and more recently parasitic infections.
2. The **NLRP3 inflammasome** composed, in addition to NLRP3, of the caspase recruitment domain (CARD)-containing protein CARDINAL, ASC, and caspase-1 was shown to regulate inflammation in a reactive oxygen species (ROS)-dependent manner upon detection of chemical irritants and host-derived danger signals (ATP, hyaluronic and uric acids, asbestos, silica, etc.) or bacterial toxins and RNA (Schroder et al. 2010; Tschopp and Schroder 2010). Interestingly, this inflammasome was recently reported to be activated upon ionic flux perturbations possibly created by viroporins like the M2 viral protein from influenza virus, the SH protein from RSV, or the protein 2B from encephalomyocarditis virus (Triantafilou and Triantafilou 2014).
3. The **NLRC4 inflammasome** (previously named IPAF inflammasome) characterized by the ability of NLRC4 to interact directly with caspase-1, therefore rendering ASC presence dispensable for minimal activity, was reported to be activated upon infections with gram-negative bacteria possessing type III or IV secretion systems such as *Legionella pneumophila*, *Salmonella Typhimurium*, *Pseudomonas aeruginosa*, or *Shigella flexneri* (Schroder and Tschopp 2010).
4. Some DNA sensors were recently involved in inflammasome assembly and activation upon viral DNA recognition. Among these, a protein from the HIN-200 family called absent in melanoma-2 (AIM-2) was reported to trigger **AIM-2 inflammasome** formation upon recognition of bacterial, viral, and even host DNA in cases of autoimmune disorders (Rathinam et al. 2012). Interestingly, IFI16, another member of the same family of proteins, was recently

Inflammasome and HIV, Fig. 1 Activation of inflammasomes controls IL-1 β processing and release. This figure represents a schematic view of inflammasome activation and IL-1 β processing and release in three steps: (1) PAMPs recognition/PRR activation: various PAMPs and DAMPs induce a first signal upon recognition by specific PRR leading to NF- κ B activation and pro-IL-1 β expression. Concomitantly, a second signal, which may involve potassium efflux, membrane damage, and generation of reactive oxygen species (ROS), is generated through either NLRP1 (responding to Bacillus anthracis lethal factor or muramyl dipeptide (MDP)), NLRP3 (responding to crystalline compounds, bacterial toxins, or UV), NLRC4 (responding to bacterial secretion system subunits or flagellin), AIM2 (recognizing cytosolic dsDNA from bacterial, viral, and mammalian origin), or IFI16 (recognizing cytosolic or nuclear dsDNA and ssDNA from viruses like HIV-1 and HSV).

(2) Inflammasome Formation: once activated, these cellular sensors form multiprotein complexes with ASC (except NLRC4) and procaspase 1, leading to inflammasome assembly. Each complex is formed through homotypic interactions and allows proximity-induced dimerization and activation of caspase-1. (3) IL-1 β processing: the precursor form of IL-1 β (pro-IL-1 β), expressed upon PRR-mediated NF- κ B activation, is then cleaved by caspase-1 and released from cells via an unconventional secretion pathway. Abbreviations used: *CARD* caspase activation and recruitment domain, *NLS* nuclear localization signal, *NACHT* NAIP, CIITA, HET-E, and TP1 domain, *LRR* leucine-rich repeats, *PYD* pyrin domain, *HIN* hemopoietic IFN-inducible nuclear proteins, *PRR* pattern recognition receptor, *ATP* adenosine triphosphate, *NADPH* nicotinamide adenine dinucleotide phosphate oxidase

proposed to contribute also to inflammasome activation upon abortive HIV infection of CD4⁺ T cells (Monroe et al. 2014), and this will be discussed below. This recent discovery leads to the hypothesis that other members from the same family, like PYHIN1 (also named IFIX) or myeloid cell nuclear differentiation antigen (MNDNA), could contribute to inflammasome activation, although the nature and source of recognized DNA require further investigation. Therefore, a new kind of inflammasome could emerge, namely, the **PYHIN inflammasome**, also reinforced by the fact that the majority of these proteins possess a pyrin domain at their N-terminus, hence inducible by type I and type II interferons, highly suggestive of a role in antiviral immunity. Although their mechanism of action is now intensively scrutinized, it seems that an evolutionary close family of proteins, namely, pyrin domain-only proteins (POP1, POP2, and POP3), could antagonize PYHIN inflammasomes function by competing with ASC recruitment. Another important aspect will be to decipher the subcellular localization of DNA recognition and subsequent spatio-temporal regulation of PYHIN inflammasomes as HIN-200 proteins harbor one or more nuclear localization signal(s) (NLS) and were indeed, in the case of IFI16, visualized in the nucleus upon herpes simplex virus (HSV) infection.

5. Recently, a noncanonical inflammasome was identified in mice and characterized by the contribution of caspase-11 in pyroptosis and in caspase-1-dependent IL-1 β and IL-18 secretion upon gram-negative bacteria infection (Lamkanfi and Dixit 2014). However, little is known in humans for which caspase-4 and caspase-5 are thought to be the orthologs of murine caspase-11, based on sequence identity. Although this noncanonical inflammasome seems to intervene in specific settings of infection, the contribution in other inflammasomes of caspase-11 in mice, and caspase-4/5 in humans, will need to be revisited in light of the discovery that *caspase-1* knockout mice were also impaired in caspase-11 expression.

In a mechanistic view, the assembly of inflammasomes is quite simple, although the amount, subcellular localization, and heterogeneity of the factors involved suggest this process to be tightly regulated. Briefly, the sensors are the central proteins in the inflammasome complex which is induced upon recognition of their specific ligand. Most of these sensors, except NLRC4 which harbors only an N-terminal CARD domain, possess an N-terminal pyrin domain (PYD) allowing interaction with the PYD domain of ASC (Fig. 1). ASC is also composed of a CARD domain which makes it an essential component of the inflammasome upon binding with the CARD domain of procaspase-1, and also procaspase-5 for NLRP1 inflammasome, therefore creating a bridge between the sensor and the protease. Then, ASC-mediated recruitment favors the proximity-dependent caspase-1 autocleavage leading to the generation of multimers containing stably active caspase-1 molecules, a structure reminiscent of apoptotic protease-activating factor 1 (APAF-1)-mediated apoptosome assembly required for caspase-9 activation. The activated caspase-1 present in inflammasomes cleaves the cytosolic -1 β (pro-IL-1 β) and pro-interleukin-18 (pro-IL-18) to convert them to active cytokines which will be released by an unconventional secretion pathway (Keller et al. 2008). While pro-IL-18 might be constitutively expressed in some myeloid cells, pro-IL-1 β expression requires a priming wave initiated upon ligand recognition by a PRR and converging toward NF- κ B activation (signal 1). Therefore, inflammasome activation could be viewed as a synergistic structure able to tune the amplification of pro-inflammatory processes with the ability to potentiate the activation and secretion of highly pyrogenic cytokines.

Inflammasome and Innate Immunity: IGNITION!

Inflammation arises from the activation and migration of various immune cells, mainly initiated by a complex cascade of events upon detection and recognition of a potential threatening

entity. Briefly, the process of inflammation starts with signals released by injured or infected cells at the challenged site which, consequently and rapidly, warn and attract resident neighboring immune cells, like macrophages, monocytes, or dendritic cells. These newly attracted cells would, therefore, take over and “ignite” the innate immune response by inducing expression and release of pro-inflammatory cytokines (IL-1 β , TNF- α , IL-6, among others) upon ingestion and recognition of the incoming threat. The pro-inflammatory components will fuel the innate immune response while chemokines will further attract specific immune cells to help in containing, degrading, and clearing the harmful elements. However, an uncontrolled and prolonged inflammation could have deleterious consequences and therefore needs to be turned off upon healing or resolution of infection. Indeed, if inflammation is not properly regulated at both the onset and after completion, then a chronic inflammatory state could occur as described for some autoimmune diseases like multiple sclerosis (MS) or inflammatory bowel diseases (IBDs).

In the case of microbial infections, specific molecular signatures of the incoming pathogen (nucleic acid, proteins, or glycolipids) could be sensed by specific PRRs, particularly in cells from a myeloid lineage which constitutively express a broad range of these receptors (“Pathogen Associated Molecular Patterns” and “Pathogen Recognition Receptors (general)”). In most circumstances, PAMPs will be sensed extracellularly by PRRs from the toll-like receptor (TLR) or C-type lectin receptor (CLR) families or intracellularly by proteins belonging to the RIG-I-like receptor (RLR) or the Nod-like receptor (NLR) families, therefore covering a wide range of possible recognized ligands or patterns. Stimulation of these pathways will converge toward the activation of the master transcriptional regulator NF- κ B and the subsequent transcription of pro-IL-1 β (signal 1), in parallel with the assembly of the engaged sensor with specific cellular components like ASC and the procaspase-1, therefore forming inflammasomes (Martinon et al. 2002; Pettrilli et al. 2005) (Fig. 1). Inflammasomes constitute, therefore, an effector arm of the innate

immune response by selectively regulating the availability of active pro-inflammatory cytokines.

An important remaining question is the characterization of the molecular mechanisms driving inflammasome assembly and activation. Briefly, some drugs or chemical messengers, like nigericin or ATP respectively, are potent activators of inflammasomes by modulating ion efflux, in particular calcium (Ca²⁺) and potassium (K⁺), through ion channel receptors (like the P2X purinoreceptor 7 P2X₇) therefore leading to a lowered intracellular potassium concentration. This hypotonic stress condition, coupled to the clustering of P2X₇ receptor with the hemichannel receptor Pannexin-I, sets the condition up for inflammasome assembly and activation. Nevertheless, all inflammasomes are not sensitive to ion efflux, like the NLRC4 inflammasome, and activation of another more common pathway was then thought to take place. Interestingly, most of the inflammasomes agonists induce the generation of reactive oxygen species (ROS), one of the most evolutionarily conserved responses upon infection or stress. This kind of free radicals could be produced, upon rapid uptake of oxygen, by the activation of a membrane-bound enzymatic complex composed of different nicotinamide adenine dinucleotide phosphate (NADPH) oxidase subunits. Outstandingly, the involvement of ROS in inflammasome activation was supported by reports showing that ROS production blockade by pharmacological compounds or knockdown of NADPH oxidase expression was potently inhibiting NLRP3 inflammasome. Furthermore, the thioredoxin-interacting protein (TXNIP or VDPU1), a negative regulator of the antioxidant factor thioredoxin, was reported to link oxidative stress with inflammasome activation. Therefore, a tight regulation of the redox system appears to influence inflammasome activity, and it is tempting to hypothesize that an increased quantity of ROS might continuously feed a preexisting inflammatory environment.

All these speculations might make sense in the case of HIV infection when looking at the different biological parameters obtained from infected patients. Indeed, it was known for a long time that HIV-infected patients were presenting all the

features of high oxidative stress with elevated levels of ROS at the onset of infection, and further during all stages of the disease, in marked contrast with a significant decrease of antioxidant levels, like vitamin A, C, and E, glutathione, and a pronounced reduction of thioredoxin in tissues. This imbalance between oxidants and antioxidants species might, therefore, perpetuate an inflammatory environment. But what is the origin of such dysregulation and why ART treatments could apparently not halt these damages are key questions to be addressed in order to improve future therapeutic strategies.

Inflammasome and Acute HIV Infection

The influence of ROS-mediated inflammasome activation could be central in setting up the pathological symptoms as it was shown to greatly contribute to both immune activation and inflammation. However, there are very few reports on HIV and inflammasome in the literature which might not reflect the interest in such topic but rather the fact that the possible conditions and settings necessary to unveil any link between both could be particularly challenging. Indeed, most of the reports on a possible role of inflammasome upon HIV-1 infection were essentially done in myeloid cells or were aimed at deciphering genetic polymorphisms in inflammasome-related genes correlating with susceptibility to HIV-1 infection. Interestingly, some myeloid subsets express constitutive pro-IL18 and are prone to express pro-IL-1 β with suboptimal doses of PAMPs like LPS, making these cells particularly relevant in inflammasome-mediated active IL-1 β and IL-18 secretion. Hence, myeloid cells constitutively express most inflammasome components which could be further greatly enhanced upon PRR-mediated recognition of PAMPs or DAMPs. A recent study, from Pontillo and colleagues, demonstrated that IL-4-differentiated monocyte-derived dendritic cells (MDDCs) pulsed with HIV-1 were highly upregulating *NLRP1*, *NLRP3*, *NLRC4*, *CASP1*, and *IL-1beta* mRNA expression. Interestingly, MDDC from HIV+ patients, derived in the same conditions, showed increased basal levels of

inflammasome-related gene expression, only slightly upregulated when challenged with HIV-1, suggesting that an established chronic inflammatory state in these patients would greatly perturb an optimal response (Pontillo et al. 2013). The same authors reported, also, that HIV-1 was able to induce a NLRP3 inflammasome response accompanied by a significant IL-1 β secretion in MDDC from healthy individuals, indicating a possible functional role of this inflammasome during acute HIV-1 infection (Pontillo et al. 2012b). Furthermore, it was also noticed that HIV-1 susceptibility was associated with single-nucleotide polymorphisms (SNPs) in the *NLRP3* and the *IL1-beta* genes, therefore further supporting a potential role of inflammasome in HIV-1 infection (Pontillo et al. 2012a). Interestingly, a recent study investigating HIV neuropathogenesis revealed a significant association between lentivirus-induced brain disease and NLRP3 inflammasome activation in microglia and likely contributing to neuronal loss in cerebral cortex and neurological deficits as evidenced in vivo in a model of feline immunodeficiency virus (FIV) infection (Walsh et al. 2014).

In a model of human monocyte-derived macrophages (MDMs), a study analyzed the ability of HIV-1 to induce inflammasome activation and showed that HIV-1 was able to promote IL-1 β secretion by inducing the first signal for NLRP3 inflammasome activation as soon as 6 h post-challenge and evidenced in combination with typical inflammasome stimuli, like ATP, Nigericin, or silica. Although, the mechanism of such activation was not characterized, the same level of inflammasome activation was observed when cells were challenged with VSV-G-pseudotyped envelope-deficient (Δ Env) HIV-1 viruses, therefore conclusively showing that HIV-1 contribution to inflammasome activation was envelope independent. Two other very recent reports claimed that the early steps of HIV-1 infection could effectively induce inflammasome activation in human myeloid primary cells or cell lines. Indeed, both studies demonstrated that TLR8-mediated recognition of infection was required for pro-IL-1 β transcription, caspase-1 activation, and secretion of active IL-1 β . While NLRP3

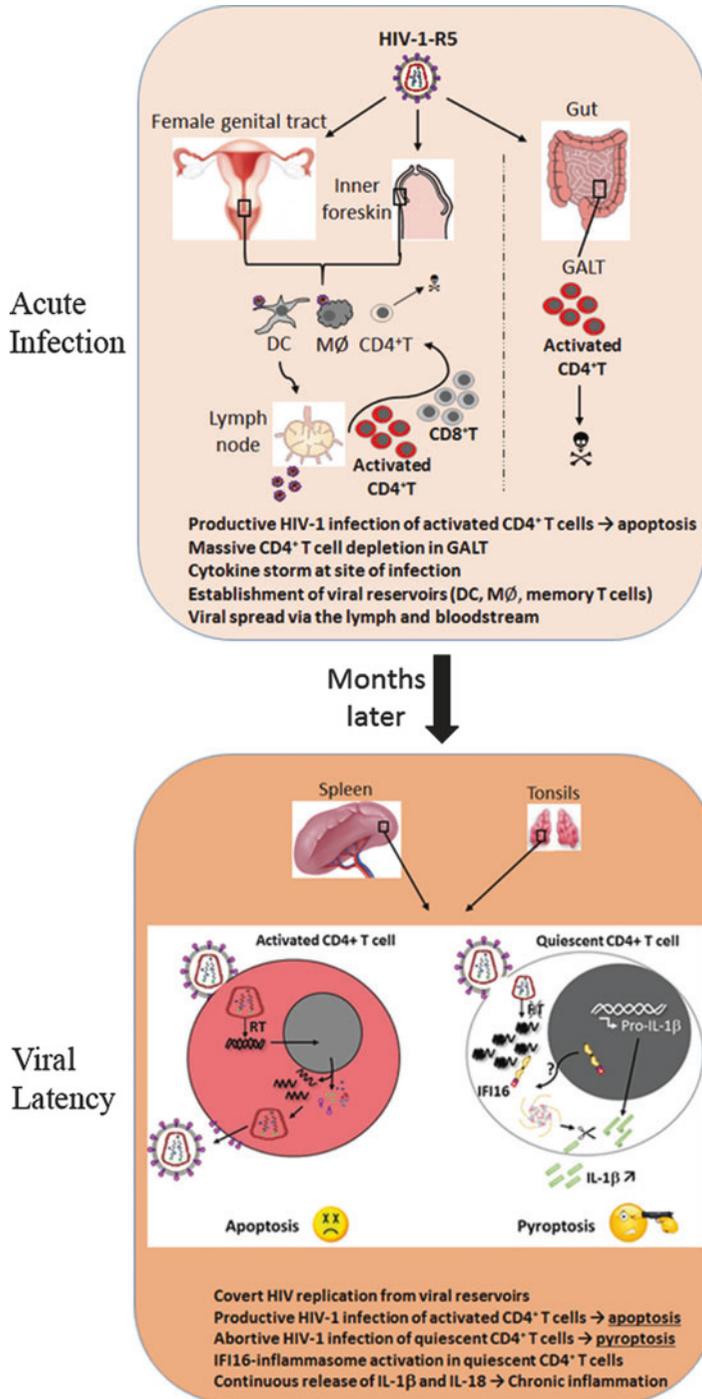

inflammasome was seemingly involved in both reports, some important discrepancies appeared, however, between them. The first study using freshly isolated human primary monocytes noticed no impact of viral fusion inhibitors (Maraviroc and T20) on HIV-1-mediated inflammasome activation, while dynasore, a cell-permeable dynamin inhibitor, or methyl- β -cyclodextrin (M β CD), a cholesterol trapping cyclic oligosaccharide, were potently blocking the virus-mediated effects, suggesting that viral endocytosis was required to induce inflammasome activation but without the need for productive HIV-1 infection (Chattergoon et al. 2014). In contrast, the other report, mainly done in the myelomonocytic leukemia THP-1 cell line, argued that HIV-1 entry, reverse transcription, and integration, but not the maturation step, were necessary to induce inflammasome activation, in parallel with the contribution of the lysosomal protease cathepsin B and virus-mediated intracellular ROS increase (Guo et al. 2014). In light of the current literature, sensing of HIV-1 during the early steps of infection leading to inflammasome activation might be an important aspect to consider in the establishment of inflammatory process, but further investigation will be definitely required to unveil the cellular mechanisms involved and, overall, to assess if uncontrolled inflammasome activation during acute infection could effectively contribute to the chronic inflammation usually observed in HIV-infected patients.

Inflammasome and Later Stages of HIV Infection

The real interest in inflammasome role upon HIV infection started with a study aimed at analyzing the virus-mediated killing of CD4⁺ T cells in human lymphoid tissues (Doitsh et al. 2010). In fact, it was well known that HIV-1 infection could promote apoptosis of CD4⁺ T cells, mainly in an envelope-dependent manner, but the massive cellular depletion occurring in some mucosa and secondary lymphoid organs could not be explained by the low rate of productive HIV infection of CD4⁺ T cells (<5%) (“► HIV

Associated Immune Exhaustion” and “► Lymphocyte Apoptosis”). The concept of “bystander” CD4⁺ T-cell death was born with the notion that a virus-mediated distal effect on neighboring cells could be the cause of such depletion. Based on previous knowledge showing that resting CD4⁺ T cells are particularly refractory to productive infection, Doitsh and colleagues revisited the HIV-mediated bystander CD4⁺ T-cell death, but using a model of human lymphoid aggregated cultures (HLACs) made from freshly dissected human tonsillar tissues or spleen. With this model, they could reproduce the expected massive CD4⁺ T-cell depletion, upon 12 days of infection with a X4-tropic HIV-1 strain, while CD8⁺ T cells levels remained almost unchanged. Surprisingly, they uncovered that CD4⁺ T-cell death was not blocked by reverse transcriptase inhibitors but could be avoided with cultures pretreated with entry or fusion inhibitors, highly suggestive of a cell death mechanism involving nonproductive infection of CD4⁺ T cells. Indeed, they demonstrated that abortive viral DNA synthesis occurring in nonpermissive, quiescent CD4⁺ tonsil T cells was a critical parameter leading to intracellular viral DNA intermediates accumulation which could be detected by specific cellular sensors (“Viral DNA Sensors”), while surprisingly not affecting the cellular DNA damage response, and promoting caspase-1- and caspase-3-mediated pro-inflammatory and pro-apoptotic innate immune responses, respectively.

Of note as well is the fact that their study was done with X4-tropic HIV-1 which, although only appearing in less than 50% of infected patients, is known to be associated with more pronounced depletion of CD4⁺ T cells compared to R5-tropic viruses. Whether the latter could also reproduce such effect was under the scope, but the authors proposed that apoptosis linked to HIV-1 productive infection could predominate during acute infection, for which a massive depletion of CCR5⁺ memory CD4⁺ T cells in gut-associated lymphoid tissue (GALT) was described, while pyroptosis induced in tonsil and spleen tissues may reflect later stages of HIV-1-induced disease (Fig. 2). Interestingly, some studies showed that the probability of X4-tropic virus emergence was

Inflammasome and HIV, Fig. 2 Mechanisms of CD4⁺ T-cell depletion during acute and asymptomatic phases of HIV-1 infection. *Upper scheme:* HIV-1-R5 acute infection in the cervix of the female genital tract or in the inner foreskin targets different mucosal immune cell subsets. HIV-1 productively infects resident CD4⁺ T cells leading

to their apoptosis, while some mucosal-resident dendritic cells (DCs) and macrophages (MØ) can intercept incoming virions in order to initiate immune response. HIV-1 captured by DC can remain infectious during days and reach proximal lymphoid tissues upon DC migration. DC-mediated immune responses allow generation of

higher in HIV-infected patients under ART than in those nontreated which could support the notion of an imbalanced chronic inflammation due to pyroptosis in the later stage of the disease (“► [Pyroptosis and HIV Replication](#)”).

Another interesting point, which remains to be answered, relies on the role of other cellular enzymes shown to recognize viral DNA intermediates and negatively regulate HIV-1 replication, like the three prime repair exonuclease 1 (TREX1), also named DNase III. Trex1 is a 3′–5′ exonuclease abundantly expressed and reported to prevent autoimmune disease by processing aberrant replication single-stranded DNA (ssDNA) intermediates (Yang et al. 2007). Interestingly, TREX1 was also shown to metabolize reverse-transcribed (RT) endogenous retroviral DNA, therefore attenuating both the DNA damage and the interferon stimulatory DNA pathways (Stetson et al. 2008). The discovery linking TREX1 with RT products prompted scientists to investigate the role of TREX1 during retroviral infection, and a study reported that TREX1 was, indeed, degrading HIV DNA intermediates generated during HIV-1 infection and, thereby, preventing recognition from cellular DNA sensors (Yan et al. 2010). Downregulation of TREX1 expression in CD4⁺ T cells, as well as in MDM, was shown to promote HIV DNA accumulation leading to an antiviral response, supposedly upon recognition of HIV DNA by specific DNA sensors. Although the antiviral response was mainly linked to type I interferon production in an IRF-3-dependent manner, it would be interesting to investigate if TREX1, or other DNases,

could exert a negative feedback control on inflammasome activation and decipher any potential lack or overwhelmed TREX1 activity upon HIV abortive infection of quiescent CD4⁺ T cells leading to pyroptosis (“► [Pyroptosis and HIV Replication](#)”).

Nevertheless, the proposed model of pyroptotic-mediated CD4⁺ T-cell depletion would perfectly fit with a long-term escalating and uncontrolled inflammatory process linked to chronic infection and immune activation, but the cellular sensor involved was still missing. It is only very recently that the same group of research uncovered IFI16 as a critical sensor of intracellular HIV-derived DNA accumulation upon abortive infection (“PRRs in HIV Recognition” and Monroe et al. 2014). Indeed, the authors developed an unbiased proteomic approach involving an affinity chromatography using a biotinylated 500-bp HIV-1 Nef DNA fragment hypothesized to represent a Nef-derived reverse-transcribed DNA likely present during abortive HIV infection. The HIV DNA was therefore incubated with tonsillar CD4⁺ T cells lysates followed by streptavidin immunoprecipitation prior to mass spectrometry analysis of the cellular proteins co-immunoprecipitated with HIV-Nef DNA. With this methodology, the authors identified numerous proteins for which IFI16 and IFIX were among the top 6 hits. Upon shRNA-mediated gene silencing experiments, they consistently observed that cell death was not occurring only when tonsillar cells were transduced with shIFI16-expressing vectors, while still observable in shSTING-, shFIX-, shAIM2-, and shDNA-

Inflammasome and HIV, Fig. 2 (continued) HIV-specific CD8⁺ and CD4⁺ T cells which can migrate to the mucosal site of infection. Lymph nodes become a site of intense HIV-1 replication due to interactions between HIV-containing DC and CD4⁺ T cells thus establishing viral reservoirs and facilitating infection propagation via the lymph and bloodstream. The same events occur in gut-associated lymphoid tissues (GALTs) upon HIV-1-R5 infection but with the hallmark of a massive CD4⁺ T-cell depletion. *Lower scheme:* In a model of spleen-derived or tonsils-derived cell culture, CD4⁺ T cells are either productively infected or resistant to HIV-1 replication. In permissive activated CD4⁺ T cells

(*left*), reverse transcription of the viral genome is efficient without recognition from cellular DNA sensors, leading to integration of viral DNA into the host cell genome and production of new virions. Productive HIV-1 infection results in caspase-3-dependent apoptosis. In quiescent CD4⁺ T cells, HIV-1 infection is restricted resulting in abortive reverse transcription and accumulation of viral DNA intermediates. These RT products are detected by IFI16 in the cytoplasm which forms inflammasomes able to activate caspase-1, involved in pro-IL-1 β processing, and release of the bioactive cytokine. Abortive HIV-1 infection results in caspase-1-dependent pyroptosis corresponding to a “cell suicide” mechanism

PK1-treated samples. While this study allowed the identification of IFI16 as a HIV DNA sensor involved in cell death of nonpermissive quiescent CD4⁺ T cells, it remains to determine the mechanism by which IFI16 is exerting its effects. Indeed, this DNA sensor was already reported to detect and respond to other viral infections, like CMV, HSV, or EBV, and drive inflammasome assembly with procaspase-1 and ASC. Furthermore, IFI16 is predominantly nuclear due to the presence of a NLS seemingly acetylated, and in the case of HSV infection, functional IFI16 inflammasomes were effectively identified in the nucleus. However, IFI16 was shown to rapidly translocate into the cytoplasm upon transfection of HIV-derived stem-rich ssDNA and also upon 4 h of HIV infection of human MDM (Jakobsen et al. 2013). The mechanisms involved in IFI16 cytoplasmic translocation upon HIV infection and how IFI16 recognizes viral DNA intermediates will need to be identified in the future.

There is, therefore, a convergence toward a possible detection of HIV-derived DNA intermediates by IFI16 inflammasome which would ultimately lead to a caspase-1-dependent pyrogenic form of cell death (Fig. 2). This was further confirmed by the group of Warner Greene in a recent report aimed at tackling HIV-1-mediated pyroptosis of tonsillar and spleen CD4⁺ T cells in their HLAC model by using pharmacological compounds (Doitsh et al. 2014). Importantly, in this study, they reproduced the pyroptotic phenotype with a R5-tropic virus, whose occurrence was also confirmed in a model of Lamina Propria Aggregate Culture (LPAC) by others (Steele et al. 2014). Interestingly, in the LPAC model, the researchers observed that microbial exposure (*Escherichia coli*) led to an increased productive infection, thereby shifting HIV-1-R5-induced caspase-1-mediated pyroptosis of lymphoid CD4⁺ T cells toward a predominant caspase-3-dependent apoptosis of infected cells. Anyway, these reports suggest that pyroptotic cell death is likely occurring in tissues in vivo, although the relevance might be questionable due to the very small proportion of CCR5⁺ cells present in some tissues. Nevertheless, Doitsh and colleagues identified in the HLAC a subset of CD4⁺/CCR5⁺

lymphoid cells, also expressing CXCR4, presenting constitutively high levels of pro-IL-1 β and becoming the predominant IL-1 β -producing cells upon HIV-R5 challenge (Doitsh et al. 2014). Outstandingly, they finally confirmed the caspase-1-dependent pyroptosis of tonsillar or splenic lymphoid CD4⁺ T cells in the HLAC model by demonstrating that VX-765, a clinically available caspase-1 inhibitor from Vertex Pharmaceuticals Incorporated, potently blocked IL-1 β release and greatly rescued cell death occurring upon HIV-1 infection. Importantly, HIV-1 infection was not restored to productive infection upon treatment with the caspase-1 inhibitor, which could have been one major concern in a therapeutic perspective. Targeting caspase-1 activity might become, therefore, a promising therapeutic strategy in combination with ART to dampen chronic inflammation while concomitantly inhibiting viral replication.

Conclusion

The hallmark of HIV-mediated immunopathology lies in an apparent chronic immune activation which correlates with a timely established chronic inflammatory state. This permanent immune dysregulation not only could affect the proper homeostasis and activity of immune cells but is also seemingly contributing to collateral damages. In the era of ART regimen, an apparent shift toward non-AIDS-related health problems is currently observed, with a particular emphasis on symptoms linked to chronic inflammation and senescence. There is now a growing interest in inflammasome role during HIV infection, particularly when considering the residual inflammatory state and appearance of immunosenescence observed during viral latency and further, even in ART-treated patients. The preliminary results reported recently show great promise and suggest that therapeutic strategies aimed at dampening inflammasome activity could represent a new and valuable add to antiretroviral therapy. Hence, treatments aimed at targeting the host rather than the virus itself would circumvent any potential emergence of viral resistance. Although the link between HIV and this damaging

inflammatory response leading to self-destruction of CD4⁺ T cells will warrant further investigation, the recent discoveries raise hope for new therapeutic avenues against AIDS.

Inflammatory Cytokines

Sheila M. Keating^{1,2}, Evan S. Jacobs¹ and Philip J. Norris^{1,2}

¹Blood Systems Research Institute, San Francisco, CA, USA

²Departments of Laboratory Medicine and University of California, San Francisco, CA, USA

Definition

Cytokines are soluble mediators of immune responses. Their secretion is a method that cells use to communicate and interact. Cells give and receive these instructional signals to perform and direct an immune response. Cytokines are produced by cells in response to a variety of stimuli, including Toll-like receptor agonists, pathogens, or other cytokines. These soluble factors bind to receptors on target cells and depending on the cytokine deliver a pro- or anti-inflammatory signal. In addition, a subset of cytokines termed chemokines deliver a chemotactic signal to cells expressing the appropriate receptor. In HIV infection, inflammatory cytokines, such as TNF- α , are elevated during the initial immune response of an acute infection, and although the intensity subsides, this inflammatory cytokine response persists throughout chronic infection even after successful antiretroviral treatment.

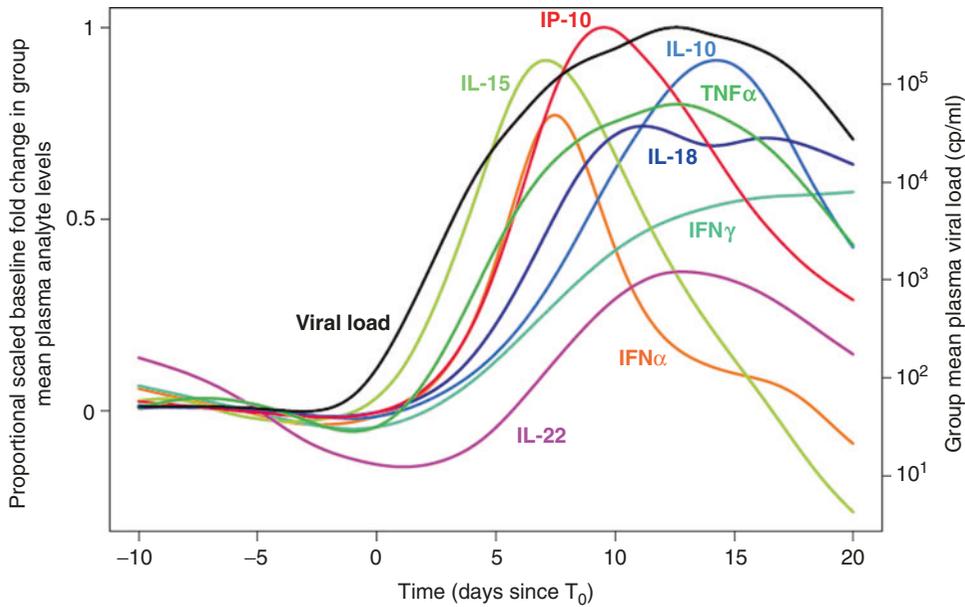

Introduction

Inflammation is a general term describing the movement of activated immune cells to a site of infection or trauma. This is mediated by a broad array of inflammatory soluble proteins which include but are not limited to cytokines, interferons, interleukins, and chemokines. They promote the innate and adaptive immune responses against infection and potentiate downstream control of pathogens. Within days of HIV infection, a cascade of inflammation begins by the virus triggering an innate immune response through pattern recognition receptors on immune cell surfaces.

The adaptive response begins with presentation of viral antigens on infected cells to CD4⁺ and CD8⁺ T cells and binding of virus to free or B cell-bound antibodies. All of these actions prompt immune cells to send out soluble mediators to direct HIV-specific immune responses. While effective early immune responses may help control virus and reduce viral set point, a maladapted response may lead to loss of control, high viral load, and maintenance of a persistent inflammatory state. With the advent of modern technology, a broad array of cytokines are now able to be easily measured to monitor immune responses to HIV. Recent research has revealed an impressive cytokine storm in early HIV infection, which resolves but does not normalize after initial infection. This phase is followed by persistent viral infection, with immune responses unable to control or eliminate the virus, and the inflammatory cytokine response fuels systemic pathogenesis during chronic infection.

Cytokines in Acute HIV Infection

HIV infection can be symptomatic or asymptomatic, and studies have suggested that patients with symptomatic acute HIV infection present with higher viral load and progress to immune deficiency and AIDS more rapidly than those with asymptomatic infection. Due to the difficulty in identifying subjects with HIV at the earliest stages of infection, the interaction between cytokine levels in early HIV and subsequent viral pathogenesis is only recently beginning to be understood. Study of paid plasma donors, who are required to be afebrile at the time of plasma donation, revealed the trajectory of cytokines through acute HIV infection up to seroconversion (Fig. 1). HIV induces successive waves of systemically detectable cytokines, beginning with inflammatory mediators like IP-10 (CXCL10), IFN- α , and TNF- α , followed by both pro- and anti-inflammatory cytokines such as IFN- γ and IL-10, respectively (Stacey et al. 2009). The cytokine storm seen in acute HIV infection is much greater in breadth and magnitude than what is appreciated in other acute infections such as

Inflammatory Cytokines, Fig. 1 The proportional fold change relative to baseline in plasma levels of selected analytes and viral load in 35 plasma donors with acute HIV infection is shown. Time is plotted in days relative

to T₀, the day of first detectable plasma HIV (Copyright © American Society for Microbiology (Journal of Virology, Vol. 83, 2009, p. 3719–33, ► <https://doi.org/10.1128/JVI.01844-08>))

hepatitis B or C viruses. One question that arises in study of HIV is whether cytokine levels during acute infection predict subsequent disease progression. Early HIV is characterized by massive CD4⁺ T cell depletion in gut-associated lymphoid tissues, and systemic cytokine responses might affect the activation and propensity to infection for CD4⁺ T cells. A study of 30 cytokines in acute HIV-infected African women revealed a subset of 5 cytokines that could predict subsequent viral load during chronic, untreated infection. It was found that IL-12p40, IL-12p70, and IFN-γ were associated with lower viral load and IL-7 and IL-15 were associated with higher viral load (Roberts et al. 2010). Clearly, the degree of inflammation induced during acute HIV infection can affect the subsequent clinical course.

Although HIV is a blood-borne pathogen and can be acquired by routes such as injection drug use or blood transfusion, most transmission occurs via mucosal surfaces through sexual activity. It is increasingly appreciated that mucosal cytokine responses play an important role in

HIV transmission. Study of mucosal cytokines is complicated by difficulties in sample collection, though advances have been made in recent years to standardize collection of samples using techniques such as vaginal wicks. Microbicides are designed to inhibit HIV replication or transmission locally within the genital tract, and early trials of microbicides failed in spite of in vitro anti-HIV activity. It has since been shown that potential microbicides such as nonoxynol-9 can increase genital tract inflammation, paradoxically increasing HIV transmission risk. A recent trial designed to down-modulate inflammation in the genital tract of rhesus macaques showed promise in decreasing transmission of SIV (Li et al. 2009). In humans genital tract inflammatory cytokines at the time of acute HIV infection have been shown to be associated with higher systemic viral load and more rapid CD4⁺ T cell depletion. While much remains to be understood about how mucosal cytokines interact with HIV, the available evidence points to a detrimental role of mucosal inflammatory cytokines in predisposing to HIV acquisition.

Interaction Between HIV and Cytokines During Chronic Infection

During early HIV infection, cytokines first appear during the viral ramp-up, and there is engagement of the innate immune response, which begins to drive the expansion of the antiviral T cell population to limit HIV viral replication. Cytokines including IL-2, IL-4, and IFN- α are not only required to support both humoral and cellular arms of the immune response but also drive activation of HIV-infected cells and replication of virus (Poli and Fauci 1992). However, not all cytokines affect viral replication in the same way. *In vitro* studies using cytokine cocultured with HIV-infected cells show differential effects on viral replication; some cytokines may aid in viral control while others continue to drive HIV replication (Keating et al. 2012). For example, HIV antigen-stimulated T cells produce the inflammatory cytokine TNF- α , which in turn pushes infected cells to increase viral replication. Inflammatory cytokines, including IL-2, IL-6, and IL-18, can trigger latently infected cells to turn on viral production, potentially useful in attempts to flush the virus out of latently infected cells to eliminate HIV from the body. On the other hand, the chemokines MIP-3 β (CCL19) and 6CKINE (CCL21) turn on resting CD4⁺ T cells to be more permissive to infection, allowing expansion of the virus reservoir (Klatt et al. 2013).

After the acute phase of the immune response, when viral replication slows down, the viral level may be controlled by an antiviral immune response mediated by the presence of antibodies and by the induction of cellular immune mechanisms to target and kill HIV-infected cells. The viral load reaches a set point and will remain at this steady state until the last stage of chronic infection. During this time, polyfunctional T cells expressing multiple cytokines have been shown to be more effective in controlling HIV replication (Perreau et al. 2013). However, activation-induced senescence in chronic infection leads to low-function T cell profiles, with decreased cytokine output leading to loss of HIV control and a greater susceptibility to opportunistic infections and microbial translocation. With continued immune activation either by

HIV or other pathogen stimulation, loss of T cell responses and increases in systemic immune activation lead to increased production of inflammatory cytokines.

While immune responses during early infection may be required for HIV control to achieve a lower viral set point, non-sterilizing immunity and uncontrolled viral replication can create a chronic inflammatory state. Cytokine and chemokine production, migration of immune cells through sites of infection, and loss of effective immune responses due to over-activation lead to immunological aging (Deeks 2011). These are all consequences of chronic activation and play a part in the development of HIV-associated comorbidities. In addition, viral or fungal coinfections or movement of commensal microbes into the bloodstream, otherwise known as microbial translocation, may occur because of weakened immune responses in the mucosa and may contribute to a persistent systemic inflammatory state. Inflammatory cytokines are elevated during chronic infection. Elevated levels of TNF- α are seen throughout the course of HIV infection, and levels are significantly higher in uncontrolled HIV replication compared to low viral levels due to successful control (Keating et al. 2011). Even in the individuals who control viremia such as elite controllers or those taking antiretroviral therapy, TNF- α concentrations are significantly higher than in HIV-negative subjects. This shows that even low-level viral replication causes persistent inflammation that is detectable in the plasma. Another inflammatory cytokine, IL-6, has been investigated in chronic HIV infection. There are no significant differences in inflammatory markers during HIV control, but significantly elevated concentrations are found in late-stage AIDS and are associated with comorbidities such as cardiovascular disease, kidney dysfunction, liver fibrosis, and an overall increased risk of death (Kuller et al. 2008).

Inflammatory Cytokines and HIV-Associated Morbidity

With immune senescence and reduced T cell function, where are the inflammatory cytokines

coming from? It is known that monocytes or macrophages express HIV coreceptors and are susceptible to HIV infection, and they are likely important sources of inflammatory cytokines in HIV disease. They are easily triggered by antigenic stimulation through Toll-like receptors, they move in response to chemokines released at infection sites, and they target sites of infection by binding to cell adhesion molecules expressed in the vascular endothelium. Macrophages produce both IL-6 and TNF- α in addition to a number of chemokines that direct immune trafficking; they are responsible for systemic surveillance and regularly move throughout blood and tissue searching for pathogens. Movement of immune cells to sites of infection and continued production of inflammatory cytokines may result in breakdown of tissue integrity, activation of cells to produce collagen, and development of fibrosis.

Adipocytes and adipose-resident immune cells are considered another major source of inflammatory cytokines. The primary function of adipocytes is metabolic regulation and energy storage, and this is sensitive to triggers that engage adipocytes to increase fat storage and produce inflammatory mediators. Cytokines act in triggering adipose cell growth, disrupting insulin-glucose homeostasis and causing insulin resistance. Adipocytes produce MIP-1 α and MCP-1, inducing CCR5-expressing inflammatory (M1) macrophage infiltration and IL-8 secretion, promoting neutrophil infiltration into adipose tissues. While it is not known whether adipocytes possess receptors for HIV, adipocytes from HIV⁺ individuals are responsive to viral antigens and express higher TNF- α and IL-18 mRNA after stimulation compared to uninfected individuals (Koethe et al. 2013). Other adipose hormones, including leptin and adiponectin, are triggered upon inflammation and play a role in the development and regulation of obesity. Leptin, a hormone structurally similar to IL-6, activates macrophages to increase TNF- α , IL-6, and IL-12 production; it promotes antigen-specific Th1 IFN- γ secretion and suppresses Th2 IL-4 production.

Uncontrolled viremia drives accelerated inflammation and induces a number of HIV-related comorbidities including cancers, cardiovascular

disease, liver fibrosis, HIV-associated nephropathy, and neurocognitive dysfunction. Even during immune-mediated viral control or antiretroviral treatment with full viral suppression, there are elevations in inflammatory cytokines. These have been measured in large HIV-treatment cohorts and found to have correlations with increased incidence of cancers, cardiovascular disease, and HIV-associated neurocognitive disorders. Mechanisms of morbidity are not well understood, but infiltration of immune cells has been linked to localized sites of pathogenesis. Cytokine, viral antigen, or microbial antigen activation of the vascular endothelium elevates expression of cell adhesion molecules, enabling targeting of immune cells to sites of infection. In response to chemokine signals, activated monocytes bind to the vascular endothelium and, in the case of HIV-associated neurocognitive disorder, cross the blood-brain barrier. Continued production of inflammatory cytokines disrupts regulatory function in the brain and results in neuronal damage and neurocognitive dysfunction. Similar mechanisms of immune cell infiltration, disruption of cellular homeostasis, and development of fibrosis are found in other comorbidities. Increases in the inflammatory cytokines TNF- α , IL-6, and IL-1 can be measured in the CSF and plasma and used as biomarkers of systemic comorbidities. More research needs to be conducted to understand the common factors that may be at play in each HIV-associated comorbidity.

Potential Therapeutic Roles of Inflammatory Cytokines in HIV

The hallmark of HIV disease is the progressive loss of CD4⁺ T cells, leading to AIDS. With the advent of highly active antiretroviral therapy (HAART), infected individuals are living longer, with improved quality of life. However, the immune systems of HAART-controlled patients are never fully restored, and to some degree, there is continual immune activation. Thus the common γ -chain cytokines (IL-2, L-7, IL-15, IL-21), which are critically important to T cell development, homeostasis, and function, have been proposed as potential adjuvants to HIV therapy. These cytokines and

their functions promote immunity to chronic infections and have been tried or proposed as therapies for HIV, with the intent of full restoration of the T cell compartment.

IL-2 is known to induce expansion of T cells, and as CD4⁺ T cells are the primary target of HIV infection, it was considered a strong candidate for use as an immunotherapeutic agent. There have been phase I and II studies reaching as far back as the 1980s and 1990s (Keating et al. 2012) and more recent phase III trials utilizing IL-2 alone or in combination with HAART to achieve full restoration of the T cell compartment. Although targeted increases in CD4⁺ T cells were achieved in clinical trials, there was no clinical benefit to the increase with respect to morbidity or disease progression. This was attributed in part to increases in regulatory T cells disproportionately to effector T cells. Additional potential uses of IL-2 therapy were investigated with the intention of purging the viral reservoir and deferring or allowing interruptions in HAART to offset the high cost and side effects of lifetime antiretroviral treatment. However, there were no observed clinical benefits with IL-2 therapy, and sometimes there was increased disease progression, resulting in higher morbidity and mortality rates (Keating et al. 2012). Thus IL-2 therapy has largely been abandoned as an immune-based therapeutic intervention in HIV.

The failure of IL-2 therapy brought to light the fact that merely increasing the size of the T cell compartment through immune therapy would not be sufficient to yield clinical benefits, even when combined with HAART. Alternative cytokine therapies were proposed; IL-7, a homeostatic cytokine that promotes differentiation and proliferation of memory CD4⁺ and CD8⁺ T cells, and IL-15, a cytokine that augments proliferation of CD8⁺ memory T cells, were both considered for use as adjuvants to HAART (Carcelain and Autran 2013; Toe et al. 2013). Both IL-7 and IL-15 have been included in multiple preclinical studies (and clinical trials for IL-7) and have shown some promise as potential adjuvants to HAART. Unfortunately, IL-15 was shown to inhibit CD4⁺ T cell recovery and impair viral control (Toe et al. 2013). These studies have raised questions about the viability of IL-15 as

an HAART adjuvant therapy. However, IL-7 remains a viable prospect, and further clinical studies, especially in the acute phase, are needed to fully vet the potential for IL-7 therapy. Other uses for IL-7 have focused on curative strategies to eradicate the latent viral reservoir. It is known that activating resting CD4⁺ T cells will induce viral replication in latently infected cells. If this is done in the presence of antiretroviral drugs that successfully prevent new infections, then it is thought that the reservoir of latently infected cells could be purged. There is evidence that IL-7 can induce latent cells to begin producing virus again, thus making these cells targets for antiretroviral drugs. There are ongoing trials investigating the ability of IL-7 to reactivate the viral reservoir; the results of these studies are pending (Carcelain and Autran 2013). Thus, it remains to be determined if IL-7 can provide the adjuvant to HAART that was hoped of the other common γ -chain cytokines.

The inflammatory cytokine IFN- α has many effects on the host immune system. It is a critical part of antiviral defense and is primarily produced by antigen-presenting cells upon encountering a wide range of foreign antigens. The evidence for dysfunction in the IFN system in HIV has been well documented since the beginning of the epidemic. This led to the investigation of its use as a therapeutic. From these studies IFN- α was first approved as a treatment for AIDS-associated Kaposi sarcoma in 1988 (Keating et al. 2012). As more treatments have been developed for HIV, the use of IFN- α as a frontline treatment for HIV has disappeared. However, pegylated IFN- α is the current standard of care for hepatitis C virus (HCV) infection, though likely to be supplanted soon by new classes of drugs. Recently, the safety and tolerability of IFN- α monotherapy was investigated in antiretroviral-naïve HIV-infected patients (Keating et al. 2012).

Interaction of Cytokines with Intrinsic HIV Restriction Factors

As the potential of IFN- α therapy is investigated, it is important to have a firm understanding of the

type 1 IFN genes that are upregulated in response to treatment. In HIV infection one important group of IFN-stimulated genes is a group that codes for proteins with potent antiviral activities. These are collectively referred to as retroviral restriction factors and impede the replication of many viruses, including HIV, in a variety of ways. There have been three major restriction factors described: apolipoprotein B mRNA editing complex catalytic subunit (APOBEC-3), tripartite motif-containing protein 5 (TRIM5), and tetherin (Neil and Bieniasz 2009). The first host gene to be associated with HIV restriction was the APOBEC-3 family, where three proteins have been identified as HIV restriction factors, APOBEC-3A/F/G. When APOBEC-3 proteins are expressed in infected cells, they are incorporated into viral particles during replication. Subsequently, when those particles infect other target cells, APOBEC-3 proteins catalyze the deamination of deoxycytosine, causing production of viral RNA with high levels of G to A mutations resulting in nonfunctional viruses. Interestingly, they are also highly upregulated by the common γ -chain cytokines IL-2, IL-7, and IL-15 (Neil and Bieniasz 2009; Stopak et al. 2007). The other two major restriction factors, TRIM5 and tetherin, function to inhibit HIV through completely different mechanisms, and both are highly upregulated by IFN- α . When expressed in target cells, TRIM5 is able to recognize viral particles, bind to them, and inactivate them prior to reverse transcription. While human TRIM5 has very weak activity versus HIV, the rhesus macaque TRIM5A α has potent inhibitory activity against SIV-1. Genetic manipulation and engineering of human cells to produce rhesus TRIM5 α in conjunction with IFN- α therapy would potentially induce novel antiviral activity. Another restriction factor induced by IFN- α , tetherin, maintains a potent inhibitory activity against HIV-1. Tetherin induces the formation of protein-based tethers that anchor budding virus particles to the surface of the infected cell, preventing further dissemination of the virus to uninfected cells. These “tethered particles” are susceptible to internalization and lysosomal degradation.

Currently, it is not clear how IFN- α therapy could be harnessed to enhance the function of

restriction factors. HIV encodes multiple proteins to antagonize the activity of APOBEC-3 proteins and tetherin, which poses a barrier to the effectiveness of immunotherapy that increases expression of these restriction factors. Clearly, there is a need for a better understanding of how these factors elicit inhibitory activity and interact with downstream adaptive immunity against HIV. A recent study has indicated that the amount of restriction factor induced is critical to realizing any potential clinical benefits (Abdel-Mohsen et al. 2014). In addition, there are over 30 restriction factors that have been associated with direct inhibition of HIV-1 in vitro that are expressed in human peripheral blood. When measured in whole peripheral blood mononuclear cells or isolated CD4⁺ T cells, many of these restriction factors are induced to supraphysiologic levels following in vivo IFN- α therapy (Abdel-Mohsen et al. 2014). Interestingly, both tetherin and A3G have significantly increased expression in CD4⁺ T cells following IFN- α therapy (Pillai et al. 2012). These studies highlight the fact that suppressive effects of restriction factors are critical to exogenous IFN- α treatment. Given the well-documented negative effects of endogenous IFN- α , it is provocative that exogenous IFN- α treatment is able to significantly increase restriction factor expression without increasing CD4⁺ T cell activation (Abdel-Mohsen et al. 2014; Keating et al. 2012). Thus the future of IFN- α as an HIV therapy is yet to be determined, and its potential points to the growing need for both in vitro and in vivo investigations into cytokine treatment to modify restriction factor expression.

Conclusions

As the ability to measure multiple cytokines simultaneously has improved, it has become clear that HIV causes a profound disruption of the cytokine network from the earliest points of HIV infection, shortly after first detection of systemic virus. This dysregulation of cytokines can be partially but not completely reversed via suppression of viral replication through pharmacologic or immunologic control. While HIV likely

exploits proinflammatory cytokines to promote viral replication, there are multiple potential avenues to use these factors to help control HIV replication or ameliorate the damage inflicted by the virus on CD4⁺ T cells. In summary, our knowledge of the depth and breadth of cytokine perturbation is increasing exponentially, and with this new knowledge comes the potential of harnessing the immune system to limit viral replication and collateral damage to the host immune system.

Definition

Heterosexual transmission is currently the major mode of HIV transmission worldwide. In addition to the CD4⁺ T cells which are the

principal target, several other potential HIV target cell types including antigen-presenting cells (APCs) (dendritic cells, macrophages) residing at mucosal sites can be also infected. The capacity of these APCs to replicate cell-free virus is low but they transfer HIV-1 to CD4 T lymphocytes efficiently. The various modes of infection are responsible for rapid and efficient replication of HIV-1 and its dissemination through the organism. Preventing cell-to-cell transmission of HIV-1 is crucial for inhibiting HIV-1 propagation, and either antiretroviral drugs or anti-HIV-1-specific antibodies (Abs) can be used.

Introduction

The annual number of new HIV infection has been in decline since 2005 and the major mode of HIV transmission is now through sexual contact. Mucosal sites (genital tracts or anal mucosa) contain various types of immune cells, antigen-presenting cells (APCs) including dendritic cells (DCs) and macrophages, and various types of T cells (principally activated or memory CD4 T lymphocytes), all initially targeted by HIV-1 (Shattock and Moore 2003; Su and Moog 2014). However, the capacity of APCs to replicate HIV is far lower than that of CD4 T cells and infected APCs are rarely detected *in vivo*. Consequently, the precise chronology of infection and replication capacity is still a matter of debate.

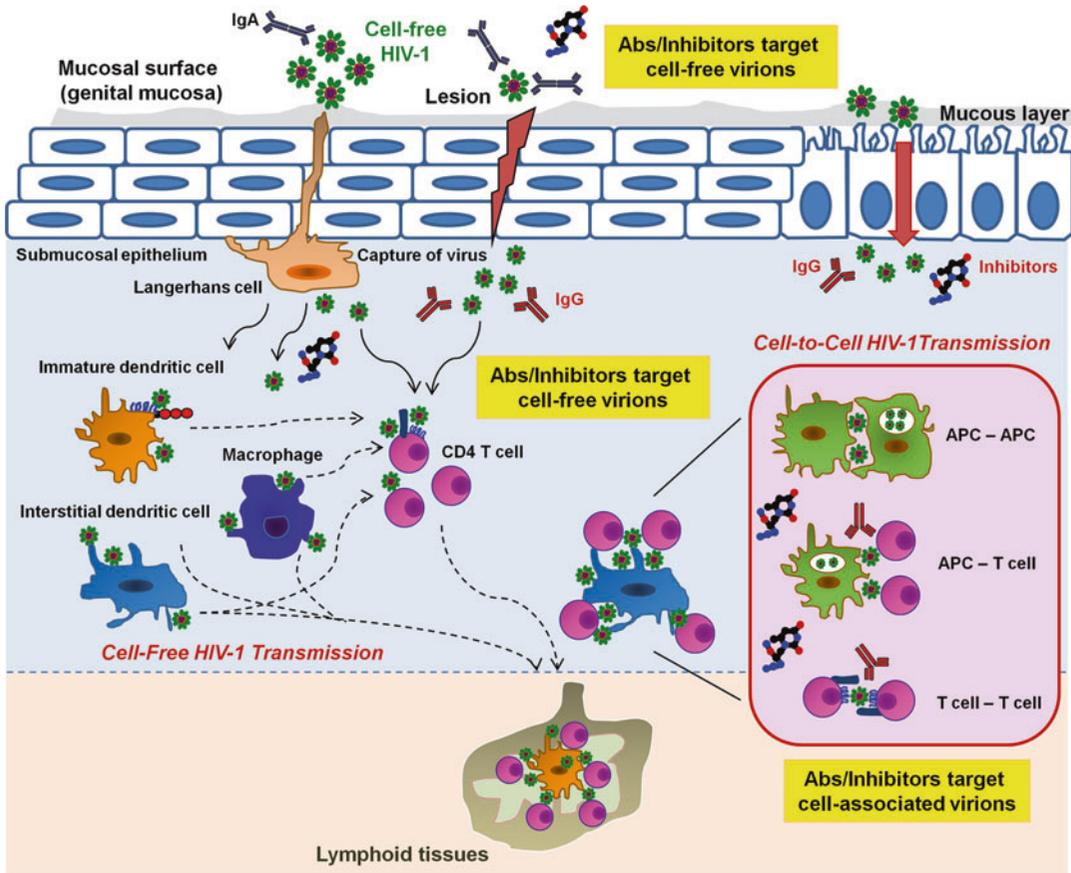

The mechanism of the migration of viral particles through the epithelial barrier remains unclear. Various modes of infection have been proposed, and they include transfer through epithelial cells, transport of HIV via DCs present at mucosal surfaces, and direct infection of resident CD4 T cells (Cunningham et al. 2013; Su and Moog 2014) (Fig. 1). Thereafter, HIV migrates to lymphoid tissues. There are two mechanisms by which HIV-1 infects immune cells: infection by cell-free virus and cell-to-cell transmission. It has been suggested that this second mode of HIV infection makes a large contribution to HIV propagation and dissemination through the body. Spread of HIV-1 infection through direct cell-to-cell transmission has been shown to be

100–1,000-fold more efficient than infection by cell-free virions (Su and Moog 2014).

The mucosal immune/humoral response involves essentially IgG and secretory IgA. IgG and IgA able to neutralize free viral particles would be expected to inhibit the infection of mucosal HIV target cells before the establishment of systemic infection. Such Abs, by preventing the infection of the first target cells of the virus, may therefore constitute the first line of defense at the portal of virus entry (Fig. 1). Also, once cells are infected, subsequent virus dissemination through cell-to-cell contact should also be inhibited. Here, the different modes of HIV-1 spread, through cell-free or cell-to-cell transmission, are described; then the inhibitory activities of Abs and antiretroviral inhibitors for both types of transmission are reviewed and their contribution to protection against HIV-1 is considered.

The Mechanisms of Cell-Free and Cell-to-Cell Transmission

The relative significance of cell-free and cell-associated virus to HIV-1 infection is still a matter of debate, but numerous studies suggest that direct cell-to-cell transmission of HIV makes a large contribution to its rapid dissemination throughout the body. This mode of transmission has substantial consequences for the design of treatments or vaccine strategies. Indeed, cell-associated HIV may be less sensitive to various therapeutic approaches, and particularly Abs, than cell-free virus. Moreover, the cellular environment of the mucosa may contribute to determining the mode of infection. In inflamed or injured tissues, the recruitment of activated T cells would tend to favor direct infection of these target cells. Several *in vitro* assays have been developed to study the infection of cells by free viral particles and by cell-to-cell transmission. Infection with free virus is dependent on the expression of the HIV-1 receptors and co-receptors and a “conventional” fusion of HIV-1 to the target cells. By contrast, there are various mechanisms associated with cell-to-cell infection (commonly called “transfer”) depending on the cells involved and

Inhibition of HIV-1 Spread: Cell-Free Versus Cell-Cell, Fig. 1 The mucosal port of HIV-1 entry. HIV-1 infection can occur via genital mucosal tissues, which comprise a multicellular layer of stratified squamous epithelial cells. Both cell-free and cell-associated infectious HIV-1 virions can infect host cells. Cell-free HIV-1 can gain access to Langerhans cells which can transport the virus into the subepithelium. Mucosal lesions may also provide an accessible pathway for HIV-1. In the subepithelium, immature DCs and macrophages which are enriched in HIV-1 attachment factors like C-type lectins and CD4⁺ T cells are infected either directly by cell-free virions or by cell-

associated virions. HIV-1-infected immature DCs then migrate to lymphoid tissues that are enriched in CD4⁺ T cells, facilitating HIV-1 dissemination through the body. These infected immature DCs can differentiate into mature DCs during migration. Mature DCs can present HIV-1 antigens to CD4 T cells in the lymphoid tissues and initiate antiviral adaptive immune responses. Cell-free virus can be bound and neutralized by mucosal IgA (IgA) at mucosal surfaces. Antiviral inhibitors and adaptive immune responses, such as secreted IgG, are important for preventing HIV-1 infection and dissemination in vivo

their phenotypes. In the environment of the mucosa, the transmission of cell-free virus is plausible, as is the transfer of cell-associated virus between various APCs and neighboring lymphocytes (Fig. 1).

The interactions between APCs and T cells were among the first to be studied. This cell-cell interaction was shown to enhance viral spread substantially, and several distinct mechanisms are involved (formation of virological synapses,

endosomes, and increased binding of virus to alternative receptors) (Sattentau 2010; Su and Moog 2014). Two mechanisms of HIV-1 transfer from DCs to T lymphocytes have been described: *trans*-infection and *cis*-infection (Coleman et al. 2013). The efficient and rapid passage of virus has been described as *trans*-infection. Several publications report that immature DCs capture HIV and efficiently transfer it to neighboring CD4 target cells (Sattentau 2010). This direct transfer can be

rapid and is highly dependent on the type of donor cells (DCs, macrophage, or T cells) and particularly on the receptors expressed and the function of the donor cells; it involves the formation of virological synapses between two cells, secretion of exosomes, or direct binding to alternative receptors (Su and Moog 2014). The *trans*-infection of CD4 T lymphocytes was demonstrated to be transient as HIV-1 transfer decayed within the first 24 h (Turville et al. 2004).

The second mode of transfer is *cis*-infection. This long-term transfer occurs after conventional HIV-1 fusion and *de novo* virus production in donor cell (Turville et al. 2004); it involves close cell-to-cell contacts following synthesis of new viral particles and possibly the formation of virological synapses.

During chronic infection, most HIV-1 replication is in CD4⁺ T lymphocytes from lymphoid tissue. Therefore, cell-to-cell transmission between T cells is likely to be the most common mode of HIV-1 spread in this stage. Indeed, virological synapses formed between T cells have been extensively described (Dale et al. 2013). Altogether, these various modes of cell-to-cell transmission of HIV may favor HIV escape recognition by or interaction with Abs/inhibitors and allow it to hijack the immune system. Inhibition of cell-to-cell HIV transfer is therefore central to the fight against this infection.

Role of Antibodies and Antiretroviral Inhibitors in Preventing HIV-1 Transmission

The protective role of neutralizing antibodies (NAbs) against HIV has been demonstrated. HIV-specific Abs (mainly IgG) can neutralize free viral particles and inhibit infection of various HIV mucosal target cells *in vitro* (Su and Moog 2014; Holl et al. 2006). However, their role in inhibition of HIV transfer is more controversial. Here, recent observations which may be informative about which Abs and antiretroviral inhibitors could contribute to protection against HIV-1 transmission through cell-free or cell-associated pathways are discussed.

Mechanisms of Inhibition of HIV Transmission via Cell-Free Mechanisms

Neutralization Activity

Abs of various subtypes can inhibit infection of HIV target cells through various mechanisms that are or are not dependent on additional effectors cells or mechanisms. The most studied HIV inhibitory activity of Abs is neutralization. Neutralization is the inhibition of HIV replication by Abs in the absence of other additional components, such as Fc receptors (FcR) or complement. Five neutralizing monoclonal antibodies (NAbs) have been analyzed extensively over more than 10 years (IgG1 b12, 2F5, 4E10, 447-52D, and 2G12), and new broadly neutralizing antibodies (bNAbs) have recently been discovered (e.g., PGT monoclonal Abs 121–123 and 125–128, VRC01, VRC03, and PG9, PG16, etc.) (Su and Moog 2014; Kwong et al. 2013). These NAbs are able to inhibit a broad spectrum of HIV-1 strains (cell-free infection) *in vitro*, as assessed in conventional neutralization assays with peripheral blood mononuclear cells (PBMCs) or HIV-1-permissive cell lines (TZM-bl) (Heyndrickx et al. 2012). They target crucial conserved epitopes of HIV (CD4bs, gp41), thereby impeding attachment and fusion processes. However, NAbs isolated from infected patients are rare and complex and result from a long maturation process (Kwong et al. 2013). bNAbs could not be induced by vaccination; however partial protection (31% efficacy) was observed in the RV144 phase III Thailand trial through the induction of non-neutralizing antibodies (NNAbs) and a moderate T-cell response (Haynes et al. 2012).

Fc Receptor-Mediated Inhibition

In addition to neutralizing HIV-1, NAbs can also inhibit HIV-1 infection through additional mechanisms. The FcR-dependent mechanism of inhibition has been observed for various HIV target cells expressing these receptors, such as DCs, Langerhans cells, and macrophages (Su and Moog 2014). The involvement of interactions with FcR in HIV inhibition is confirmed with the cell line TZM-bl expressing various Fc γ Rs. This Fc-mediated inhibition increased by 10–1,000-

fold the inhibitory activity of NAbs against the infection of FcR-bearing cells. Some HIV-1-specific Abs lacking neutralizing activities display Fc-mediated inhibitory activities (Su and Moog 2014; Holl et al. 2006). Such Abs, able to inhibit HIV-1 replication by the Fc γ R-dependent mechanism only, are referred to as non-neutralizing inhibitory Abs (NNIAbs) (Holl et al. 2006). Binding to Fc γ RI can augment the conventional entry-inhibiting neutralizing activity of Abs recognizing multiple epitopes on gp120 and gp41 of HIV-1 (Perez et al. 2013). Neutralization titers for NAbs 4E10 and 2F5 were increased as much as 5,000-fold in the presence of Fc γ RI expression on the surface of TZM-bl (Perez et al. 2013). For APCs bearing Fc γ R, binding of immune complexes formed between Abs and HIV leads to destruction of the virus by phagocytosis and its degradation by specific lysosomes. High affinity between IgG and HIV-1 may therefore be relevant for both neutralizing activity and FcR-mediated transcytosis of the virus-IgG complex. These findings illustrate the potential role of Fc γ R-mediated innate and adaptive immune functions in the mechanism of HIV protection. In addition, FcR can be also involved in Abs-dependent enhancement of HIV-1 binding to, and infection of, certain cell types.

ADCC Activity

ADCC (antibody-dependent cellular cytotoxicity) is also related to FcR-dependent mechanisms (Forthal et al. 2013; Su and Moog 2014). It mainly involves FcRIII (CD16) and consists of recognizing an infected target cell by Abs. The additional binding of the Fc domain of Abs to the FcR of an effector cell (mainly NK cells) induces the lysis of the infected cell following NK cell degranulation.

ADCVI Activity

ADCVI (antibody-dependent cell-mediated virus inhibition) results from an interaction between an infected target cell, an HIV-specific Ab, and an effector cell expressing one or several Fc γ Rs. ADCVI encompasses multiple effector function activities related to lytic (e.g., ADCC) and non-cytolytic (e.g., production of β -chemokines) mechanisms dependent on Fc γ Rs that may

interfere with HIV infection and replication (Forthal et al. 2013; Su and Moog 2014; Holl et al. 2006).

Overall, the inhibitory activity of NAbs against virus infection of these target cells is due to distinct mechanisms of inhibition: classical neutralization of the virus infectivity involving the Fab part of the antibody and FcR-dependent mechanisms of inhibition, such as phagocytosis, ADCC, or ADCVI. Therefore, cell-free virus can be inhibited by various inhibitory mechanisms expressed by Abs to prevent infection of diverse HIV target cells.

Mechanisms of Inhibition of HIV-1 Spread via Cell-to-Cell Transmission

Inhibition of cell-associated HIV-1 infection (also called cell-to-cell transfer) is even more complex. Numerous mechanisms lead to cell-to-cell transfer and *cis/trans*-infection, and they differ according to the donor and target cells. Several groups have studied the inhibition of HIV-1 transfer by Abs, but a multitude of diverse models of HIV-1 transfer have been used (Fig. 2). Inhibitory activity may differ between donor and target cells, viral strains, and technique for assessing transfer; consequently, results are divergent and controversial, with some indicating that HIV-1 transfer is resistant to NAbs, whereas others demonstrate an efficient inhibition of HIV-1 replication by entry inhibitors or NAbs (reviewed in Fig. 2) (Schiffner et al. 2013; Su and Moog 2014). The chapter below presents some mechanistic explanations for inhibition of cell-to-cell transfer by HIV-1-specific Abs or inhibitors.

Inhibition of Cell-to-Cell Transfer Is Cell Type Dependent

Co-cultures of various HIV-1 donor cells with specific target cells in cell-to-cell transfer assays allow efficient HIV-1 transmission mainly via the formation of virological synapses. T cell-to-T cell and APC-to-T cell transfer experiments have been used to analyze the activity of specific anti-HIV-1 Abs and inhibitors against HIV-1 transmission. Most work on T cell-to-T cell HIV transmission describes the close contact between CD4 T lymphocytes leading to HIV transfer in *trans*

Inhibition of HIV-1 Spread: Cell-Free Versus Cell-Cell, Fig. 2 Inhibition of cell-to-cell HIV-1 transfer by HIV-1 specific Abs/inhibitors

via the formation of virological synapses to be resistant to inhibitory Abs and entry inhibitors (Fig. 2); the Jurkat cell line was used as the donor cells in these assays. Other studies, based on other cell lines or primary lymphocytes in HIV-1 transfer assays, found that, on the contrary, Abs were able to inhibit HIV-1 transfer (Fig. 2). Indeed, the characteristics of the cell-to-cell contact appear to depend on the donor/target cells used. Zhong et al. recently showed that HeLa and Jurkat T cells produced and released 10- and 40-fold less cell-free HIV than HEK293, respectively (Fig. 2). However, they showed that co-cultures of Jurkat donor cells with HeLa, MT4, and Jurkat target cells resulted in HIV spread being about 100-fold more efficient, associated with greater resistance of HIV-1 transmission to NAbs. In contrast, co-cultures of HEK293 donors and MT4 target cells, which are highly permissive to cell-free HIV-1, were most sensitive to all NAbs tested. These findings suggest that the strength of the synapse established and the efficiency of HIV-1 transfer influence the inhibitory activity of Abs.

Abela et al. showed that bNAbs VRC01 did not block cell-mediated HIV-1 transmission from HIV-1-infected PBMC donor cells to TZM-bl target cells and proposed that cell-to-cell transmission enables HIV-1 to evade inhibition by these Abs (Fig. 2). Sagar's team reported a similar phenomenon (Fig. 2): using TZM-bl as target cells, they found that NAbs directed against the transmembrane domain membrane proximal external region gp41 were much more effective than CD4bs-directed Abs at restricting cell-associated HIV-1 transmission (Fig. 2). This preferential inhibition by anti-gp41 Abs may be linked to the use of TZM-bl as target cells. Indeed, these cells overexpress CD4/CCR5 HIV-1 receptor/co-receptor entry molecules which may artificially augment the first attachment step of HIV-1; consequently, the inhibitory activity of anti-gp120 Abs will be weaker than that of anti-gp41 Abs.

Although the cell lines used as effectors and target cells are generally accepted as appropriate models for analysis of HIV-1 transfer, they are poorly representative of HIV-1 transfer because they may not reflect the cross talk that takes place between primary immune cells *in vivo*.

Immunological synapses formed between cell lines differ from those involving primary cells (Sattentau 2010). For example, the close interaction (cross talk) observed between primary DC/T cells involves adhesion molecules such as ICAM-1 and LFA-1 (Su et al. 2014; Rodriguez-Plata et al. 2013), independent of HIV-1 envelope proteins (Rodriguez-Plata et al. 2013); this is absent from TZM-bl cell lines.

The immunological synapses formed between primary DCs and T cells may be the most pertinent because DCs can be considered to be APCs closely interacting with autologous lymphocytes for the initiation and modulation of the immune response. Interestingly, with these two primary cell types, almost every NAb tested showed efficient inhibitory activity (Fig. 2). By dissecting the early steps of HIV-1 transfer from DCs to autologous primary CD4 T lymphocytes, Su et al. showed that NAbs, added to HIV-1-exposed DCs at the same time as CD4 T lymphocytes, were able efficiently to inhibit the transfer of HIV-1 *in trans* and *in cis* from DCs to CD4 T lymphocytes (Fig. 2). Similar inhibitory activity by Abs/inhibitors has also been observed by others (Fig. 2) (Su and Moog 2014), suggesting that HIV-1 transfer from DCs to T lymphocytes is not resistant to Abs/inhibitors.

Virus Types in the Cell-to-Cell HIV-1 Transfer Assay
Most work with cell-to-cell transfer assays has used laboratory-adapted HIV-1 strains and particularly the molecular clone NL4-3 or recombinant Env-pseudovirus particles encoding a green fluorescent protein (GFP) or luciferase protein (Luc) (Fig. 2). Primary HIV isolates, such as subtype B HIV-1_{BaL}, have also been tested by several laboratories (Fig. 2). Although primary viral isolates are more biologically relevant than pseudovirus particles, the most pertinent viruses for studies of the inhibition of HIV-1 transfer would be HIV-1 transmitted/founder (T/F) viruses. Indeed, they are of particular interest as they display the specific features supporting their selection, propagation, and dissemination. However such viruses have not yet been studied in analyses of the inhibition of HIV-1 transfer, and clearly this is required.

Inhibition of HIV-1 Binding, Fusion, or Replication and Readout for Cell-to-Cell HIV-1 Transfer

Various steps of the inhibition of HIV-1 transfer have been studied. Indeed, cell-associated HIV-1 infection of target cells depends on the following steps: CD4 binding, co-receptor binding, membrane fusion, and viral replication. The results, or readout, will depend on the virus used (pseudovirus particles expressing or not expressing GFP/Luc or fully replication-competent virus). Van Montfort et al. analyzed HIV-1 binding by confocal microscopy and showed that transfer of virus to T cells can be enhanced if the virus is coated with Abs and taken up via the Fc receptor on DCs (Fig. 2). They showed that 2F5-neutralized virus captured by immature DCs was able to bind and subsequently be transferred to CD4 T lymphocytes following the formation of virological synapses, whereas NAb b12 had no such effect. Blocking DC-SIGN completely abolished the uptake of 2F5-neutralized virus, indicating that DC-SIGN mediated the capture of the 2F5/HIV-1 immune complex by immature DCs. However in this study the late steps of virus fusion and replication of the virus transferred was not defined. On the contrary, by analyzing these late steps of HIV-1 replication, inhibition of HIV-1 transfer by Abs/inhibitors was observed. Cavrois et al. showed that truncated recombinant soluble CD4 (sCD4) inhibits the uptake of surface-bound HIV-1 virions using virion-based fusion assays (Fig. 2). This inhibition of *trans*-infection by surface-accessible HIV was confirmed by Yu et al. (Fig. 2). Frankel et al. showed that NAbs b12, 2F5, and 2G12 were able to inhibit HIV replication in the supernatants of co-cultured DC/T cells (Fig. 2).

Massanella et al. reconciled the diverse effects of Abs on HIV-1 transfer (Fig. 2). They showed that, although anti-gp41 NAbs 4E10 and 2F5 were not able to block the formation of virological synapses, HIV-1 spread between T cells was fully sensitive to all NAbs tested; this suggests that HIV is transmitted between T cells by a neutralization-sensitive mechanism involving HIV budding from infected cells and capture by target cells. Indeed, DCs may sequester intact infectious HIV-1 particles into compartments destined for lysosomal degradation. Cavrois et al. showed

that the virus internalized into these compartments does not substantially contribute to productive transfer of infection but rather leads to viral degradation (Fig. 2). This model of HIV-1 binding and transfer was also described recently for macrophages infected with HIV-1 (Fig. 2). Thus, the internalized virus did not need to be inhibited by NAbs as it was destined for degradation. However, they found that HIV-1 is transmitted by a sensitive viral fusion step. Fluorescence microscopy and electron tomography studies showed that the viruses were retained on the external plasma membrane and consequently remained accessible to neutralizing monoclonal Abs and to various HIV-1 fusion inhibitors (Fig. 2). This illustrates how better understanding of the mechanisms of HIV-1 binding to and entry into immunologically privileged endocytic compartments will help reveal inhibition-relevant characteristics that will contribute to the analysis of cell-to-cell HIV-1 transmission.

Nevertheless, although they analyzed virus replication, some studies found that Abs and antiviral drugs fail to inhibit T-cell-associated HIV-1 transmission (Fig. 2). Ganesh et al. measured early HIV replication by p24 ELISA and flow cytometry and found that the percentage of HIV-1 transfer from DCs to T cells was not substantially affected by NAbs b12 and 2F5 (Fig. 2). This lack of inhibition may be due to virus produced by the donor cells. Indeed, Holl et al. showed that DCs become highly competent for HIV replication in the context of co-culture with CD4 T cells (Holl et al. 2010). If donor DCs were infected before addition of NAbs, they will escape from Ab inhibition and a first round of HIV replication will occur. It is therefore essential to know if transfer studies are performed with noninfected HIV-1-loaded DCs, or with HIV-1-infected DCs/macrophages, or with HIV-1-infected PBMC, or with productively infected T cells in the context of T cell-to-T cell HIV-1 transmission (Fig. 2). If donor cells are infected before addition of Abs, this will unavoidably affect the apparent inhibitory activity of NAbs especially if early HIV-1 replication is analyzed.

Increased transmission of CXCR4-tropic virus associated with NAbs was reported by van

Montfort et al. (Fig. 2). Again, this may be explained by modifications of DC features in co-cultures; indeed, maturation of DCs has been observed in the presence of CD4 T lymphocytes (Fig. 2) (Su and Moog 2014). Such DC maturation may favor transmission and replication of X4 viruses using DC donor cells.

Overall, the modification of phenotype and the effective replication of HIV in co-cultured donor DCs raise numerous issues for the analysis of inhibition of HIV transmission by Abs. Further studies are needed to clarify these phenomena to facilitate the analysis of HIV replication in transfer experiments from DCs.

FcR-Mediated Inhibition of Cell-Associated Infection

As donor and target cells produce virus, it is important to determine which of these cell types produce the newly synthesized virus. This is particularly important for DCs and macrophages as these cells express FcRs. Abs can bind FcRs and inhibit HIV-1 transfer via FcR-mediated inhibitory activity. Some NNABs, like 246-D, which do not affect HIV-1 transfer from infected DCs to CD4 T lymphocytes, have been found to reduce significantly the percentage of infected DCs in co-cultures (Su et al. 2012). For these Abs, a strong association was found between Fc γ R-specific binding capacity, inhibition of HIV-1 replication, and DC maturation. This suggests that the binding of these Abs to DCs induces the maturation of these cells, resulting in lower levels of R5 virus replication (Su et al. 2012). Indeed, the major effect of Fc γ Rs engagement in DCs is induction of maturation. Also, HIV infection and provirus formation are impaired in immature DCs in the presence of HIV-specific IgG and complement: the long-term transfer of HIV from DCs to CD4 T cells was impeded by HIV-specific IgG, whereas the addition of these Abs and/or complement to activated PBMC did not protect them from HIV infection (Wilflingseder et al. 2007). There may be unconventional mechanisms of HIV inhibition in DCs but not in PBMC, leading to the suggestion that the lower levels of infection mediated by HIV/IgG immune complexes may result from interactions between

virus-bound IgG and Fc γ RIIb expressed on DCs (Wilflingseder et al. 2007). Therefore, Fc-mediated inhibitory activity of Abs on the infection of DCs may also participate in decreased HIV-1 transfer to T cells.

Comparison of HIV-1 Inhibitory Activity of Abs Against Infection with Cell-Free Versus Cell-to-Cell Transfer

Comparisons of the inhibitory activities of Abs between cell-free and cell-associated virus is tricky because of the diverse inhibitory mechanisms involved. Su et al. showed that the inhibitory activity of NABs against HIV-1 transfer was similar to that observed in neutralization assays involving PBMCs or CD4 T lymphocytes (Fig. 2). Both cell-to-cell and cell-free viral spread are similarly sensitive to entry inhibition (Fig. 2). However, studies comparing inhibition of cell-free transmission and cell-associated transfer with T-cell lines mostly observed weaker inhibition of cell-associated transfer (Fig. 2). For example, Chen et al. demonstrated that patient sera that neutralize 78–99% of cell-free infection but have little or no effect on Jurkat cell line-to-T cell HIV-1 transfer (Fig. 2). At the same concentration, the same patient sera were capable of blocking only 38–50% of cell-associated HIV-1 transfer (Fig. 2). Zhong et al. using luciferase assays showed that NABs efficiently inhibit cell-free HIV-1 but were less effective against cell-associated virus and that cell-to-cell transmission can overcome multiple combinations of donor/target cell lines barriers (Fig. 2). In addition, two studies using TZM-bl cells as target cells also found that NABs directed against the CD4-binding site were very much less potent in HIV-1 transfer studies (Fig. 2). Overall, they found HIV-1 transfer involving cell lines to be quite resistant to Ab inhibition compared to cell-free infection. Conversely, the type of cell-free assay may also influence the outcome of the comparison. For PBMC neutralizing assay conditions, the cells are incubated with free virus particles and are then cultured for several days. During this period, the cells are in close contact with each other and cell-to-cell HIV-1 transfer may occur. Therefore, conventional neutralization assays

involving PBMC and readouts of HIV-1 replication after several rounds of HIV-1 replication may in fact assess the capacity of Abs to inhibit cell-to-cell transmission of HIV-1; consequently, comparisons between the inhibition of cell-free and of cell-associated virus need to be interpreted with caution.

Antiretroviral Inhibitor-Mediated Inhibition of Cell-Associated Infection

Cell-associated HIV-1 infection may increase the probability of viral escape from antiretroviral inhibition. Sigal et al. observed that the antiretroviral drugs tenofovir and efavirenz substantially decreased cell-free infection whereas infections involving cell-to-cell spread were markedly less sensitive without requiring drug-resistance mutations (Sigal et al. 2011). This result suggests that antiretroviral therapy may not interfere with the persistence of viral replication due to cell-associated infection in vivo. On the contrary, others found that antiretroviral drugs blocked T cell-to-T cell HIV-1 transmission with an efficacy equivalent to that for blocking cell-free infection (Permyer et al. 2012). These divergent results were recently resolved by Duncan et al. (Fig. 2): using equivalent multiplicities of infection for macrophage-produced virus and for T-cell infection by the cell-free and cell-to-cell routes, they observed that inhibition by antiretroviral drugs (raltegravir, nevirapine, and azidothymidine) was equally effective in both cell-free and cell-to-cell infections (Fig. 2). They demonstrated that the effectiveness of inhibition is not influenced by the mode of viral transmission but is dependent on the multiplicity of infection.

Spread of HIV-1 Infection In Vivo and Their Inhibition by Antibodies

HIV-1 transmission in vivo occurs by the transfer of blood, vaginal secretions, semen, or breast milk. The combination of both cell-free particles and HIV-1-infected immune cells present in these bodily fluids in vivo can influence early HIV transmission and also its inhibition. Almost all studies of cell-to-cell HIV-1 transfer have been

based on focused on in vitro models, and there have been few relevant studies in vivo.

The effects of Abs and antiretroviral drugs on HIV-1 transfer in vivo remain unclear. The protective role of HIV-1-specific Abs has been extensively studied in various experimental models of infection, including nonhuman primate models (NHP), with cell-free virus challenges (Klein et al. 2013; Su and Moog 2014), but never following infection with cell-associated virus. Cell-free virus infection at mucosal sites may involve various steps of HIV-1 transfer from cell-to-cell for efficient replication and dissemination (Fig. 1). The potential role of Fc γ R-mediated innate and adaptive immune functions in addition to neutralization has been repeatedly demonstrated in the mechanism of HIV protection (Su and Moog 2014). Dennis Burton's group has shown that neutralizing monoclonal IgG1 b12, devoid of Fc-Fc γ R functions, has decreased protective potential following vaginal challenge in NHPs (Hessell et al. 2007). NNIAbs were able to reduce the viral load in challenged macaques without conferring complete protection (Moog et al. 2014; Burton et al. 2011). The activation of human macrophages, through Fc γ R cross-linking, may contribute to the natural protection against HIV infection. In addition, it has been reported that NNAb activities correlated with the reduction of acute viremia in vaccinated macaques, demonstrating that NNABs elicited by immunization may play an important role in the control of the acute phase of infection; possibly, this could be exploited to fight HIV (Forthal et al. 2013). A correlation between the presence of a particular allele of Fc γ R and an increased risk of infection has been evidenced in a subgroup of volunteers with low-risk practices (Forthal et al. 2013). These results suggest that some specific HIV Abs may possibly have a deleterious effect in a subpopulation of patients with a particular Fc γ R genotype. These various observations clearly indicate that, in addition to neutralization, Fc γ Rs are important in the mechanism of protection in vivo. Such effective protection observed in vivo suggests that HIV-specific Abs inhibit infection by cell-free virus and cell-to-cell transfer, both mechanisms contributing to HIV-1 replication and dissemination in the body.

Conclusion

The last decade has witnessed enormous advances in our knowledge about HIV-1 transmission. Nevertheless, the protective role of HIV-1-specific Abs/inhibitors against cell-to-cell transfer of HIV both in vitro and in vivo, although extremely important, has not been fully elucidated. Neutralization of cell-free HIV-1 infection in vitro has been extensively studied, but deciphering the divergent findings for inhibition of cell-to-cell transfer of HIV-1 would be of great help in the development of anti-HIV strategies. The inhibitory activities of various agents are diverse and appear to depend on the donor and target cells, on the viruses used, and the way the results of transfer experiments are scored; nevertheless, numerous studies indicate that some NAbs can efficiently inhibit cell-to-cell HIV-1 transfer and replication. In addition, although experimental challenges involve cell-free viruses, there is likely to be cell-associated HIV-1 transfer following challenges at mucosal sites; NAbs that are effective in such assays may therefore be effective against cell-to-cell HIV-1 transmission in vivo. These are very encouraging observations for the development of effective vaccines. Further in vivo studies are needed to explore mechanistic aspects of inhibition of HIV-1 cell-to-cell transmission in more detail. In particular, work involving challenges with transmitted/founder viruses and infected cells, for example, may confirm the potential of NAbs and antiretroviral drugs for inhibition of HIV-1 transfer. Altogether, a better understanding of HIV-1 transmission via cell-free mechanisms and cell-associated mechanisms would lead to new therapeutic and next-generation vaccine approaches for inhibiting HIV-1 transmission (Su and Moog 2014; Kwong et al. 2013; Klein et al. 2013).

Initial Antiretroviral Regimens

Joel Gallant

Southwest CARE Center, Santa Fe, NM, USA

Definition

The first antiretroviral drug regimen used to treat a previously treatment-naïve HIV-infected patient.

Introduction

Although there are many possible choices for initial antiretroviral therapy (ART) in an HIV-infected patient, only a small subset of the potential options are now recommended in treatment guidelines used in most resource-rich settings. Recommendations are based on a combination of efficacy, safety, tolerability, convenience, and in some cases cost. This review will focus primarily on regimens recommended and used in the United States, where cost has traditionally not been a criterion for guideline

selection. However, that may change as less expensive generic drugs become available.

US guidelines include those from the Department of Health and Human Services (DHHS), which are updated approximately once a year (Panel on Antiretroviral Guidelines for Adults and Adolescents 2015), and those from the International Antiviral Society (IAS-USA), updated every 2 years (Gunthard et al. 2014). In the past, it was customary to classify individual drugs as “preferred” or “alternative.” Clinicians then used the guidelines to combine a “backbone” consisting of two nucleoside or nucleotide analog reverse transcriptase inhibitors (NRTIs) with a “third agent” (at that time a protease inhibitor [PI] or non-nucleoside reverse transcriptase inhibitor [NNRTI]).

This approach has been replaced by the categorization of specific regimens – as opposed to agents – as either “recommended” or “alternative.” The reason for this change is that not all recommended third agents (to which integrase strand transfer inhibitors [INSTIs] have been added) have been studied equally with the two recommended NRTI backbones, and when they have, efficacy may differ. However, this review will discuss agents by class, as well as discuss specific regimens.

The Nucleoside “Backbone”

It may seem surprising that today, almost 20 years after the introduction of highly active antiretroviral therapy (HAART) in the mid-1990s, all recommended initial ART regimens still include two NRTIs plus a third agent. Multiple “NRTI-sparing regimens,” two-drug regimens, and even single-drug regimens have been studied, but while it is assumed that there is nothing “magic” about three drugs, nothing else to date has performed well enough to replace this standard approach in US guidelines or practice.

Only two backbones are currently recommended: tenofovir disoproxil fumarate (TDF) with emtricitabine (FTC) and abacavir (ABC) with lamivudine (3TC). Both are coformulated as single tablets and also with third agents as single-tablet regimens (STRs).

Tenofovir/Emtricitabine (TDF/FTC)

TDF/FTC is a component of more recommended regimens than ABC/3TC, as it has been more extensively studied, and it was more effective than ABC/3TC when combined with either efavirenz (EFV) or ritonavir-boosted atazanavir (ATV/r) in patients with high baseline viral loads (Sax et al. 2011). It is generally safe and well tolerated but does have two important potential toxicities: nephrotoxicity and loss of bone mineral density.

The primary mechanism of TDF-associated nephrotoxicity is proximal tubulopathy, typically manifested by proteinuria, glycosuria, and/or urinary phosphate wasting. The presence of glucose in the urine in a nondiabetic, a high fractional excretion of phosphate (>20%), and overt Fanconi syndrome (with or without evidence of glomerular dysfunction) are fairly specific for tubulopathy. However, patients on TDF may develop a decline in the estimated glomerular filtration rate (eGFR) without laboratory evidence of tubulopathy. In such cases, while the decline in kidney function may be due to other factors (e.g., hypertension, diabetes, or other nephrotoxic agents), it may still be appropriate to discontinue TDF to avoid exacerbating progression of kidney disease. Alternatively, the dosing interval can be increased based on the eGFR according to labeled indications. Discontinuation is preferred over dose modification in patients with evidence of TDF-associated tubulopathy.

A decline in bone mineral density (BMD) is observed after the initiation of all currently available NRTI-based regimens. This decline occurs within the first 6–12 months of therapy and then stabilizes over time. The decline is more pronounced with TDF-containing regimens. It also appears to be at least partially reversible, since discontinuation of TDF is associated with an increase in BMD. This effect should be a consideration in patients with preexisting osteoporosis or osteopenia. In the United States, routine BMD testing is now recommended in HIV-infected postmenopausal women and men over 50 years old.

When patients fail therapy with a TDF/FTC-containing regimen, they typically first develop

the M184V mutation, conferring high-level resistance to 3TC and FTC but increasing susceptibility to TDF and zidovudine (ZDV). With ongoing viral replication, K65R, the signature TDF mutation, may emerge, resulting in a decrease in TDF and ABC susceptibility but further increasing ZDV susceptibility. From a resistance standpoint, ZDV would be a logical NRTI choice after failure of TDF/FTC with K65R and M184V, but this strategy is no longer recommended because of the toxicity and poor tolerability of ZDV, as well as the availability of other options.

TDF and FTC are available as a coformulated product and are also combined with other agents (efavirenz, rilpivirine, and elvitegravir/cobicistat) in three STRs.

Abacavir/Lamivudine (ABC/3TC)

The DHHS guidelines currently recommend ABC/3TC as an NRTI backbone in combination with the integrase strand transfer inhibitor (INSTI) dolutegravir. A coformulated single-tablet regimen combining these three drugs is available. It is recommended as an alternative backbone in combination with ritonavir- or cobicistat-boosted darunavir. The DHHS guidelines no longer list the combination of ABC/3TC with either EFV or boosted ATV as either recommended or alternative regimens because of the lower efficacy in patients with baseline viral loads above 100,000 c/mL compared with TDF/FTC (Sax et al. 2011). This difference in efficacy based on viral load was not observed with the combination of ABC/3TC with DTG, which is why it is a recommended regimen (Walmsley et al. 2013).

ABC can cause a serious hypersensitivity reaction (HSR) during the first weeks of therapy. Deaths have been reported with ABC rechallenge after resolution of HSR. Fortunately, the possibility of HSR can essentially be excluded by pre-testing for HLA-B*5701. ABC should not be prescribed to those who test positive, and the negative predictive value is 100%.

In some observational studies, ABC has been associated with an increased risk of myocardial infarction. While the mechanism of this potential association is unknown, and it has not been observed in clinical trials or in all observational

studies, guidelines recommend avoiding ABC in patients who are at high cardiac risk.

When patients fail therapy with an ABC/3TC-containing regimen, they typically first develop the M184V mutation, conferring high-level resistance to 3TC and FTC and a modest decline in susceptibility to ABC. M184V increases susceptibility to TDF and ZDV. With ongoing viral replication, L74V, the signature ABC mutation, may emerge, resulting in a further loss of ABC susceptibility. While TDF should retain activity in the presence of M184V and L74V, this sequencing strategy has never been shown to be effective clinically, perhaps because of the presence of K65R at low levels in patients failing ABC.

Both ABC and 3TC are available in generic form. The two drugs are coformulated and are also components of a single-tablet regimen in combination with dolutegravir.

Other NRTIs

No other NRTIs are currently recommended in current US guidelines. *Stavudine* (d4T) causes mitochondrial toxicity, including peripheral neuropathy, lipoatrophy, hepatic steatosis, and lactic acidosis. In addition to those toxicities, *didanosine* (ddI) also causes acute pancreatitis and has been associated with irreversible non-cirrhotic portal hypertension. Although still widely used worldwide, *zidovudine* (AZT, ZDV) causes gastrointestinal side effects, fatigue, macrocytic anemia, lipoatrophy, hepatic steatosis, and lactic acidosis.

Investigational NRTIs

Like TDF, *tenofovir alafenamide* (TAF) is a pro-drug of tenofovir (TNF). However, compared to TDF, TAF achieves higher intracellular TNF levels, including distribution into the lymphoid tissue, with lower plasma levels. There is early evidence that the lower plasma levels result in less loss of bone density and possibly less kidney toxicity and that the higher intracellular levels may increase activity against NRTI-resistant virus. It is expected that TAF will first be approved in coformulation with elvitegravir, cobicistat, and FTC. Later products will include coformulations with FTC, rilpivirine/FTC, and eventually darunavir/cobicistat/FTC.

Integrase Inhibitors

All but one of the DHHS-recommended regimens for initial ART contain INSTIs, which block the integration of reverse-transcribed viral DNA into the host DNA. As a class, INSTIs are highly effective, safe, and well tolerated. They also suppress viral load more rapidly than other antiretroviral classes, although the clinical significance of this characteristic is unknown.

Raltegravir (RAL)

RAL was the first approved INSTI. It was initially used primarily for treatment-experienced patients with drug resistance, but subsequent studies demonstrated outstanding efficacy and tolerability in treatment-naïve patients as well. RAL has few side effects. Creatine kinase elevation has been observed but is rarely clinically significant. There are few significant drug interactions. RAL is dosed twice daily, although a once-daily formulation is being studied. No coformulated products containing RAL have been approved. Failure on a RAL-based regimen can lead to INSTI mutations, which typically result in cross-resistance to elvitegravir. Dolutegravir may retain activity, except in the presence of the Q148 mutation in combination with at least two other INSTI mutations. RAL is a recommended INSTI in pregnant women.

Elvitegravir (EVG)

EVG is the only INSTI that requires pharmacologic “boosting.” Cobicistat (COBI) is generally used for that purpose, and while both drugs are available as stand-alone products, they are more commonly used as components of an STR that also includes TDF and FTC. This combination is a recommended regimen for initial therapy in DHHS and IAS-USA guidelines. Because it is a cytochrome P450 (CYP) 3A4 inhibitor, COBI interacts with many other drugs, with an interaction profile that is similar, but not identical, to that of the PI ritonavir. EVG/COBI is dosed once daily. It is generally well tolerated, although nausea can occur, typically resolving after the first few days of therapy (Clumeck et al. 2014; Wohl et al. 2014). Failure on an EVG-based regimen

can lead to INSTI mutations that typically cause cross-resistance to RAL. However, dolutegravir may retain activity except in the presence of the Q148 mutation in combination with at least two other INSTI mutations.

COBI inhibits tubular secretion of creatinine, resulting in a modest increase in serum creatinine and a decline in the estimated glomerular filtration rate (eGFR). This effect is seen within the first few weeks of therapy and then stabilizes. It is a laboratory effect only and does not represent true nephrotoxicity. Any progressive decline in eGFR cannot be attributed to COBI and should prompt an evaluation for other causes of kidney damage, including TDF toxicity.

EVG can also be given in combination with boosted PIs, although this is a strategy that would apply only to treatment-experienced patients.

Dolutegravir (DTG)

DTG is a potent, well-tolerated INSTI. The DHHS guidelines recommend DTG in combination with either ABC/3TC (with which it is coformulated as an STR) or with TDF/FTC. In treatment-naïve patients, it was superior to both EFV and DRV/r based on better tolerability (Walmsley et al. 2013; Clotet et al. 2014). In INSTI-naïve, treatment-experienced patients, it was superior to RAL. It has relatively few drug interactions, though somewhat more than RAL.

Like COBI, DTG inhibits tubular secretion of creatinine, with a resulting decline in eGFR that does not represent true nephrotoxicity.

No drug resistance has yet been reported in treatment-naïve patients taking DTG in an initial regimen, suggesting that it has a higher genetic barrier to resistance than either RAL or EVG. It remains to be seen whether its resistance barrier is as high as that of boosted PIs. DTG retains activity against some RAL- and EVG-resistant virus, especially when given at a higher dose (50 mg twice daily). The presence of a Q148 mutation in combination with at least two other INSTI mutations substantially decreases DTG susceptibility.

Investigational INSTIs

Cabotegravir is an unboosted INSTI that is being studied both in oral form and as a long-acting

injection that could be administered infrequently for treatment or prevention (preexposure prophylaxis) of HIV. Although it is an analog of DTG, resistance has been observed in patients failing cabotegravir.

GS-9883 is an unboosted, once-daily INSTI currently in phase II testing. It appears to have characteristics similar to those of DTG. If approved, it is expected to be coformulated with TAF/FTC.

Protease Inhibitors

PIs bind to HIV protease, preventing cleavage of polyproteins required for viral assembly. Although they have been mainstays of therapy since their introduction in the mid-1990s and are still widely used in treatment-experienced patients, they are less frequently used for initial therapy because of the availability of other options, most notably the INSTIs. PIs are almost always used in combination with either ritonavir (RTV) or COBI, which are used as pharmacoenhancers or “boosters” to increase serum levels, prolong half-life, and allow for lower doses and/or less frequent administration. In addition, patients without preexisting PI resistance do not appear to develop PI resistance on boosted PIs, which was not the case when PIs were used without boosting. For that reason, boosted PI-based regimens continue to be popular choices for initial therapy in patients with unreliable adherence.

Both RTV and COBI inhibit tubular secretion of creatinine, resulting in the early increase in eGFR, discussed above. The effect is somewhat more pronounced with COBI than with RTV. There are no other significant tolerability or toxicity differences between the two agents.

Both RTV and COBI are CYP3A4 inhibitors and therefore have many drug interactions.

Darunavir (DRV)

DRV boosted with RTV is now the only PI recommended in the DHHS guidelines for initial therapy, based on the demonstration of superiority over atazanavir in a large clinical trial (Lennox et al. 2014). DRV requires pharmacologic

boosting, traditionally with RTV. However, the coformulation of DRV with COBI is now approved and is currently categorized as an alternative PI by the DHHS guidelines. When used for initial therapy, ritonavir-boosted DRV (DRV/r) and COBI-boosted DRV (DRV/c) are given at doses of 800/100 mg and 800/150 mg, respectively. Treatment-experienced patients who have DRV resistance mutations should use only DRV/r at a dose of 600/100 mg twice daily.

DRV is well tolerated but can sometimes cause rash, which may or may not be self-limiting. It has more gastrointestinal side effects (e.g., loose stools) than RAL or DTG but fewer than ATV/r. DRV should be taken with food for maximal absorption.

DRV/r is a recommended PI in pregnant women.

Atazanavir (ATV)

ATV, boosted either with RTV or COBI, is now categorized as an alternative PI, based primarily on a large clinical trial showing inferiority to DRV/r and RAL (Lennox et al. 2014). This was based primarily on tolerability and toxicity differences. Specifically, ATV causes an increase in indirect bilirubin, which can sometimes lead to overt jaundice or scleral icterus. ATV was also associated with more gastrointestinal toxicity than RAL or DRV/r in that trial. Other known toxicities of ATV include nephrolithiasis, nephrotoxicity, and cholelithiasis. ATV requires gastric acid for absorption and should be used with caution and appropriate dose separation with antacids, H₂ blockers, and proton pump inhibitors. ATV should be taken with food.

ATV is usually dosed at 300 mg daily, boosted either with RTV (100 mg) or as a coformulated product with COBI (150 mg) (Gallant et al. 2013). However, unlike DRV, ATV does not achieve adequate serum levels when given at a dose of 400 mg daily without boosting, which is a consideration in patients where tolerability concerns or drug interactions prevent boosting. Boosting is required when ATV is given with TDF, which lowers ATV levels.

ATV/r is a recommended PI in pregnant women.

Other PIs

Lopinavir/ritonavir (LPV/r) was an important PI for many years and was the first to be coformulated with a booster. It is still the most widely used agent for second-line therapy in resource-limited settings. However, it is no longer recommended in the United States because of its poorer tolerability and greater toxicity and higher pill burden compared with DRV and ATV. The dose of RTV in LPV/r is 100 mg twice a day, compared to the 100 mg once-daily dose used with DRV and ATV. This may partly explain why it has more gastrointestinal side effects and metabolic toxicity, including dyslipidemia. LPV/r remains a recommended PI in pregnant women.

Fosamprenavir (FPV) is a well-tolerated PI that can be given either boosted with RTV (700/100 mg twice daily or 1400/100–200 mg once daily for PI-naïve patients) or unboosted 1400 mg twice daily. It is infrequently used because of the availability of better studied PIs with lower pill burdens (DRV and ATV). The use of unboosted FPV is not recommended as it can lead to cross-resistance with DRV. FPV can cause a rash, which may or may not require discontinuation.

Saquinavir (SQV) is boosted with RTV at a dose of 1000/100 mg twice daily. It is no longer recommended, mainly because compared to DRV and ATV, it has a higher pill burden (6 per day), a higher dose of RTV with greater metabolic toxicity, and the potential for QTc prolongation.

Nelfinavir (NFV) is the only PI that is given only in unboosted form. It is not recommended because of poorer efficacy and toxicity (diarrhea).

Indinavir (IDV) can be given either unboosted (800 mg every 8 h) or boosted with ritonavir (800/100 mg twice daily). It is no longer recommended because of toxicity, including insulin resistance, GI side effects, retinoid-like effects (alopecia, dry skin, mouth, and eyes), nephrolithiasis and nephrotoxicity, indirect hyperbilirubinemia, lipodystrophy, hyperlipidemia, and paronychia.

Tipranavir (TPV) is used only in treatment-experienced patients with PI resistance. Because

of its greater toxicity compared to DRV, it is typically reserved only for patients with virus that is susceptible to TPV but not to DRV.

Non-nucleoside Reverse Transcriptase Inhibitors

NNRTIs inhibit the activity of viral reverse transcriptase by binding directly to the enzyme. They have been mainstays of initial therapy for many years but are being used less frequently in the United States because of the availability of INSTIs. No NNRTI-based regimen is included in the list of recommended regimens in the April 2015 version of the DHHS guidelines.

Efavirenz (EFV)

EFV has been a gold standard agent for many years and is still a component of recommended regimens in most treatment guidelines used worldwide, with the exception of the DHHS guidelines. It is also available in a single-tablet regimen coformulated with TDF and FTC. It has an outstanding record for safety and efficacy but also has significant tolerability disadvantages. Specifically, it is associated with neuropsychiatric side effects such as dizziness, vivid dreams or nightmares, sleep disturbance, concentration difficulties, and less commonly depression and hallucinations. These effects are most pronounced during the first days to weeks of therapy and then improve or resolve. However, some side effects can be persistent, and one study found an increased risk of suicidality (suicidal ideation or attempted or completed suicide) in patients taking EFV. EFV can also cause a rash with early therapy, which may or may not require discontinuation.

EFV is a recommended NNRTI in pregnant women, but only after the first eight weeks of pregnancy because of the potential for neural tube defects.

Rilpivirine (RPV)

RPV is classified as an alternative agent in the DHHS guidelines, for use in patients with

baseline viral loads below 100,000 copies/mL and CD4 counts above 200 cells/mm³. It is available in a single-tablet regimen coformulated with TDF and FTC. Its primary advantage is outstanding tolerability. The disadvantages include poorer efficacy at high viral loads and low CD4 counts, the requirement for dosing with a meal, and the effect of proton pump inhibitors, H2 blockers, and antacids on absorption. In addition, resistance to RPV can lead to partial cross-resistance to all other NNRTIs, including etravirine, because of the signature E138K mutation. Like etravirine, RPV is active against EFV- and NVP-resistant virus with the K103N mutation. Clinical trials have demonstrated excellent efficacy and tolerability in patients who switched from other NNRTIs or PIs to RPV/TDF/FTC.

Nevirapine (NVP)

NVP is still widely used worldwide, but the initiation of NVP-based regimens is no longer recommended in the United States, primarily because of the potential for serious early toxicity: hepatotoxicity, including hepatic necrosis, and skin toxicity, including Stevens-Johnson syndrome and toxic epidermal necrolysis. These toxicities are more common in women and in patients with higher baseline CD4 counts. In addition, NVP has not been as well studied as EFV in combination with the two recommended NRTI backbones: TDF/FTC and ABC/3TC. NVP is also more likely than EFV to select for mutations that cause cross-resistance to etravirine, most notably Y181C.

Other NNRTIs

Etravirine (ETR) is an effective and well-tolerated agent that may have a higher barrier to resistance than other NNRTIs. However, it has not been well studied for initial therapy and is approved only for use in treatment-experienced patients, generally those with resistance to “first-generation” NNRTIs (NVP and EFV).

Delavirdine (DLV) is rarely used because of inconvenience (three times daily dosing) and relative lack of efficacy data compared to recommended NNRTIs.

Investigational NNRTIs

Doravirine (DOR) is an investigational NNRTI that appears to have activity against virus with common NNRTI mutations, including K103N and Y181C.

Entry Inhibitors

There are two approved entry inhibitors: *maraviroc* (MVC), a CCR5 antagonist, and *enfuvirtide* (ENF, T20). MVC can only be given to patients with exclusively R5-tropic virus, determined by tropism testing. ENF requires twice-daily subcutaneous injections and causes painful injection site reactions. Neither is recommended for initial therapy in treatment-naïve patients.

Choosing the Initial Regimen

The choice of the initial regimen should be made after consideration of a variety of factors, including comorbidities, concomitant medications, food requirements, possibility of pregnancy, and likelihood of adherence.

The most recent version of the DHHS guidelines lists five “recommended” regimens (Table 1), all but one of which consist of two NRTIs plus an INSTI. However, they point out that “alternative” regimens may be preferred in some patients. The following is a discussion of the choice of initial regimen for specific patient types and clinical scenarios:

Desire for a Single-Tablet Regimen (STR)

Two STRs are classified as “recommended” regimens in the DHHS guidelines: EVG/COBI/FTC/TDF and DTG/ABC/3TC. Either is an excellent choice for a large proportion of patients. The former has the advantage of including TDF/FTC as the NRTI backbone, which has generally been preferred in other regimens. However, there are potential renal and bone toxicities associated with TDF and drug interactions with COBI. DTG/ABC/3TC appears to have a higher barrier to resistance than EVG/COBI/FTC/TDF.

Initial Antiretroviral Regimens, Table 1 Advantages and disadvantages of antiretroviral drugs and regimens for initial therapy

Recommended initial regimens all consist of two NRTIs (the “backbone”) plus one “third agent”			
Drug/regimen	Forms and brand names	Advantages	Disadvantages
Nucleoside analog reverse transcriptase inhibitor “backbones” (to be combined with third agent)			
Tenofovir/emtricitabine (TDF/FTC)	<i>Truvada</i> (and part of <i>Atripla</i> , <i>Complera</i> , and <i>Stribild</i>)	<ul style="list-style-type: none"> • The recommended NRTI backbone in combination with most third agents • Three single-tablet regimens (STRs) available: <i>Atripla</i>, <i>Complera</i>, and <i>Stribild</i> • Both drugs are active against hepatitis B • A preferred NRTI backbone in pregnancy 	<ul style="list-style-type: none"> • Can cause kidney toxicity (monitor creatinine and urinalysis) • Causes more loss of bone density than other drugs
Abacavir/lamivudine (ABC/3TC)	<i>Epzicom</i> , <i>Kivexa</i> (and part of <i>Trizivir</i> and <i>Triumeq</i>)	<ul style="list-style-type: none"> • No kidney toxicity • Less effect on bone density than TDF • Available in an STR with DTG • A preferred NRTI backbone in pregnancy 	<ul style="list-style-type: none"> • Must pretest with HLA-B*5701 to avoid ABC hypersensitivity reaction • Less effective than TDF/FTC when combined with EFV or ATV/r in patients with viral loads >100,000 c/mL • May increase risk of myocardial infarction (controversial): avoid or use with caution in patients with multiple cardiac risk factors
Didanosine (ddI)	<i>Videx</i> , <i>Videx EC</i> , or generic	None	Not recommended
Stavudine (d4T)	<i>Zerit</i> , <i>Zerit XR</i> , or generic	None	Not recommended
Zidovudine (ZDV, AZT)	<i>Retrovir</i> or generic (and part of <i>Combivir</i> , <i>Trizivir</i>)	A preferred NRTI backbone in pregnancy (ZDV/3TC)	Not recommended
Third agents			
Non-nucleoside reverse transcriptase inhibitors			
Efavirenz (EFV)	<i>Sustiva</i> (and part of <i>Atripla</i>)	<ul style="list-style-type: none"> • Extensively studied • STR available (<i>Atripla</i>) • Remains in the blood for a long time: “forgiving” of missed doses • See TDF advantages (for <i>Atripla</i>) • Preferred NNRTI in pregnancy after the first 8 weeks 	<ul style="list-style-type: none"> • Can cause neurologic or psychiatric side effects, especially in the first few weeks; long-term effects also occur • Potential for rash • Resistance is common if treatment fails • May cause birth defects if given to pregnant women during the first trimester <ul style="list-style-type: none"> • Less CD4 increase than with other third agents (PIs, INSTIs) <ul style="list-style-type: none"> • See TDF disadvantages (for <i>Atripla</i>)
Rilpivirine (RPV)	<i>Edurant</i> (and part of <i>Complera</i> , <i>Eviplera</i>)	<ul style="list-style-type: none"> • STR available (<i>Complera</i>) • Better tolerated than <i>Sustiva</i> and <i>Atripla</i> (less rash, neurologic side effects, and effect on lipids) • See TDF advantages (for <i>Complera</i>) 	<ul style="list-style-type: none"> • Must be taken with a meal • Gastric acid is required: decrease absorption with proton pump inhibitors, H2 blockers, antacids • Resistance is common with treatment failure, including cross-resistance to ER • Recommended only if viral load <100,000 c/mL and CD4 > 200 cells/mm³ • See TDF disadvantages (for <i>Complera</i>)

(continued)

Initial Antiretroviral Regimens, Table 1 (continued)

Recommended initial regimens all consist of two NRTIs (the “backbone”) plus one “third agent”			
Drug/regimen	Forms and brand names	Advantages	Disadvantages
Delavirdine (DLV)	<i>Rescriptor</i>	None	Not recommended
Etravirine (ETR)	<i>Intencele</i>	<ul style="list-style-type: none"> • Well tolerated • May be less prone to resistance than other NNRTIs • Can be dissolved in water 	Not recommended for initial therapy because of lack of data
Nevirapine (NVP)	<i>Viramune</i> , <i>Viramune XR</i> , or generic	<ul style="list-style-type: none"> • Well tolerated and safe after the first few weeks/months • Safest NNRTI in pregnancy • Generic form available 	<ul style="list-style-type: none"> • Not recommended for initial therapy (US guidelines) • Can cause severe liver toxicity or skin rash during the first few weeks, especially in women with pretreatment CD4 counts >250 cells/mm³ or men with counts >400 cells/mm³ • Resistance is common if treatment fails; more likely to cause ETR cross-resistance than EFV
Protease inhibitors			
Atazanavir/ritonavir (ATV/r), atazanavir/cobicistat (ATV/COBI), or atazanavir (ATV)	<i>Reyataz</i> / <i>Norvir</i> , <i>Evotaz</i> , or <i>Reyataz</i>	<ul style="list-style-type: none"> • The best PI if boosting is not possible • Resistance is unlikely with failure (when boosted) • A preferred PI in pregnancy (ATV/r) 	<ul style="list-style-type: none"> • Can cause jaundice • Should be taken with food • Should not be taken with proton pump inhibitors • More GI side effects than DRV • Can cause nephrolithiasis, cholelithiasis, nephrotoxicity
Darunavir/ritonavir (DRV/r) or darunavir/cobicistat (DRV/COBI)	<i>Prezista</i> / <i>Norvir</i> or <i>Prezcobix</i>	<ul style="list-style-type: none"> • The only recommended PI (DRV/r) in the DHHS guidelines • The best tolerated PI • Resistance is unlikely with failure • A preferred PI in pregnancy (DRV/r) 	<ul style="list-style-type: none"> • Should be taken with food • Can cause rash • More GI toxicity than RAL
Lopinavir/ritonavir (LPV/r)	<i>Kaletra</i> , <i>Aluvia</i>	Resistance is unlikely with failure	<ul style="list-style-type: none"> • No longer a recommended PI for initial therapy in US guidelines • More GI side effects than ATV/r or DRV/r • More lipid effects than ATV or DRV
Fosamprenavir (FPV)	<i>Lexiva</i>	Can be given unboosted	<ul style="list-style-type: none"> • No longer recommended for initial therapy • Greater pill burden than recommended PIs, with no COBI coformulation • Potential for DRV cross-resistance (when given unboosted)
Indinavir (IDV)	<i>Crixivan</i>	None	Not recommended
Nelfinavir (NFV)	<i>Viracept</i>	None	Not recommended
Ritonavir (RTV)	<i>Norvir</i>	Used only as a low-dose booster for other PIs	Should not be used at full dose to treat HIV infection
Saquinavir (SQV)	<i>Invirase</i>	None	Not recommended
Integrase inhibitors			
Raltegravir (RAL)	<i>Isentress</i>	<ul style="list-style-type: none"> • Few side effects • Few drug interactions • Preferred INSTI in pregnancy 	<ul style="list-style-type: none"> • Twice-daily dosing • No STR available • Lower barrier to resistance than DTG

(continued)

Initial Antiretroviral Regimens, Table 1 (continued)

Recommended initial regimens all consist of two NRTIs (the “backbone”) plus one “third agent”

Drug/regimen	Forms and brand names	Advantages	Disadvantages
Elvitegravir (EVG)	<i>Vitekta</i> (and part of <i>Stribild</i>)	<ul style="list-style-type: none"> • Part of an STR • Tolerability advantages over EFV or PIs • See TDF advantages (for <i>Stribild</i>) 	<ul style="list-style-type: none"> • Lower barrier to resistance than DTG • <i>Stribild</i>: <ul style="list-style-type: none"> – See TDF disadvantages – COBI drug interactions similar to RTV – COBI inhibits creatinine secretion, resulting in decreased eGFR without true nephrotoxicity <ul style="list-style-type: none"> – Indicated only for patients with creatinine clearance >70 mL/min; should be discontinued if creatinine clearance falls to <50 mL/min
Dolutegravir (DTG)	<i>Tivicay</i> (and part of <i>Triumeq</i>)	<ul style="list-style-type: none"> • Few side effects • Few drug interactions • Higher barrier to resistance than RAL or EVG • <i>Triumeq</i>: <ul style="list-style-type: none"> – See ABC advantages – The only non-TDF-containing STR 	<ul style="list-style-type: none"> • Inhibits creatinine secretion, resulting in decreased eGFR without true nephrotoxicity • See ABC disadvantages (for <i>Triumeq</i>)

However, it requires pretesting for HLA-B*5701, and the potential toxicities of ABC must be considered. Both COBI and DTG inhibit tubular excretion of creatinine, causing an early decline in eGFR that does not represent nephrotoxicity.

Multiple Cardiac Risk Factors

Although the association between ABC and myocardial infarction remains controversial, guidelines recommend avoiding ABC in patients with high cardiac risk. In such patient, TDF is preferred, assuming normal renal function. Potential options would include EFV/COBI/FTC/TDF or DTG plus TDF/FTC.

Chronic Kidney Disease (CKD)

TDF should generally be avoided in patients with CKD. The one exception might be the patient who presents with HIV-associated nephropathy (HIVAN), which is expected to improve on ART. Patients with ESRD on hemodialysis can safely be treated with weekly TDF, provided no recovery of renal function is expected. In general, ABC is preferred in patients with CKD, though such

patients may also have multiple cardiac risk factors, in which case an NRTI-sparing regimen could be considered (see below). Potential options for the patient with CKD but low cardiac risk would include DTG/ABC/3TC or RAL plus ABC/3TC. Because DTG interferes with tubular creatinine excretion, an early decline in eGFR should be expected but does not represent worsening of CKD. If a PI-based regimen is chosen, DRV is preferred over ATV because of the potential nephrotoxicity of ATV. Either RTV or COBI can be used as pharmacoenhancers, although COBI will cause a somewhat greater decline in eGFR.

Questionable Adherence

When there are questions about the patient’s ability to adhere to therapy, a regimen with a high barrier to resistance has generally been preferred. Counterintuitively, this typically meant prescribing a PI-based regimen, which required taking multiple pills, as opposed to an easier to take single-tablet regimen (typically EFV/TDF/FTC). Today, PI-based regimens require only two pills

per day (either DRV/c or ATV/c plus either TDF/FTC or ABC/3TC). In addition, the single-tablet regimen DTG/TDF/FTC appears to have a high barrier to resistance. It remains to be seen whether it is as high as that of a boosted PI, but many clinicians are already extrapolating from clinical trials and using this regimen in patients with questionable adherence, assuming that resistance will not occur with failure. The investigational single-tablet regimen DRV/COBI/FTC/TAF will be another promising option for such patients. Patients who demonstrate good adherence on ART over time have the option of switching therapy.

Hepatitis B Coinfection

Whenever possible, patients with HIV/HBV coinfection should be treated with a regimen that includes TDF/FTC (or TDF plus 3TC), since all three drugs have activity against HBV. In patients who cannot take TDF, usually because of kidney disease, entecavir should be added to the regimen. An ABC/3TC-based regimen without entecavir is not sufficient, since it will lead to the development of 3TC-resistant HBV.

Hepatitis C Coinfection

There are no drugs that are contraindicated in patients with HCV coinfection, but the potential for interactions with drugs used to treat HCV makes RAL and DTG ideal choices for the third agent. Ledipasvir increases tenofovir levels. Since RTV-boosted PIs also boost tenofovir levels, there is concern that the combination could result in a higher risk of TDF toxicity, a concern that may also apply to COBI-boosted PIs and EVG. When changing the ART regimen is not possible, frequent monitoring of kidney function is advised during the course of HCV therapy.

Pregnancy

Current perinatal guidelines recommend an NRTI backbone of TDF/FTC, ABC/3TC, or ZDV/3TC plus either ATV/r, DRV/r, or RAL for the treatment of HIV-infected pregnant women. However, since ZDV is not recommended in any other setting and may exacerbate the nausea of pregnancy, TDF/FTC and ABC/3TC are generally preferred.

EFV has been associated with neural tube defects in the first trimester and should never be chosen in a woman planning to become pregnant or who is sexually active with men and not using birth control. However, EFV does not need to be discontinued in a woman who is found to be pregnant, since the neural tube will have already closed by that time, and it is now the preferred NNRTI after the eighth week of pregnancy. Worldwide, EFV is the most commonly used third agent, including in women of child-bearing potential.

Drug Interactions

Among the commonly used ART regimens, COBI and RTV have the greatest potential for drug interactions. There are too many interacting drugs to describe here, but clinicians should be especially aware of interactions with nasal and inhaled steroids (especially fluticasone), intra-articular steroid injections, statins, oral contraceptives, rifampin, and rifabutin. The third agents with the fewest drug interactions are RAL and DTG. The absorption of ATV and RPV is inhibited by proton pump inhibitors, H₂ blockers, and antacids, which should be avoided or taken only with careful dose separation, depending on the agent.

Food Restrictions

Some of the commonly used regimens should be taken with food for maximum absorption. These include regimens that include DRV, ATV, and EVG. RPV is especially dependent on food and should be taken with a meal. EFV is typically taken on an empty stomach, at least 2 h after a meal, to decrease CNS side effects. For patients who would have problems with these restrictions, DTG- or RAL-based regimens may be the best choices.

Transmitted Resistance

No generalizations can be made about the treatment of patients with baseline transmitted resistance mutations, since treatment must be individualized based on the resistance patterns. The NNRTI class is the one most likely to be affected by transmitted mutations, followed by

NRTIs. It would be unusual for a patient to be infected with a virus that was fully resistant to any PI, so boosted PI-based regimens have typically been used in such patients. The frequency of transmitted integrase mutations remains low, and baseline INSTI resistance testing is not currently recommended. Because of its high barrier to resistance, a DTG-based regimen might also be considered in a patient with some transmitted NRTI resistance, although there is limited experience with this approach.

Initiation of ART Without Baseline Resistance Data

This would typically be considered in a patient who needed immediate ART because of acute HIV infection, or in a patient with advanced HIV infection, especially if accompanied by a condition that could only be treated by ART (e.g., HIVAN, progressive multifocal leukoencephalopathy, or HIV dementia complex). PI-based regimens are often chosen, in part, because transmitted PI resistance is uncommon but also because of concerns about adherence in patients who present at these stages. As noted above, DTG-based regimens might also be considered in such cases. It is not known whether the more rapid viral suppression seen with INSTIs has clinical advantages. In patients with advanced disease, there is speculation that it could be a disadvantage, by potentially increasing the risk of immune reconstitution inflammatory syndrome (IRIS).

Side Effects or Desire for Simplification

Virologically suppressed patients who are experiencing side effects on ART or who desire simplification to a single-tablet regimen can easily switch therapy, provided there is no resistance to any of the components of the new regimen. There are strong safety and efficacy data from trials evaluating switches to RPV/TDF/FTC and EVG/COBI/TDF/FTC, and it is assumed that switches to DTG-based regimens would also be safe and effective. In the case of switches to RPV/TDF/FTC, the pretreatment viral load does not appear to affect efficacy the way it does when the regimen is used for initial therapy.

Patients Who Cannot Take Either TDF or ABC

The typical example is a patient with either kidney disease or osteoporosis who also has multiple cardiac risk factors or is positive for HLA-B*5701. There are currently no “NRTI-sparing regimens” recommended by guidelines, and selection of such regimens requires some extrapolation from existing data. The combination of a boosted PI and an NNRTI has been studied, but not with contemporary agents. The combination of LPV/r and EFV was effective but associated with unacceptable side effects and metabolic toxicity. Regimens containing DRV/r plus ETR have been studied but only in treatment-experienced patients. Thus, a combination of either DRV/r or DRV/c plus either ETR or RPV could be considered.

More commonly, clinicians tend to use boosted PIs plus INSTIs. To date, all studies evaluating such regimens have used RAL. For unclear reasons, the combination of DRV/r plus RAL has shown decreased efficacy compared to standard therapy in patients with high baseline viral loads (Raffi et al. 2014). Whether the results would have been different with DTG cannot be determined.

Patients who cannot take TDF or ABC can still take 3TC or FTC, which can be added to the regimens discussed above in the hope that this will increase efficacy. In fact, the data supporting “nuke-lite” regimens consisting of a boosted PI plus 3TC alone are stronger than those supporting boosted PIs plus INSTIs, offering a third potential approach to patients unable to take TDF or ABC.

At the present time, all NRTI-sparing regimens should include a boosted PI if possible. However, other approaches are under study, including DTG plus either RPV or 3TC, and an induction-maintenance strategy in which patients are switched to RPV plus the investigational INSTI cabotegravir after achieving virologic suppression.

Conclusion

There are now a number of outstanding options for initial therapy. The enthusiasm for INSTI-based regimens, which now comprise four of the five recommended regimens in the DHHS guidelines, is justified based on their established

efficacy, safety, and tolerability. Until more is known about the resistance profile of DTG, a PI-based regimen (usually with DRV/r or DRV/c) is a reasonable choice for patients with unreliable adherence.

The guidelines point out that while the number of recommended regimens for initial therapy has become relatively small, patients doing well on other agents do not necessarily need to switch therapy. A switch from older NRTIs (i.e., ZDV, d4T, ddI) is advisable because of their long-term toxicity, including damage to mitochondrial DNA. Switching from an older PI (e.g., LPV/r) to boosted DRV or ATV may improve lipids and decrease gastrointestinal toxicity. However, patients experiencing no side effects on NVP or EFV may safely remain on their existing regimen, since these drugs are not known to cause long-term toxicity if it is not clinically apparent.

Continued improvements and new treatment options can be expected in the future. TAF is likely to replace TDF for a large proportion of patients, mainly because of its apparent safety advantages and potential for coformulation with numerous other agents. Doravirine has the potential to return NNRTIs to the list of recommended regimens. BMS-955176, an investigational maturation inhibitor, is being studied for initial therapy. Long-acting injectable regimens such as cabotegravir plus rilpivirine appear promising, although the optimal patient population remains unclear since missed injections could lead to drug resistance. Long-acting regimens might be ideal for patients in supervised settings such as prisons or methadone clinics. They might also be considered for the small subset of patients who take no oral medications, who prefer shots over pills, or who are non-adherent with oral medications but who keep their clinic appointments.

The effect of drug cost and approval of generic medications cannot be underestimated or predicted. Currently, the only recommended and widely used antiretroviral agents available in generic form are ABC and 3TC, but the difference in cost between generic and brand name agents has often not been sufficient to force a breakup of coformulated branded products (ABC/3TC and DTG/ABC/3TC). However, the eventual

availability of generic EFV and TDF could have a significant impact on practice. EFV use has been declining steadily, and it is no longer a recommended agent in DHHS guidelines for reasons discussed above. However, it has a long track record for safety and effectiveness, and there may be considerable pressure on clinicians to start therapy with EFV, reserving other agents for those who do not tolerate it. Similarly, there may be pressure to start therapy with TDF rather than TAF, since TDF toxicity is not universal and generally only becomes apparent after prolonged use.

There is also interest in lower-cost, two-drug regimens. While there was brief interest in boosted PI monotherapy for initiation or simplification, this has been replaced by enthusiasm for the combination of a boosted PI plus generic 3TC, which looks promising in several clinical trials (Cahn et al. 2014). A particularly intriguing combination now under study is the combination of DTG and 3TC. If this regimen, which would presumably have an outstanding safety and tolerability profile, turns out to be effective with the same lack of resistance seen so far with other initial DTG-based combinations, it would be an extremely attractive choice for initial therapy, one that would be hard for any other regimen to compete with. However, such an approach – using a two-drug, non-PI-containing regimen – still seems radical today, at a time when we remain wedded to the same NRTI backbone plus third-agent approach that has been the standard of care for almost 20 years.

Integrase Inhibitors

Jill Blumenthal and Charles Hicks

Division of Infectious Diseases, Department of Medicine, University of California San Diego, San Diego, CA, USA

Definition

The fundamental approach to most antiretroviral therapy (ART) is based on a strategy of targeting the function of HIV enzymes critical to viral replication. Three such targets are HIV reverse transcriptase, HIV protease, and HIV integrase. After viral entry into the CD4+ T cell, viral RNA is reverse-transcribed into DNA by HIV reverse transcriptase after which HIV integrase forms a pre-integration complex comprised of virally encoded DNA and other cofactors. HIV integration is a two-step process catalyzed by HIV integrase, the first step consisting of the integrase enzyme removing a nucleotide from each 3' DNA terminus, resulting in the exposure of reactive hydroxyl groups. Next, the pre-integration complex enters the host cell nucleus where it binds to host DNA, after which the integrase enzyme nicks each strand of the host DNA, exposing the 5' phosphate end which allows bonding between host and viral DNA. After this step, called integrase strand transfer, is accomplished, host cellular enzymes repair gaps in the DNA.

The HIV integrase enzyme was shown to be susceptible to inhibition by oligonucleotides and synthetic peptides in 1995 (Ojwang et al. 1995) and thus became a target for ART development. In 2000, a seminal study described the first promising compound which targeted the strand transfer step of viral integration (Hazuda et al. 2000). Thus, the integrase strand transfer inhibitors (INSTIs) became the first drugs to target this critical enzyme in the HIV life cycle.

Introduction

Until recently, initial antiretroviral therapy (ART) typically consisted of two nucleoside

reverse transcriptase inhibitors (NRTIs) and a ritonavir-boosted protease inhibitor (PI) or a non-nucleoside reverse transcriptase inhibitor (NNRTI). While highly efficacious, these combinations often were limited by side effects, drug interactions, and complicated dosing regimens. Subsequent drug development focused on improving tolerability and convenience while maintaining or improving virologic efficacy. The emergence of HIV InSTIs as a new class of antiretrovirals has helped fulfill these drug development goals. Three InSTIs are currently available in the United States for the treatment of HIV infection: raltegravir (RAL), elvitegravir (EVG), and dolutegravir (DTG). Long-term safety and efficacy data have been shown for these drugs when used as part of combination therapy for the treatment of individuals infected with HIV. All have activity against a wide range of wild-type and drug-resistant HIV-1 isolates, including HIV-1 clades A, B, C, D, E, F, and G, and are also active against HIV-2. The current Department of Health and Human Services (DHHS) Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents include five different ART regimens as recommended for initial treatment of HIV-1-infected patients, four of which are InSTI based (DHHS 2015). In addition, InSTIs are increasingly used in the management of ART-experienced patients.

HIV-1 Integrase Inhibitors

Raltegravir

Description and Indications

Raltegravir was the first licensed HIV integrase inhibitor, FDA approved in 2007. It is indicated in combination with other antiretroviral agents for treatment of HIV infection in adult patients. Raltegravir plus emtricitabine/tenofovir is a recommended InSTI-based first-line regimen in the US and European treatment guidelines (DHHS 2015; EACS 2015). It can be used effectively in both treatment-naïve and treatment-experienced patients.

PK Parameters

Raltegravir is rapidly absorbed with a T_{max} of approximately 3-h postdose in the fasting state, and steady-state concentrations are achieved within 2 days. Serum half-life is about 9 h. C_{max} is 2.17 µg/ml, C_{min} is 68.6 ng/ml with 400 mg twice-daily dosing, and area under the curve (AUC) is 6.91 µg/ml.h. Bioavailability of raltegravir is approximately 32%. Raltegravir has been shown to achieve meaningful drug concentrations in cerebral spinal fluid (CSF) and genital compartments. It is metabolized through UGT1A1-mediated glucuronidation. Recommended dosing is 400 mg twice daily without food restrictions (Raltegravir package insert, 2014).

Adverse Event Profile

Clinical trials involving both treatment-naïve and treatment-experienced patients demonstrate that raltegravir is well tolerated. In treatment-naïve patients in the STARTMRK study, the rate of treatment discontinuation due to adverse events was 5% in subjects receiving raltegravir (plus emtricitabine/tenofovir) and 10% in subjects receiving efavirenz (plus emtricitabine/tenofovir) (Rockstroh et al. 2013). The most common adverse events of moderate to severe intensity ($\geq 2\%$) are insomnia, headache, dizziness, nausea, and fatigue. In addition, creatine kinase elevations, myopathy, and rhabdomyolysis have been occasionally observed in subjects receiving raltegravir (Raltegravir package insert, 2014).

Drug-Drug Interactions

Raltegravir is metabolized by a low-affinity, high-capacity pathway which helps limit the potential for drug-drug interactions. Interactions can occur when concomitant medications induce or inhibit the activity of UGT1A1. Rifampin is a potent inducer of UGT1A1, and thus a 100% increase in the dose of raltegravir (800 mg twice daily) is recommended if the two drugs are used together (Raltegravir package insert, 2014). In addition, coadministration or staggered administration of aluminum and/or magnesium hydroxide-containing antacids and raltegravir is not recommended. Other drugs that induce

UGT1A1 less strongly, such as phenytoin and phenobarbital, may also reduce concentrations of raltegravir, but this has not been fully characterized. Therefore, no dose modifications are currently recommended for these drugs.

Resistance

Resistance to HIV integrase inhibitors occurs with varying frequency depending on the drug being administered and the circumstances in which resistance is induced. It occurs with higher frequency with raltegravir (RAL) than with some other InSTIs and has been found in up to two-thirds of patients experiencing virological failure on raltegravir-based regimens, particularly if the drug continues to be administered after viral rebound occurs. The genotypic changes associated with raltegravir resistance usually include primary mutations Y143R/Y143H/Y143C, N155H, or Q148H/Q148K/Q148R, and most instances of high-level resistance are seen when the Q148 mutation is accompanied by additional secondary mutations (L74M + E138A, E138K, or G140S). In the STARTMRK trial of ART-naïve individuals, emergence of primary raltegravir resistance-associated mutations was observed in four of the 12 patients with virological failure (two with Y143H/Y143R and two with Q148H/Q148R). Continued administration of raltegravir after virological failure occurs is usually associated with ongoing evolution of resistance mutations.

InSTI resistance that occurs after raltegravir treatment failure is usually associated with resistance to a second InSTI, elvitegravir (see below). In contrast, a majority of raltegravir-resistant viruses remain susceptible to the most recently approved InSTI, dolutegravir.

Clinical Trials

Treatment-Naïve Patients The STARTMRK trial was the largest study of raltegravir among treatment-naïve patients; 563 patients were randomly assigned to raltegravir (given twice daily) or efavirenz in combination with tenofovir/emtricitabine. Raltegravir was found to be non-inferior to efavirenz with regard to viral load suppression at 48 weeks (86% in the raltegravir arm

vs. 82% in the efavirenz arm) with ongoing durability at weeks 96 and 240 (Rockstroh et al. 2013). In addition, the mean increase in CD4 cells was also significantly greater in the raltegravir arm (189 vs. 163 cells/mL). At week 240, there was a larger mean increase in CD4 cells and fewer neuropsychiatric side effects or other drug-related adverse events in the raltegravir arm. In an effort to determine if once-daily administration of raltegravir would be efficacious, the QDMRK study compared once- versus twice-daily raltegravir given with tenofovir/emtricitabine in a randomized, noninferiority trial of 775 patients. Once-daily raltegravir was found to be *not* non-inferior to twice-daily dosing with 83% patients taking once-daily raltegravir achieving viral suppression compared to 89% of those taking the drug twice daily (95% CI -10.7 to -0.83 , *p*-value for noninferiority = 0.044) (Eron et al. 2011).

Treatment-Experienced Patients The pivotal BENCHMRK trial was designed to assess the value of raltegravir in the treatment of HIV-infected patients with extensive prior antiretroviral treatment experience and resistance to at least three classes of ART. At study entry, the median CD4 cell count was 120 cells/mL, and 35% had a baseline HIV viral load of >100,000 copies/mL. When combined with an optimized background regimen, raltegravir demonstrated potent activity with 57% of raltegravir recipients (*n* = 462) achieving HIV suppression after 96 weeks of follow-up compared with 26% of those randomized to an optimized background regimen plus placebo (*n* = 237) (Steigbigel et al. 2010). Among patients experiencing virological failure while taking raltegravir (166 of 462 patients), 60% developed raltegravir resistance mutations (Eron et al. 2013b). At the 48-week evaluation visit, the prevalence of raltegravir resistance mutations was lower in isolates from individuals who were taking two or more active drugs in addition to raltegravir, compared to those for whom raltegravir was the only active agent.

Switch Studies In patients taking a virologically suppressive antiretroviral regimen, switching to

an alternative raltegravir-based regimen should be done with caution and generally only when the other agents in the regimen are fully active. This principle became clear based on results from the SWITCHMRK trials, two randomized studies involving 707 HIV-infected persons with HIV suppression achieved using an HIV protease inhibitor (lopinavir/ritonavir)-based regimen. These studies were designed to evaluate the effect of switching the protease inhibitor to raltegravir compared to continuation of the lopinavir/ritonavir regimen. Although lipid profiles significantly improved in patients who switched to raltegravir, the trial was terminated early because there were significantly more virological failures in those who switched to raltegravir compared to those who did not (16% vs. 9%) (Eron et al. 2010). Thus, switching to raltegravir was inferior to remaining on lopinavir-/ritonavir-based regimen, particularly in those with previous virological failure, suggesting that previously accumulated resistance predisposed patients to virological failure when raltegravir was substituted for a suppressive protease inhibitor.

Elvitegravir

Description and Indications

Elvitegravir was FDA approved in 2012 as part of a coformulated single-pill combination that also includes cobicistat, tenofovir, and emtricitabine. A stand-alone version of the drug was subsequently approved in September 2014. Cobicistat/elvitegravir/emtricitabine/tenofovir is one of the recommended initial therapy regimens for the treatment of HIV-1 infection, but, because of potential renal toxicity, it should only be prescribed to adult patients with an estimated creatinine clearance ≥ 70 mL/min (DHHS 2015; EACS 2015).

PK Parameters

With PK enhancement from cobicistat or ritonavir, elvitegravir is rapidly absorbed with a T_{max} of approximately 4 h. Steady-state concentrations are achieved within approximately 7 days. Serum half-life is ~ 3 h when dosed alone and ~ 9 h with PK enhancement. C_{max} is 1.7 ± 0.1 $\mu\text{g/ml}$, C_{min}

0.45 ± 0.26 $\mu\text{g/ml}$ with 150 mg once-daily dosing, and AUC 23.0 ± 7.5 $\mu\text{g/ml.h}$. Bioavailability has not been established. Elvitegravir CSF concentrations have not yet been established but are currently being studied, and penetration into genital compartments has only been evaluated in rhesus macaques (Mased et al. 2015). Metabolism is predominantly through cytochrome P450 (CYP3A4) with minor pathways via UGT1A1/UGT1A3 glucuronidation and oxidative metabolism. Standard dosing is 150 mg daily plus a booster (150 mg of cobicistat or 100 mg ritonavir) to be taken with meals (Elvitegravir package insert, 2014).

Adverse Event Profile

Large-scale clinical trials have shown that the once-daily combination pill that includes elvitegravir is generally well tolerated. The most common adverse drug reactions to coformulated elvitegravir (incidence greater than or equal to 10%, all grades) are nausea and diarrhea. When administered with tenofovir/emtricitabine, 6% of study subjects discontinued treatment due to adverse events with coformulated elvitegravir compared to 7.4% with tenofovir/emtricitabine/efavirenz and 8.5% with atazanavir plus ritonavir (Sax et al. 2012; DeJesus et al. 2012). In the same studies, elvitegravir/cobicistat was associated with a significantly greater median increase in serum creatinine than comparator arms, a finding previously shown to be due to cobicistat inhibition of tubular secretion of creatinine without effect on actual glomerular filtration rate (GFR). Still, 13 (1.9%) subjects in the coformulated elvitegravir arm and eight (2.3%) subjects in the atazanavir plus ritonavir arm discontinued study drug due to a renal adverse reaction, attributed primarily to tenofovir. Discontinuations were due to both true renal toxicity events and creatinine elevations from the effect of cobicistat when the cause was uncertain (Elvitegravir package insert, 2014).

Drug-Drug Interactions

Elvitegravir is principally metabolized through the cytochrome p450 pathway; therefore, drugs that induce or inhibit cytochrome P450 enzymes

are very likely to have drug-drug interactions with elvitegravir. Because elvitegravir is currently only used with the CYP3A4 inhibitor cobicistat, other drugs that are substrates for this enzyme may also have drug-drug interactions. Selected drug interactions are presented in Table 1.

Resistance

In clinical trials of elvitegravir as initial therapy, 57% of those with virological failure developed genotypic InSTI resistance, often accompanied by resistance to at least one of the nucleoside RT inhibitors being taken concurrently. The frequency of InSTI resistance among those with virological failure was similar to that seen with NNRTI-based ART (DeJesus et al. 2012; Sax et al. 2012). The primary integrase resistance mutations include T66I, E92Q, Q148R, and N155H with the latter three also conferring resistance to raltegravir. As noted above, given the high degree of cross-resistance between raltegravir and elvitegravir, switching between these two InSTIs is not recommended.

Clinical Trials

Treatment-Naïve Patients In treatment-naïve patients, a phase III trial among 708 individuals comparing elvitegravir, emtricitabine, tenofovir, and cobicistat with ritonavir-boosted atazanavir and the same NRTI backbone showed the elvitegravir-based regimen to be noninferior to the atazanavir-based regimen in terms of viral suppression (90% vs. 87%) (DeJesus et al. 2012). In addition, HIV suppression rates were also noninferior among the subset of patients with a baseline viral load >100,000 copies/mL (85% vs. 82%). Results at 96 weeks confirmed continued viral suppression in both treatment groups. Another study of 700 HIV-infected patients compared an elvitegravir-based ART regimen to an efavirenz-based ART regimen and found the elvitegravir regimen to be noninferior to the efavirenz regimen at 48 weeks, with viral suppression rates of 88% versus 84%, respectively. Viral suppression rates among patients with a baseline viral load of >100,000 copies/mL were comparable between the two treatment

arms (Sax et al. 2012). Increases in CD4 counts were significantly higher in the elvitegravir arm versus the efavirenz arm (239 vs. 206 cell/microL). Viral suppression was maintained at 96 weeks in both groups (84% vs. 82%).

Treatment-Experienced Patients A phase III noninferiority trial examined the efficacy and safety of ritonavir-boosted elvitegravir compared to raltegravir among 702 HIV-infected patients with a history of virological failure. Nearly half of the patients had baseline CD4 counts <200 cells/microL, and two-thirds had documented HIV resistance to two or more ART drug classes. The study demonstrated that HIV viral load suppression was similar in both arms (59% vs. 58%) with comparable efficacy among patients with a baseline viral load >100,000 copies/mL. Rates of serious adverse events were low overall, but diarrhea was more common in the elvitegravir arm, and liver abnormalities were more frequent in individuals taking raltegravir (Molina et al. 2012). Of note, the use of elvitegravir in treatment-experienced patients is uncommon since most use occurs in early therapy with the fixed-dose combination, and the requirement for pharmacologic boosting makes it more challenging to use in the complex regimens often necessary in treatment-experienced patients. Thus, raltegravir and dolutegravir are almost always preferred in treatment-experienced patients.

Switch Studies Elvitegravir administered as a component of the combination four-drug tablet (tenofovir, emtricitabine, elvitegravir, cobicistat) is indicated as a regimen switch strategy in patients who are virologically suppressed (viral load <50 copies/mL) on a stable antiretroviral regimen for at least 6 months with no history of previous treatment failure and no known resistance mutations to the individual components of the four-drug combination. In the STRATEGY-PI study, subjects were randomized 2:1 to switch to the four-drug combination elvitegravir pill (n = 293) or stay on their baseline antiretroviral regimen of a boosted PI plus tenofovir/emtricitabine (n = 140) (Arribas et al. 2014). The mean baseline

Integrase Inhibitors, Table 1 Selected drug interactions with elvitegravir in adults

Drug name	Concentration effect	Comment
Protease inhibitors		
Atazanavir	↔ Atazanavir ↑ elvitegravir	There are no data to make dosing recommendations for coadministration with doses of atazanavir/ritonavir other than 300/100 mg once daily
Lopinavir/ritonavir	↔ Lopinavir ↑ elvitegravir	There are no data to make dosing recommendations for coadministration with doses of lopinavir/ritonavir other than 400/100 mg twice daily
NNRTIs		
Efavirenz	↓ Elvitegravir	Coadministration decreases elvitegravir plasma concentration, which may result in loss of therapeutic effect and in development of resistance. Coadministration is not recommended
Nevirapine	↓ Elvitegravir	Coadministration decreases elvitegravir plasma concentration, which may result in loss of therapeutic effect and development of resistance. Coadministration is not recommended
Other agents:		
Acid-reducing agents: Antacids*	↓ Elvitegravir	Elvitegravir plasma concentrations are lower with antacids due to the formation of ionic complexes in the GI tract. It is recommended to separate elvitegravir and antacid administration by at least 2 h
Anticonvulsants: Carbamazepine Oxcarbazepine Phenobarbital Phenytoin	↓ Elvitegravir	Coadministration of phenobarbital, phenytoin, carbamazepine, or oxcarbazepine (CYP3A inducers) with elvitegravir may decrease elvitegravir plasma concentrations, which may result in loss of therapeutic effect and in development of resistance
Antifungals: Ketoconazole*	↑ Elvitegravir ↑ ketoconazole	Concentrations of ketoconazole may increase when used with elvitegravir in combination with protease inhibitors/ritonavir
Antimycobacterials: Rifampin, rifapentine	↓ Elvitegravir	Coadministration of rifampin or rifapentine, both potent CYP3A inducers, with elvitegravir may lead to decreased elvitegravir exposures, which may result in loss of therapeutic effect and in development of resistance. Coadministration is not recommended
Rifabutin	↑ Rifabutin ↓ elvitegravir	When rifabutin is used with elvitegravir and a protease inhibitor/ritonavir, dose reduction of rifabutin by at least 75% of the usual dose of 300 mg/day is recommended. Increased monitoring for rifabutin-associated adverse events is suggested. No dose adjustment of elvitegravir is required when coadministered with the reduced dose of rifabutin
Systemic corticosteroids: Dexamethasone	↓ Elvitegravir	Systemic dexamethasone may decrease elvitegravir plasma concentrations, which may result in loss of therapeutic effect and development of resistance
Herbal products: St. John's wort (<i>Hypericum perforatum</i>)	↓ Elvitegravir	Coadministration is not recommended
Hormonal contraceptives: Norgestimate/ethinyl estradiol	↑ Norgestimate ↓ ethinyl estradiol ↔ elvitegravir	Plasma concentration of ethinyl estradiol may be decreased when used with elvitegravir and a protease inhibitor/ritonavir

*Adapted from Elvitegravir 2014 package insert product information

CD4⁺ was 610 cells per mm³. Maintenance of virological suppression at 48 weeks occurred in 94% in the four-drug combination elvitegravir arm compared to 87% in the boosted PI arm with 1% in each arm having virological failure. In the STRATEGY-NNRTI study, subjects were randomized 2:1 to switch to the four-drug combination elvitegravir pill (n = 291) or to stay on their baseline antiretroviral regimen of an NNRTI plus tenofovir/emtricitabine (n = 143) (Pozniak et al. 2014). The mean baseline CD4⁺ was 588 cells per mm³. Maintenance of virological suppression at 48 weeks occurred in 93% in the four-drug combination elvitegravir arm compared to 88% in the NNRTI arm with 1% in each arm having virological failure.

Dolutegravir

Description and Indications

Dolutegravir is the most recently FDA-approved InSTI in August 2013 and is indicated for use in both ART-naïve and ART-experienced HIV-infected adults and children aged 12 and older in combination with other antiretroviral medications. In contrast to raltegravir and elvitegravir, dolutegravir remains active against many HIV strains with integrase mutations that cause resistance to raltegravir and elvitegravir.

PK Parameters

Dolutegravir is rapidly absorbed with a T_{max} of 1 h, and steady state is reached within approximately 5 days. Serum half-life is ~15 h. The absolute bioavailability of dolutegravir has not yet been established. C_{max} is 3.67 µg/ml, C_{min} 1.11 µg/ml, and AUC 53.6 µg/ml.h with 50 mg once-daily dosing. Dolutegravir achieves meaningful concentrations in the genital tract and colorectum, which support the evaluation of its use in HIV prevention and preexposure prophylaxis. It is metabolized primarily through UGT1A1-mediated glucuronidation with cytochrome P450 (CYP3A4) as a minor pathway. Recommended dosing is 50 mg daily in InSTI-naïve patients and 50 mg twice daily in InSTI-experienced patients with no food restrictions (Dolutegravir package insert 2014).

Adverse Event Profile

Side effects are uncommon with dolutegravir. In clinical trials, the most common adverse reactions of moderate to severe intensity (≥2%) were insomnia, fatigue, and headache (Dolutegravir package insert 2014). In clinical trials of treatment-naïve patients, rates of dolutegravir discontinuation due to adverse events were 2% in the SPRING-2 trial (Raffi et al. 2013) and 3% in the SINGLE study (Walmsley et al. 2013). It should be noted that dolutegravir inhibits creatinine secretion in the proximal tubule so small increases in serum creatinine after initiation are common and generally do not reflect decreased GFR.

Drug-Drug Interactions

Dolutegravir does not interact with many other drugs given its metabolism predominantly through UGT1A1-mediated glucuronidation. Potentially significant drug-drug interactions include some with antiretroviral, antimycobacterial, and anti-epileptic medications, as well as estrogens, and are listed in Table 2.

Resistance

Dolutegravir retains activity against most viruses that acquire resistance to raltegravir and elvitegravir. As such, it can be a useful agent as part of combination ART used to treat patients who have failed prior InSTI-containing regimens (Llibre et al. 2015) – (see also description of VIKING studies below). Probably because of its high potency, dolutegravir appears to have a high barrier to acquisition of integrase resistance similar to that seen with initial HIV protease inhibitor therapy. To date, treatment failure with InSTI resistance has not been seen when dolutegravir has been used as part of an initial ART regimen.

Clinical Trials

Treatment-Naïve Patients Four trials have supported the use of dolutegravir-based ART in treatment-naïve individuals. The SPRING-1 trial was a dose-ranging study of dolutegravir (10, 25, 50 mg) compared to standard doses of efavirenz, each administered in combination with two NRTIs (van Lunzen et al. 2012). Eighty-two percent of

Integrase Inhibitors, Table 2 Selected drug interactions with dolutegravir in adults

Drug name	Concentration effect	Comments
NNRTI		
Etravirine	↓ Dolutegravir	Use of dolutegravir with etravirine without coadministration of atazanavir/ritonavir, darunavir/ritonavir, or lopinavir/ritonavir is not recommended
Efavirenz	↓ Dolutegravir	Adjust dose of dolutegravir to 50 mg twice daily for treatment-naive and treatment-experienced, InSTI-naive patients
Other agents:		
Medications containing polyvalent cations (e.g., Mg or Al): Cation-containing antacids or laxatives Sucralfate Buffered medications	↓ Dolutegravir	Administer dolutegravir 2 h before or 6 h after taking medications containing polyvalent cations
Oral calcium or iron supplements	↓ Dolutegravir	Administer dolutegravir 2 h before or 6 h after taking supplements containing calcium or iron. Alternatively, dolutegravir and supplements containing calcium or iron can be taken together with food
Anticonvulsants: Carbamazepine Oxcarbazepine Phenobarbital Phenytoin	↓ Dolutegravir	Coadministration is not recommended
Herbal products: St. John's wort (<i>Hypericum perforatum</i>)	↓ Dolutegravir	Coadministration is not recommended
Antimycobacterials: Rifampin	↓ Dolutegravir	Adjust dose of dolutegravir to 50 mg twice daily for treatment-naive and treatment-experienced, InSTI-naive patients. Use alternatives to rifampin for InSTI-experienced patients with certain InSTI-associated resistance substitutions or clinically suspected InSTI resistance
Hypoglycemic agents: Metformin	↑ Metformin	Consider dose reductions in metformin when coadministered with dolutegravir

*Adapted from Dolutegravir 2014 package insert product information

all participants who received dolutegravir achieved an HIV viral load <50 copies/mL through week 96, and no patients who received the 50 mg dose developed a viral load of >400 copies/mL or resistance mutations. In the SINGLE trial, patients were randomized to dolutegravir plus abacavir/lamivudine (n = 414) versus tenofovir/emtricitabine/efavirenz (n = 419) (Walmsley et al. 2013). At week 48, those randomized to the dolutegravir arm had significantly higher rates of viral suppression <50 copies/mL than those treated with efavirenz (88% vs. 81%, p = 0.003). The difference between the two treatment arms was driven primarily by increased discontinuations due to adverse events related to efavirenz. The

SPRING-2 trial compared dolutegravir to raltegravir, each given with an investigator-selected NRTI background of either tenofovir/emtricitabine or abacavir/lamivudine. 411 patients were randomly allocated to receive dolutegravir and 411 to receive raltegravir and received at least one dose of study drug. At 48 weeks, the dolutegravir-based regimens were noninferior to the raltegravir-based regimens, with rates of viral suppression to <50 copies/mL of 88% and 85%, respectively (adjusted difference 2.5%, 95% CI -2.2 to 7.1) (Raffi et al. 2013). Finally, the FLAMINGO trial compared dolutegravir to the protease inhibitor darunavir/ritonavir, each administered with a tenofovir/emtricitabine or abacavir/lamivudine nucleoside RT inhibitor

backbone. In the analysis 484 patients were included, with 242 in each arm. Those randomized to dolutegravir had significantly higher rates of HIV suppression at study week 48 with the adjusted difference of 7% in viral suppression meeting criteria for superiority compared to darunavir-/ritonavir-based regimens (90% vs. 83%, $p = 0.025$) (Clotet et al. 2014).

Treatment-Experienced Patients In the SAILING study, 715 HIV-infected patients with HIV treatment failure (HIV RNA >400 copies/mL) and resistance to two or more classes of ART were randomized to optimized background ART and either dolutegravir ($n = 354$) or raltegravir ($n = 361$) (Cahn et al. 2013). At week 48, 71% patients on dolutegravir had viral loads <50 copies/mL versus 64% patients on raltegravir (adjusted difference 7.4%, 95% CI 0.7–14.2) with superiority of dolutegravir versus raltegravir also concluded ($p = 0.03$). The VIKING studies were designed to evaluate the efficacy of dolutegravir as rescue therapy in treatment-experienced patients infected with HIV strains with resistance mutations to raltegravir and/or elvitegravir. VIKING-1–VIKING-2 were a dose-ranging phase IIb trial which found that 50 mg twice-daily dolutegravir compared to once daily could significantly decrease HIV-1 viral load with more subjects achieving the primary end point in the twice-daily cohort (23 of 24 [96%]) compared with the once-daily cohort (21 of 27 [78%]) at day 11. In addition, at week 24, 75% in the twice-daily cohort versus 41% in the once-daily cohort attained viral loads <50 copies/mL (Eron et al. 2013a).

VIKING-3 was a single-arm phase III study in which therapy-experienced adults with INI-resistant virus received dolutegravir 50 mg twice daily while continuing their failing regimen (without raltegravir or elvitegravir) through day 7, after which the regimen was optimized with ≥ 1 fully active drug and dolutegravir continued. Mean change in HIV-1 viral load at day 8 was $-1.43 \log_{10}$ copies/mL, and 69% of subjects achieved <50 c/mL at week 24 (Castagna et al. 2014). However, VIKING-3 also revealed that the efficacy of dolutegravir 50 mg twice daily was reduced in patients with an InSTI resistance

Q148 substitution plus two or more additional InSTI resistance substitutions. Further, virological response rates declined significantly with fold changes between 4 and 10 and greater than 10. Finally, VIKING-4 was a phase III study of 30 therapy-experienced adults with raltegravir- or elvitegravir-resistant virus randomized to dolutegravir 50 mg twice daily or placebo while continuing their failing regimen (without raltegravir or elvitegravir) for 7 days (Akil et al. 2015). At day 8, all subjects switched to open-label dolutegravir 50 mg twice daily and optimized background therapy including ≥ 1 fully active drug. Adjusted mean change in HIV-1 viral load at day 8 was $-1.06 \log_{10}$ copies/ml for the dolutegravir arm and $0.10 \log_{10}$ copies/ml for the placebo arm (treatment difference $-1.16 \log_{10}$ copies/ml [$-1.52, -0.80$], $p < 0.001$). Overall, 47% and 57% of subjects had viral loads <50 and <400 copies/ml at week 24 and 40% and 53% at week 48, respectively. Longer-term efficacy and safety during the open-label phase were in line with the results of the larger VIKING-3 study.

Investigational Integrase Inhibitors

Cabotegravir (S/GSK1265744)

Cabotegravir, an investigational InSTI, was initially evaluated in a once-daily oral formulation but is currently being developed as a long-acting parenteral agent intended to be used for monthly or even quarterly administration. The Long-Acting Antiretroviral Treatment Enabling (LATTE) trial was a phase IIb study to determine if two antiretroviral agents suitable to be developed as very long-acting drugs would be sufficiently active as antiretroviral maintenance therapy in patients who had achieved and maintained viral suppression with an initial three-drug induction regimen. This trial of cabotegravir and the NNRTI rilpivirine included 243 patients randomized to the induction regimen of once-daily oral cabotegravir 10 mg, 30 mg, or 60 mg or efavirenz 600 mg with tenofovir/emtricitabine or abacavir/lamivudine through week 24, followed by a two-drug oral

maintenance regimen of a blinded cabotegravir plus rilpivirine 25 mg through week 96 (Margolis et al. 2014). Following induction therapy, oral cabotegravir and rilpivirine maintained virological suppression at a rate of 76% in the cabotegravir arm and 63% in the efavirenz arm. Results of this trial suggest the combination may be a future option for both HIV maintenance therapy and possibly preexposure prophylaxis (PrEP) for HIV-uninfected persons. In addition, the long-acting injectable cabotegravir nano-suspension has been shown to be protective against acquisition of simian/human immunodeficiency virus in a low-dose viral challenge monkey model (Andrews et al. 2014).

GS-9883

GS-9883 is an investigational once-daily oral InSTI, which does not require pharmacological boosting. It is early in the clinical development cycle with a phase Ib trial of safety, PK, and antiviral activity having been completed assessing doses ranging from 5 to 100 mg (clinicaltrials.gov 2015). Additional studies being done include evaluation of the PK of GS-9833 in persons with impaired renal function and a phase II study assessing the safety and efficacy of GS-9833 versus dolutegravir – each paired with emtricitabine/tenofovir alafenamide.

MK-0518

MK-0518 is an investigational reformulated version of raltegravir which is intended to be administered once daily. In a multidose, randomized, three-treatment, crossover PK study of 24 healthy male and female subjects, subjects received either 1200 mg once daily of the raltegravir formulation (3 × 400 mg tablets), 1200 mg once daily of MK-0518 (2 × 600 mg tablets), or 400 mg twice daily of raltegravir for 5 days. Results suggested high tolerability, less dependence on meal type, and high probability of MK-0518 achieving non-inferiority to 400 mg twice-daily raltegravir (Rizk et al. 2014). Data from this study supported the continued investigation of a once-daily dosing regimen with reformulated raltegravir. OnceMRK is an ongoing phase III, multicenter, non-inferiority RCT of an estimated 750 ART-naïve

adult patients designed to assess the safety and efficacy of MK-0518 1200 mg once daily compared to raltegravir 400 mg twice daily, both given in combination with emtricitabine/tenofovir (Merck 2015).

Clinical Use of HIV Integrase Inhibitors

Initial ART

In April 2015, the US Department of Health and Human Services (DHHS) Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents were changed to include five initial ART regimens as recommended for treatment-naïve HIV-1-infected patients: one protease inhibitor-based regimen and four InSTI-based regimens (DHHS 2015). The four recommended InSTI-based regimens are dolutegravir/abacavir/lamivudine, dolutegravir plus tenofovir/emtricitabine, elvitegravir/cobicistat/tenofovir/emtricitabine, and raltegravir plus tenofovir/emtricitabine. Increasingly, InSTI-based ART regimens are the default choices for initial antiretroviral therapy based on their favorable characteristics of high efficacy, infrequent adverse events, and (for raltegravir and dolutegravir) infrequent drug-drug interactions. Furthermore, in the head-to-head comparisons between darunavir/ritonavir and dolutegravir (FLAMINGO), the InSTI-containing regimen had a significantly higher viral suppression rate. While the selection of the optimal ART regimen must be individualized, InSTI-based ART represents an excellent option for most patients.

ART in Treatment-Experienced Patients

HIV integrase inhibitors have been demonstrated to have significant value in the treatment of HIV-infected patients failing ART with resistance to other antiretroviral agents. Raltegravir and dolutegravir both are indicated for treatment-experienced patients and are frequently critical components of successful ART in this setting, particularly in patients who are naïve to InSTI. Moreover, based on findings from the VIKING-3 study, twice-daily dolutegravir can provide significant benefit in many patients who have

acquired InSTI resistance due to failure of raltegravir- or elvitegravir-based regimens (Castagna et al. 2014). However, because patients with the Q148 integrase mutation plus two or more secondary InSTI mutations respond less well to dolutegravir, it is recommended that such patients undergo integrase genotypic or phenotypic resistance testing prior to initiating dolutegravir.

Regimen Switching

In patients on successful ART who are experiencing problems with tolerability or who are receiving complex regimens that challenge adherence, switching to a simpler InSTI-based regimen may be a good option. Review of any previously identified antiviral resistance is an important step in determining if such a switch can be done safely since the presence of accumulated nucleoside reverse transcriptase inhibitor resistance may diminish the likelihood of sustaining HIV suppression after such a switch. InSTI-based treatment regimens have become a popular option for switch strategies.

Use in Specific Clinical Scenarios

The use of HIV integrase inhibitor-based ART regimens may be particularly appealing in certain patient situations, though there are important caveats to consider:

1. **Patients requiring treatment with drugs affected by CYP3A4 inhibitors (pharmacologic boosters ritonavir or cobicistat)** should avoid elvitegravir since it requires boosting to be effective. Drug-drug interactions become problematic in this setting.
2. Raltegravir may be appealing for **patients already taking medications that require twice-daily dosing**. The resultant dose symmetry can facilitate improved adherence. On the other hand, in patients with adherence concerns based on the need for twice-daily dosing, raltegravir should probably be avoided.
3. **In patients who are HLA-B5701 positive**, abacavir is contraindicated. Thus, the use of the single-pill dolutegravir fixed-dose combination (with abacavir/lamivudine) must be avoided in this group. Screening for abacavir hypersensitivity risk (HLA-B5701 screen) is essential prior to initiating the dolutegravir single-pill combination.
4. **In patients with significant renal insufficiency**, tenofovir should generally be avoided. Thus, the use of elvitegravir as part of a fixed-dose single-pill combination treatment regimen (which contains tenofovir/emtricitabine) is not recommended for patients with a creatinine clearance of <70 mL/min.
5. **In patients with lipid disorders**, it is usually prudent to avoid the booster cobicistat due to drug interactions and its potential to impact lipid profiles. Therefore, the coformulated single-pill elvitegravir regimen should generally be avoided in this population.
6. Similarly for **patients with cardiovascular disease (CVD) or significant risk of CVD who require ongoing statin therapy**, it may be appropriate to avoid using cobicistat with certain statins including lovastatin and simvastatin to preclude possible harmful drug interactions. Concerns about associations between abacavir and CVD also make the use of the dolutegravir-based single-pill combination (which contains abacavir) problematic in this population.
7. Because of the relatively low risk of drug-drug interactions with both raltegravir and dolutegravir, these drugs are particularly good options for **patients coinfecting with hepatitis C virus (HCV)**. No clinically significant interactions have been found between these two medications and the most commonly used anti-HCV drugs, including ribavirin, simeprevir, and coformulated ledipasvir/sofosbuvir. The recently approved coformulated HCV drug ombitasvir/paritaprevir/ritonavir plus dasabuvir can be safely used with raltegravir, but its safety with dolutegravir has not yet been evaluated.
8. **In patients coinfecting with hepatitis B virus (HBV)**, all three InSTIs can be safely used with HBV therapy. However, most such patients should be on the dual HBV combination of tenofovir/emtricitabine. The combination tablet dolutegravir/abacavir/lamivudine would not be recommended in this setting since abacavir is not active against HBV, and an

additional antiviral agent would need to be added for adequate HBV treatment.

9. In **patients in whom poor adherence is a significant concern**, the usual preferred strategy has been to start a protease inhibitor-based treatment regimen since virological failure with boosted PIs does not engender PI resistance. A similar outcome has been noted with dolutegravir-based initial therapy, but there are too few observations to be certain of this effect. Many clinicians now prefer starting dolutegravir in such patients since its improved tolerability and single-tablet combination availability may facilitate adherence. Further data will help determine if this approach is optimal.

Conclusion

The addition of the HIV integrase inhibitor class of antiretroviral drugs has significantly strengthened available antiretroviral treatment regimens for all types of patients. With high potency and a low potential for drug-drug interactions, InSTIs are increasingly replacing the use of NNRTI- and PI-based ART regimens. As a result of their well-documented treatment efficacy, excellent tolerability, and simplicity and convenience, HIV InSTIs have emerged to become a mainstay of HIV-1 therapeutics.

Integration

- Angela Ciuffi¹ and Frederic D. Bushman²
¹Institute of Microbiology, University Hospital Center and University of Lausanne, Lausanne, Switzerland
²Department of Microbiology, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA, USA

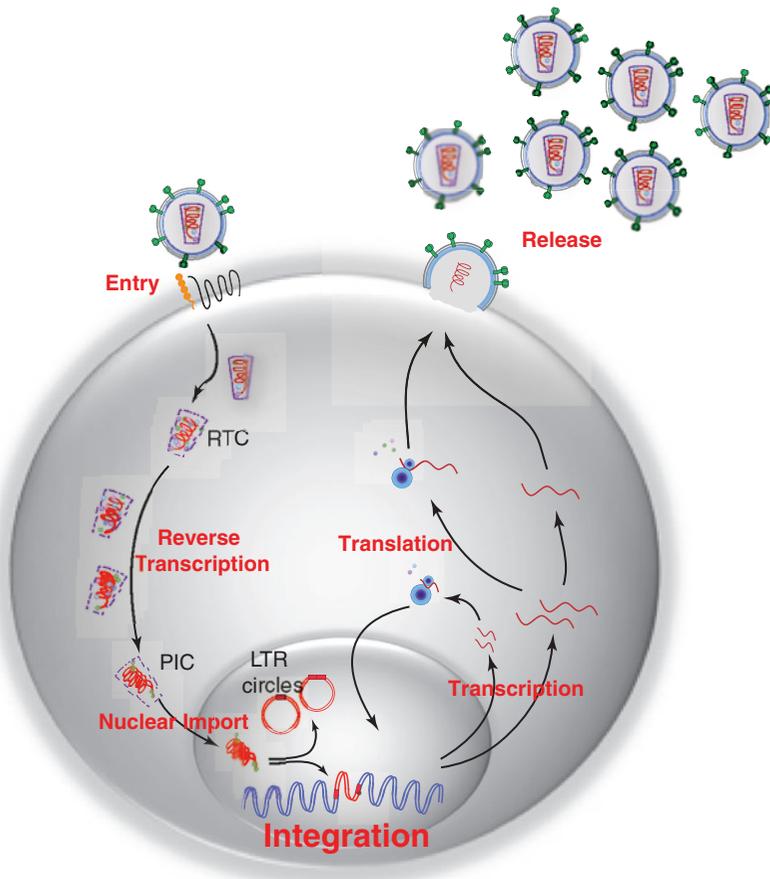

Definition

Integration refers to the stable connection of the viral DNA produced by reverse transcription to the host chromosomal DNA.

Introduction

Human immunodeficiency virus type 1 (HIV-1), like all retroviruses, is characterized by two steps in the replication cycle, reverse transcription and integration (Fig. 1; Suzuki and Craigie 2007; Flint et al. 2009; Nordkin 2009; Bushman et al. 2011;

► **Overview: Life Cycle**). HIV-1 particles contain two copies of the viral genome as single-stranded positive-sense RNA molecules. Upon entry and release of the viral core in the cytoplasm of the host cell, the viral RNA genomes are used as templates by the viral reverse transcriptase (RT) to generate a linear and blunt-ended double-

Integration, Fig. 1 HIV-1 replication cycle overview. HIV-1 particles attach to target cells through the subsequent interaction of viral envelope with CD4 and a chemokine co-receptor (CXCR4 or CCR5), triggering viral entry and core release in the cytoplasm of the host cell. Core-derived nucleoprotein complex, named reverse transcription complex (RTC), contains minimally matrix, capsid, nucleocapsid, RT, IN, and viral RNA genome. During reverse transcription, RTC evolves toward a preintegration complex (PIC) containing the viral linear cDNA genome

copy and migrates to the nuclear membrane along microtubules. Through interactions with nuclear pore proteins, the PIC translocates into the nucleus. The viral cDNA is then either degraded or circularized by host DNA repair proteins yielding 1-LTR or 2-LTR circles or integrated into the host chromosome through IN action. Once integrated, the viral genome uses the host cell machinery to transcribe and translate the viral components necessary to produce viral particle progeny

stranded cDNA copy (► [Fusion](#); ► [Uncoating and Nuclear Import](#); ► [Reverse Transcription](#)). This viral cDNA genome copy encodes the nine HIV-1 open reading frames (ORF) and at the ends contains ~634-bp direct repeats, the long terminal repeats (LTR). The LTRs contain cis-acting sequences needed for integration as well as sequences necessary for subsequent viral transcription. The viral cDNA genome is associated with multiple viral and cellular proteins, including the virally encoded integrase (IN), in a nucleoprotein complex called the preintegration complex (PIC). The exact composition of the PIC is still unclear but includes IN, matrix (MA), and capsid (CA) viral proteins as well as cellular proteins (Suzuki and Craigie 2007). Some PIC components, including CA, interact with nuclear pore proteins, thereby allowing PIC translocation into the nucleus of nondividing cells as well as dividing cells. Once in the nucleus, the viral DNA becomes integrated into the host genome. Integration typically occurs between 10 and 20 h post-viral exposure in susceptible CD4⁺ T cells. Only a minority of viral particles ultimately succeeds to integrate under most conditions. Integrated proviruses can affect the transcription of neighboring cellular genes by a number of pathways (insertional mutagenesis). The persistence of the integrated provirus is one of the biggest barriers to virus elimination from the infected individual (Siliciano and Greene 2011; Desfarges and Ciuffi 2012).

The Viral Integrase Enzyme

The HIV-1 *polymerase (pol)* gene codes for the three viral enzymes: protease (PR), reverse transcriptase (RT), and integrase (IN). The key protein required for viral genome integration is IN (Neamati 2011). IN is first incorporated into virions as part of a Gag-Pol precursor protein, which is processed by the viral PR to generate the mature protein products, including IN. A viral particle is estimated to contain about 40–100 molecules of IN.

The prototypical IN enzyme (HIV-1 group M subtype B strain HxB2, NCBI Reference Sequence NP_705928.1) is a 32 kDa protein consisting of 288 amino acids and is divided into three structural and functional domains (Fig. 2). These include the N-terminal domain (NTD) containing residues 1–50, the central catalytic core domain (CCD) encompassing residues 51–212, and the C-terminal domain (CTD) with residues 213–288 (Neamati 2011).

The NTD is a bundle of 4 α -helices that is stabilized by the coordination of a zinc via four conserved residues, H¹², H¹⁶, C⁴⁰, and C⁴³, constituting the characteristic HHCC motif. The NTD is involved in viral DNA binding as well as in IN multimerization.

The CCD is characterized by a conserved acidic triad motif, D,D-35-E, which constitutes the catalytic site motif that is highly conserved among retroviruses, retrotransposons, and DNA

Integration, Fig. 2 HIV-1 IN sequence. The prototypical HIV-1 IN sequence (HIV-1 group M subtype B strain HxB2) consists in 288 amino acids and is divided into three functional structural and functional domains: (i) the N-terminal domain (NTD) consisting of residues 1–50, containing the HHCC motif (highlighted in *bold*) involved in zinc binding, (ii) the catalytic core domain (CCD)

encompassing residues 51–212, characterized by the D, D-35-E motif (highlighted in *bold*) required for Mg²⁺ coordination and catalytic activities of the enzyme, and (iii) the C-terminal domain (CTD) containing residues 213–288. The three domains are involved in IN multimerization and in DNA binding

transposons. The catalytic D⁶⁴D¹¹⁶E¹⁵² coordinates two divalent metal ions (Mg²⁺) necessary for the integration steps catalyzed by IN. Although Mg²⁺ is physiologically abundant and thus likely to be the divalent metal ion coordinated by IN in vivo, Mn²⁺ can also support integration in vitro. In addition to its catalytic activity, the CCD is also involved in DNA binding of both viral and DNA sequences, as well as in IN multimerization. In vitro studies identified multiple CCD residues that contact viral DNA ends, including Y143 and Q148. Overall, the fold of this domain is that of the RNase H superfamily of polynucleotidyl phosphotransferase enzymes.

The CTD is a less well-conserved domain consisting of five antiparallel β -strands arranged in a SH3-like β -barrel. It is implicated in IN multimerization and contains positively charged regions (mostly K residues clustered on the protein surface) involved in nonspecific DNA binding.

IN Structure

The full-length structure of HIV-1 IN is not yet solved at high resolution. However, the structures of the three individual IN domains, or pairs of IN domains, have been determined by nuclear magnetic resonance (NMR) or X-ray crystallography (Li et al. 2011; Neamati 2011; Craigie and Bushman 2012). More importantly, the structure of the complete retroviral prototype foamy virus (PFV) IN complexed with viral DNA (i.e., PFV intasome) has been solved both with and without target DNA (Cherepanov et al. 2011; Li et al. 2011). Although not identical to HIV-1 intasome, the PFV intasome provides valuable information on IN structure and function particularly that IN catalyzes strand transfer as a homotetramer, with only one active catalytic site in each IN dimer, and that the host target DNA is severely bent to bring host target DNA and viral DNA ends in close vicinity, which is required for strand transfer (ligation of viral and cellular DNA). Thus, the PFV intasome structure specifies IN residues in direct contact with viral and target DNAs. In addition, the PFV structure has been solved with integrase inhibitors bound, specifying key aspects

of the mechanism of action (section “[Compounds Inhibiting HIV-1 Integrase](#)” below).

IN Mutants

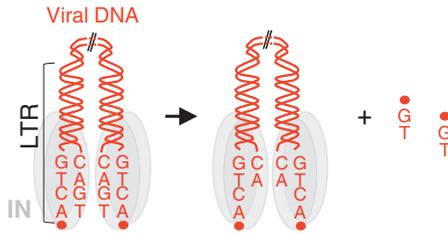

IN function has been probed extensively using site-directed mutagenesis. Two classes of mutants, class I and class II, have been identified (Engelman et al. 1999; Neamati 2011; Craigie and Bushman 2012). The first class of IN mutants defines enzymes that are selectively impaired in IN-mediated reactions. The second class of mutants, intriguingly, does not affect IN activity only but rather has pleiotropic effects on other HIV-1 replication steps, including reverse transcription and assembly/release of infectious viral particles. Indeed, IN can directly interact with RT, thereby improving RT efficiency. Mutations in the IN sequence of *pol* can affect PR-mediated processing of Gag-Pol polyproteins, thereby affecting the maturation of viral particles. These data suggest that HIV-1 IN protein has additional roles in viral infection in addition to the insertion of the viral genome into the host chromosome.

The Integration Reaction

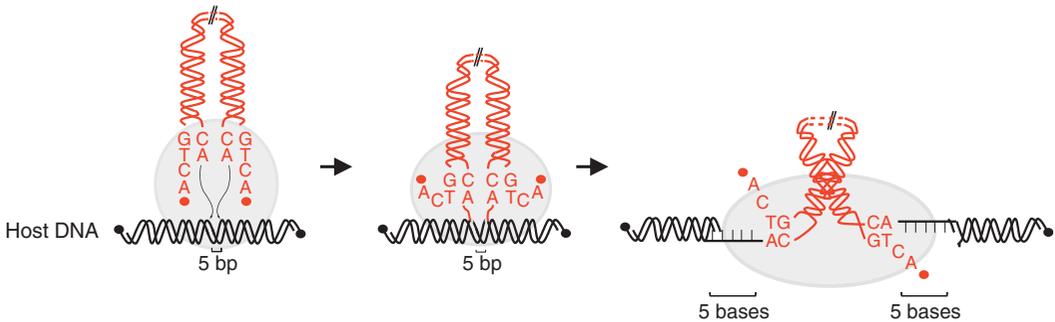

The integration process is divided in three steps (Fig. 3): (i) 3' processing, (ii) strand transfer, and (iii) repair (Desfarges and Ciuffi 2010; Neamati 2011; Arts and Hazuda 2012; Craigie and Bushman 2012; Hazuda 2012). The first two steps are catalyzed by IN; the last one is not fully clarified but probably carried out by the DNA repair machinery of the host cell.

The 3' processing reaction, also called terminal cleavage, consists in the removal of a dinucleotide at the 3' ends of the viral termini, generating CA-3' recessed hydroxyl ends. This reaction is catalyzed in the cytoplasm by a dimer of IN that is bound on each viral LTR end. The presence of the invariant 3' CA nucleotides in the LTR sequence is essential for efficient processing. In vitro this process can be recapitulated using purified IN and a duplex of oligonucleotides, usually of 21–32 bp long, mimicking the viral LTR ends. Experimentally, radioactive labeling of the 5' end of the cleaved strand of a duplex oligonucleotide

3' processing:

Strand transfer:

Repair (host):

Integration, Fig. 3 HIV-1 integration reaction. The integration process can be divided in three steps: 3' processing or terminal cleavage (*top panel*), strand transfer or joining (*middle panel*), and gap repair (*low panel*). 3' processing requires an IN dimer (IN depicted as ovals) at each viral end and consists in the IN-mediated cleavage of a dinucleotide at each 3' end of the viral cDNA genome, leaving recessed invariant 3' CA-OH ends. Strand transfer requires an IN tetramer (depicted as a *circle*) and consists in

IN-mediated breaking of the host DNA on opposite strands with a 5 bp stagger and simultaneous joining of the host DNA to the 3' recessed ends of the viral DNA. The last step is carried out by host DNA repair proteins, which fill in the 5 single-stranded nucleotide gap, remove the two protruding 5' viral nucleotides, and ligate the target host DNA to the viral DNA, ultimately leading to the stable integration of the viral DNA into the host genome. Filled circles at DNA ends represent 5' ends

model substrate allows monitoring of the reaction progression by gel electrophoresis.

The strand transfer or 3' joining reaction consists in the asymmetric break of the host target DNA 5 bp apart and simultaneous joining of the viral 3'-OH recessed ends by a one-step transesterification mechanism (Engelman et al. 1991). This process involves a tetramer of IN molecules and occurs in the nucleus. The reaction can be recapitulated *in vitro* with model substrates. In these, one viral end (half-site integration) or both viral ends (full-site or concerted integration) can

become joined to a target DNA. Half-site integration has been widely used and consists in mixing purified IN with a short oligonucleotide duplex (mimicking viral LTR end, as for *in vitro* 3' processing reactions) and subsequently with a target DNA, thereby reproducing the joining of one viral DNA end to a target DNA. A more faithful *in vitro* reproduction of strand transfer takes advantages of using longer donor DNAs containing mimics of viral 3' recessed LTR ends on both termini, thereby allowing full-site or concerted integration, i.e., the joining of both viral 3' recessed ends to

both strands of target DNA, with a 5 bp stagger. Although IN is able to carry out the 3' processing and strand transfer reactions alone as demonstrated by *in vitro* assays, its interaction with viral and cellular proteins may contribute to integration efficiency. This is best exemplified by lens epithelium-derived growth factor (LEDGF)/p75, a cellular protein interacting with IN, which improves integration efficiency both *in vitro* and *in vivo* and guides the viral genome integration into nonrandom sites of the host DNA (see section “[Integration Target Site Selection](#)”).

Proteins of the host DNA repair machinery probably fill in the five unpaired nucleotides of the host DNA on each side of the viral genome, remove the two viral 5' protruding nucleotides, and ligate the 5' viral ends to the repaired 3' host DNA ends. The specific host cell enzymes involved are unclear, though cocktails of known DNA repair enzymes can carry out the reaction on model substrates *in vitro*. For HIV-1, the repair process generates a 5-bp duplication at each host-virus DNA junction. The repair reaction completes the stable insertion of the viral DNA copy of the RNA genome into the host chromosome, forming the integrated provirus.

Circularization of the Viral DNA

In addition to correct integration, the viral cDNA is sometimes recognized by the host DNA repair machinery to generate 1-LTR or 2-LTR circles. 1-LTR circles are thought to arise from an aberrant RT product or from LTR-LTR homologous recombination. 2-LTR circles arise from the ligation of the two ends of the viral linear cDNA, through the action of the non-homologous end joining pathway (NHEJ), which is comprised of cellular Ku80, XRCC4, and ligase IV NHEJ components. Two-LTR circles are a useful marker for *in vitro* and *in vivo* studies because they are likely to reflect successful early steps, from entry to nuclear import. However, the LTR circles are considered to be dead-end products for viral replication, and only the correctly integrated viral genome (provirus) allows for productive infection, *i.e.*, for efficient transcription of all the viral genes and thus the assembly and release of infectious viral particles (Craigie and Bushman 2012).

Integration Target Site Selection

Although IN is able to catalyze the strand transfer of the viral genome into any host DNA phosphodiester bond *in vitro*, multiple *in vivo* studies have demonstrated that the integration of the viral genome into the host cell chromosome is not random (Desfarges and Ciuffi 2010; Craigie and Bushman 2012). Thanks to the publication of the human DNA genome sequence, it has become possible to map HIV-1-specific integration site distributions, revealing favored host DNA sites for integration. Preferential HIV-1 integration sites (i) display a weak GT^A/TAC DNA sequence consensus with AT-rich local target region; (ii) occur at distorted, bent DNA, at the outer surface of DNA wrapped nucleosomes and at major grooves; (iii) take place in gene-dense regions; (iv) are found in active transcription units, with no bias along the gene, and in both exons and introns; (v) are associated with epigenetic marks characterizing active transcription (histone acetylation, H3K4me1/2, H3K9me1, H3K27me1, H3K36me3); and (vi) occur frequently in regions rich in Alu repeats. HIV-1 integration is disfavored in intergenic regions, in long interspersed nuclear element (LINE) repeats, and in near epigenetic marks associated with repressed transcription (H3K9me2/3, H3K27me2/3, H3K79me3, DNA CpG methylation).

Host Cofactors Involved in Integration

IN is the major viral determinant of HIV-1 integration site targeting in the host DNA (Craigie and Bushman 2012; ► [Cellular Cofactors as Drug Targets, Overview](#)). However, many cellular proteins can interact with HIV-1 IN, thereby potentially affecting integration. Retroviral integration is favored on nucleosomal DNA *in vitro*, and analysis of integration site patterns *in vivo* suggests favored integration on outward-facing major grooves of nucleosome-wrapped DNA. Cellular factors may help to condense and organize the viral DNA. One candidate is the barrier-to-autointegration factor (BAF) which is involved in DNA condensation and prevents suicidal viral autointegration products, and another is LEDGF/p75 (more on the latter below) (Neamati 2011;

Craigie and Bushman 2012; Suzuki et al. 2012). Additional cellular proteins have been shown to interact with HIV-1 IN or assist integration in vitro, including high-mobility-group chromosomal protein A1 (HMGA1), integrase interactor 1 (Ini-1), Gemin2, importin 7, UNG2, VBP1, NUP153, NUP62, p300, DNA-PK, hsp60, EED, transportin 3 (TNPO3/TRN-SR2), and HRP-2 (Suzuki and Craigie 2007; Neamati 2011; Ao et al. 2012; Craigie and Bushman 2012; Suzuki et al. 2012; Taltynov et al. 2012). In general, to date the importance of these proteins to HIV-1 integration in vivo has not been fully clarified, but they do provide interesting hypothesis for further study. Similarly, genome-wide siRNA screens and mass spectrometry binding studies suggest additional potential cellular cofactors (for review and extensive references, see Desfarges and Ciuffi (2010) and Craigie and Bushman (2012)).

Recently, TRN-SR2 and RANBP2 were suggested to be involved in PIC nuclear translocation through an interaction with viral CA, and TRN-SR2 was also shown to interact with the HIV-1 intasome (Larue et al. 2012; ► [Transportin-SR2 \(TNPO3\)](#), [Nuclear Import](#)). Knockdowns of these two cellular factors or specific CA mutants resulted in altered integration site targeting. Although the detailed mechanism is still unclear, these data suggest a functional coupling between nuclear import and proper integration (Suzuki and Craigie 2007; Neamati 2011; Ao et al. 2012; Craigie and Bushman 2012; Suzuki et al. 2012; Taltynov et al. 2012).

LEDGF/p75

LEDGF/p75 is a 530 aa cellular protein belonging to the hepatoma-derived growth factor (HDGF) family that was first identified as a transcriptional co-activator ► [LEDGF/p75](#), [Cofactors of Integration](#). LEDGF/p75 contains an N-terminal chromatin-binding domain as well as a C-terminal integrase-binding domain (IBD), thereby allowing tethering the viral PIC to chromatin, facilitating integration and dictating integration target site selection (Desfarges and Ciuffi 2010; Neamati 2011; Craigie and Bushman 2012; Desfarges and Ciuffi 2012). Biochemical

and structural studies have identified residues involved in this interaction: critical LEDGF/p75 residues comprise I³⁶⁵, D³⁶⁶, F⁴⁰⁶, and V⁴⁰⁸, while IN key residues map to CCD and include L¹⁰², A¹²⁸, A¹²⁹, W¹³¹, and W¹³² on one IN monomer and residues D¹⁶⁷ to H¹⁷¹ on the second IN monomer. These IN residues participate in forming a hydrophobic pocket at the IN dimer interface into which a LEDGF/p75 protein loop structure can be inserted (Li et al. 2011; Neamati 2011).

Cell systems using LEDGF/p75 over-expression, knockdown or knockout, have shown that (i) small amounts of LEDGF/p75 are sufficient for contribution to HIV replication, (ii) LEDGF/p75 protects HIV-1 IN from proteosomal degradation, (iii) LEDGF/p75 improves integration efficiency, and (iv) LEDGF/p75 is the major cellular determinant of HIV-1 integration site targeting preferences.

HIV-1 integration site distribution can be successfully modified by generating LEDGF/p75 constructs in which the chromatin-binding domain of LEDGF/p75 was replaced with other domains which have different chromatin-binding specificities. Expression of such constructs in cells depleted for wild-type LEDGF resulted in altered HIV-1 integration site distributions in cells. This provides strong evidence that a simple tethering mechanism mediates HIV-1 integration targeting by LEDGF/p75. Hepatoma-derived growth factor-related protein 2 (HRP-2), another member of the HDGF family, also contains an IBD and interacts with HIV-1 IN. Recent studies investigated the role of HRP-2 in HIV-1 integration, in the absence of the major cofactor LEDGF/p75, and confirmed that HRP-2 could function as an alternative tether for HIV-1 IN, although less efficiently than LEDGF/p75 (Desfarges and Ciuffi 2010, 2012; Neamati 2011; Craigie and Bushman 2012).

Consequences of HIV-1 Integration

Retroviral integration can affect cells by altering the activity of host genes surrounding the integrated provirus (Craigie and Bushman 2012; Desfarges and Ciuffi 2012). HIV-1 may have evolved to target integration preferentially in

active transcription units in order to allow efficient transcription after integration, thereby improving the chances of productive infection and viral progeny production (Craigie and Bushman 2012). On the host cell side, gene disruption provoked by viral genome insertion may lead to altered transcription of the host gene. Retroviral integration is well-documented to be associated with cancer in numerous animal models, and a rich literature documents the mechanisms by which retroviral integration can cause transformation. Gammaretroviruses, which have different integration site preferences than does HIV-1, have been used as viral vectors in successful gene therapy clinical trials but have been associated with tumor development correlated with insertion of the viral vector genome in the vicinity of proto-oncogenes.

In the case of HIV-1, however, though HIV+ individuals may develop HIV-associated cancers, these tumors do not appear to be mediated directly by HIV-1 – analysis of tumor cells does not show integrated HIV-1 proviruses. Thus other causes appear to mediate HIV-related malignancies, such as loss of immune surveillance due to the immunodeficient state or activation of cancer-associated infectious agents. The lack of insertional activation by HIV-1 is likely linked to the propensity to infect postmitotic cells, and the presence of at least two cytotoxic/cytostatic HIV-1 gene products (HIV-1 *vpr* and *env*).

HIV-1 Latency

The stable integration of the viral genome into the host cell chromosome ensures a lifelong association of the virus with the infected cell. The long-term persistence of the integrated provirus is one of the main barriers to eradicating HIV-1 from infected individuals (Siliciano and Greene 2011). HIV+ patients treated effectively with antiretroviral therapy (ART) have no detectable plasma viremia, but cessation of ART leads to viral rebound, establishing the existence of long-lived latently infected cells. Extensive efforts are currently being devoted to understanding the repressive mechanisms responsible for latency (viral

transcriptional silencing). Multiple factors likely influence the efficiency of HIV-1 transcription – for example, the physiological reduction of T-cell transcription associated with formation of the memory compartment is one likely mechanism (► [Transcription \(Initiation, Regulation, Elongation\)](#)). Another potential factor effecting transcriptional efficiency is the genomic site of viral DNA integration. The effects of chromatin environment on transcription are well known, for example, through studies of position-effect variegation in model organisms. Although HIV-1 integrates preferentially into active transcription units, this is only a statistical trend, so that a minority of proviruses can be found in less favored regions. Studies of HIV-1 integration site positions for poorly transcribed proviruses have suggested several possible effects of integration site. Integration in highly transcribed host transcription units may be associated with poor transcription of HIV-1 due to transcriptional interference (conflict between cellular and viral gene transcription). Integration within centromeric heterochromatin, as indicated by integration within centromeric alphoid repeats, or in gene deserts, may lead to repression by heterochromatin formation (Siliciano and Greene 2011; Craigie and Bushman 2012).

Compounds Inhibiting HIV-1 Integrase

HIV-1 viral genome integration is a key step for productive infection, and thus an attractive drug target for inhibition (Neamati 2011; Arts and Hazuda 2012; Hazuda 2012). Identifying inhibitors of HIV-1 IN was challenging but ultimately succeeded with the approval of raltegravir by the US Food and Drug Administration (FDA) in 2007. These compounds bind to the active site formed upon completion of the terminal cleavage reaction, making contacts to both the enzyme and cleaved viral DNA ends. The compounds thus selectively block the DNA strand transfer reaction. Importantly, structural studies using the PFV model further suggest that compound binding displaces the viral DNA end from its correct position in the enzyme active site, thereby interfering

with the chemistry of the strand transfer step (Cherepanov et al. 2011; Li et al. 2011).

Viral escape mutants have arisen that contain amino acid substitutions in the IN protein that reduce sensitivity to raltegravir and related molecules. Two primary pathways have been documented, one involving N155H, the other Q148H. A variety of further substitutions optimize replication of viruses containing the primary substitutions.

Due to the emergence of drug-resistant viruses, identification of novel integrase inhibitors is an important next goal. The resolution of the PFV intasome structure and the identification of essential HIV-1 IN cofactors open new opportunities for inhibiting integration through structure-based design of small molecules and through different mechanisms, such as blocking IN-LEDGF/p75 interaction or IN multimerization (Taltynov et al. 2012).

Conclusion

HIV-1 DNA integration is a key step in viral replication, allowing establishment of a productive infection. Although the enzymatic reactions catalyzed by the HIV-1 IN have been elucidated, many cellular proteins contributing to successful viral integration remain to be validated or uncovered, particularly at the level of cellular repair proteins. Recently, novel cellular proteins (TRN-SR2, RANBP2) highlighted a role for nuclear import in integration targeting, suggesting a functional coupling between these two viral steps. LEDGF/p75 and HRP-2 tether the HIV-1 integration complexes to chromatin and dictate integration site selection. The solved structure of the PFV IN in complex with viral and target DNAs represents a major advance in the molecular understanding of integration. The possible role of integration target site selection in HIV latency is another important topic for further study. A detailed and complete picture of HIV-1 integration process, including cellular players, is starting to be unveiled, and may help identifying novel drug targets and new inhibitors of this essential step of HIV-1 replication.

Integrin Alpha4beta7

Ester Ballana and José A. Esté
IrsiCaixa, Hospital Universitari Germans Trias i
Pujol, Universitat Autònoma de Barcelona,
Badalona, Spain

Definition

The integrins are a superfamily of cell adhesion receptors that play central roles in the biology of metazoans by controlling cell adhesion to the extracellular matrix, cell migration, growth, differentiation, and apoptosis. Integrins are prime examples of physiologically important receptors that have been usurped by viruses for attachment and/or cell entry, including HIV. Various integrins have been recognized as host factors that influence HIV replication. Integrin $\alpha 4\beta 7$, the gut-homing receptor, can serve as a receptor and a signaling molecule for HIV, by interaction with HIV gp120 protein. The specific affinity of gp120 for $\alpha 4\beta 7$ provides a mechanism for HIV-1 to target activated cells that are critical for efficient virus propagation and dissemination following sexual transmission.

The Integrin Superfamily

The integrins are a superfamily of transmembrane receptors that bind to extracellular matrix ligands, cell-surface ligands, and soluble ligands, to mediate adhesion of cells and intercellular interactions. Integrins are the main receptor proteins that cells use to both bind to and respond to the extracellular matrix (Takada et al. 2007).

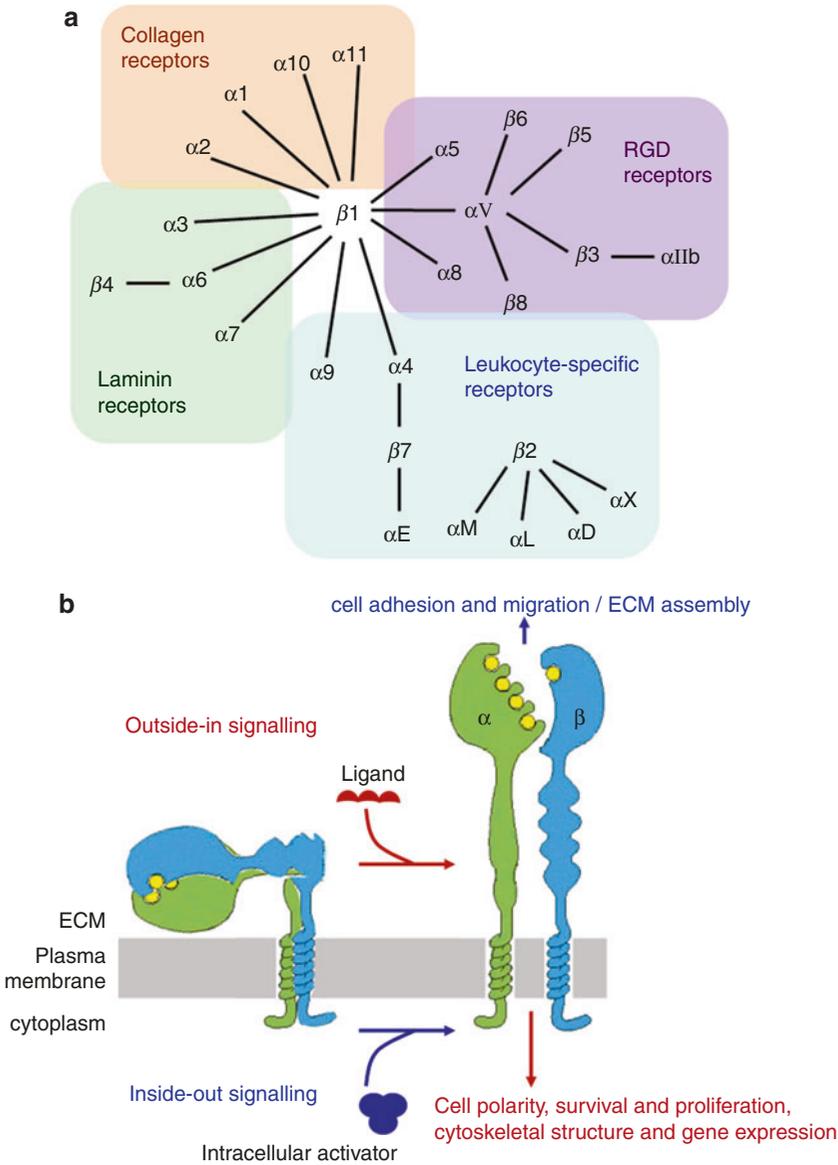

An integrin molecule is composed of two non-covalently associated transmembrane glycoprotein subunits, named α - and β -subunits. In humans, at least 18 α - and eight β -subunits are known, generating 24 different heterodimers, each of them with different cell expression patterns and ligand specificities (Fig. 1a) (Takada et al. 2007). Members of this family have been found in mammals, chicken, and zebra fish, as

well as lower eukaryotes (sponges, the nematode *C. elegans*, and the fruit fly *D. melanogaster*). The α - and β -subunits have distinct domain structures, with extracellular domains from each subunit contributing to the ligand-binding site of the heterodimer (Fig. 1b).

A given integrin can have different ligand-binding specificities in different cell types, mainly due to the existence of specific factors that by interacting with integrins modulate their binding activity (Fig. 1a). On the other hand, many matrix proteins are recognized by multiple integrins, for example, at least eight integrins bind fibronectin and at least five bind laminin (Takada et al. 2007). The sequence arginine-glycine-aspartic acid (RGD) was identified as a general integrin-binding motif, although individual integrins are also specific for particular protein ligands. The binding of integrins to their ligands depends on extracellular divalent cations (Ca^{2+} or Mg^{2+} , depending on the integrin), reflecting the presence of divalent cation-binding domains in the extracellular part of the α - and β -subunits (Shattil et al. 2010). The type of divalent cation can influence both the affinity and the specificity of the binding of an integrin to its ligands.

Integrins contribute to the regulation of development, immunity, inflammation, and hemostasis and to the development of diseases including autoimmunity, atherothrombosis, and neoplasia (Takada et al. 2007). Integrins function as traction receptors that can both transmit and detect changes in mechanical force acting on the extracellular matrix. They serve as transmembrane links between extracellular contacts and the actin microfilaments of the cytoskeleton, whose behavior integrins also regulate and modulate.

There are two directions of integrin signaling, which have different biological consequences. Signals generated inside the cell can either enhance or inhibit the ability of integrins to bind to their ligand outside the cell (Fig. 1b). The ability of a cell to control integrin-ligand interactions from within is termed *inside-out* signaling. On the other hand, integrins also behave like traditional signaling receptors in transmitting information into cells by *outside-in* signaling (Shattil et al. 2010).

Integrin Alpha4beta7, Fig. 1 Human integrin structure and function. (a) The members of human integrin family and how they combine to form heterodimeric integrins. Eighteen α - and eight β -subunits have been identified, which are able to generate 24 different integrins. Integrin subunits that bind to each other to form a heterodimer are connected by *solid lines*. Although each integrin has distinct ligand-binding specificity, they can be grouped with respect to the similarity of their ligands and function. (b) Schematic representation of integrin function. The inactive

integrin is in a V shape with the ligand-binding domain close to the membrane. There is close association between the α - and β -subunits in the membrane-proximal region. There are two directions of integrin signaling. A cell can regulate the adhesive activity of its integrins from within (inside-out signaling, *blue lines*). Integrins also function as signal transducers, activating various intracellular signaling pathways when activated by matrix binding (outside-in signaling, *red lines*)

During *inside-out* signaling, an intracellular activator binds to the β -integrin tail, leading to conformational changes that result in increased affinity for extracellular ligands (integrin

activation). *Inside-out* signaling controls adhesion strength and enables sufficiently strong interactions between integrins and extracellular matrix proteins to transmit the forces required for cell

migration and extracellular matrix remodeling and assembly. The integrin affinity for a given ligand directly regulates the nature of the binding and appears to tune the degree and kinetics of cell adhesion.

On binding extracellular ligands, mammalian integrins cluster in the membrane and transduce signals inside the cell (*outside-in* signaling). Extracellular ligand binding induces conformational changes that lead to the interaction of the cytoplasmic tail with intracellular signaling molecules. The intracellular signals are responsible for the control of cell polarity, cytoskeletal structure, gene expression, and cell survival and proliferation.

Both signaling processes are often closely linked; integrin activation can increase ligand binding, resulting in *outside-in* signaling. Conversely, ligand binding can generate signals that cause *inside-out* signaling, i.e., integrins transduce signals into the cell, but they can also receive intracellular signals that regulate their ligand-binding affinity (Shattil et al. 2010). In most cells, integrins are usually maintained in an adhesion-competent state, with the exception of platelets and leukocytes, where *inside-out* signaling is particularly important as integrins usually have to be activated before they can mediate adhesion. Regulated adhesion allows leukocytes to circulate unimpeded until they are activated by an appropriate stimulus. Moreover, because the integrins do not need to be synthesized de novo, the response is extremely fast.

Integrins in Virus Infections

When searching for their host tissues, animal viruses frequently attach to cell-surface receptors that have key roles in normal cell function. Integrins are a prime example of physiologically important receptors that have been usurped by viruses for attachment and/or cell entry. Using integrins as an “entrance door,” viruses take advantage of the wide integrin expression, as well as of the variety of cells expressing integrins throughout the body. Moreover, integrin ligation by pathogens elicits potent signaling responses that promote cytoskeletal reorganization and/or cell entry (Stewart and Nemerow 2007).

Both enveloped and nonenveloped viruses utilize integrins for cell invasion, and they do so with a variety of mechanisms (Stewart and Nemerow 2007). Viruses such as adenoviruses elicit potent signaling events via ligation of integrins that enhance infection of different host cells. Adenoviruses interact with αV integrins via a long flexible RGD loop on the surface of the penton base. Several large enveloped DNA viruses, such as herpesviruses, use also integrins to invade host cells. Several members of the Hantaviruses family (enveloped viruses containing a negative-stranded RNA genome) use also integrins as receptors; pathogenic strains utilize $\beta 3$ integrins, whereas $\beta 1$ integrins are commonly used by nonpathogenic Hantaviruses. $\beta 3$ integrins, rather than $\beta 1$ integrins, have a significant role in vascular permeability; therefore, the use of $\beta 3$ integrins by pathogenic Hantaviruses can explain why infection by these strains results in severe disease.

One of the most commonly used integrin receptors by members of diverse virus families is integrin $\alpha V\beta 3$, which is known to exhibit substantial diversity in ligand recognition. Thus, multiple viruses have evolved to take advantage of the promiscuous attributes of integrin $\alpha V\beta 3$. Because integrins are capable of recognizing relatively small peptide sequences, this may provide a convenient pathway for virus evolution as integrin-ligand sequences can be readily incorporated without drastically altering virus structure.

Integrins and HIV

Infection by HIV-1 causes a profound depletion of CD4⁺ T cells. This depletion eventually leads to the progression of HIV disease ultimately resulting in AIDS. To enter and infect a permissive cell, HIV-1 requires CD4 and the chemokine receptors CCR5 or CXCR4. Besides the normal association between the external envelope gp120 and the appropriate cell-surface receptors, other interactions between the virion and receptors on the target cell surface also contribute to the formation of a replication-competent environment. Adhesion molecules including integrins have been recognized as host factors that influence HIV replication. Several integrins have been

involved as host factors affecting HIV replication at different steps of the virus life cycle.

LFA-1 Integrin

Besides interactions between the viral envelope glycoproteins with cell-surface receptors, the interaction between cell-derived molecules incorporated into virions and their ligand could also modulate the HIV replication cycle. HIV-1 incorporates a vast array of host cell membrane molecules during budding, including the intercellular adhesion molecules (ICAM-1), which is an immunologically important integrin ligand, generally expressed on inflamed endothelium and antigen-presenting cells (APC).

Engagement of ICAM-1 with the integrin lymphocyte function-associated antigen 1 (LFA-1), its natural ligand (also known as CD18 or integrin $\beta 2$), increases viral infectivity by several folds. In $CD4^+$ T lymphocytes that express functional LFA-1, this phenomenon is associated with an enhancement of both HIV-1 attachment and virus-cell fusion (Tardif and Tremblay 2005).

LFA-1-mediated adhesion plays a key role in immune surveillance and the mounting of a potent immune response. More specifically, LFA-1 is involved in the arrest of rolling lymphocytes along blood vessels facilitating extravasation and migration of the activated T cells to infection sites. The integrin LFA-1 participates in the formation of the immunological synapse between T cells and APCs (Bromley et al. 2001). These events require a rapid modulation of adhesion/deadhesion and the adhesion needs to be stable for hours to sustain the immunological synapse. Hence, activation of LFA-1 must be tightly regulated. Engagement of ICAM-1 induces *outside-in* signaling that triggers lateral diffusion of heterodimers in the plasma membrane, a process regulating the adhesion strengthening. Upon T-cell activation, the *inside-out* signaling generates an intermediate affinity state and activates the cysteine protease calpain that releases LFA-1 from its cytoskeleton constraint and favors lateral diffusion of LFA-1, triggering cell adhesion. In the context of HIV infection, LFA-1-mediated cytoskeleton remodeling and signaling are key events to achieve an increase in HIV-1 entry in primary $CD4^+$ T lymphocytes (Bromley et al. 2001).

αV Containing Integrins and HIV Infection in Macrophages

Human blood monocytes, originated from hematopoietic precursors in the bone marrow, give rise to mature macrophages which are distributed ubiquitously in all tissues. Adhesion molecules, particularly integrins, have been shown to upregulate when monocytes differentiate into macrophages, suggesting that integrins play an important role in macrophage adhesion, migration, and tissue infiltration. Blood monocytes and tissue resident macrophages are important *in vivo* cell targets of HIV infection. Macrophages may become chronically infected or serve as reservoirs of latent virus. Furthermore, HIV may sequester macrophage immunoregulatory function, that is, inducing secretion of proinflammatory cytokines that lead to recruitment and activation of new target cells for HIV, including $CD4^+$ T cells.

Monocytes, but not monocyte-derived macrophages (MDM), are difficult to infect by HIV. A productive viral infection may only occur after monocytes are differentiated following serum or cytokine stimulation, a process that leads to the upregulation of different cell-surface markers and receptors, including αV integrins (De Nichilo and Burns 1993). Conditional αV knockout mice models have shown that the absence of αV did not affect lymphocyte migration to lymphoid organs or *in vitro* activation of lymphocytes. On the contrary, these models indicate an important role for αV integrin on myeloid cells (macrophages, dendritic cells, and/or neutrophils) in immune regulation.

In macrophages, blocking αV integrin interaction with its ligands initiates a signaling cascade, mediated by MAP kinases, that finally compromises HIV-1 replication by downregulating NF- κB -dependent HIV-1 transcription (Ballana et al. 2009). Integrin αV can be coupled with various β -integrin subunits ($\beta 1$, $\beta 3$, $\beta 5$, $\beta 6$, and $\beta 8$), forming heterodimeric proteins that could differently affect HIV replication. A significant role in HIV-1 infection of macrophages has been reported in the case of the $\alpha V\beta 5$ integrin dimer (Ballana et al. 2011).

The complex interactions between monocytes/macrophages and HIV are of special importance,

since these cells are relatively refractory to the cytopathic effects. Adhesion to the substrate and differentiation state enhance HIV replication in macrophages. Although several α - and β -subunits are expressed in macrophages, integrin $\alpha V\beta 5$ is one of the mediators of the replication enhancement seen in macrophages.

Integrin $\alpha 4\beta 7$ Role in HIV Infection

Lymphocyte recirculation depends on specific interactions between the lymphocyte cell surface and the surface of the specialized endothelial cells lining the postcapillary venules in the peripheral lymphoid organs. Many cell types in the blood come into contact with these endothelial cells, but only lymphocytes adhere and then migrate out of the bloodstream. The lymphocytes initially adhere to the endothelial cells via homing receptors that bind to specific ligands on the endothelial cell surface. Expression of the integrin $\alpha 4\beta 7$, together with the chemokine receptor CCR9, is essential for a preferential homing of T cells to the gut. The vitamin A metabolite, retinoic acid, enhances the expression of $\alpha 4\beta 7$ and CCR9 on T cells upon activation and imprints them with the gut tropism.

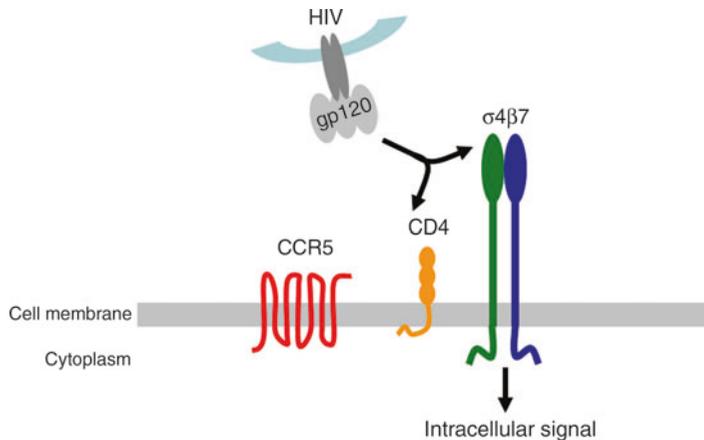

Regardless of the route of transmission, HIV-1 rapidly establishes infection in gut-associated lymphoid tissue (GALT), destroying the majority of CD4+ T cells during the acute phase of infection. This structural and functional damage is accompanied by nonspecific systemic immune activation and cell death, and it has been proposed that this depletion represents an irreversible insult to the immune system, which ultimately results in AIDS.

The $\alpha 4\beta 7$ integrin functions principally as a gut-homing receptor, facilitating the migration and retention of lymphocytes from gut inductive sites (Peyer's patches and mesenteric lymph nodes) to the lamina propria. These sites within GALT play central roles in the initial phases of infection. In the acute phase of HIV infection, following mucosal transmission, the bulk of HIV replication occurs in Peyer's patches and mesenteric lymph nodes. Concurrently, HIV mediates a massive depletion of lamina propria CD4+ T cells. Integrin $\alpha 4\beta 7$ facilitates the migration of

lymphocytes from gut inductive sites to the lamina propria. Thus $\alpha 4\beta 7$ is functionally linked to the major sites of HIV replication and CD4+ T-cell depletion during acute infection.

A specific biochemical interaction between the HIV-1 envelope protein gp120 and $\alpha 4\beta 7$ on CD4+ T cells has been described (Arthos et al. 2008). The HIV-1 envelope protein gp120 binds and signals by means of an activated form of integrin $\alpha 4\beta 7$ on CD4+ T lymphocytes. The explicit linkage between $\alpha 4\beta 7$ and Peyer's patches, mesenteric lymph nodes, and lamina propria and the early phase of acute infection suggest that gp120- $\alpha 4\beta 7$ interaction plays an important role at an early point in HIV infection in vivo (Fig. 2). Different facts support the role of $\alpha 4\beta 7$ (Arthos et al. 2008). First, the highest frequencies of HIV-1 infection occur in the memory CD4+ T-cell compartment in the gut, in which, unlike in almost all other tissue compartments, memory CD4+ T cells express activated $\alpha 4\beta 7$. Second, the gp120- $\alpha 4\beta 7$ interaction is conserved across the four major HIV-1 subtypes. gp120 binding to $\alpha 4\beta 7$ is mediated by the Leu-Asp-Val tripeptide in the V2 loop, which effectively mimics a similar epitope on the natural ligands of $\alpha 4\beta 7$. Despite the fact that the tripeptide resides in one of the most variable domains of gp120, it is highly conserved. Finally, gp120 activates LFA-1 in a $\alpha 4\beta 7$ -dependent way. As mentioned above, LFA-1 is capable of increasing the efficiency of HIV infection. This structural mimicry, along with the high degree of conservation across subtypes, implies that binding to $\alpha 4\beta 7$ confers a replication advantage to HIV.

Transmission of CCR5 viruses is strongly favored over CXCR4 in sexual transmission. The subset of CD4+ T cells localized within mucosal tissues that express high levels of $\alpha 4\beta 7$ are also distinct in expressing high levels of CCR5 and relatively low levels of CXCR4 and therefore represent an ideal target population for productive infection. On these cells $\alpha 4\beta 7$ is closely associated with both CD4, the entry receptor, and CCR5, the fusion coreceptor (Cicala et al. 2009). The marked coexpression of CCR5 and $\alpha 4\beta 7$ and the close physical association of these two surface markers with CD4, on cells that are highly

Integrin Alpha4beta7, Fig. 2 Schematic representation of $\alpha 4\beta 7$ interaction with HIV-1 virions. $\alpha 4\beta 7$ demarcates a distinct subset of CCR5/CD4⁺ T cells that are prone to productive infection. $\alpha 4\beta 7$ is closely associated with CD4,

and therefore, the affinity of HIV gp120 for $\alpha 4\beta 7$ would increase the likelihood of establishing a productive infection by specifically targeting this highly susceptible subset of cells

susceptible to productive infection, provide at least a partial explanation for the strong bias toward R5 virus transmission across mucosal surfaces (Fig. 2).

Unlike CCR5, $\alpha 4\beta 7$ is not hidden from HIV when a virion engages a CD4 receptor. $\alpha 4\beta 7$ is a prominent receptor, approximately three times the size of CD4, that gp120 can engage independently of CD4 (Cicala et al. 2010). However, both receptors reside in close proximity on the CD4⁺ T-cell surface. The gp120 V2 loop, which mediates binding to $\alpha 4\beta 7$, is positioned near the apex of an envelope spike. In this way, both $\alpha 4\beta 7$ and its binding epitope on a virion spike are well positioned for the initial engagement between the virion and the target CD4⁺ T cell. Expression pattern is also different for CD4 and $\alpha 4\beta 7$ receptors; CD4 exhibits a near-uniform expression regardless of whether they are metabolically active or resting, whereas $\alpha 4\beta 7$ is highly expressed on activated cells (Arthos et al. 2008). In this manner, $\alpha 4\beta 7$ provides a structural mechanism for HIV-1 to target activated cells that express high levels of CCR5.

The interaction between gp120 and $\alpha 4\beta 7$ triggers a signal that is not yet fully defined. However, gp120-mediated signal transduction is known to impact viral replication in several cellular subsets. HIV-1 gp120 is a ligand that can mediate signals

at least through CD4 and the chemokine receptors, CCR5 and CXCR4 (Berger et al. 1999). The capacity of gp120 to trigger signals that promote viral replication in both activated and resting cells may facilitate infection, an activity that may be particularly important during mucosal transmission. gp120 signals may provide the necessary metabolic stimulus to achieve a productive infection, and it has been speculated that gp120- $\alpha 4\beta 7$ signal transduction may play an important role and could be a major factor in the transmission of HIV at the mucosal surface.

Virological synapses allow efficient transfer of viral proteins from an infected cell to an uninfected target cell (Piguet and Sattentau 2004). A virological synapse is a structure formed between an APC and T cells and precedes T-cell activation. The formation of an HIV-1 virological synapse is facilitated by the interaction of envelope with CD4. Integral to the virological synapses are adhesion molecules including LFA-1, whose activation is one of the consequences of gp120- $\alpha 4\beta 7$ interaction (Arthos et al. 2008). gp120- $\alpha 4\beta 7$ mediate a rapid activation of LFA-1, and therefore, it is plausible that gp120-mediated signaling through host cell-expressed $\alpha 4\beta 7$, CD4, and CCR5 works together to promote infection by reiterating events that are associated with the formation of a virological synapse.

In summary, the explicit linkage between $\alpha 4\beta 7$ and the major sites of HIV replication following mucosal transmission suggests that this interaction plays an important role at an early phase in the HIV infection cycle. $\alpha 4\beta 7$ is not required for infection but appears to increase the efficiency of infection. The capacity of the HIV envelope to bind to $\alpha 4\beta 7$ represents a strategy whereby HIV is able to more efficiently infect a highly susceptible subpopulation of CD4⁺ T cells. In this manner the probability of a productive infection following sexual/mucosal transmission is increased.

Conclusion

It is not surprising that HIV, like other viruses, have usurped integrins for cell invasion, because integrins are expressed on a wide variety of cells throughout the body. Moreover, integrin ligation by viruses elicits potent signaling responses that promote cell entry and viral replication and transmission. HIV takes advantage of various integrins that recognize different ligands and are expressed in different cell types, being an example the case of LFA-1, αV , and $\alpha 4\beta 7$. LFA-1 stabilizes the cell-to-cell contacts, αV -containing integrins are relevant in macrophages, and $\alpha 4\beta 7$ plays a key role in GALT during the initial phases of infection. Although none of them is required for HIV infection, all of them have important roles in specific settings and contribute to HIV pathogenesis.

Interactions Between HIV-2 and Host Restriction Factors

Shmona Simpson and Sabelle Jallow
Nuffield Department of Medicine, University of Oxford, Oxford, UK

Definition

Host restriction factors mount a first line response to viral infection, yet, are often hampered by specific viral proteins which directly resist their

action. The HIV-2 proteins *gag*, *vif*, *env*, and *vpx* serve to modify the actions of four major host restriction factors: TRIM5 α , APOBEC, Tetherin, and SAMHD1, respectively. The HIV-2 proteins utilise no specific enzymatic function in their roles as antagonists, but rather act as “linker molecules”; connecting host restriction factors to the proteins of cellular pathways that facilitate their sequestration or degradation, and in so doing-enabling viral replication and transmission. This article explores the complex interplay between the host restriction factor and the HIV-2 protein antagonist.

Introduction

Human Immunodeficiency Virus Type 2 (HIV-2) arose during the zoonotic transfer of sooty mangabey Simian Immunodeficiency Virus (SIV_{sm}) on at least eight occasions. Of the resulting eight lineages, HIV-2 A-H, only A and B are endemic, resulting in an estimated one to two million cases, mainly across West Africa. Like HIV-1, HIV-2 is a blood-borne virus, primarily transmitted via heterosexual contact. However, the rate of transmission is substantially lower than that of HIV-1. The majority of HIV-2-infected persons exhibit a phenotype similar to that of HIV-1 long-term non-progressors. This phenotype is characterized by low to undetectable viral load, with little to no symptoms of immunodeficiency. Nevertheless, 20% of people living with HIV-2 progress to AIDS in a manner identical to that of HIV-1-infected persons.

Box 1 Defining Host Restriction Factors

Restriction factors are host proteins that mount a first line response to viral infection. HIV specifically antagonises the action of human restriction factors, yet is severely hampered by analogous restriction factors in non-human primates, indicating the pivotal role of restriction factors in cross-species transmission. Restriction factors
(continued)

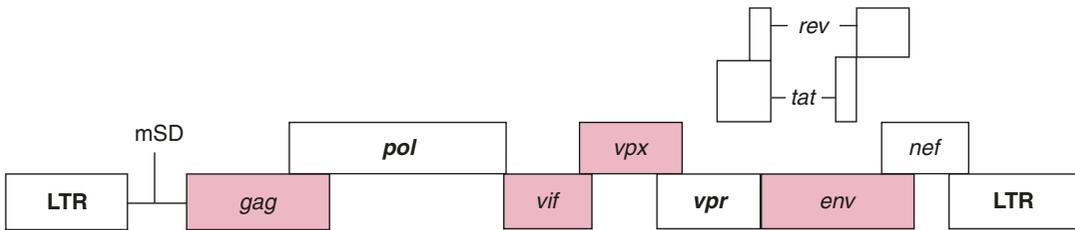

Box 1 (continued)

in the context of HIV-2 infection are characterised by:

- Derivation from functionally autonomous genes that are unusually variable
- Sensitivity to immune activation and viral infection resulting in notable changes in their expression
- The identification of specific viral proteins which directly resist their action
- A significant decrease in retroviral activity during their overexpression, or attenuation of antagonist-deficient retroviral infection

Experimental infection of macaques has been the dominant animal model for HIV research, resulting in the discovery of several gene expression signatures that interfere with virus transmission and disease progression. The discovery that HIV-1 could not replicate in rhesus macaques despite its similarity to SIV led to the identification of endogenous factors that restrict a number of retroviruses. These proteins, termed host restriction factors (Box 1), are encoded by functionally autonomous genes and tend to be unusually variable. In fact, their counterparts in nonhuman primates are also unusually variable, suggesting that they have evolved under diversifying selection. They are believed to have a role in immunity and inflammation because transcription of the genes encoding these proteins is in most cases stimulated by the innate immune system. The distinctive feature of host restriction factors is that several retroviruses have evolved to resist their action by, in most cases, encoding accessory genes that antagonize their function.

HIV-2 bears more similarity to nonhuman primate lentiviruses than to HIV-1. However, HIV-2 has a highly similar protein structure to HIV-1, and yet is a less pathogenic virus. A better understanding of the interaction between HIV-2 and the human host could play an important role in determining methods to counteract the highly pathogenic HIV-1. Furthermore, the ability of host

Interactions Between HIV-2 and Host Restriction Factors, Fig. 1 HIV-2 Genes which antagonise the function of Host Restriction Factors. Structural proteins

gag and *env*, and accessory proteins *vif* and *vpx*, are involved in HIV-2 antagonism of host restriction factors

restriction factors to counteract HIV-2 infection should yield important insights into mechanisms that may reduce virulence of the human immunodeficiency viruses.

Like all primate lentiviruses, HIV-2 possesses the major structural genes *gag*, *pol*, and *env*, which encode the essential proteins for infection and replication. The genome also contains the regulators of viral expression *tat* and *rev*, along with four accessory genes, *vif*, *vpx*, *vpr*, *nef* (Fig. 1) The HIV-2 proteins *gag*, *vif*, *env*, and *vpx* serve to modify the actions of four major host restriction factors: TRIM5 α , APOBEC, Tetherin, and SAMHD1 respectively. The HIV-2 proteins utilize no specific enzymatic function in their roles as antagonists, but rather act as “linker molecules,” connecting host restriction factors to the proteins of cellular pathways that facilitate their sequestration or degradation, and in so doing facilitating viral replication and transmission.

Gag Versus TRIM5 α

The HIV Capsid encoded by Gag was previously thought to be an inert packaging shell that protects the genomic material. However, it has emerged that it has several domains that allow interaction with host proteins, such as Cyclophilin A and the cleavage and polyadenylation specific factor 6 (CPSF6). Recent studies into host restriction factors have shown that the Capsid serves as a pathogen-associated molecular pattern (PAMP) for TRIM5 α which is a pattern recognition receptor (PRR) (Pertel et al. 2011).

The species-specific retroviral restriction properties of TRIM5 α were discovered because HIV-1 could not grow in certain Old World monkey cells. TRIM5 α is a member of the *Tripartite Motif* family of proteins that have the three protein domains: RING, B-Box, and Coiled Coil. TRIM5 α has an additional domain, the PRYSPRY/B30.2 domain, that interacts with the retroviral capsid and is responsible for species specificity (Stremlau et al. 2005). Depending on the mammalian species or cell line, TRIM5 α may mediate a postentry block of lentiviral replication either before or after reverse transcription. Although the exact mechanism of retroviral restriction is not known, several mechanisms have been proposed with supporting experimental data. Oligomeric TRIM5 α recognition of and binding to the incoming intact capsid destabilizes the capsid core, leading to accelerated or premature uncoating, which perturbs reverse transcription. The E3 ligase activity of the RING domain can add ubiquitin molecules to itself and to other proteins, leading to proteasome-mediated protein degradation of the capsid-TRIM complex. TRIM5 α is also a pattern recognition receptor that recognizes and binds to the viral capsid, causing a cascade of innate immune signaling that leads to an antiviral state, restricting retroviral replication.

Human TRIM5 α has very limited effect on HIV-1 but can restrict N-tropic murine leukemia virus (N-MLV) potently and can limit HIV-2 replication to certain extent. HIV-1 restriction by human TRIM5 α maps to the v1 region of the PRYSPRY domain, where a change from arginine or any positively charged residue at position

332 to a proline or any uncharged residue results in potent restriction of both HIV-1 and SIVmac (Yap et al. 2005; Li et al. 2006). Restriction of N-MLV is different from that of HIV-1, in that a larger area of the PRYSPRY domain is involved as well as the coiled coil for restriction of N-MLV mutant L117H (Yap et al. 2005). Human TRIM5 α restriction of HIV-2 was also mapped to a single amino acid at position 119 of HIV-2 ROD capsid. HIV-2 viruses with a proline at this position were much more sensitive to human TRIM5 α restriction than those without (glutamine or alanine) (Song et al. 2007). Further studies showed that presence of hydrophobic amino acids or those with ring structures were associated with sensitivity to TRIM restriction and those with small side chains or amide groups were linked to TRIM5 α resistance (Miyamoto et al. 2011). Three-dimensional modeling of the HIV-1 and HIV-2 capsids showed that the N terminal domains each consist of 7 α -helices from which 3 loops protrude. Position 119 of the HIV-2 capsid is located in the loop between helices 6 and 7. When a proline is present at position 119, the loop between helices 6 and 7 (L6/7) is closer to the loop between helices 4 and 5 (L4/5), a region that directly interacts with cyp A in HIV-1 (Miyamoto et al. 2011). The presence of hydrophobic or ring-structure residues at position 119 of the capsid maintained a certain conformation at L4/5 that is characteristic of sensitive viruses. Curiously, the equivalent position in the N-tropic Murine Leukemia Virus (N-MLV), at position 110, determined viral susceptibility to Human TRIM5 α ; it was suggested that while HIV-1 and HIV-2 are restricted by different mechanisms, human TRIM5 α utilizes a similar mechanism of recognition for N-MLV and HIV-2 (Miyamoto et al. 2011). Further information on TRIM5 α in the context of HIV-2 infection is available elsewhere in this chapter (“► TRIM5 Alpha and HIV-2 Infection”).

Vif Versus APOBEC

Viral infectivity factor (Vif) is an accessory protein conserved across all primate lentiviruses.

Vif-deficient HIV-1 is unable to spread physiologically in relevant macrophage and T-cell cultured cells (Ribeiro et al. 2005). Instead, Vif-deficient virions are produced in normal quantities, but the ability of these virions to infect the subsequent target cell is compromised. This is due to the presence of APOBEC proteins. The APOBEC (apolipoprotein B mRNA editing enzyme, catalytic polypeptide-like) proteins have several members, A-H, that have been studied in the context of HIV infection. The APOBEC protein most explored in HIV-1 research, APOBEC3G (A3G), is expressed in the majority of cell types. In the absence of Vif, A3G is packaged into nascent virions and acts during reverse transcription to hypermutate viral DNA and decrease cellular cDNA levels. The expression of A3G is sensitive to viral infection and interferon, and so the amount of A3G incorporated into nascent virions is proportionate to its expression level in the producer cell. The net effect of its increased expression, and packaging into nascent virions, is a restriction of HIV-1 infection.

APOBEC proteins mediate their effect utilizing two zinc-coordinating deaminase domains (Z domains) at each end of the protein:

The carboxy-terminal Z domain is responsible for deamination.

The amino-terminal Z domain mediates A3G's incorporation into viral particles and is also recognized by HIV-1 Vif.

In order to package itself into assembling virions, A3G uses its amino terminal to bind RNA and attach the Z domain to the NC region of Gag. Following its incorporation into assembling virions, it is transported from the producer cell to the target cell. Once the virion has fused with the target cell, A3G dimerizes and associates with the viral reverse transcriptase complex. A3G then deaminates cytidine residues to uridine in nascent, single-stranded, negative strand cDNA. These uridine-rich transcripts can be degraded. However, if salvaged, during the synthesis of the DNA plus strand, adenosines are incorporated instead of the original guanines resulting in G to A mutations. Up to 10% of cytidines may be

edited resulting in G to A hypermutation of the plus strand sequence, and the loss of genetic integrity. However, not all of the hypermutation occurring in Vif-deficient HIV-1 restriction can be attributed to A3G. A3G has a substantial preference for mutating the second C of CC but not TC. APOBEC3F (A3F), a sister cytidine deaminase to A3G with high sequence identity, favors TC and also serves to induce G to A hypermutations resulting in nonfunctional HIV provirus. The combined effect of A3G and A3F restriction results in hypermutated proviruses that are largely nonfunctional, and to decreased levels of cDNA during Vif-deficient HIV infection. In the case of wild-type HIV-1, the expression of APOBEC proteins has no effect on viral infectivity. Vif is able to bind A3G and A3F, and recruit them to a cellular ubiquitin ligase complex that comprises cullin5, elongins, Rbx2, and an E2 conjugating enzyme. The polyubiquitination of APOBEC proteins results in their proteosomal degradation, and thus thwarts their incorporation into nascent viral particles.

Conversely, A3G and A3F do not play a major role in the replication of Vif-deficient HIV-2. The Vif-deficient HIV-2 virus is able to replicate in the majority of cell lines, including the lymphocyte and macrophage cell lines that are not permissive to Vif-deficient HIV-1. In fact, the Vif of SIVsm (the parent strain of HIV-2) is able to rescue the replication of Vif-deficient HIV-1 in human H9 cells. Though Vif is conserved across all primate lentiviruses, HIV-2 Vif has only 30% amino acid identity with HIV-1 Vif, and it is evident that APOBEC proteins interact with the two very differently. Regardless of the amount of A3G expressed in a cell, the infectivity of Vif-deficient HIV-2 remains very high (Abada et al. 2005). A substantial reduction in infectivity is only observed in the presence of HIV-2 Vif mutants. These Vif mutants confer a reduction in Vif expression and occur in small motifs essential for Vif function and stability. It is possible that such mutants make Vif more susceptible to APOBEC proteins; however, the infectivity of these mutants is unaltered by increases in A3G expression. Furthermore, regardless of whether a reduction in infectivity is observed in HIV-2 Vif mutant studies,

no alteration is observed in the steady state of deaminase. This indicates that the deamination conferred by A3G is ineffective against HIV-2.

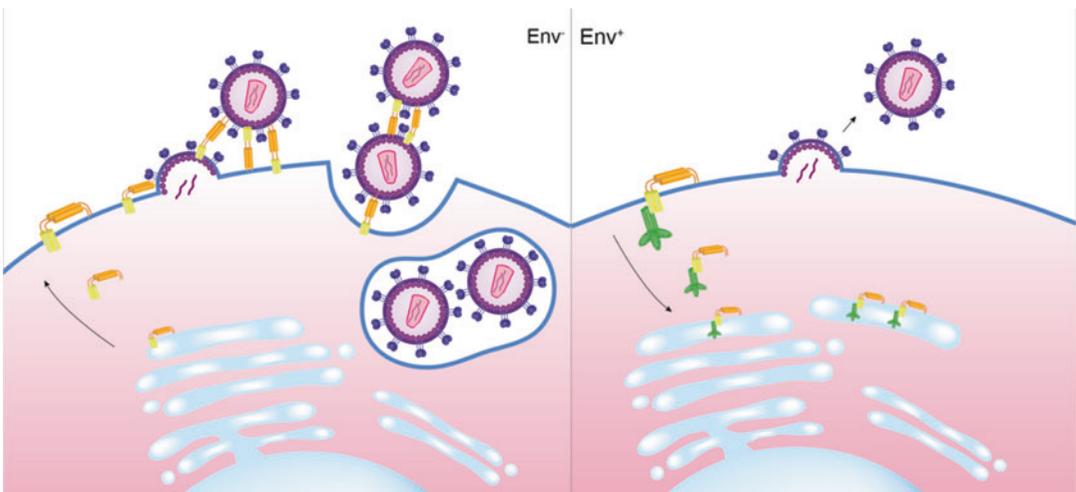

Paradoxically, even though A3G is ineffectual for Vif-deficient HIV-2 infectivity, HIV-2 Vif strongly degrades A3G. Furthermore, the effect of HIV-2 Vif is not limited to A3G. HIV-2 Vif can also antagonize A3F, A3H haplotype II, and A3B, with intermediate to high sensitivity, and A3D with low sensitivity. Despite the variation in sensitivity of HIV-2 Vif induced degradation of APOBEC proteins, all known APOBEC proteins except A3A bind to HIV-2 Vif. Now, HIV-2 Vif is better at restricting both A3G and A3F than HIV-1 Vif. In fact, experiments show that HIV-1 Vif reduces A3G by 90% and HIV-2 Vif reduces A3G by almost 100%. The effect of HIV-2 Vif antagonism on A3F is even more disparate, showing a 100% reduction compared with only 83% by HIV-1 Vif. This is because HIV-2 Vif interacts with separate and distinct domains on APOBEC proteins from those that HIV-1 Vif interacts with. For example, HIV-1 Vif targets a short motif in A3G at position 128–130. This region is essential for HIV-1 Vif's antagonism of A3G. However, HIV-2 Vif targets multiple, non-neighboring residues found between positions 163 and 321 of A3G (Smith et al. 2014). This indicates that HIV-2 Vif has a broader range of interaction sites, which may result in a greater propensity to degrade A3G than HIV-1 Vif.

It is evident that APOBEC proteins are less able to resist HIV-2 Vif than HIV-1 Vif, and that HIV-2 Vif is better at antagonizing APOBEC proteins than HIV-1 Vif (Wiegand et al. 2004). But despite the complex interplay between HIV-2 Vif and APOBEC proteins, to date there is no physiologically relevant evidence for their interaction in the context of HIV-2 infection of the human host. It is possible that the deamination resulting from APOBEC proteins is countered by another virus mechanism or accessory protein which is presently unknown. Finally the mechanism by which APOBEC proteins are incorporated into nascent HIV-2 virions has yet to be confirmed, and it is very possible that this mechanism may yield important insights into how the effect of APOBEC proteins is managed by HIV-2.

Env Versus Tetherin

The Env protein which forms the HIV-2 envelope comprises transmembrane protein gp36 and glycoprotein gp125 and serves to bind and initiate a conformational change in the host cell membrane facilitating virus to cell fusion. HIV-2 env is not only able to utilize a greater range of coreceptors, but its interaction with these coreceptors leading to virus/cell fusion occurs twice as fast, when compared to that of HIV-1 Env. In addition to its role in virus entry, HIV-2 Env is responsible for a four to sixfold increase in virus export, a function analogous to that of HIV-1 vpu (Abada et al. 2005). Infection of CD4+ T-cells with HIV-1 mutants lacking the accessory gene vpu leads to poor HIV-1 production, and the accumulation of mature virions on cell surfaces and within vacuolar structures. It was observed that protein tetherin was responsible for this retention of vpu-defective HIV-1 virions. The envelope glycoprotein of some HIV-2 isolates is able to stimulate the release of vpu-defective HIV-1 virions from tetherin positive cells.

Tetherin is a type II transmembrane protein which is constitutively expressed on several cell types and is upregulated in response to pro-inflammatory cytokines. Tetherin is found at the cell membrane from which wild-type HIV-2 is exported in infected cells, and also in intracellular compartments such as the trans-Golgi network and endosomes which package proteins into membrane-bound vesicles. Tetherin is able to facilitate transport between the cell membrane and the Golgi apparatus and endosomes using clathrin adaptors. Anchored at both the N and C terminals to the plasma membrane, the extracellular coiled coil domain protrudes. Acting as a dimer, tetherin cross-links viral membranes, and viral and cellular membranes to each other. In this manner, it is able to tether nascent virions, preventing their release (Fig. 2). Instead, they remain tethered to the infected cell. The virions are then internalized into endosomal compartments where they are degraded. In addition, it is also highly likely that tetherin serves an additional function in cell signaling. As antigen-presenting cells are targets for HIV-2, the

Interactions Between HIV-2 and Host Restriction Factors, Fig. 2 Env-mediated Down Regulation of Cell Surface Tetherin. In Env deficient HIV-2 infection, tetherin moves from the ER, through the Golgi network, to the plasma membrane through the anterograde trafficking pathway where it is recycled between the TGN and the cell surface. Tetherin is available to cross link viral membranes,

and viral and cellular membranes to each other, resulting in the tethering of nascent virions to the cell. The virions are internalised and degraded. In wild-type HIV-2 infection, HIV-2 Env attaches to tetherin redirecting it away from the plasma membrane and causing its retention in the trans-golgi network. Nascent HIV-2 virions are able to bud from the infected cell

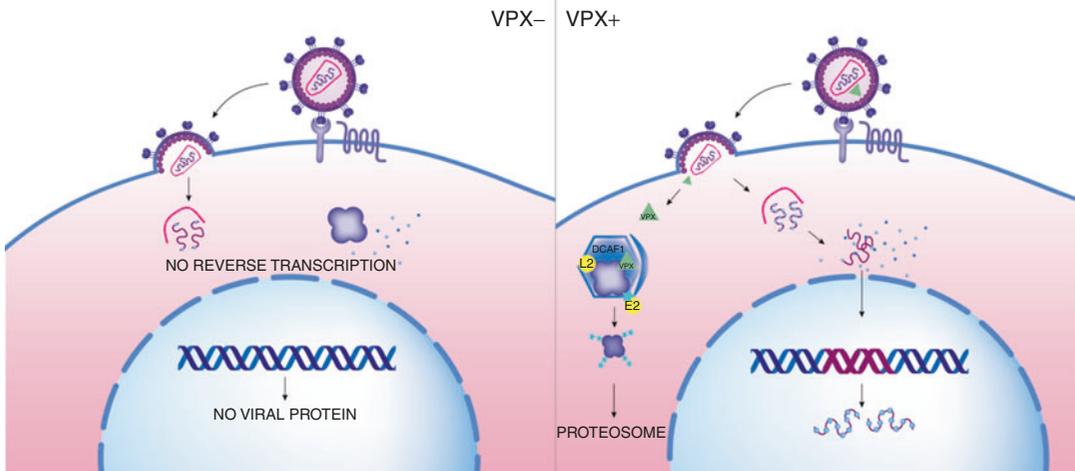

degradation of nascent virions in phagosomes likely leads to the presentation of viral particles to the adaptive immune system. Further, the tetherin promotor contains binding sites for NF-AT and NF- κ B (IFN and interleukin response elements). As tetherin is induced by signals that also trigger type I IFN production, the induction of the type I IFN response and tetherin is linked. Recent data show that tetherin may act as an innate sensor of viral infections that activates NF- κ B to induce an inflammatory response (Hotter et al. 2013).

As observed with TRIM and APOBEC proteins, HIV-2 is able to antagonize host restriction factors by the recruitment of ubiquitin ligases, targeting them for degradation. An alternative method employed by HIV-2 to counteract host defenses is by altering the trafficking pathways used by the host factors to prevent their expression at the cell surface. HIV-2 Env does not reduce total cellular levels of tetherin, as studies have yet to find evidence of tetherin degradation. However, HIV-2 Env acts to downregulate the total level of cellular expression of tetherin in two ways: firstly the downregulation of cell-surface tetherin and secondly through tetherin accumulation in the trans-Golgi network, with the net effect of excluding tetherin from virus assembly and export sites. HIV-2 Env attaches its cytoplasmic tail to tetherin, forming a link between it and the clathrin adaptor complex AP-2 and serves to redirect *de novo* or recycling tetherin away from the plasma membrane and to perinuclear compartments via clathrin-mediated endocytosis (Le Tortorec et al. 2011). However, while Env promotes the release of virions and facilitates subsequent viral infection, this may come at a cost to the virus. In the case of HIV-1, the anti-tetherin effect is mediated by an accessory protein: vpu. However, HIV-2 Env is a major structural protein which accompanies tetherin along the clathrin-mediated endocytosis pathway, and into its sequestration. This reduction in cellular Env may decrease the levels of Env available during assembly of virus, and thus the amount of virus which can be exported. This is one theory for the reduced virulence of HIV-2.

Vpx Versus SAMHD1

HIV-2 encodes two accessory proteins that are homologous to HIV-1 Vpr: Vpr and Vpx. Vpx is unique to HIV-2, SIVsm, and SIVmac, and arose from gene duplication of Vpr during the evolution of primate lentiviruses (Planelles and Barker 2010). Vpx is considered a paralogue of HIV-1 Vpr. They are both packaged into budding viral particles and are able to assemble into an E3 ligase complex with cellular proteins (Fujita et al. 2010). These functions suggest that Vpx plays an important role in early infection by targeting certain proteins for proteosomal degradation. Early studies showed that Vpx is dispensable for HIV-2 infection of lymphocyte or monocyte derived immortalized cell lines. However, Vpx-deficient HIV-2 shows impaired replication in monocyte-derived macrophages, PBMCs, and primary T-cells. This indicates that Vpx is essential for HIV-2 replication only in nondividing/slow dividing cell lines. Further, though human cells of myeloid lineage and resting CD4 T-cells possess the necessary receptors to allow HIV-1 capture and entry, they are not readily infected by HIV-1. In this case, HIV-1 infection is rescued by the intracellular delivery of Vpx (Sharova et al. 2008). The reason HIV-1 encounters a blockade in non- and slow-dividing cells was found to be due to a host restriction factor: Sterile alpha motif (SAM) and histidine/aspartic acid (HD) domain protein 1 (SAMHD1).

SAMHD1 is found in all cell types and localizes to the nucleus. It possesses nuclease and deoxyribonucleoside triphosphate phosphohydrolase (dNTPase) activity. As a dNTPase, SAMHD1 forms a tetramer and acts to sequester dNTPs, thus keeping them at very low levels outside of the S phase of the cell cycle (Yan et al. 2013). This reduction in cellular dNTP halts reverse transcription (Fig. 3). SAMHD1 also possesses exonuclease activity against single-stranded DNAs and RNAs, and preferentially cleaves 3' overhangs in double-stranded substrates. This function further contributes to virus restriction by direct cleavage of viral nucleic acids (Beloglazova et al. 2013). SAMHD1 is

Interactions Between HIV-2 and Host Restriction Factors, Fig. 3 SAMHD1 Blocks Reverse Transcription in the Absence of Vpx. In Vpx-deficient HIV-2 infection, SAMHD1 reduces the amount of dNTP available for reverse transcription halting the production of viral protein.

In wild-type HIV-2 infection, Vpx couples SAMHD1 with the Cul4/DDB1/DCAF1 ubiquitin ligase complex facilitated by cyclin L2, resulting in proteasomal degradation of SAMHD1. As a result, dNTP is available for viral reverse transcription leading to production of viral proteins

regulated by phosphorylation at position T592. In cycling cells, SAMHD1 is phosphorylated, and while its dNTPase activity is unaltered, it is unable to block retroviral restriction (White et al. 2013). Phosphorylation is mediated through SAMHD1's interaction with the cell cycle regulator cyclin-dependent kinase (CDK1). CDK1 is inactive in resting cells, hence explaining why Vpx is only essential for HIV-2 replication in non- or slow-dividing cells. The C-terminal region of SAMHD1 contains a Vpx binding motif, which is important for the ability of Vpx to degrade SAMHD1. Vpx counteracts SAMHD1 restriction by binding to the restriction factor, and coupling with the Cul4/DDB1/DCAF1 ubiquitin ligase complex. This results in the proteasomal degradation of SAMHD1 (Fig. 3). Vpx requires DCAF1 interaction for efficient macrophage infection by HIV-2. Studies on other DCAF-1 interacting proteins revealed that SAMHD1 forms a complex with cyclin L2 which facilitates SAMHD1 interaction with DCAF1. In fact, knockdown of cyclin L2 resulted in a five-fold, threefold, and fourfold reduction in the replication of HIV-1, HIV-2, and Vpx deficient HIV-2, respectively (Kyei et al. 2015). While in HIV-2 infection, Vpx tags SAMHD1 to DCAF resulting in its proteasomal

degradation, it is evident that cyclin L2 assists Vpx in proteasomal degradation of SAMHD1.

Vpx also antagonizes APOBEC3A (A3A) and interferon regulatory factor 5 (IRF5), providing insight into why A3A is the only APOBEC protein which does not bind to HIV-2 Vif. Unlike A3G, A3A exerts its effect in myeloid cells, monocytes, dendritic cells, and macrophages. Silencing of A3A in primary macrophages, dendritic cells, and monocytes results in an increased susceptibility to HIV-1 and augmented replication of R5 HIV-1 tropic viruses. Further, treatment of myeloid cells with IFN α results in increased resistance to HIV-1 infection which coincides with a threefold increase in A3A expression. The antiviral effect mediated by A3A results in a decrease in viral DNA accumulation. Like A3G, A3A is believed to act as a cytidine deaminase, destroying viral DNA through extensive deamination of cytosine. In addition, A3A exerts a cytotoxic effect by:

- Inducing strand breaks in genomic DNA which results in cell-cycle arrest
- Degrading foreign DNA
- Blocking retrotransposition of LINE-1, Alu, and TLR

Experimental evidence shows that A3A, but not A3G, co-immunoprecipitates with Vpx proteins derived from HIV-2 and SIVmac. That same study concluded that SIVmac Vpx antagonizes A3A by inducing its degradation in the early stages of infection (Berger et al. 2011). Biochemical analysis of A3A activity reveals its enclosure in autophagosomal membrane compartments and cell nuclei (Pham et al. 2013). In the case of IRF5, Vpx inhibits IRF5-mediated transactivation by a mechanism that is not completely understood. IRF5 is involved in the production of pro-inflammatory cytokines and Type 1 interferon. Expression of Vpx can reduce mRNA levels and protein production of Toll-like receptor-dependent IL6, IL12, and TNF α , which would interfere with the upregulation of interferon-sensitive host genes (Cheng and Ratner 2014).

The interaction of Vpx with SAMHD1, while fascinating, has yet to result in substantial clinically relevant findings. Vpx contains a highly conserved polyproline motif (positions 103–109) which is critical for its effective translation. Mutation of multiple prolines to alanines in this motif resulted in minimal expression of Vpx. Yet, a study of Vpx sequences from HIV-2 progressors and nonprogressors revealed that only one mutation at position 68 reduced SAMHD1 antagonism in vitro. It is possible that further studies of the interaction between Vpx and SAMHD1 in multiple populations may reveal clinically relevant mutations in host or virus that have a clinical impact on the course of HIV-2 disease progression.

Conclusions

It is widely believed that there are many more host restriction factors to be uncovered, and further roles of HIV-2 proteins to be described. It is plausible that the reduced virulence of HIV-2 when compared to HIV-1 may be due to modulation of viral replication by host restriction factors. Furthermore, several HIV-2 proteins alter the course of mutant HIV-1 infection, and in addition, the mutation of HIV-1 amino acids to achieve greater identity to their HIV-2 counterparts substantially

alters retroviral replication in several instances. Proteins such as MOV10 and TRIM22 are presently under investigation for their role in retroviral disease progression. Research into TRIM5 α , APOBEC, tetherin, and SAMHD1 in the context of HIV-2 infection presents significant scope for therapeutic exploitation. Gene therapies that modify host restriction factors to better restrict retroviral infection and agents that block interactions between antagonistic viral proteins and host restriction factors are attractive approaches for the development of new antiretroviral therapies.

Jail and Prison Populations, Epidemiology of HIV/AIDS

Lauren Brinkley-Rubinstein
Department of Social Medicine/Center for Health Equity Research, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA
University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

Definition

Human immunodeficiency virus (HIV) is the virus that causes acquired immunodeficiency syndrome (AIDS) and can lead to a diminished immune system – opening one up to the risk of developing opportunistic infections. Individuals in jail or prison have higher rates of HIV, and HIV and incarceration share many risk factors (e.g., illicit substance use). Often jails and prisons are thought of as synonymous, but it is important to note that there are important differences. Jails are facilities in which individuals are housed while either serving short-term sentences (typically no longer than one year) or are being detained pre-trial. In contrast, prisons house those who are incarcerated for longer time periods (e.g., greater than a 1 year).

Introduction

Whereas the last several years have had a slight decline in the number of individuals incarcerated, the rate of incarceration in America continues to soar (Kaeble and Glaze 2015). Today over 6.7 million people are involved in the criminal justice (Carson 2014). Those who are incarcerated have a disproportionate burden of health issues, including HIV (Brinkley-Rubinstein 2013). Incarcerated individuals are three times greater more likely than their non-incarcerated counterparts to have HIV (Maruschak 2001–2010). Approximately 14% of all HIV-positive individuals will go to jail at some point in any given year (Spaulding et al. 2009). Rates of AIDS are also elevated among incarcerated individuals with the rate of AIDS being about 2.4 times that of the general population (CDC 2012).

HIV testing in jails and prisons provides a unique opportunity for screening that might not otherwise be accessible. Access to HIV treatment may increase while incarcerated. For example, incarcerated HIV-positive individuals may be maintained on antiretroviral medications and often experience subsequent viral load suppression (Meyer et al. 2014). Therefore, correctional settings can provide a unique opportunity to address HIV among a particularly vulnerable population.

Demographics and Risk Factors of Incarcerated HIV-Positive Individuals

Low-income communities of color are disproportionately impacted by both the criminal justice system and HIV. According to the CDC (2012), black men are seven times more likely to be incarcerated than their White counterparts. Mirroring this trend is the disparate rate of HIV among minorities. Blacks account for 44% of all new HIV-positive individuals while only accounting for about 12% of the general population (CDC 2014). While the reasons for why minorities have a disproportionate risk of both HIV and incarceration can be difficult to isolate, scholars have pointed to both structural and individual-level risk factors (Brinkley-Rubinstein 2013). Macro-level policy related to the war on drugs, the limiting of access to treatment for those with mental illnesses, poverty, and lack of access to insurance and medical treatment have been cited as contributing to disproportionate minority contact in prison and jails and to disparate rates of HIV in communities of color (Brinkley-Rubinstein 2013; CDC 2012).

HIV Criminalization

HIV criminalization adds a unique layer of complexity to the possible health impact of the criminal justice system. In many states, the sexual transmission of HIV from one person to another is viewed as a criminal act if the HIV-positive person knows that he or she has HIV and does not tell the other person. Often such laws go further than just criminalizing sexual transmission of HIV and extend to include additional incidents of person-to-person contact in an attempt to minimize risk of transmission via fighting, spitting, or other routes. Galletly and Lazzarini (2013) found that from 2000 to 2010, 44% of all HIV exposure charges in their study area were for nonsexual modes of transmission.

Moreover, in 13 states, prostitution charges can be modified for those who are HIV positive. For example, in some states, if a person is charged with prostitution and is known or later found to be

HIV positive, his or her charge is upgraded from a misdemeanor to a felony offense. HIV-positive individuals who are convicted of a prostitution charge are sometimes required in select states to register as sex offenders for the rest of their lives. For example, Galletly and Lazzarini (2013) surveyed data on HIV-specific charges from 2000 to 2010 in a midsized Southern city and identified 25 arrests for HIV exposure and 27 for aggravated prostitution, most of which did not involve allegations of transmission.

HIV Transmission in Prisons and Jails

While a majority of HIV-positive individuals in prison/jail acquired HIV in the community, there are routes of HIV transmission that are unique to correctional settings (CDC 2006; Federal Bureau of Prisons 2006; National HIV/AIDS Strategy 2010). The prison environment can include overcrowding and lack of access to and low quality of healthcare and access to medications (Brinkley-Rubinstein and Turner 2013). In addition, prisoners often do not have access to clean needles that would lower the risk of HIV after engaging in intravenous drugs use or tattooing. Additional risks include lack of access to condoms and engagement in unprotected sex. However, as Hammett (2006) reports, correctional settings vary from place to place and depend on the type of facility (e.g., prison or jail). As such, questions remain about just how much transmission of HIV is occurring in the carceral setting.

In the early years of the HIV epidemic, there were many attempts to lower both the incidence of HIV among prisoners and the mortality rate of inmates who were already infected. The initial correctional response to HIV prevention in jails included mandatory testing and segregation of HIV-positive inmates. This, in part, was an attempt to stem transmission of HIV from prisoner to prisoner *in the correctional setting*. However, over the years many more comprehensive and effective strategies to HIV prevention in correctional settings have been developed (Hammett 2006).

HIV Testing in Prisons and Jails

HIV exploded onto the public health scene in the late 1970s, and the first cases of HIV/AIDS were discovered in a New York State correctional facility in the early 1980s. A study by Hammett and his colleagues (Hammett 1986) found that, of 766 inmates who were diagnosed with AIDS, nearly half of them died by the time the study period was over. This shocking mortality rate highlighted the dire impact the epidemic was having on correctional populations. However, over the years correctional facilities have begun to normalize HIV testing and screening.

In 2009, most states had some form of HIV testing implemented in jails and prisons/carceral settings. There are three types of possible testing options. Voluntary testing encompasses testing policies that are both active and passive. This type of testing is recommended by the National Commission on Correctional Health Care, the American Public Health Association, and the World Health Organization. However, very few states test exclusively upon prisoner request. Routine testing is an approach to testing in which prisoners are tested unless they refuse. Finally, mandated testing is conducted by several prison and jail systems including the Federal Bureau of Prisons. Mandatory testing can take place at intake, discharge, or in the event of a high-risk incident.

Institutional barriers to testing may restrict the effectiveness of testing and screening. For instance, jail facilities often have high turnover rates of inmates with short sentences or those who are being transferred to other facilities. These logistical constraints can make it hard to administer tests *and* provide results since HIV testing can sometimes take longer than one might be incarcerated. Rapid tests may lessen this barrier but come at an increased financial cost. Regardless of the barriers, HIV screening and testing have had a great impact on linkage to care during incarceration and continuation of care post-release by easing the ability to identify HIV-positive inmates. HIV testing has also caused a major decline in the number of inmates dying AIDS-related deaths. To illustrate: the number of

AIDS-related deaths in 2008 was 120, while in 1995 it was 1110 (Maruschak 2005; CDC 2012).

HIV Treatment in Correctional Facilities

Incarcerated individuals are the only population that has a constitutional guarantee of healthcare (Estelle vs. Gamble 1976). However, research related to treatment and medication access in correctional settings is mixed, demonstrating both positive and negative experiences. For instance, Meyer et al. (2014) reported that viral suppression during incarceration was attained due to regular access to antiretroviral medication in the correctional setting. However, other studies have illuminated barriers to well-being that are salient to HIV-positive populations, including stigma, restricted access to medical care, and lack of trust of medical providers (Brinkley-Rubinstein and Turner 2013). Federal funding for linkage to care post-release is available for low-income individuals via the Ryan White Care Act. Funds from this act are treated as funds of last resort meaning that they are available for those who could not otherwise afford treatment and other related medical and social services.

Linkage to Services and Health Impact of Incarceration Post-Release

While HIV treatment during incarceration can have health benefits, the impact of incarceration post-release may be more negative. During community re-entry linkage to HIV services can be challenging. In addition, HIV outcomes post-release can be worse than even before incarceration (Iroh et al. 2015). For example, in Maryland, HIV-positive drug users who had recently been briefly incarcerated were seven times more likely to experience virological failure than HIV-positive drug users who had not been incarcerated (Wilson et al. 2012). However, some linkage services post-release have been demonstrated as an effective way to keep those who have been incarcerated healthy and linked to medical care. The

Health Resources and Services Administration funded EnhanceLink, which provides augmented linkage services to medical and social services for people just released from jail (Spaulding et al. 2012). EnhanceLink included 10 cities and 20 jails. The initiative linked participating individuals to medical care and other transitional services post-release. This is but one example of a successful intervention aimed at linkage post-release.

Conclusion

While much has changed over the years, those in correctional facilities continue to have very disparate rates of HIV. Prevention and treatment initiatives such as screening and testing, treatment while in jail or prison, and linkage to services post-release have been effective at reducing mortality rates of those who have experienced incarceration. However, incarceration is often a factor that is overlooked as a contributor to the health outcomes of HIV-positive individuals. There is preliminary evidence of effective practices to help maintain individual health, stem transmission, and ease the post-release experience; but, existing research also highlights the need for continued research and innovation to limit the intersectional impact of HIV/AIDS and the incarceration experience on health.

Hill, NC, USA

Definition

Kaposi sarcoma-associated herpesvirus (KSHV) or human herpesvirus 8 (HHV-8) is a virus that is associated with the original AIDS-defining tumor, Kaposi sarcoma (KS). This virus is necessary for the development of KS. Expression of the viral protein, LANA, represents the definitive diagnostic marker for KS. In addition to KS, KSHV is also associated with primary effusion lymphoma and a plasmablastic variant of multicentric Castlemann disease.

KSHV is a double-stranded DNA virus. There exists no vaccine against this virus. Viral DNA replication is sensitive to ganciclovir. The virus establishes lifelong latency in the infected host.

Introduction

The development of Kaposi sarcoma (KS) is linked to infection with Kaposi sarcoma-associated herpesvirus (KSHV, also known as human herpesvirus 8). This association was established when Drs. Yuan Chang and Patrick Moore discovered viral DNA in KS biopsies, but not in the skin from healthy controls. KSHV is present in essentially every tumor cell within a KS lesion (Chang et al. 1994). Within each tumor cell, the viral latent proteins, as well as the viral micro-RNAs, are expressed. Other viral proteins may be expressed as well depending on tumor subtype and the particular signals that emanate from the tumor microenvironment, e.g., hypoxia can activate lytic replication and gene expression of specific KSHV genes (Davis et al. 2001). In addition to KS, KSHV also drives the pathology of primary effusion lymphoma (PEL) (Cesarman et al. 1995) and a plasmablastic variant of multicentric Castlemann disease (MCD) (Carbone et al. 2009; Soulier et al. 1995). In KS and PEL the virus predominantly exists in its latent form and does not replicate to high levels. MCD may be an exception, since it is associated with high-level expression of the viral IL6 homologue and other lytic proteins. Primary infection or reactivation from tumor cells and latently infected CD20⁺ B cells leads to systemic viremia, salivary

shedding, and person-to-person transmission. In extremely severe cases, high-level viremia can lead to KS-associated inflammatory cytokine syndrome (KICS) (Polizzotto et al. 2012).

Transmission

KSHV is transmitted orally or by sexual routes, blood transfusion, or the transplantation of infected organs (reviewed in Bagni and Whitby (2009)). In endemic areas such as sub-Saharan Africa and the Mediterranean region, the prevalence of KSHV is high. KSHV is detected in breast milk and maternal saliva suggesting an oral route of transmission in children. Close family relatives are positive for viral DNA in their saliva, also suggesting an oral transmission route. By comparison to endemic and epidemic regions, Western Europe and the USA have a low prevalence of KSHV. Here the virus is thought to be transmitted sexually, particularly in men who have sex with men (MSM). The mechanism of transmission here may be largely through the use of saliva as a lubricant. The reason for this apparent geographic difference in transmission pattern is unknown. Blood-borne transmission, as well as transmission by a transplanted organ, can also occur. At present the blood supply even in endemic areas or for high-risk donors is not routinely screened for KSHV. It is noteworthy that unlike HIV, KSHV appears to be an old virus that coevolved with humans.

Kaposi Sarcoma

The incidence of KS reflects the prevalence of KSHV. In certain high-prevalence regions, such as sub-Saharan Africa, KS is not uncommonly seen in children, the elderly, and transplant recipients independent of HIV infection. Whether there exists a genetic susceptibility locus for KSHV infection or for the development of KS is currently unknown. KS is one of the most common cancers in sub-Saharan Africa where it causes significant morbidity and mortality (Jemal et al. 2012). HIV

coinfection substantially increases the risk for developing KS. In Western Europe and the USA, the number of KS cases has declined since the introduction of combination antiretroviral treatment (cART), but KS still occurs even in the presence of high CD4 counts and low-HIV viral load (Krown et al. 2008). For example, KS rates in the San Francisco area for white men were ~30 per 100,000 during 1987–1991 (pre-cART era) and declined to 2.8 in 1998 (post-cART era). A further decline however did not happen and KS incidence in the US has stabilized since 2000. There are multiple epidemiological forms of KS:

- (i) “Classic” KS afflicts elderly men of Mediterranean or eastern European origin. Classic KS occurs in the absence of HIV coinfection.
- (ii) “Endemic” KS occurs in Central and Eastern Africa in the absence of HIV coinfection. It is often a disease of children or young adults.
- (iii) “Transplant-associated” or iatrogenic KS develops in immunosuppressed individuals e.g., organ transplant patients. This also occurs in the absence of HIV coinfection.
- (iv) “Epidemic” KS also known as AIDS-KS is the most common AIDS-defining cancer, which predominantly afflicts HIV-infected MSM, although women can also develop KS.

These forms intermix, as HIV is now prevalent in KS endemic areas, even in children, and HIV+ patients undergo organ transplantation. In addition KS has been noted to flare up shortly after the start of cART, a phenomenon that is called KS immune reconstitution inflammatory syndrome (KS-IRIS). KS is also seen in some cases of KSHV-associated herpesvirus inflammatory syndrome (KICS), which is a recently described clinical entity that is associated with high-level KSHV replication (Polizzotto et al. 2012).

Systemic KSHV viral load is associated with KS development and often precedes it. It is important to consider, however, that KSHV levels in the plasma of KS patients are low (200–30,000 copies) compared to other herpesviruses. There is no

direct correlation between the severity of disease or number of lesions and KSHV viral load. This suggests that KS lesions result from the seeding of infected cells (analogous to traditional metastasis) as well as de novo infection of peripheral, lymphatic endothelial cells (reviewed in Ganem (2010)). In addition, local seeding and autocrine stimulation may help local KS lesions grow once they begin.

Kaposi Sarcoma-Associated Herpesvirus (KSHV): Genetic Structure

KSHV is a double-stranded DNA virus. Its genome is approximately 130,000 bp in length. A long unique region encodes all known viral proteins and is flanked on either end by a varying number of terminal repeat sequences. Upon circularization the terminal repeat sequences fuse and serve as the latent origin of replication and as the anchor point by which the viral extrachromosomal plasmid is tethered to the host chromosome. During latency the host cell DNA-dependent DNA polymerase is used to replicate the latent episomes. By contrast, lytic viral replication initiates at two conserved regions (oriLyt) and is dependent on the viral DNA-dependent DNA polymerase, as well as a complex of core replication proteins. The viral DNA polymerase is sensitive to ganciclovir, azidothymidine, foscarnet, and cidofovir, but not acyclovir. Two viral kinases (Orf36 and Orf21) mediate susceptibility to ganciclovir and azidothymidine.

KSHV encodes approximately 84 open reading frames. These can be categorized in multiple ways. Blocks of co-regulated proteins exhibit homology to other herpesviruses and mediate viral DNA replication, entry, capsid, envelope, and tegument formation. A second set of genes (K genes) are unique to KSHV or only present in the lymphotropic lineage of herpesviruses, which includes ► [Epstein-Barr-Virus \(EBV\)](#), as well as the monkey and mouse homologues of KSHV (reviewed in Chang and Moore (1996), and Damania (2004)). Several KSHV genes are homologues of human cellular genes and appear to have been acquired from the human genome.

KSHV Structure

KSHV virions exhibit an electron-dense capsid surrounded by a lipid bilayer envelope. In between the capsid and the envelope is a morphologically amorphous but highly organized proteinaceous layer called the tegument. The envelope is studded with viral glycoproteins, which engage host cell surface receptors and participate in viral entry. KSHV encodes seven glycoproteins: ORF22 (gH), ORF39 (gM), ORF47 (gL), ORF53 (gN), ORF68 (gB), and K8.1. Three of these, gB, gH, and gL, are required to mediate membrane fusion. The tegument contains multiple proteins and RNA transcripts. The herpesvirus tegument proteins are important as they are delivered into the target cell upon primary infection and may thus contribute to early reprogramming events before the synthesis of immediate-early proteins. The KSHV capsid architecture and polypeptide composition have been determined. Cryo-EM reconstruction has revealed that the icosahedral capsid is symmetric ($T = 16$) with 20 triangular faces. The building blocks are composed of hexamers and pentamers of the major capsid protein (MCP/ORF25) and interconnected by heterotrimer structures comprised of the minor capsid proteins ORF62 and ORF26 (Deng et al. 2008).

KSHV Entry

The virus enters target cells through multiple receptors and coreceptors (reviewed in Chandran (2010)). The $\alpha V\beta 3$ and $\alpha V\beta 5$ integrins serve as receptors for KSHV (Akula et al. 2001). The viral gB protein contains the signature integrin-binding RGD motif. Antibodies to either integrins or RGD peptides block entry. xCT is another receptor for KSHV. It is part of the cell surface CD98 (4F2 antigen) complex. Expression of xCT restores permissivity for KSHV and antibodies against xCT block infection. DC-SIGN (CD209) is also a receptor for KSHV. KSHV infection can be blocked by an anti-DC-SIGN monoclonal antibody and soluble DC-SIGN. Most recently, ephrin receptor A2 has been shown to act as a coreceptor

of KSHV by binding to the viral gH and gL proteins (Hahn et al. 2012). Lastly, heparin sulfate increases the efficiency of infection. Since this virus enters multiple cell types (B lymphocytes, monocytes, endothelial cells, epithelial cells), different receptors may be utilized in different cell lineages; they may be essential for some cells but only serve auxiliary roles in others.

Upon entry, the virus immediately triggers an innate host response and induces interferon. In monocytes, KSHV activates TLR3 resulting in its upregulation and induction of downstream mediators, including IFN- β 1 and the chemokine CXCL10 (also called IP-10). In plasmacytoid dendritic cells (pDCs), which are the chief IFN-producing cells in the body, KSHV activates TLR9 (reviewed in West et al. (2012)). In endothelial cells KSHV downregulates TLR4.

KSHV Gene Regulation

Many of the studies of KSHV gene regulation have been done in PEL cell lines. These studies have shown that viral reactivation, replication, egress, and infectious virion production can be triggered by a variety of signaling pathways (reviewed in Mesri et al. (2010)). The initial trigger event leads to the coordinated transcription of three kinetic classes of transcripts: those encoding immediate-early proteins (RTA/Orf50, K-bZIP), those encoding early proteins (MTA/Orf57, polymerase and its associated factors, vGPCR/Orf74), and those encoding late genes (capsid and tegument proteins).

The viral immediate-early transactivator RTA is necessary and sufficient to initiate KSHV viral replication (reviewed in Deng et al. (2007) and Staudt and Dittmer (2007)). The KSHV *Rta* gene encodes a 691-amino-acid protein that is highly phosphorylated and localizes to the nucleus of mammalian cells. Deletion of 160 amino acids in the C-terminal activation domain of the KSHV Rta/ORF50 results in the production of a truncated but stable Rta/ORF50 protein. This truncated Rta/ORF50 protein forms multimers with wild-type Rta/ORF50 in PEL cells and functions as a dominant negative inhibitor of Rta/ORF50.

A KSHV deletion mutant missing the *Rta* gene is unable to reactivate upon chemical treatment. Rta/ORF50 is present in KSHV virions, i.e., it can be considered a virion transactivator and thus ensures lytic replication upon primary infection. Rta/ORF50-responsive promoters fall into one of two subgroups: those where Rta/ORF50 directly binds promoter DNA and those where Rta/OrRF50 does not directly bind promoter DNA, but rather transactivates the promoter by establishing protein-protein interactions with cellular transcription factors that mediate sequence-specific DNA binding. Most important among these interactions is the binding of Rta/ORF50 to cellular RBP-J κ to modulate KSHV transcription. RBP-J κ is a sequence-specific DNA-binding protein that is a downstream effector of cellular Notch signal transduction. KSHV can usurp the function of cellular RBP-J κ without the requirement for Notch-ligand interaction, as the binding of KSHV Rta/ORF50 protein to RBP-J κ converts RBP-J κ from a transcriptional repressor to a transactivator.

Of note, the pattern of KSHV gene transcription is not as rigid as for other herpesviruses. Specific signaling stimuli and cellular environments can induce specific and sporadic transcription patterns. Stimuli that sporadically activate the transcription of oncogenic viral proteins, such as K1, viral interleukin-6 (vIL-6), or vGPCR, in the absence of complete replication (which would destroy the infected cell) are thought to contribute to oncogenesis in a paracrine fashion. Periodic reactivation and reinfection cycles are also thought to contribute to viral persistence in endothelial lineage cells.

Histone deacetylase inhibitors (vorinostat, valproic acid, sodium butyrate), signaling inducers such as TPA (Renne et al. 1996), and ligands for Toll-like receptors (TLRs) such as TLR7/8 agonists can induce KSHV reactivation from latency in culture. Interferon-alpha does not induce KSHV in its entirety, but only the expression of specific viral genes, e.g., the vIL-6 protein.

KSHV Carcinogenesis

All KS and PEL cells consistently express the viral latent proteins LANA/Orf73, vCyclin/

Orf72, vFLIP/Orf71, kaposin, the viral microRNAs, and one or more of the viral interferon regulatory factor (vIRF) homologues (Dittmer 2011). These exhibit transforming activities in specialized assays. Other viral proteins like K1, vIL6, and vGPCR are strongly transforming in multiple assays in culture. They are expressed at low and varying levels in latent KSHV-infected cells but are highly upregulated during the lytic replication cycle. Abrogation either of latent proteins, latent protein-induced signaling, receptor-induced signaling, or purging of the viral episome is incompatible with tumor growth, demonstrating that KSHV is required for KS.

LANA is the major latency protein involved in latent viral replication and maintenance of the latent genome. LANA tethers the viral episome to histones on the host chromosome. During normal cell division, viral genomic DNA is replicated and segregated along with host chromosomes, thereby ensuring that each of the daughter cells also contain viral genomes. LANA also functions to augment cell proliferation and survival. LANA has been shown to bind the tumor suppressors p53 and Rb (reviewed in Ballestas and Kaye (2011) and Damania and Pipas (2009)).

LANA, vCyclin, and vFLIP are expressed on a polycistronic transcript. vFLIP is a viral homologue of cellular FLIP (FLICE [protein FADD-like interleukin-1 beta-converting enzyme, now called caspase-8] inhibitory protein). vFLIP strongly activates the NF κ B signaling pathway and is thought to contribute to KSHV-associated oncogenesis (reviewed in Mesri et al. (2010)). Another latency-associated protein is vCyclin; vCyclin is a homologue of cellular cyclin D. vCyclin binds and activates CDK6 and is thought to promote S-phase entry. vCyclin transgenic mice develop lymphomas only in the context of p53 deficiency (reviewed in Damania and Pipas (2009)).

A working model of how the different molecular effectors that are encoded by KSHV work together to bring about the molecular phenotypes that are associated with KSHV infection can be constructed based on our knowledge of homologous viruses. The related gammaherpesvirus, herpesvirus saimiri (HVS), only requires two proteins,

STP and TIP, to transform human T cells in culture, yet it encodes homologues of many of the genes of KSHV, which function primarily in modulating host interactions, in vivo persistence, and pathogenesis. The KSHV K1 protein can functionally substitute for STP and engages signaling pathways, principally PI3K/AKT/mTOR, through its ITAM motif. Whereas K1 is located on the left end of the KSHV genome, K15 another viral receptor signaling protein is located on the right side. K15 engages TRAFs 1, 2, and 3, which leads to the activation of NF κ B and NF κ B-regulated cytokines. It also triggers mitogen-activated protein kinase (MAPK) signaling. The KSHV K1 and K15 proteins appear to phenocopy the two principal EBV-transforming genes LMP1 and LMP2A (reviewed in Damania (2004)), thus establishing a receptor-initiated signaling environment as a common theme for all lymphotropic herpesviruses.

KS is arguably one of the most angiogenic tumors that arises in the human population. It is thought that KSHV viral proteins expressed in endothelial (and surrounding epithelial cells) induce the overexpression of angiogenic factors like vascular endothelial growth factor (VEGF). vGPCR, K1, and vIL-6 have been shown to induce VEGF and function to stimulate angiogenesis in a paracrine fashion (reviewed in Mesri et al. (2010)). KSHV infection can also reprogram endothelial cells creating a gene expression phenotype that is intermediate between blood and lymphatic endothelium (reviewed in Dimaio and Lagunoff (2012) and Hong et al. (2004)).

Please note that the clinical and systemic manifestations of KSHV infection and KSHV-associated cancers are discussed elsewhere (Ablashi et al. 2002; Dittmer and Krown 2010).

KSHV MicroRNAs

The most recent addition to our understanding of KSHV biology has been the discovery of the KSHV microRNAs (miRNA). KSHV encodes 12–20 mature miRNAs (reviewed in Cullen (2011) and Skalsky and Cullen (2010)). Each mature miRNA is made from a looped, double-stranded pre-miRNA. Depending on cell type and

the exact RNA sequence, one or the other strands are preferentially processed and incorporated into the active RISC complex. Hence, there exists extensive variation in the count of mature miRNAs. KSHV miRNAs are expressed in KS and PEL and together with the cellular miRNA profile can be used to distinguish stages of KSHV infection. At present the function of all the miRNAs is not completely known. Thrombospondin 1, TGF-beta, and Bach1 are examples of some proteins known to be targeted by the KSHV miRNAs. Analogous to viral proteins, which mimic functions of host proteins, some viral miRNAs also share seed sequence (and therefore the same target range) as cellular miRNAs, most notably miR-K12-11 and miR-155. Downregulation of cellular miR-155 has been implicated in terminal plasma cell differentiation and it can be reasoned that by ectopically expressing an ortholog, KSHV can stall this process.

KSHV Immune System Interactions

Equally important to carcinogenesis is the means by which KSHV proteins modulate the immune system (reviewed in Lee et al. (2010) and Moore and Chang (2003)). These events may have systemic effects long before the development of clinically apparent lymphoma and KS. For instance, KSHV encodes a homologue to CD200/Ox2. Cellular CD200 is a negative regulator of inflammation. CD200 knockout mice exhibit increased susceptibility to experimentally induced autoimmune disease. The viral homologue of CD200, K14, is soluble and can bind to the CD200 receptor. How exactly this event modulates target cell function is not currently known.

KSHV also encodes homologues to cellular interferon regulatory factors (IRFs). The cellular IRFs transmit the activating signals from TLR or IFN alpha/beta receptors to the nucleus. This initiates and subsequently increases interferon production in a positive feedback loop. KSHV encodes four viral IRFs, vIRF1–4. The vIRF3 protein is constitutively expressed in latently infected PEL; vIRF1 is expressed in latent KS cells, whereas vIRF2 and vIRF4 have thus far

only been seen upon lytic infection. vIRF1, 2, and 3 interfere with IFN signaling. The molecular mechanism by which these proteins function is quite varied. For example, vIRF1 binds to cellular IRF-1 and IRF-2 and inhibits these proteins in a classical dominant negative mechanism. However, vIRF1 also binds to CBP/p300, p53, and Bim. For a more detailed review of the function of the four vIRFs, please see review article Jacobs and Damania (2011).

As mentioned above, KSHV encodes for a viral IL6 homologue, vIL-6 (reviewed in Sin and Dittmer (2012)). Unlike human IL-6, vIL-6 does not need to bind to the gp80 subunit of the IL-6 receptor complex to activate signal transduction. vIL-6 has been shown to activate cell signaling in an intracrine, autocrine, and paracrine fashion. vIL-6 can augment cell survival, prevent apoptosis, and activate angiogenesis through the upregulation of the proangiogenic factors, VEGF and angiopoietin 2. Depletion of vIL-6 in PEL has also been shown to inhibit their ability to proliferate.

In addition to coding for a viral IL6 homologue as described above, KSHV also encodes homologues to cellular inflammatory cytokines. These are vCCL1/vMIP-I/ORFK6), vCCL-2/vMIP-II/ORFK4), and vCCL-3/vMIP-III/ORF K4.1). KSHV vCCL-1 signals through CCR8; vCCL-2 signals through CCR8 and CCR3; and vCCL-3 signals through CCR4. Thus, these KSHV chemokines activate chemokine receptors that are present on CD4+ Th2 cells. vCCL-2 can also bind to multiple other chemokine receptors, but this binding is nonproductive and therefore diminishes signaling through the cognate, cellular ligand.

Conclusion

KSHV encodes an arsenal of viral proteins that control cell proliferation, cell survival, and angiogenesis. Moreover, KSHV viral proteins help the virus evade both adaptive and innate immune responses in the infected host. Several KSHV proteins are homologues of cellular proteins, while others are uniquely encoded by KSHV. By

modulating cellular signaling, apoptotic, and immune pathways in the infected cell, KSHV creates an environment that maintains virus survival and allows for virus dissemination and spread within the infected individual, as well as viral transmission from person to person. By commandeering the host environment in the aforementioned ways, KSHV infection may inadvertently result in cellular transformation and subsequent malignancy in some infected and susceptible hosts.

Definition

The killer cell immunoglobulin-like receptors (KIRs) belong to the immunoglobulin (Ig) superfamily of receptors and consist of a group of regulatory molecules that are expressed on natural killer (NK) cells and a subset of T cells. *KIR* genes are arranged in a “head-to-tail” cluster on human chromosome 19q13.4 within the leukocyte receptor complex (LRC) (Fig. 1). To date, 16 *KIR* genes have been identified, of which two are pseudogenes. *KIR2DL* and *KIR3DL* genes with long cytoplasmic tails are inhibitory by virtue of the immunoreceptor tyrosine-based inhibition motifs (ITIMs) present in their cytoplasmic domains, whereas the short-tailed *KIR2DS* and *KIR3DS* encode activating receptors. Short-tailed KIRs transmit activating signals through their

interaction with the adapter molecule DAP-12 (DNAX activation protein of 12 kDa.), which contains an immunoreceptor tyrosine-based activation motif (ITAM). There is substantial *KIR* gene content and allelic variation observed in humans. Two basic groups of *KIR* haplotypes termed A and B have been described (Fig. 1). Haplotype A is uniform in terms of gene content and is composed of nine genes that encode predominantly inhibitory receptors. The B haplotypes on the other hand are a diverse group that contain variable numbers of activating and inhibitory receptors. Diversity of the B haplotypes appears to be a function of unequal crossing-over, and the number of genes present on B haplotypes ranges from 4 to 17. Multiple alleles exist for each *KIR* gene, which can result in differences in expression level or functional capacity of a given gene. The likelihood that unrelated individuals share identical *KIR* haplotypes is exceedingly low. Another notable feature of the *KIR* locus is that expression of *KIR* genes is variegated on NK cells and clonally restricted.

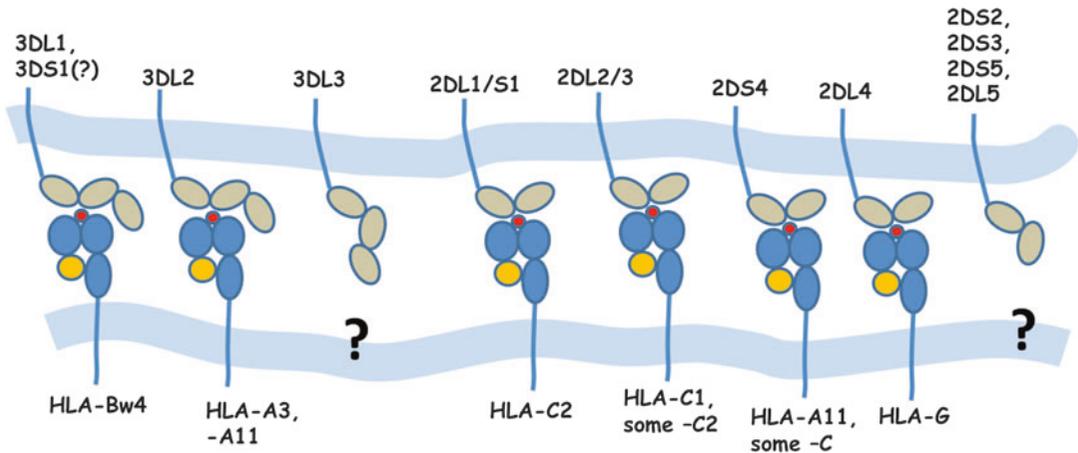

KIR Ligands

Thus far, only HLA class I molecules have been identified as ligands for KIRs (Fig. 2). Receptor-ligand relationships between HLA and KIR are allotype specific. *KIR3DL1* recognizes HLA-B molecules and a subset of HLA-A molecules that have the serologically defined Bw4 motif (amino acid positions 77–83). Some *KIR3DL1* subtypes exhibit a stronger inhibitory effect in the presence of HLA-B Bw4 subtypes that have isoleucine at position 80 (Bw4-80I) as opposed to threonine at the same position (Bw4-80 T). The alternative HLA-B Bw6 allotypes do not serve as ligands for KIR. The activating *KIR3DS1* and inhibitory *KIR3DL1* segregate as alleles of the same locus, and they share >97% similarity in their extracellular domains. There is no direct evidence of interactions between *KIR3DS1* and Bw4 allotypes, although genetic epidemiological, functional, and population genetic data suggest that some form of interaction, either direct or indirect, occurs between them. On the basis of

KIR Locus Variation, Fig. 1 Haplotypic diversity of the KIR gene cluster. KIR haplotypes vary extensively in gene content. The A haplotype is fixed in terms of gene content. The B haplotypes are characterized by variable gene numbers (shown in parentheses). The centromeric (*KIR3DL3*,

KIR3DP1) and telomeric (*KIR2DL4*, *KIR3DL2*) framework genes are present on virtually all haplotypes. Genes encoding activating KIR are shown in red, inhibitory KIR in blue, and pseudogenes in grey

KIR Locus Variation, Fig. 2 KIRs and their HLA ligands. HLA-C2 = HLA-C allotypes with Asn77/Lys80. HLA-C1 = HLA-C allotypes with Ser77/Asn80. Bw4 = HLA allotypes with the serologically defined Bw4 motif

dimorphisms in the HLA-C $\alpha 1$ domain that are characterized by Ser77/Asn80 and Asn77/Lys80, all HLA-C allotypes can be divided into two distinct groups (C group 1 and group 2, respectively). The inhibitory KIR2DL1 interacts with group 2 allotypes, while KIR2DL2 and KIR2DL3, which segregate as alleles of the same locus, interact with group 1 allotypes. KIR3DL2 interacts with HLA-A3 and HLA-A11, and KIR2DL4 recognizes the nonclassical class I molecule HLA-G. KIR2DS4 binds to subsets of HLA-C groups 1 and 2 and HLA-A*11. The activating KIR2DS1 demonstrates weak binding to

C group 2, but its high-affinity ligand has not been identified. The ligands for the activating KIR2DS2, KIR2DS3, and KIR2DS5 and the inhibitory KIR2DL5 and KIR3DL3 have not been identified.

Natural Killer Cells

► **Natural killer (NK) cells** are components of the innate immune system, and they represent the first line of defense against virally infected cells and tumor cells. They comprise about 10–15% of

peripheral blood lymphocytes. KIRs are mainly expressed on CD56^{dim}CD16^{pos} NK cells, which constitute the bulk of peripheral blood NK cells and have high cytotoxic potential. Through the interaction of inhibitory KIR with HLA class I, healthy cells are protected from spontaneous destruction by NK cell-mediated cytotoxicity, but they eliminate cells that express either nonself or aberrant levels of class I (altered or missing self). Thus, downregulation of class I on tumor cells or virally infected cells, a mechanism that allows these cells to escape T cell recognition, theoretically confers vulnerability to NK cell-mediated killing. The importance of NK cell receptors in defense against viral infections can be inferred from the complex mechanisms used by viruses to evade immune recognition. The HIV-1 Nef protein, for example, selectively downregulates HLA-A and HLA-B as a means of evading T cell recognition while preserving HLA-C expression as a means of avoiding destruction by NK cells. The *HLA* class I and *KIR* loci exhibit extensive genetic polymorphism and likely influence functional capacities of NK cells across individuals.

KIR in HIV Disease Outcomes: Overview

The diversity of clinical outcomes after HIV infection is broad, ranging from progression to AIDS within 1–3 years after seroconversion to the control of HIV without drugs for more than two decades. A small fraction of individuals are also resistant to HIV infection, even upon repeated exposure, and there is abundant information regarding host genetic variation and its consequence on outcome of HIV infection. Most genetic variants associated with HIV outcome are within or near genes encoding molecules involved in the acquired or innate immune response. The *HLA* and *KIR* molecules are encoded by two of the most diverse gene families in the human genome. Given the involvement of these molecules in fundamental immune processes, such as antigen presentation to T cells and regulation of NK cell responses, it is no surprise that the extreme diversity characterizing the *HLA* and *KIR* loci impacts HIV disease pathogenesis

KIR Locus Variation, Table 1 *KIR* associations with HIV^a

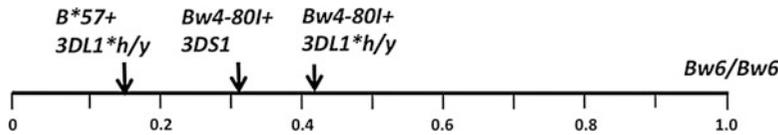

Genotype	Effect
<i>KIR3DS1/HLA-B Bw4-80I</i>	Delayed progression to AIDS Protection against AIDS-defining opportunistic infections
<i>KIR3DS1</i> homozygosity	Reduced risk of infection
<i>KIR3DL1* h/y/HLA-B Bw4-80I</i>	Delayed progression to AIDS
<i>KIR3DL1* h/y/HLA-B* 57</i>	Reduced risk of infection
↑Effective <i>KIR3DS1/L1</i> count	Lower viral load set point
<i>KIR2DS2</i>	Rapid progression to AIDS
Group B <i>KIR</i> haplotypes	Lower CD4 ⁺ T cell counts
<i>KIR2DS4* 001</i>	Increased risk of transmission
<i>KIR2DL2/2DL3/absence of C grp1</i>	Reduced risk of infection
<i>KIR3DL1/absence of Bw4</i>

differentially across individuals (Table 1; Reviewed in Bashirova et al. 2011; Sobieszczyk et al. 2011).

KIR3DL1/S1

The combination of the activating *KIR3DS1* and *HLA-B* alleles having isoleucine at position 80 (*HLA-B Bw4-80I*) has been shown to exert a protective effect against AIDS progression after HIV infection based upon genetic association analyses of ART-naïve AIDS cohorts (Martin et al. 2002). This was the first study describing an epistatic interaction between *KIR* and *HLA* in disease association and indicated the likelihood that activating *KIR* may have biological significance in viral infections. The *KIR3DS1/HLA-B Bw4-80I* compound genotype also correlates with lower viral load and protection from opportunistic infections. The proposed hypothesis is that *KIR3DS1* binds *HLA-B Bw4-80I* allotypes on target cells, thereby signaling the NK cell to kill the HIV-infected target. Although there is no direct

KIR Locus Variation, Fig. 3 *KIR3DL1/S1+ HLA-B Bw4* continuum of HIV viral load control. Odds ratios of protective genotypes relative to the Bw6/Bw6 control group in terms of their distribution in the <2,000 versus the

>10,000 HIV RNA mean viral load groupings are shown. KIR3DL1*h/y = KIR3DL1 allotypes with high cell surface expression (Martin et al. 2007)

evidence for a KIR3DS1: HLA-B Bw4-80I interaction, in vitro studies have demonstrated that NK cells expressing KIR3DS1 specifically expand in acute HIV-1 infection in the presence of Bw4-80I and are able to effectively suppress HIV-1 replication in Bw4-80I⁺ target cells in vitro (Alter et al. 2009). It should be noted, however, that other studies have failed to replicate the synergistic protective effect of KIR3DS1 + HLA-B Bw4-80I, which could be the result of differences in the characteristics of the cohorts as well as differences in analytical methodologies (Gaudieri et al. 2005; Barbour et al. 2007).

KIR3DL1 allotypes can be divided into those with high expression and high inhibition and those with lower expression and lower inhibition. Ironically, the strongly inhibitory *KIR3DL1* alleles + *HLA-B* alleles with the *Bw4-80I* motif are also very protective. Notably, the most protective *HLA-B* allele, *B*57*, belongs to the *Bw4-80I* group, and individuals carrying both the strongly inhibitory *KIR3DL1* allotypes and *B*57* were shown to have the strongest genetic protection both in terms of AIDS progression and viral load (Martin et al. 2007; Fig. 3). Involvement of NK cells in this protection is supported by data indicating high functional potential of NK cells isolated from individuals with strongly inhibitory *KIR3DL1* allotypes and *B*57* (Boulet et al. 2010). These observations imply that the *B*57* protection is due at least, in part, to its interaction with KIR in addition to its well-characterized role in the adaptive immune system involving the presentation of HIV epitopes to CTL (see ► [MHC Locus Variation](#)). Overall, the data suggest that efficient engagement of both activating and inhibitory KIR is beneficial for the host in viral infection, which may confer benefit at different times after HIV infection. Interactions between

inhibitory KIR and HLA class I play a key role in establishing tolerance to healthy cells as well as determining the activation potential of mature NK cells. Thus, protection by highly inhibitory allotypes may be the result of more effective tuning of the high-expressing KIR3DL1-positive NK cells during their maturation process, resulting in stronger NK cell activation when their ligand is down-regulated, as is HLA-B by HIV-1 Nef.

KIR3DL1/S1 Copy Number Variation (CNV)

Copy number variation (CNV) is defined as a segment of DNA that is 1 kb or larger and is present at variable copy numbers in comparison with the reference genome. They are present abundantly in the human genome and have been shown to associate with disease susceptibility. Because of their homology and tandem arrangement on chromosome 19q13.4, *KIR* genes are susceptible to nonallelic homologous recombination, which causes deletions or duplications of genes within the locus and formation of novel hybrid genes in some cases. A recent genome-wide screen in a large HIV-1 positive cohort identified a CNV in the *KIR* region that associates with HIV control as measured by plasma viral load at set point, specifically the *KIR3DL1/S1* locus. The vast majority of *KIR* haplotypes has a single copy of either *KIR3DL1* or *KIR3DS1*. Subsequent quantification of *KIR3DS1* and *KIR3DL1* copy numbers by quantitative PCR showed that increased *KIR3DS1* CNV was associated with lower viral load set point, but only if its putative ligand *HLA-B Bw4-80I* was present (referred to as effective *KIR3DS1* count), regardless of *KIR3DL1* status. In contrast, an increase in

effective *KIR3DL1* count (i.e., *KIR3DL1* + *HLA-B Bw4-80I* or *Bw4-80 T*) was protective only when at least one effective copy of *KIR3DS1* (i.e., *3DS1* + *Bw4-80I*) was also present. Functional studies demonstrated that individuals with a single effective copy of *KIR3DL1* and *KIR3DS1* had an increased capacity to inhibit HIV replication in vivo, and this effect was even more pronounced in individuals with multiple copies of *KIR3DL1*. In addition, there was a significant expansion in the frequency of *KIR3DS1*⁺ NK cells, which was also more pronounced in individuals with multiple copies of *KIR3DL1* (Pelak et al. 2011). This suggests that there is a beneficial interaction between *KIR3DL1* and *KIR3DS1*, which may reflect more robust NK cell licensing in the presence of *KIR3DL1*. In support of a contribution of *KIR3DL1* through NK cell licensing, another study reported stronger NK cell responses to HLA-deficient K562 cells among HIV-infected slow progressor individuals with *KIR3DL1* and *HLA-Bw4* as compared to individuals without this receptor-ligand combination (Kamya et al. 2012). Interestingly, increasing copy numbers of the activating *KIR3DH* also associate with the control of SIV replication in rhesus macaques during primary infection (Hellmann et al. 2011).

Additional KIR Genes and Haplotypes

Presence of the activating *KIR2DS2* has been shown to associate with more rapid progression to AIDS. In addition, the carriage of group B *KIR* haplotypes that contain varying numbers of activating *KIR* (including *KIR2DS2*) is associated significantly with lower CD4⁺ T cell counts (but not viral load levels) in the absence of *HLA-Bw4* and *HLA-C* group 1 (which serve as ligands for the inhibitory *KIR3DL1* and *KIR2DL2/3*, respectively) in chronically HIV-1-infected subjects (reviewed in Sobieszczyk et al. 2011). An earlier study also found that *KIR3DS1* in the absence of its putative ligand *HLA-B Bw4-80I* was associated with accelerated disease progression (Martin et al. 2002). Aberrant immune activation is a feature of late-stage HIV disease, so the most parsimonious

explanation for these findings collectively is that group B *KIR* haplotypes (with varying numbers of activating *KIR*) and absence of ligand for inhibitory *KIR* favor NK cell activation, which is deleterious in the late stages of HIV-1 infection.

KIR-Mediated Immune Escape in HIV Infection

There is strong evidence for selection pressure of CD8⁺ T cells on HIV sequence evolution over the course of infection. Following the peak in CD8⁺ T cell response, the virus begins to show dramatic changes in sequence. Most of these changes arise within the HLA class I-restricted CD8 T cell epitopes and therefore disrupt binding of viral peptide to HLA class I or impair recognition by the T cell receptor as a means of viral escape. It is now becoming apparent that NK cells can also mediate immune pressure on the virus in part via *KIR*-associated HIV-1 sequence polymorphisms. A recent report described several amino acid polymorphisms within the HIV-1 sequence that were significantly associated with the presence of specific *KIR* genes (Alter et al. 2011). Functional analyses showed that polymorphisms in a region encoding the carboxy-terminal end of Vpu and the amino-terminal end of Env enhanced the binding of the inhibitory *KIR2DL2* to HIV-1 infected targets, thereby reducing the antiviral activity of NK cells. Interestingly, common HIV-1 peptide variants have also been shown to mediate differential binding of *KIR3DL1* to its HLA-Bw4 ligand. For example, point mutations that are frequently selected by CD8⁺ T cells within dominant HLA-B*57-restricted HIV-1 epitopes abrogate binding of *KIR3DL1* to HLA-B*5701, including one within the well-characterized TW10 epitope (T242N) (Fadda et al. 2011). In line with these data, an early emerging mutation in the TW10 epitope (G9E) was identified in two HLA-B*5703+ patients acutely infected with HIV-1 (Brackenridge et al. 2011). This change was not associated with strong escape from CD8 T cell recognition but was found to abrogate *KIR3DL1* binding.

KIR in HIV-1 Infection/Transmission

The innate immune response, which involves NK cells, could potentially be important in protection from HIV infection in the absence of vaccination. NK cell activity in a group of highly exposed uninfected (EU) intravenous drug users (IVDU) was found to be significantly greater than that from infected patients and unexposed individuals. Subsequently, it was shown that the *KIR3DS1/3DL1* transcript ratio was higher among the protected individuals (Ravet et al. 2007). A role for *KIR3DS1* in the protection from HIV infection is further supported by the demonstration that exposed HIV-1 seronegative individuals have a higher frequency of *KIR3DS1*, while the frequency of *KIR3DL1* plus/minus *Bw4* was decreased. The *KIR3DL1* h/y + HLA-B Bw4-80I* genotype is also associated with reduced risk of infection, which is consistent with the effect of this compound genotype on viral load and disease progression (Boulet et al. 2008). Overall, these results emphasize the need to consider not only the presence or absence of each *KIR* gene but also the expression levels and allelic differences. The data support the idea that strong NK cell responses may contribute to the protection from HIV infection, though additional support is necessary. Additional *KIRs* have also been found to associate with mother to child transmission as well as heterosexual transmission, but these data need to be confirmed in larger studies (Table 1).

Conclusion

Genetic diversity of immune response genes, such as *HLA* and *KIR* loci, holds promise for explaining, in large part, the variability in outcome to HIV infection among exposed individuals. Understanding how this diversity influences the immune response presents new opportunities for the development of effective therapeutics and vaccines, especially in light of the failure of recent HIV-1 vaccine trials to induce protective immunity in humans.

L

Latin America and the Caribbean: Specific Characteristics of the HIV/AIDS Epidemic

Giuliana Cerro¹ and Eduardo Gotuzzo²

¹Universidad Peruana Cayetano Heredia, Lima, Peru

²Instituto de medicina Tropical alexander von Humboldt, Universidad Peruana Cayetano Heredia, Lima, Peru

Introduction

Latin America is the region in the Americas where Spanish or Portuguese are the main national languages. It includes islands in the Caribbean, a region consisting of islands of the Caribbean Sea, and surrounding coasts (Oxford Dictionary Definition of Latin America in English 2015). Other smaller nations and colonies in proximity to Latin America have Creole, French, English, or Dutch as their national languages, along with other local languages.

The population of this region is around 600 million, approximately 8% of the world's population, with Brazil the most populous country (Central Intelligence Agency Country Comparison: Population 2014). According to the Economic Commission for Latin America and the Caribbean, despite poverty reduction and economic growth in the last 5 years, this region harbors immense economic and health disparities

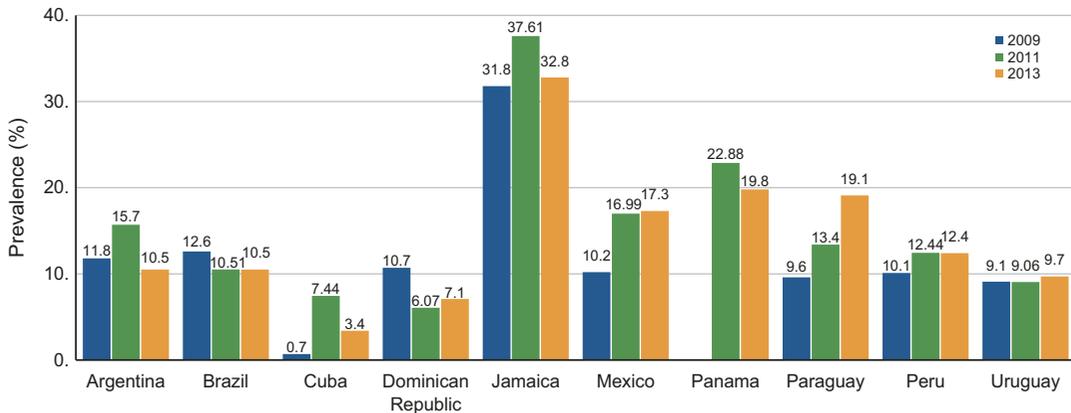

(Cecchini and Rodrigo Martínez 2012). Similarly, there are disparities in the prevalence of HIV/AIDS among countries and within their regions as well.

Epidemiology

The first cases of HIV in Latin America were reported in Haiti between 1979 and 1982. Of the first 61 cases reported, 85% were men. High-risk exposure such as bisexual activity or blood transfusions were identified in 17% of male and 22% of females (Pape et al. 1983). Demographically there has been a substantial change in the pattern of the population at risk. An infection that was used to be most prevalent in men who have sex with men (MSM), sex workers, and persons who inject drugs or had frequent blood transfusions is now somewhat more widely distributed in the general population including heterosexual men and women with few sexual partners (Joint United Nations Programme on HIV/AIDS (UNAIDS) 2008).

Incidence and Prevalence

The Joint United Nations Program on HIV/AIDS (UNAIDS), in its 2014 report, estimated that in Latin America, there were 1.6 million people living with HIV (PLHIV) on 2013. New infections in 2013 numbered 94,000, a decline of 3% between 2005 and 2013. Children represented 1,800 of these new cases of HIV infection.

Latin America and the Caribbean: Specific Characteristics of the HIV/AIDS Epidemic, Fig. 1 Prevalence (%) of HIV infection in men who have sex with men in Latin America and the Caribbean (UNAIDS 2015)

In the Caribbean the prevalence of HIV is estimated to be 1% of the population, higher than in any other region besides sub-Saharan Africa (Joint United Nations Programme on HIV/AIDS (UNAIDS) 2008) (Fig. 1). According to the UNAIDS 2014 fact sheet, in 2013, there were 250,000 PLHIV in the Caribbean, including 12,000 new infections. This reflects a decline of 40% from 2005 to 2013. Of these new cases, fewer than 1,000 were children (UNAIDS Communications and Global Advocacy 2014).

Women make up around 31% and 52% of the adults living with HIV in Latin America and the Caribbean (LAC), respectively (UNAIDS Communications and Global Advocacy 2014). By 2013, the Pan American Health Organization (PAHO) estimated that in Latin America and the Caribbean (LAC), an estimated of all PLHIV, 71% were aware of their diagnosis. Approximately 35% of newly diagnosed cases are identified later in the course of the infection (UNAIDS Communications and Global Advocacy 2014).

Mortality

In Latin America, AIDS-related causes accounted for around 47,000 deaths in 2013, a fall of 31% between 2005 and 2013. In the Caribbean, in 2013, 11,000 people died of AIDS-related causes,

representing a decrease of AIDS-related deaths by half. Within the Caribbean region, Haiti alone accounted for 59% of all these deaths in 2013 (UNAIDS Communications and Global Advocacy 2014).

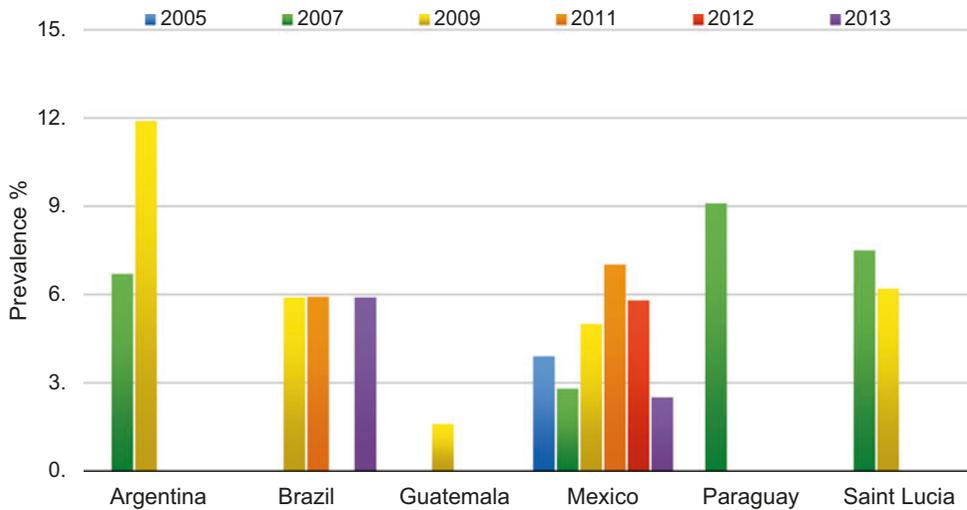

Patterns of Transmission

Men Who Have Sex with Men

Men who have sex with men (MSM) represent a population defined by their sexual behaviors regardless of their sexual orientation or gender identity. Worldwide, the HIV prevalence is highest among MSM and transgender persons and, this population shows, an increasing prevalence over time. Despite this, there is a lack of high-quality data on MSM HIV prevalence in LAC (Beyrer and Baral 2012).

Prevalence among MSM ranges from 3.4% in Cuba to 32.8% in Jamaica. These rates are far higher than the overall HIV prevalence of 1% in LAC.

Unprotected anal intercourse is the principal route of transmission in this group. Factors such as the use of illicit drugs and having multiple partners increase this risk. Furthermore, a 2001–2008 review found that 40–70% of MSM in developing countries had never been tested for HIV, which translates into increased risk of transmission, lower access to HIV care, and a

Latin America and the Caribbean: Specific Characteristics of the HIV/AIDS Epidemic, Fig. 2 Prevalence (%) of HIV infection in people who inject drugs in Latin America and the Caribbean (UNAIDS 2015)

need for reinforcement of prevention strategies (Geibel 2010).

Persons Who Inject Drugs (PWID)

Another route of HIV transmission is the injection of intravenous drugs. The United Nations Office on Drugs and Crime (UNODC) estimated in 2013 that there were 14 million PWID worldwide, 1.6 million of them were living with HIV, an 11.5% of all the PWID population. In LAC, the prevalence of HIV among PWID was estimated to be 6.9% (UNODC 2013).

As shown in Fig. 2, the prevalence is particularly high in Mexico, especially along the border with the United States as well as in the southern countries of America (Argentina, Brazil, and Paraguay). Once again, data regarding the number of PWID and the proportion infected with HIV are scarce (WHO, Global HIV/AIDS response 2011).

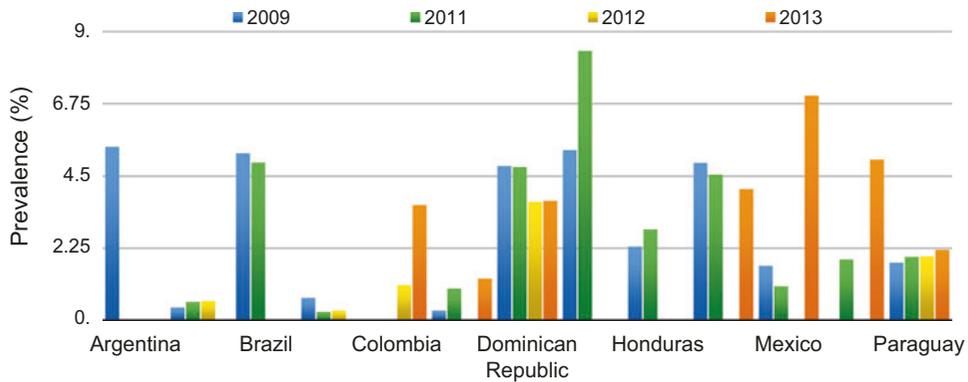

Countries which have instituted aggressive HIV control campaigns have seen a reduction in high-risk behaviors and as a consequence a markedly drop in the incidence of HIV (Geibel 2010). Policies such as disposable and clean needles and syringes exchange programs and opiate substitution therapy with buprenorphine or methadone have reduced the likelihood of HIV transmission (UNODC 2013).

Female Sex Workers

A meta-analysis, in 2012, showed that the prevalence among female sex workers (FSW) on 11 countries in LAC was 6.1% (5.7–6.6, 95% CI) (Joint United Nations Programme on HIV/AIDS (UNAIDS) 2013). As shown in graph N° 3 (Fig 3), prevalence is variable among the countries in the region, with Haiti as the country with highest rates. Once again, the lack of quality data is detrimental, and the real prevalence may be much higher than reported. FSW have 12 times higher odds of being infected with HIV in comparison to the female population of low- and middle-income countries (Baral and Beyrer 2012).

Heterosexual Population

According to the 2007 epidemic update from UNAIDS, in Latin America, there is an increasing number of heterosexual men and women living with HIV. Monogamous women get the infection from their male sexual partners who at the same time got infected from unprotected sex with another man or woman. In Argentina on 2005, four out of five new HIV diagnosis were attributed to unprotected sex, mainly heterosexual. Furthermore, in Uruguay, unprotected sex (mostly heterosexual) causes around two thirds of the

Latin America and the Caribbean: Specific Characteristics of the HIV/AIDS Epidemic, Fig. 3 Prevalence (%) of HIV infection in female sex workers in Latin America and the Caribbean (UNAIDS 2015)

reported HIV cases. This pattern is also seen in Chile, Peru, and Brazil (Joint United Nations Programme on HIV/AIDS (UNAIDS) 2008).

Introduction of ART

Antiretroviral therapy (ART) was started in LAC in 1990 in Argentina and in 1991 in Brazil. The number of people infected with HIV on ART in LAC has progressively increased. The PAHO reports that by the end of 2013, around 720,000 people, 75% of the eligible population, were taking ART. LAC is the region with the highest ART coverage; the worldwide coverage of ART for eligible PLHIV is 61% (WHO/UNAIDS/UNICEF 2013).

According to the UNAIDS 2013 report and using all PLHIV as the denominator, 44% [34–50%] of all PLHIV in LAC were receiving treatment. This shows a 31% increase from the previous report in 2011. In children younger than 14 years old, the coverage is estimated to be 51% [38–63%] (WHO/UNAIDS/UNICEF 2013). Furthermore, the PAHO and WHO in their 2014 Public Health Analysis in LAC, reported that by 2013, of the population eligible for ART in LAC, 56% were estimated to be receiving ART and, of the people on ART, 77% had achieved viral suppression (Pan American Health Organization 2014).

Estimates from Mexico, El Salvador, and Paraguay suggest that more than 30% of the HIV-positive population remains unaware of their diagnosis (Table 2). A higher risk of transmission can be expected from this subgroup.

Multiple factors need to be considered in order to assess optimal access to HIV care and treatment. Among these are (1) the proportion of PLHIV who do not know their status, (2) the proportion of diagnosed persons who do not get effectively linked to care, (3) the criteria used in each country to start ART, (4) the public policies that guide the accessibility of ART, and (5) retention and adherence of persons on ART.

The CD4+ cell cutoff has increased throughout the years often following PAHO and WHO guidelines. Earlier initiation of ART is being encouraged in order to improve survival. The CD4 cutoff for HIV treatment is 500 cells/ μ L in most countries according to the 2013 WHO recommendations (Table 1). An exception is Brazil, where there is no CD4 cutoff for ART initiation. Other criteria to start ART include active tuberculosis (TB) disease, hepatitis B virus (HBV) confection with chronic liver disease, and pregnant or breastfeeding women with HIV (World Health Organization 2013).

As shown in Table 3, the percentage of PLHIV on ART is variable among countries due to differing public policies on ART coverage, strength of

the underlying health system, and social factors like stigma, isolation, and discrimination. Some of the barriers that the countries must face include medication shortage and limited services for persons without coverage through the national health and social security systems. Another barrier is the cost of the drugs, since generic and low-cost drugs are scarce in LAC. Furthermore, although the drug prices have decreased significantly, there are still disparities between countries (Chequer et al. 2002).

ART and Mortality

Mathematical models for the HIV epidemic in Latin America showed that in the year 2008, a 16% HIV annual mortality was likely, substantially lower than the estimated 21% mortality modeled for 2004. This likely due to the increased availability and access of ART in the region, albeit with imperfect coverage and adherence (World Health Organization 2009).

Gonzales et al. in (2011), analyzed the available data in 11 countries in Latin America regarding ART and mortality. They found that the standardized mortality rates before the implementation of public policies with wider availability of

ART ranged from 2.2 to 15.6 per 100,000 (mean 5.7 CI 4.1–7.2). After the adoption of stronger ART policies, the mortality rates had similar ranges: 2.5–14.0 per 100,000 (mean 5.1 CI 4.5–5.7; $p = 0.4$). Although, there has been an increase in the ART coverage over the time, the mortality had not yet decreased significantly in the study.

However, when analyzed by countries, the mortality rates showed two different patterns. Argentina, Brazil, Chile, Costa Rica, and El Salvador reported a significant decrease in HIV mortality rates after ART was made available. Panama also presented a decrease in mortality, though it was not significant. The second pattern was seen in Colombia and Ecuador, where there was paradoxical increment in the HIV mortality rates. Mexico, Venezuela, and Uruguay had an overall increased mortality pattern as well but with varying trends.

When the mortality rate was analyzed in relation to the ART coverage percentage, the countries with higher coverage rates (over 70%) had lower mortality rates, except for Uruguay with an increased mortality rate despite a reported 95% ART coverage. In general countries with lower coverage rates had increases in this mortality rates (Gonzalez et al. 2011).

Opportunistic Infections

Tuberculosis and Multidrug-Resistant Tuberculosis

The association between HIV infection and tuberculosis is well known. People living with HIV are 29 times (CI: 26–31) more likely to develop tuberculosis compared to people without HIV who live in the same region. Of all deaths due to tuberculosis in the world during 2009, 24% were people with HIV coinfection (WHO 2011).

Patients with HIV develop tuberculosis in around 40% of the cases, especially in those who remain undiagnosed or have not been started yet

on ART. During the first 12 months after ART is initiated, the risk of developing TB may increase paradoxically, perhaps due to the ease of diagnosis after partial immune reconstitution. Nonetheless, many trials document the vital benefits of ART for the treatment of TB-HIV coinfecting persons.

An active search for HIV infection is encouraged by the WHO for all TB patients. In 2009, 43% of patients with TB were tested for HIV. Of these, 17% had HIV infection. Countries with high rates included Colombia (23% HIV-TB coinfection), Brazil (22%), Mexico (21%), and Ecuador (20%) (WHO 2014).

In Peru, among the newly diagnosed patients with tuberculosis, 1.5–4% are found to be coinfecting with HIV (Cerro and Gotuzzo, unpublished).

A study conducted in Peru showed that PLHIV were at ten times greater risk of developing multidrug-resistant (MDR) TB than HIV-negative patients (Campos et al. 2003). Although in a selected population, this raises concern for the importance of TB surveillance in HIV patients, both for their care and to reduce MDR-TB transmission to the general population.

Leishmania

An increase of visceral leishmaniasis (VL) has been seen in Latin America, especially among children and young adults. The area of spread coincides with the regions of higher HIV incidence. Therefore, coinfection of HIV and visceral leishmaniasis is believed to be responsible of the increased rates of VL in Latin America, notably in Brazil that harbors more than 90% of all the cases of visceral leishmaniasis in Latin America. The clinical picture between those with visceral leishmaniasis alone compared to those with HIV-visceral leishmaniasis coinfection is similar, both with fever and hepatosplenomegaly. However, there is a slight increase in the proportion of cases that present with diarrhea in the PLHIV group. Furthermore, HIV-visceral leishmaniasis coinfection also results in higher rates of relapse, with 10–56.5% of all cases. Mortality reports have ranged from 8.7% to 23.5% in this coinfecting group (Lindoso et al. 2014; WHO 2003).

Chagas Disease

Trypanosoma cruzi has surfaced as an opportunistic pathogen in people with HIV infection in Latin America, mainly Brazil, Argentina, and Colombia. Although, in this region, Chagas disease is a characteristic of rural areas, and HIV infection is more common in urban areas, the urbanization of the rural population is responsible for coinfection. Recently, oral transmission has been identified, which allows to understand the new transmission pattern.

It is estimated that between 20% and 40% of people with HIV and *T. cruzi* coinfection may experience reactivation, with levels of parasitemia compared to the ones seen in acute infection. Furthermore, death is more common in coinfecting persons and occurs earlier.

For HIV-Chagas coinfecting persons, two manifestations have been described: (1) acute myocarditis with anasarca and (2) encephalitis with multiple necrotizing foci. Tissue samples show multiple amastigotes. Many patients may have the tumor or pseudotumor form (brain “chagoma”), making it part of the differential diagnosis with toxoplasmosis (Pitella 2009). This phenomenon is reported also in Latin

Americans living abroad making the screening for coinfection necessary (Andrade et al. 2014). In a recent systematic review of 83 articles and 291 patients, the mortality due to Chagas meningoencephalitis without treatment was 100% (Almeida et al. 2011).

HIV-Associated Malignancies

A study published by the Caribbean, Central and South America Network for HIV Research (CCASAnet) in 2011 showed that in a cohort of 455 cancers from 428 patients, 406 of the reported cancers (82%) were AIDS defining, particularly Kaposi sarcoma and non-Hodgkin’s lymphoma. Of the non-AIDS-defining cancers, the most common were Hodgkin’s lymphoma and skin cancers. In this cohort, almost half of the cancers were diagnosed within 1 year after the HIV diagnosis (Fink et al. 2011).

The same study also found low rates of invasive cervical cancer. However, most of the patients included in the cohort were male, and many women were receiving regular cervical screening. The cases of invasive cervical cancer that were found were mostly in advanced stages, presumably in unscreened women (Andrade et al. 2014). Since this malignancy develops relatively faster in HIV-infected women, it has been suggested that countries change their screening programs with Papanicolaou smears every 6 months. Human papillomavirus (HPV) is also responsible for anal carcinoma, a prevalent malignancy among both MSM and women which makes screening for HPV.

Conclusions

Latin America and the Caribbean countries have had some stability in HIV transmission patterns in recent years, with the number of people living with HIV having plateaued. There has been a change in the pattern as well, with a rising proportion of heterosexual women and men, though the epidemic among MSM continues to drive the epidemic in many LAC nations.

An increasing number of PLHIV are now on ART in the LAC region, due to changes in public policies and efforts on expanding coverage. However, there are still no massive screening policies in place, ART coverage is still suboptimal, and there are no broad prevention strategies being promulgated, such as the diffusion of the use of condoms, especially in heterosexual men and women who were not considered as population at risk of being infected.

Challenges facing LAC include the need to expand the HIV continuity of care, testing, linkage, care with ART, and adherence/retention (Fink et al. 2011; García et al. 2014; De Boni et al. 2014). Strengthening health systems as well as improving public policies are vital, as is addressing the widespread stigma of HIV infection in LAC. Improved partnerships with political and religious forces in the region are needed.

Definition

Leishmaniasis is a group of chronic parasitic diseases caused by a number of species of flagellate protozoa of the genus *Leishmania*. Up to 20 *Leishmania* species can cause disease in humans. The infection can be localized in the skin (cutaneous leishmaniasis, or CL, classifiable as localized cutaneous and diffuse cutaneous leishmaniasis), mucosae (mucocutaneous leishmaniasis, or ML), or disseminated in the reticuloendothelial system (visceral leishmaniasis, or VL).

Introduction

Leishmaniasis is usually a zoonosis transmitted by sandflies, which are endemic in and of Southern Europe, Asia, Africa, and the Americas. Transmission may follow an anthroponotic or zoonotic cycle that also varies by region. Sporadic interhuman transmission through needle exchange in intravenous drug users (IDUs) has also been reported, especially in Southern Europe

(Monge-Maillo et al. 2014). Infection may be asymptomatic or may manifest as a cutaneous disease that is pleomorphic in presentation, a mucocutaneous disease or the visceral form that may be lethal if untreated. The clinical expression of leishmaniasis depends on a complex interaction between the type of infecting species and the host's immune response; the result of this interaction may range from asymptomatic carriage to fatal disease (Pace 2014).

HIV-infected individuals and transplant recipients have an increased risk of developing the disease. The most common clinical presentation of leishmaniasis in HIV-infected individuals is a disseminated visceral disease syndrome, but the distribution varies geographically, reflecting differences in the predominant parasitic species. In Europe, visceral disease has been reported in 95% of cases (87% typical visceral, 8% atypical visceral) (Alvar et al. 2008). In contrast, in Brazil, mucocutaneous (43%) and cutaneous (20%) are the most common forms (Lindoso et al. 2014).

In Southern Europe, before the introduction of combined antiretroviral treatment (cART), the prevalence of VL among HIV-infected patients was 2–9%, 10,000 times the rate in the general population. Since cART was introduced in 1997, a marked decrease in the number of coinfecting cases in this region has been reported (from 1,440 cases during the period 1990–1998 to 299 cases during 2001–2006, though this reduction was not so marked in Portugal) (Monge-Maillo et al. 2014). The development of new diagnostic methods to identify accurately the level of parasitemia and the risk of relapse is one of the main challenges in improving the treatment of coinfecting patients.

Until recently, antimonial drugs were the mainstream choice for VL treatment, despite resistance having emerged, especially in the Indian subcontinent, and this class of drugs having been proven to be more toxic in immunosuppressed patients. Liposomal amphotericin B, miltefosine, and combined treatments have been investigated more recently as active agents for VL in HIV-infected individuals (Murray 2012). Treatment options for CL and ML are still suboptimal.

Biology, Epidemiology, and Transmission

Biology

Leishmaniasis is a group of vector-borne diseases that are transmitted by sandflies and caused by obligate intracellular protozoan parasites of the genus *Leishmania*, belonging to the family Trypanosomatidae, order Kinetoplastida. The genus *Leishmania* is named after Sir William Leishman, who discovered the flagellate protozoa.

All member of the genus *Leishmania* spend their life cycle in two hosts: the mammalian host and the insect vector, the female sandfly. In humans and other mammalian hosts, they multiply within macrophages, in which they occur exclusively in amastigote form, having an ovoid body containing a nucleus and kinetoplast. In the sandfly, they occur in the promastigote form, with a spindle-shaped body and a single flagellum arising from the anterior end.

The genus *Leishmania* includes a number of different varieties and subspecies, which differ in several features such as antigenic structure, isoenzymes, and other biochemical characteristics, growth properties, and host specificity. *Leishmania* species can also be classified on the basis of geographical distribution. Human infection is caused by about 21 of the 30 species that infect mammals. These include the *L. donovani* complex with two species: *L. donovani* and *L. Infantum* (also known as *L. chagasi* in the New World), both causing VL, although *L. infantum* can may also lead to CL; the *L. tropica* complex with three species: *L. tropica*, *L. major*, and *L. aethiopica*; the *L. mexicana* complex with three main species: *L. mexicana*, *L. amazonensis*, and *L. venezuelensis*; and the subgenus *Viannia* with four main species: *L. (V.) braziliensis*, *L. (V.) guyanensis*, *L. (V.) panamensis*, and *L. (V.) peruviana*, all causing CL and/or ML.

The vector responsible for the transmission of the *L. donovani* and *L. tropica* complexes is the *Phlebotomus* species, and for *L. braziliensis* and *L. mexicana*, it is the sandfly of genus *Lutzomyia*.

Epidemiology and Transmission

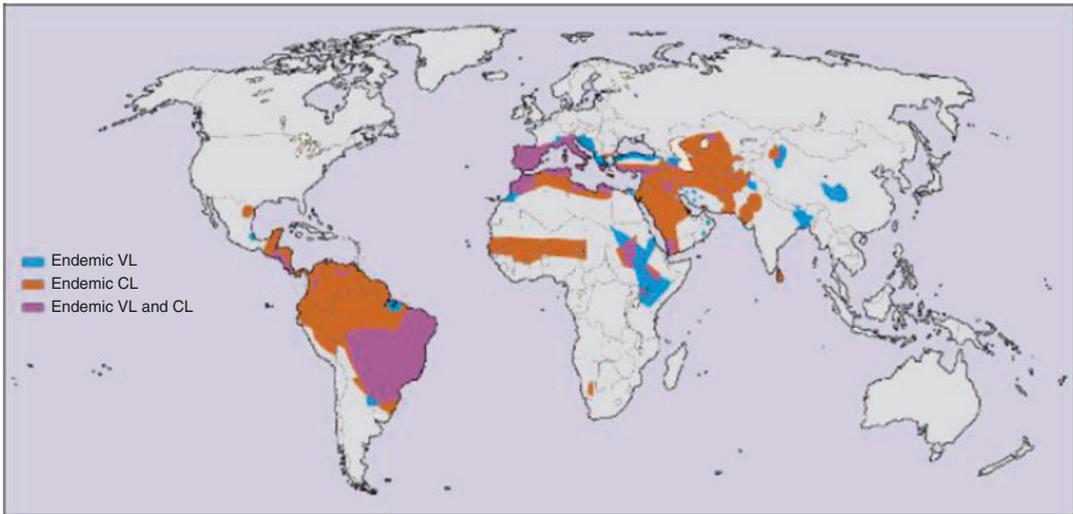

Global leishmaniasis annual incidence is 1.5 million new cases.

Globally, the most frequent form is cutaneous leishmaniasis, accounting for 0.7–1.3 million new cases annually. This form is present mainly in the Americas, Mediterranean countries, the Middle East, and Central Asia. Visceral leishmaniasis (kala-azar) is less frequent, with 200,000–400,000 new cases every year and is highly endemic in India and East Africa (Alvar et al. 2008).

HIV-*Leishmania* coinfection has been reported since the very start of the HIV epidemic in the 1980s, mainly in Southern European countries. The widespread adoption of cART has caused a notable reduction in incidence in developed countries, and nowadays the Mediterranean basin only adds 2,000–3,000 new diagnoses to the global burden (Monge-Maillo et al. 2014). In low-income areas such as the Indian subcontinent, Latin America, and East Africa, HIV-*Leishmania* coinfection still represents a major concern. Contrary to the situation in Europe and North America, incidence in these areas seems to be increasing. As an example of this, the proportion of HIV infections in new leishmaniasis diagnoses in Brazil increased from 0.7% in 2001 to 8.5% in 2012 (Lindoso et al. 2014). Similar increases have been observed in some areas of India, where HIV patients accounted for 0.88% of all *Leishmania* infections in 2000, increasing to 2.18% in 2006. Higher incidences are found in some areas of East Africa, like the Ethiopian region of Humera, where the prevalence of HIV between patients with leishmaniasis is as high as 31% (Masur et al. 2014). Figure 1 shows the distribution of different forms of leishmaniasis in different endemic regions (Davidson 2010).

There are some well-known risk factors for the acquisition of the infection, the most decisive being related to poverty (poor hygienic and domestic conditions, migration, etc.) and climate change (global warming and land degradation).

It has also been established that there is a new transmission cycle mediated by needle sharing among intravenous drug users, particularly in areas of Southern Europe and the Mediterranean

Leishmaniasis and HIV, Fig. 1 Geographical distribution of leishmaniasis

basin, like Spain, where 34–55% of used needles were found to contain *Leishmania*.

Clinical Presentation

All forms of leishmaniasis, particularly visceral leishmaniasis, behave as opportunistic infections in immunosuppressed HIV-infected patients, yet they are not included in the CDC classification of opportunistic infections. The predominant presentation depends on the epidemiology and the involved species; in Brazil, for example, mucocutaneous, visceral and cutaneous clinical presentations are seen in comparable proportions in HIV-infected individuals, but in southern Europe, cases are almost exclusively visceral.

cART has decreased the proportion of symptomatic cases in Europe, but its impact on the clinical presentation in resource-limited settings is much more restricted.

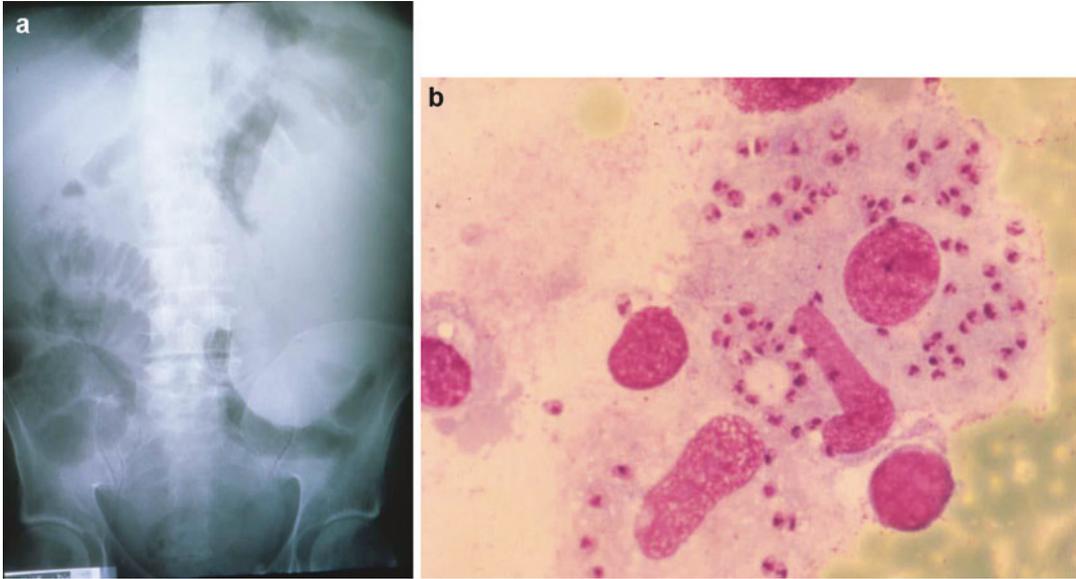

Visceral Leishmaniasis in HIV-infected Patients

The clinical presentation of visceral leishmaniasis in HIV-infected patients is very similar to that in HIV-seronegative individuals, but cases of progressive disease are more frequent. Patients have

typically less than 200 CD4 cells/ μ l and are infected with *L. infantum* (Europe), *L. donovani* (Africa and India), or *L. infantum/chagasi* (South America). Nevertheless, asymptomatic infections are not infrequent.

The incubation period can be as short as days following infection with the parasite, but most cases develop as result of the reactivation of an asymptomatic prior (even years-old) infection with *Leishmania* when immunosuppression progresses, most frequently in patients with less than 200 CD4 cells/ μ l, and most severe cases with visceral leishmaniasis have less than 100 CD4 cells/ μ l.

Clinical presentation frequently includes fever, splenomegaly and hepatomegaly, generalized lymphadenopathy, and profound weakness. Pancytopenia is prominent in routine lab tests. Frequently associated abnormalities are hypergammaglobulinemia (both due to HIV and to leishmania infections) and renal involvement. Acute and proliferative glomerulonephritis have been described, as well as proteinuria and abnormalities in globular filtration. Gastrointestinal symptoms, such as diarrhea, are more frequent in HIV-infected patients than in HIV-uninfected individuals, as a result of a profound parasite infiltration into the bowel. Atypical organ involvement seems to be more frequent in HIV-infected patients.

Leishmaniasis and HIV, Fig. 2 51-year-old male, heterosexual, diagnosed in 1994 with HIV stage C3. He had a history of *Pneumocystis jiroveci* pneumonia (PCP) and disseminated nocardiosis. His CD4 count was 28 cells/ μ L. The patient received antiretroviral treatment and secondary prophylaxis of opportunistic infections irregularly. In 1997, he was admitted for febrile syndrome, an enlarged

spleen of 12 cm below the costal margin and severe pancytopenia. The abdominal radiography showed a splenic silhouette that reached the left iliac crest (a). A bone marrow aspirate showed numerous leishmania amastigotes in the cytoplasm of a cell of the mononuclear phagocyte system (b) (May-Grünwald-Giemsa, x1000). The NNN medium culture was positive for *Leishmania donovani*

Leucopenia and thrombocytopenia are less frequent and less marked in patients receiving cART. Clinical relapses are more frequent in HIV-positive patients than in the HIV-uninfected population and frequency decreases with cART, but an undetectable viral load does not prevent relapse where immunological recovery has not been achieved. Patients relapsing have higher chances of further relapses, in part due to the delayed CD4 cell recovery in these patients.

Clinical presentation does not differ markedly according to CD4 cell count, although prognosis is poorer and mortality higher in patients with more pronounced immunosuppression.

Although the initial clinical presentation of visceral leishmaniasis is similar in HIV-infected and noninfected patients, there are major differences in outcomes. Global mortality is higher among HIV-positive patients compared to HIV-negative individuals, particularly if other concomitant opportunistic infections are present. Toxicity related to antileishmania treatment is also higher. Patients have extremely high relapse rates and the

clinical course is very frequently much prolonged. If patients are not receiving cART, relapse rates are as high as 90% within 12 months. Figure 2 shows some clinical and laboratory features of a case of visceral leishmaniasis.

Cutaneous Leishmaniasis in HIV-infected Patients

Localized cutaneous leishmaniasis is typically seen in patients with limited immunosuppression, and clinical presentation resembles that of HIV-uninfected individuals: papules, plaques, or ulcers in exposed body areas. The pathology of these cases is the same as that of HIV-negative patients. The incubation period does not seem to be affected.

Nevertheless, the parasite can disseminate and cause disseminated cutaneous leishmaniasis much more frequently than in HIV-negative patients, particularly in those with more pronounced immunodeficiency. This may or may not be associated with a concomitant visceral leishmaniasis. Indeed, every HIV-infected

patient with cutaneous leishmaniasis should be examined carefully to exclude visceral leishmaniasis. As for visceral leishmaniasis, recurrence and treatment failures are higher in HIV-positive patients.

Post-Kala-Azar dermal leishmaniasis follows the treatment of visceral leishmaniasis in a small proportion of cases due to *L. donovani*. Although it is rarely seen in the Americas or Europe, when reported – following cases due to *L. infantum* or *L. chagasi* – it has been in HIV-positive individuals. Cutaneous lesions may persist for long periods of time and consist of hyperpigmented or hypopigmented macules that progress to papules, nodules, and verrucous forms.

Mucocutaneous Leishmaniasis

ML is more frequently seen in South America and, as described for visceral and cutaneous leishmaniasis, the clinical course is frequently more aggressive and treatment failure more frequent.

Diagnosis

The techniques for diagnosing *Leishmania* infection in HIV patients have not changed significantly in recent years.

Microscopy

The demonstration of amastigotes in smears of tissue aspirates is the gold standard for the diagnosis of VL (Elmahallawy et al. 2014). Possible specimens include peripheral blood, bone marrow, splenic aspirate, and enlarged lymph nodes. Useful stains for the smears are Giemsa, Hematoxylin, and Eosin or Wright's stain. Stained smears are examined under an oil immersion objective. Amastigote parasites are seen within macrophages.

While splenic aspiration is the most sensitive method (98% sensitive), bone marrow puncture (50–85%, positive) is a safer procedure, as there is risk of hemorrhage in splenic puncture particularly in patients with an advanced stage of disease with soft enlarged spleens. Splenic aspiration is contraindicated in patients with prolonged prothrombin time or if platelet count is less than

40,000/mm³. Liver biopsy may often be diagnostic but also carries risk of hemorrhage.

Culture

Different tissue materials or blood are cultured on an NNN medium. This is a rabbit blood agar slope consisting of two parts of salt agar and one part of defibrinated rabbit blood. The material is inoculated in water of condensation, and the culture is incubated at 22–24 °C for 1–4 weeks. At the end of each week, a drop of culture fluid is examined for promastigotes. Other biphasic media, like Schneider's drosophila tissue culture medium with added fetal calf serum, can also be used.

Serology

Serological tests are not considered accurate methods for diagnosis of VL in HIV patients because of their limited sensitivity. The available evidence indicates that serological tests should not be used to rule out VL in HIV-infected patients.

The combined use of the direct agglutination test (DAT) and the rK39-immunochromatographic test (rK39-ICT), both rapid and easy to use methods, has been shown to have a sensitivity of 98% for VL diagnosis HIV-positive patients.

The detection of *Leishmania* antigen in urine using the latex agglutination test, commercialized as KAtex, initially appeared to be a promising, noninvasive tool for VL diagnosis and treatment follow-up. Its sensitivity in different studies in Europe, including both HIV-positive and HIV-negative patients, ranged from 69% to 100%, and a positive result after treatment was strongly associated with relapse, even though this has not been confirmed.

Molecular Biology

In recent years, peripheral blood-PCR analysis has been validated as a sensitive and specific tool to detect *Leishmania* parasites in coinfecting patients. Whereas classical diagnostic methods, such as bone marrow aspirate culture and microscopy, are still in use, diagnosis in more and more clinics is mainly based on the combination of the molecular detection of parasite DNA in peripheral blood by PCR and serology.

Bone marrow aspirates are still a source for parasite detection by PCR because of the increased sensitivity when compared with peripheral blood analysis. Despite the widespread use of molecular diagnosis techniques for leishmaniasis, there is, however, still a lack of consensus on the method for diagnosis of VL in HIV infected patients. Further development of common guidelines for diagnosis is needed.

It has been proposed to use real-time PCR as a suitable tool for monitoring the parasite load during follow-up of coinfecting patients and to predict the risk of relapses after treatment together with CD4+ cells, secondary prophylaxis, and previous history of VL relapse.

WHO guidelines for VL/HIV diagnosis have no specific regional considerations. The methods for diagnosis and follow-up (to determine cure and to predict relapses), therefore, vary considerably but are mainly based on a culture of buffy coat from peripheral blood, blood PCR, and bone marrow aspirate microscopy and culture and/or bone marrow PCR.

Differential Diagnosis (see Table 1)

Differential diagnosis is large and depends on the geographical localization, the clinical presentation (visceral, cutaneous, or mucosal leishmaniasis), and the degree of immunosuppression.

In HIV-patients with no or mild immunosuppression, differential diagnosis is the same as in HIV-uninfected patients.

The late stage of visceral leishmaniasis, most frequently seen in severely immunosuppressed patients, must be differentiated from hematological and lymphatic malignancies, from disseminated tuberculous and nontuberculous mycobacterial (infections and from progressive histoplasmosis. Acute visceral leishmaniasis has a much larger differential diagnosis including malaria, enteric fever, and several other conditions related to the specific epidemiological context.

Differential diagnosis of cutaneous and mucocutaneous leishmaniasis includes cutaneous tuberculosis, atypical mycobacterial infections, fungal infections such as histoplasmosis, paracoccidioidomycosis or sporotrichosis, leprosy, and neoplasms of the skin.

Anti-*Leishmania* Treatment

Management of leishmaniasis is complex and depends on the clinical syndrome and the causative organism. Only a few anti-leishmanial drugs are available, and their efficacy varies according to the species and region of infection. *L. donovani*, for example, does not respond to drugs in the same way in the Indian subcontinent and in East Africa. Some patients relapse within 6 months to

Leishmaniasis and HIV, Table 1 Differential diagnosis of leishmaniasis in HIV-infected patients^a

Visceral leishmaniasis	Cutaneous leishmaniasis	Mucosal leishmaniasis
Hematological malignancies ^b	Sporotrichosis	Disseminated histoplasmosis ^b
Lymphatic malignancies ^b	Chromomycosis	Paracoccidioidomycosis
Disseminated histoplasmosis ^b	Lobomycosis	Basal cell carcinoma
Disseminated mycobacterial infections	Leprosy	Midline granuloma
Brucellosis	Cutaneous tuberculosis	Nasal cavity lymphomas
Typhoid fever and enteric fevers	Cutaneous nontypical mycobacteria	
Malaria	Neoplasms of the skin	
Infectious mononucleosis	Chronic ulcerative lesions caused by typical bacteria	
Hemophagocytic syndromes		
Infectious endocarditis		
Hepatosplenic and acute schistosomiasis		

^aDifferential diagnosis largely depends on degree of immunosuppression, epidemiology, and geographical area. In patients without immunosuppression, differential diagnosis of leishmaniasis resembles that of seronegative individuals

^bParticularly in patients with severe immunosuppression

1 year irrespective of the regimen used, relapse being more common among untreated HIV coinfecting individuals. In recent years, intensified research efforts have led to significant changes in the therapeutic approach to VL. Despite this, treatment options for CL and ML are still poor.

Treatment of Visceral Leishmaniasis(VL) (see Table 2)

Until the 1990s, VL therapy was based on pentavalent antimonials, with amphotericin B deoxycholate and pentamidine as second-line drugs. In recent years, miltefosine, paromomycin, and, above all,

Leishmaniasis and HIV, Table 2 Options for treatment and secondary prophylaxis for visceral leishmaniasis in HIV-infected adults

Drug	Posology	Remarks
First episode ^a		
<i>First Line</i>		
Liposomal Amphotericin B	4 mg/kg/day days 1–5, 10, 17, 24, 31, and 38 (to achieve a total cumulative dose of 20 to 60 mg/kg body weight)	Monitoring for dose-dependent nephrotoxicity. Premedication with diphenhydramine, paracetamol, or limited doses of corticoids reduces the rate of infusional adverse events
<i>Alternative regimens</i>		
Amphotericin B lipid complex	3 mg/kg/day for 10 days iv	
Amphotericin B deoxycholate	0.7 mg/kg/day for 28 days (to achieve a total dose of 1.5 to 2.0 g)	
Miltefosine	150 mg/day (50 mg/8h) po 28 days po	
Liposomal Amphotericin B + Miltefosine	30 mg/kg body weight liposomal amphotericin B divided as 6 equal dose infusions iv, combined with 14 days of 50 mg/12h miltefosine po	Only observational data available in a study from India
Meglumine antimoniate	20 mg/kg/day for 28 days or im	More toxicity observed in HIV-infected individuals. Avoid if possible
Relapses		
Same regimens as for first episode	Higher doses and longer duration of treatment may be needed	Consider combined treatments, although level of evidence is low
Secondary prophylaxis		Maintain secondary prophylaxis until HIV-RNA is suppressed and CD4 T-cell count is above 200–350 cells/μL during 3–6 months. Combined treatments may also be considered
<i>First line</i>		
Liposomal amphotericin B	4 mg/kg every 21 days iv	
Amphotericin lipid complex	3 mg/kg every 21 days iv	
<i>Alternative regimens</i>		
Miltefosine	100 mg 2 times weekly po	
Pentavalent antimony	20 mg/kg every 28 days iv or im	
Pentamidine ^b	6 mg/kg/14–28 days iv	

^aParomomycin (an aminoglycoside) has been shown to be used successfully in a small number of HIV-negative visceral leishmaniasis patients in India. No efficacy data are available in HIV-infected patients

^bPentamidine is no longer recommended to treat primary visceral leishmaniasis. It is only an alternative regimen for secondary prophylaxis when other options are not available

liposomal amphotericin B have also been approved for VL treatment. These drugs largely increased the therapeutic options, but their efficacy varies geographically and not all products have been evaluated to the same degree in every region. In general terms, the best therapeutic option seems to be liposomal amphotericin B. Despite the level of evidence being lower, combination regimens have proven useful in many clinical conditions and may be the future of VL treatment, although more data are needed. In 2010 WHO published evidence-based recommendations for every geographical region, although the price and availability of each single drug may represent a challenge for VL treatment, especially in low-income countries. In 2016, the Infectious Diseases Society of America (IDSA) and the American Society of Tropical Medicine and Hygiene (ASTMH) updated the diagnosis and treatment guidelines (Aronson et al. 2016).

Immunocompromised patients have lower cure rates, higher mortality, and more relapses compared with HIV-negative patients. The side effects of anti-leishmanial drugs are more frequent and severe than in immunocompetent patients, and a full course of antimonials is generally considered too toxic for use in coinfecting patients. Based on a few clinical trials on efficacy and safety of anti-leishmanial treatment in HIV-infected individuals, liposomal amphotericin B is considered the drug of choice and is given in a total dose of 40 mg/kg (4 mg/kg on days 1–5, 10, 17, 24, 31 and 38) (Aronson et al. 2016; Iribarren et al. 2016). Despite this currently being the best treatment option, mortality and parasitological failure rates are still high at 7–12%, and up to 32%, respectively.

Amphotericin B deoxycholate (0.7 mg/day for 28 days) and amphotericin B lipid complex (3 mg/kg/day iv for 10 days) can be an alternative (Aronson et al. 2016; Iribarren et al. 2016). More recent data from an observational study in India have also proven that combined treatment with liposomal amphotericin B (L-amB) and miltefosine (30 mg/kg body weight intravenous L-amB divided as 6 equal dose infusions combined with 14 days of 100 mg/day oral miltefosine) may be useful as a first option for the treatment of VL in HIV-coinfecting patients

(Mahajan et al. 2015). Second-line treatment options for visceral leishmaniasis in HIV-coinfecting patients also include miltefosine and paromomycin. In the treatment of relapse, new courses of L-amB (at conventional or higher doses) or combined treatment can be administered. Limited data are available on the use of miltefosine for the treatment of VL relapses; in an observational study, miltefosine induced (an often transient) remission in 64% of patients (Marques et al. 2008).

Many VL patients are very ill when they are diagnosed. Dehydration, renal, and/or hepatic dysfunction, anemia, hypoproteinemia with ascites and edema, subsequent cardiac decompensation, and concurrent infections are seen as complications of VL. Supportive treatment is a milestone for treatment of VL, and all patients should be properly hydrated, have their hydroelectrolytes balanced, and should be given nutritional supplements. Many may need blood transfusions and treatment for concomitant infections such as tuberculosis, pneumonia, and diarrhea (Boelaert and Shundar 2014). Patients responding to treatment become afebrile in 4–5 days, and the other clinical symptoms and biological parameters slowly normalize. Complete regression of splenomegaly may take several months. An initial cure can be declared if there is clinical improvement at the end of treatment. If the patient is clinically well after 6 months of treatment, this can be taken as an indicator of definite cure.

Antiretroviral treatment has improved survival in HIV/*Leishmania* coinfection and prevents the development of clinical VL in asymptotically coinfecting patients. cART should be started as soon as possible (within 2 weeks) after starting specific *Leishmania* treatment and should not be stopped if already being taken. As noted below, after cART initiation, an immune reconstitution syndrome may be observed. Some preliminary *in vitro* data have demonstrated certain anti-leishmanial activity of the HIV protease inhibitors. Based on this, some authors postulate that the initial antiretroviral treatment in coinfecting patients should contain an HIV protease inhibitor (van Griensven et al. 2013), since it could improve

the initial response to *Leishmania* treatment and help in secondary prophylaxis to prevent relapse of visceral leishmaniasis. The use of HIV protease inhibitors for visceral leishmaniasis should, however, be further investigated in a clinical context.

Treatment of Cutaneous and Mucocutaneous Leishmaniasis

Few data are available on the efficacy of treatment for cutaneous, mucocutaneous, or diffuse cutaneous leishmaniasis in HIV coinfecting patients. On the basis of data in HIV-negative patients with cutaneous leishmaniasis and case reports in HIV coinfecting patients, first-line treatments include liposomal amphotericin B, and pentavalent antimony, by IV or IM route, for 3–4 weeks depending on the form of the disease and the clinical response. Nevertheless, pentavalent antimony was demonstrated to increase viral transcription and HIV replication in cultures of human peripheral blood mononuclear cells, raising concerns about its use in coinfecting patients. A first-line parenteral treatment should be used for mucocutaneous and disseminated cutaneous disease and for localized cutaneous disease caused by *L. braziliensis*, the species most likely to cause mucocutaneous disease. Potential second-line alternatives for cutaneous leishmaniasis include miltefosine, topical paromomycin, intralesional pentavalent antimony, and local heat therapy. However, the effectiveness of these modalities is dependent on the infecting species of *Leishmania*.

Secondary Prophylaxis/Maintenance Therapy

The high frequency of relapses is the most salient feature in the treatment of HIV/*Leishmania* coinfection. In a patient not on antiretroviral therapy, VL almost always relapses within 1 year, but this can be partially prevented with secondary prophylaxis regimens.

Numerous schemes have been proposed, although a definitive recommendation cannot be made because of lack of controlled data: monthly injections of antimonial, twice-monthly injections of L-amB, or of pentamidine, oral miltefosine twice weekly, daily allopurinol or itraconazole. Most data about secondary prophylaxis/maintenance therapy come from the

Mediterranean region. A randomized trial compared amphotericin lipid complex (3 mg/kg every 21 days) with no prophylaxis; this trial reported relapse rates of 50% versus 78%, respectively, after 1 year of follow-up. In retrospective studies, monthly pentavalent antimony or lipid formulations of amphotericin every 2–4 weeks were also associated with decreased relapse rates. Daily allopurinol, in a dose of 300 mg three times daily, used for maintenance therapy is less effective than monthly pentavalent antimony and is not recommended. Although no published data on efficacy are available, maintenance therapy might be offered in immunocompromised patients with cutaneous leishmaniasis with multiple relapses after adequate treatment (Masur et al. 2014).

Although data are insufficient to provide a strong evidence-based recommendation, discontinuation of secondary prophylaxis after successful treatment of leishmaniasis might be considered after a sustained (i.e., more than 3–6 months) viral suppression and an increase in the CD4⁺ count to levels greater than 200 or 350 cells/ μ L after initiation of cART (Masur et al. 2014). In coinfecting patients suffering multiple relapses, splenectomy may restore hematological parameters and reduce the need for blood transfusions, but it does not protect from relapses (Fig. 3).

Antiretroviral Therapy Initiation & IRIS

cART in HIV-*Leishmania* coinfecting patients is known to improve survival and decrease relapses after anti-*Leishmania* treatment cessation. There is no evidence-based recommendation about when to start treatment, but international guidelines recommend to start or to optimize HIV treatment as soon as patient can tolerate it (Masur et al. 2014; Iribarren et al. 2016).

Unmasking immune-reconstitution inflammatory syndrome (IRIS) is uncommon in the setting of HIV-*Leishmania* coinfection, although it has been reported in clinical cases, appearing between 2 weeks and 4–8 months after ART initiation. The most well-described form of IRIS is the post-Kala-azar dermal leishmaniasis (PKDL), but cases of disseminated visceral leishmaniasis and disseminated cutaneous leishmaniasis in the context of

Leishmaniasis and HIV, Fig. 3 Differential diagnosis of cutaneous and mucosal leishmaniasis. **(a)** Cutaneous leishmaniasis in an HIV negative patient. Infection acquired in an endemic area in the Amazon region. **(b)** Cutaneous ulcer due to disseminated histoplasmosis in a severely immunosuppressed HIV-infected patient. Histoplasmosis

in an important differential diagnosis. **(c)** Mucosal leishmaniasis in an HIV-negative patient. Infection was acquired in an endemic region in Brazil. **(d)** Mucosal involvement in a severely immunosuppressed HIV-infected patient due to disseminated histoplasmosis. Histoplasmosis in an important differential diagnosis

cART initiation have also been reported. Evidence supporting any specific clinical management for this condition is not available (Zijlstra 2014).

Prevention

Today no vaccine is yet available for use in humans, but candidate vaccines are in development for VL and CL (Pace 2014).

Primary prevention of leishmanial infection relies on reservoir host control in areas with zoonotic transmission; vector control activities, such as indoor residual spraying and/or insecticide-treated nets; and measures to decrease the transmission of infectious agents in IDUs, such as needle-exchange programs. The prevention of exposure to parasites of the *Leishmania* species should be based on canine health surveillance in regions where the disease is prevalent such as in

the Mediterranean basin, where *L. infantum* is predominant, and on avoiding exposure to dogs especially in the case of immunosuppressed patients. Measures to decrease the transmission of infectious agents in IDUs, such as the abovementioned needle-exchange programs, are also encouraged.

Primary prophylaxis is not indicated in HIV-infected *Leishmania*-seronegative individuals (Iribarren et al. 2016).

Conclusion

Although the introduction of cART has led to a decline in Leishmaniasis incidence in the Mediterranean region, the disease is still prevalent in other endemic areas. Efforts to improve

diagnostic tools (especially in monitoring responses to treatment and so reducing risk of relapses) and more clinical trials on treatment focusing on combination therapy in HIV-infected individuals in different endemic areas are needed in order to improve the management of this neglected parasitic disease.

Long-Acting Nanoformulated Antiretroviral Therapy

Zhiyi Lin and Howard E. Gendelman

 NE, USA
 Department of Pharmacology and Experimental
 Neuroscience, University of Nebraska Medical
 Center, Omaha, NE, USA

Definition

Antiretroviral therapy remains the gold standard for the treatment of human immunodeficiency virus infection. While having dramatic effects on disease morbidity and mortality, it demands life-long adherence. Secondary toxicities, viral mutation, comorbid disease, constitutional drug-associated symptoms, adherence of complex regimens “pill burdens,” and drug-drug interactions are further complicating limitations. Nanoformulated long-acting antiretroviral therapy with half-lives measured in week(s) to month (s) requires infrequent administration but with equivalent or superior therapeutic efficacy compared to standard drug regimens and has the potential to revolutionize current antiretroviral therapy. Cell-targeted nanoformulations provide yet another boost by improving drug delivery to

reservoirs and affecting opportunities for viral eradication.

Introduction

While antiretroviral therapy (ART) has significantly improved human immunodeficiency (HIV) infection-associated morbidity and mortality, it has failed to eradicate virus and is not a disease cure. While infected people can readily achieve virologic control and long productive lives as a result of ART interruption of the cycles of viral replication, ART does not affect latent or restricted infections. Such infections predominantly target naïve and long-lived memory CD4⁺ T cells and mononuclear phagocytes (MP; monocytes, tissue macrophages, microglia, and dendritic cells). Indeed, HIV infection is incurable due to its persistence in the central nervous system (CNS), lymphoid tissue (spleen, lymph nodes, and gut-associated lymphoid tissue (GALT)), bone marrow, and the genital tract. Integrated provirus contained within host cellular DNA currently is not readily removed and circumvents any effective host innate and adaptive immune responses. A number of recent studies have focused on therapies to affect viral latency by stimulating productive infection and immune clearance or by directing excising viral DNA. Limitations abound in the specificity and sensitivity of such approaches. For now, lifelong ART remains the gold standard for the treatment of HIV infection with the goals including maximally and durably suppression plasma HIV viral load, restoration and preservation of immunologic function, reduction of HIV-associated morbidity and mortality, and prevention of HIV transmission. Complicating such goals rests in medication compliance and its parallel development of viral mutations and resistance of ART. Natural elimination of chronically infected cells over time is also a limitation secondary to the long-lived nature of latently infected cells, and low level spreading viral infection that occurs as a consequence of limited antiretroviral drug (ARV) penetrance in reservoirs of infection poses yet an additional hurdle for any strategy seeking to

eliminate virus in its human host. Secondary toxicities also pose limitations. To the ends of increased ARV penetrance into cellular and anatomical reservoirs of HIV infection and reduction of longer-term viral persistence, improved ART compliance and pharmacokinetics and the ability to deliver ARV to subcellular action sites would not only improve therapeutic endpoints but also improve ARV delivery and positively affect viral eradication strategies. To such ends, long-acting nanoformulated antiretroviral therapy (nanoART) was developed. Long-acting nanoART has shown early success, in models of viral infection, to improve ARV biodistribution to anatomical reservoirs including those tissues with restricted drug access. While cellular reservoirs including, but not limited to, latently infected resting memory CD4⁺ T cells and long-lived MP are not eliminated, pharmacodynamics studies demonstrate improved viral clearance. With a half-life of restricted resting memory CD4⁺ T cells of 44 months and the unfortunate conclusion that over 60 years of ART would be required for the eradication (Pierson et al. 2000), long-acting nanoART provides the means to limit ongoing viral replication with the potential to improve both compliance and viral elimination strategies.

Nanotechnology, Nanomedicine, and Nanoformulation

The merger of improved ARVs with nanomedicine for drug delivery is a potential formidable combination. Newer integrase and non-nucleoside reverse transcriptase inhibitors (NNRTI) have shown greater therapeutic indices and drug half-lives. When nanotechnologies are added to allow for improved reservoir targeting, drugs can remain in protected subcellular compartments, and the drug's half-lives extend even further. Nanotechnology is the engineering and manufacturing of materials at the atomic and molecular scale. Nanomedicine, according to the National Institutes of Health (NIH), is the application of nanotechnology to disease treatment, diagnosis, monitoring, and control of biological system. Rational design of nanoformulations for

the delivery of different therapeutic agents including small molecule drugs, peptides or proteins, and genes is the most active research area in nanomedicine. Many reviews have been published to report the recent progress in the management of HIV infection that was achieved through the application of nanoformulation contributed by experienced and diligent scientists across the world (Edagwa et al. 2014). The particle sizes of these nanoformulations range from 1 to 1,000 nm, which give them unique physical, chemical, and biological properties that are distinct from those of bulk materials or single molecules. For example, nanosized particles can provide higher bioavailability of drugs because of the increased surface area followed by an increased dissolution rate of the drug compounds according to the Noyes-Whitney equation. Importantly, nanoparticles with smaller size and proper composition have the potential to cross the blood-brain barrier (BBB), delivering antiretroviral drugs to the brain, the anatomical reservoir of HIV.

Nanoformulations that have been used for the delivery of ARV can be roughly divided into four categories: drug suspension (nanosuspension), polymer-based nanoformulation, lipid-based nanoformulation, and inorganic nanoparticles.

Nanosuspensions, also known as drug suspension or nanocrystals, are submicron colloidal dispersions of pure particles of drug, which are stabilized by surfactants. It is the most promising type of nanoformulation that can be used for the development of long-acting nanoART. Compared to other nanoformulations, the key features of nanosuspensions are the minimal use of excipients and the industrial feasibility. The former advantage implies both high drug content and diminished excipient-related toxicity. For other nanoformulations, low drug loading, potential excipient-related toxicity, and manufacturing difficulties have severely constrained the clinical application. For example, liposome, the first generation of nanoformulation and one of the most successful drug delivery systems, was first described by Bangham and his co-workers in 1961, and the first liposomal pharmaceutical product, Doxil[®], received clinical approval in 1995. It took more than 30 years for the liposomal

pharmaceutical products to appear on the market. But it was less than 10 years for the first nanosuspension product, Rapamune[®], to be available on the market after the first patent application of nanosuspension filed in the beginning of the 1990s. Besides those two essential benefits that have been mentioned above, as one type of nanoformulation, the sizes of nanosuspensions are usually between 200 and 600 nm, which lead to enhanced dissolution, absorption, and bioavailability of drugs. This type of nanoformulation has already been widely used for water-insoluble drugs. But some hydrophilic drugs which undergo chemical modification to improve their hydrophobicity can also be manufactured using this technique. Besides that, scientists recently developed novel solid-in-oil nanosuspensions for hydrophilic drugs. Another prominent advantage of nanosuspension is the reduced injection volume as a result of nearly 100% drug loading, which is essential for intramuscular (IM) and subcutaneous (SC) administration, namely, depot injections, that allows the nanosuspension to release its active therapeutic agents in a consistent way over a long period of time to further improve the sustained release profile of the drugs. However, it can also be administrated through other routes like oral, topical, intravenous, ocular, and pulmonary routes.

Nanosuspension can be prepared by two basic methods, bottom-up technologies and top-down technologies. Bottom-up technology is an assembling method to form nanoparticles by precipitation. Top-down technology involves the particles size reduction of large particles, which comprises high-pressure homogenization and bead/pearl milling methods. However, the combination techniques, pretreatment followed by a size reduction step, are also being employed. The ingredients used in the formulation of nanosuspension include crystalline-active therapeutic agents along with stabilizers (surfactants, polymers), tonicity agents (salts, sugars), cryoprotectants, and solvents.

Polymer-based nanoformulations use different polymers as the carriers for therapeutic agents. Nano-conjugates, nanoparticles, micelles, dendrimers, and polyplexes are important classes of polymer-based nanoformulations. The most widely studied polymers include natural polymer

such as carrageenan, chitosan and gelatin, and synthetic polymer including polyethylene glycol (PEG), poly(ethylene oxide) (PEO), polypropylene oxide (PPO), polycaprolactone (PCL), etc. The therapeutic agents can be conjugated to the polymers or entrapped by the polymers to improve the chemical, enzymatic, and metabolic stability of drugs.

Nanoparticles (Woodrow et al. 2009) with a size of less than 200 nm were developed using FDA-approved biodegradable and biocompatible polymers poly(lactic-co-glycolic acid) (PLGA). Over 1,000 siRNA molecules targeted against the gene encoding for mitogen-activated protein kinase (MAPK1) were encapsulated per particle using spermidine as a counterion. When applied topically to the vaginal mucosa, this nanoformulation led to efficient and sustained gene silencing for at least 14 days with less irritation and inflammation compared to siRNA lipoplexes. This study clearly demonstrated sustained release potential of PLGA nanoparticles that can be investigated for the control of sexually transmitted infections and prevention of HIV transmission.

Liposome and solid lipid nanoparticles (SLN) are two extensively explored classes of lipid-based nanoformulations. Numerous studies have used lipid-based nanoformulations containing lipids to enhance the oral bioavailability of some poorly water-soluble, highly lipophilic drugs. But these systems can also be easily modified for topical, pulmonary, or parenteral delivery. In fact, parenterally administered liposomes are naturally cleared by mononuclear phagocytic system (MPS), which can be employed for macrophage targeting, the cellular reservoirs of HIV, and then lymphatic systems such as lymph node, anatomical reservoirs of HIV. And SLN has been extensively studied because of its BBB crossing ability for targeting CNS besides lymphatic tissues, which is its prominent advantage among drug carriers. Both natural lipids obtained from plant or animal sources and synthetic phospholipids, such as phosphatidylcholine (PC), phosphatidylethanolamine (PE), and phosphatidylglycerol (PG), are used for the preparation of lipid-based nanoformulations.

SLN (Chattopadhyay et al. 2008) loaded with atazanavir (ATV) was formulated by a thin film

hydration technique. The mean particle size of a freshly prepared SLN was about 167 nm with high encapsulation efficiency. Uptake studies using a well-characterized human brain microvessel endothelial cell line hCMEC/D3 and [³H]-ATV demonstrated that there was a significantly higher uptake of ATV in hCMEC/D3 cells when it was delivered by SLN and no toxicity was observed up to a concentration corresponding to 200 nM of ATV. This study suggested that SLN could be a promising nanoformulation to enhance brain uptake of ARV.

Inorganic nanoparticles can be tailored to act as carriers for therapeutic or imaging agents. Silver, gold, magnetic, silica, and calcium nanoparticles have been evaluated for the treatment and prevention of HIV. They also can be used in the pathologic research of HIV infection. It was reported (Bade et al. 2015) that brain region-specific HIV-1-induced neuropathology in chronically HIV-1-infected NOD/scid-IL-2R γ ^{null} (NSG)-humanized mice can be detected by manganese (Mn²⁺)-enhanced magnetic resonance imaging (MEMRI).

Synthesis and Characterization of NanoART

A variety of nanosuspensions (Nowacek et al. 2011) were prepared for crystalline indinavir (IDV), ritonavir (RTV), ATV, and efavirenz (EFV) by wet milling. The influence of the physical characteristics of these formulations, including particle size, surfactant coating, and surface charge and shape, on the cell uptake, release, and antiretroviral efficacy was evaluated in a monocyte-derived macrophage (MDM) based *in vitro* testing system. It was concluded that drug type, surfactant coating, and shape demonstrated profound impact on particle uptake, drug release, and antiretroviral activity, while particle charge and size only had minor effects. For example, it was shown that long-rod-shaped nanoparticles were taken up more rapidly than short rods, and spherical particles were taken up even slowly than short rods.

Several different nanoformulations (Balkundi et al. 2011) were manufactured for crystalline

IDV, RTV, ATV, and EFV by three different methods, namely, wet milling, homogenization, and sonication using a variety of excipients, and the properties of these formulations were compared by using an established MDM scoring indicator system. The results showed that the manufacturing methods affected the physicochemical properties of the nanoformulations. The IDV nanosuspensions were the most diverse with sizes of 252 and 418 nm and charges of -40.6 and -15.1 mV, manufactured by wet milling and homogenization, respectively, and the IDV PLGA nanoparticles prepared by sonication had a size of 367 nm and a charge of -9.6 mV. Different preparation methods and excipients also affected the biological, immune, virological, and toxicological properties of these formulations demonstrated by mixed results from drug uptake, retention, release, and antiretroviral activity studies. For example, in *in vitro* cell uptake study, ATV concentration in cells after 8 h incubation was three- to fourfold lower following PLGA nanoparticles treatment than that for homogenized or milled particles. However, it is shown that the most significant difference that affects cell targeting and antiretroviral activity of nanoparticles was the drug itself. Based on those results, it was proposed that the clinical utility of nanosuspension might depend on the choice of drug and formulation composition.

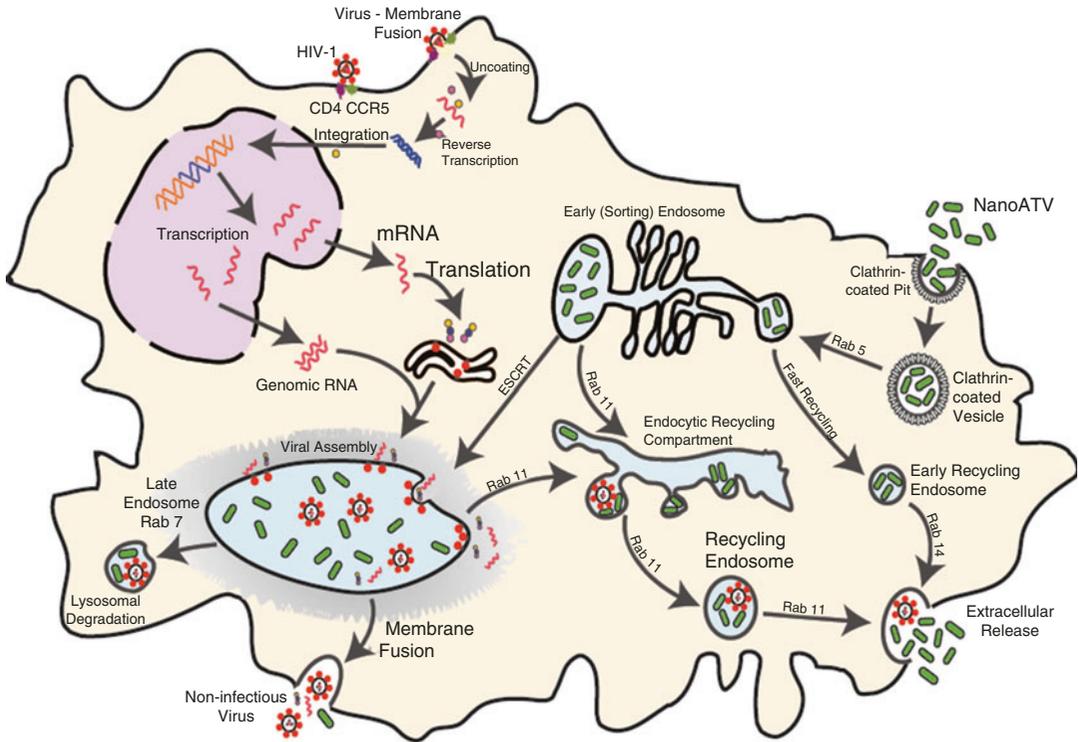

Subcellular ARV Delivery by NanoART

Intracellular trafficking (Kadiu et al. 2011) of RTV nanosuspension from the point of initial uptake to final release in MDM was investigated. It was now known that most nanoparticles taken up by MDM through clathrin-dependent endocytosis were sorted into a recycling pathway, from early endosome to recycling endosome, while bypassed lysosomal degradation, and drugs finally were released intactly from MDM without reduction in antiretroviral efficacy. siRNAs against Rab8, Rab11, Rab14, and brefeldin-A (BFA), a disruptor of recycling and secretory activities, were used to disrupt this pathway. Compared to untreated, siRNA scramble- and

Rab8 siRNA-treated MDMs, Rab11 and Rab14 siRNA-treated cells retained more drugs and released fewer drugs into the media. MDM treated with BFA showed similar impaired drug release, resulting in aggregation of nanoparticles in the perinuclear region. Proteomic and biological analysis suggested that particle recycling was primarily Rab11 regulated. Interestingly, it was shown that intact nanoparticles could be released from MDM with same size and shape as the original particles and maintained the antiretroviral activities. These results suggested the potential and advantages of targeting macrophage for cell-based drug delivery.

A further study (Guo et al. 2014) demonstrated that ATV nanosuspension (nanoATV) enhanced drug antiretroviral efficacy by improving the establishment of the subcellular drug depots and altering drugs distribution toward sites of active viral replication (Fig. 1). Late and recycling endosome compartments were pulled down by immunoaffinity chromatography with Rab-specific antibodies conjugated to magnetic beads, and ATV nanoparticles were seen in these subcellular compartments. It was discovered that nanoATV persisted in Rab7⁺ late endosomal compartments of HIV-1-infected MDMs, the site of active viral assembly, while most of nanoparticles are stored in Rab11⁺ recycling endosomes of uninfected MDMs. These results were cross validated by immunofluorescent staining of these compartments for confocal microscopy. Since infectious HIV-1 released from MDM are assembled in late endosomes, such colocalization between HIV and nanoATV in subcellular compartments might provide additional benefits in restricting viral replication. Thus it was reasoned that the action of nanoART could be amplified by directing nanoART to the late endosomal sites operative for viral assembly.

Quantitative SWATH-MS proteomics (Arainga et al. 2015) was applied to investigate cellular proteins that are deregulated by native ATV or nanoATV with or without HIV-1 infection in MDMs. The results showed that HIV-1 and nanoATV engaged endolysosomal trafficking for assembly and depot formation, respectively. Compared to virus, nanoATV oppositely regulated

Long-Acting Nanoformulated Antiretroviral Therapy, Fig. 1 Intracellular pathways of HIV-1 and nanoATV. NanoATV enters MDMs via clathrin-coated pits and is then transported to the early endosome. Then most of the nanoparticles are transported to the Rab11⁺ recycling endosome

in uninfected MDMs, while most of the nanoparticles persisted in Rab7⁺ late endosomal compartments in HIV-1-infected MDMs, the site of active viral assembly (Modified with permission from Guo et al. (2014))

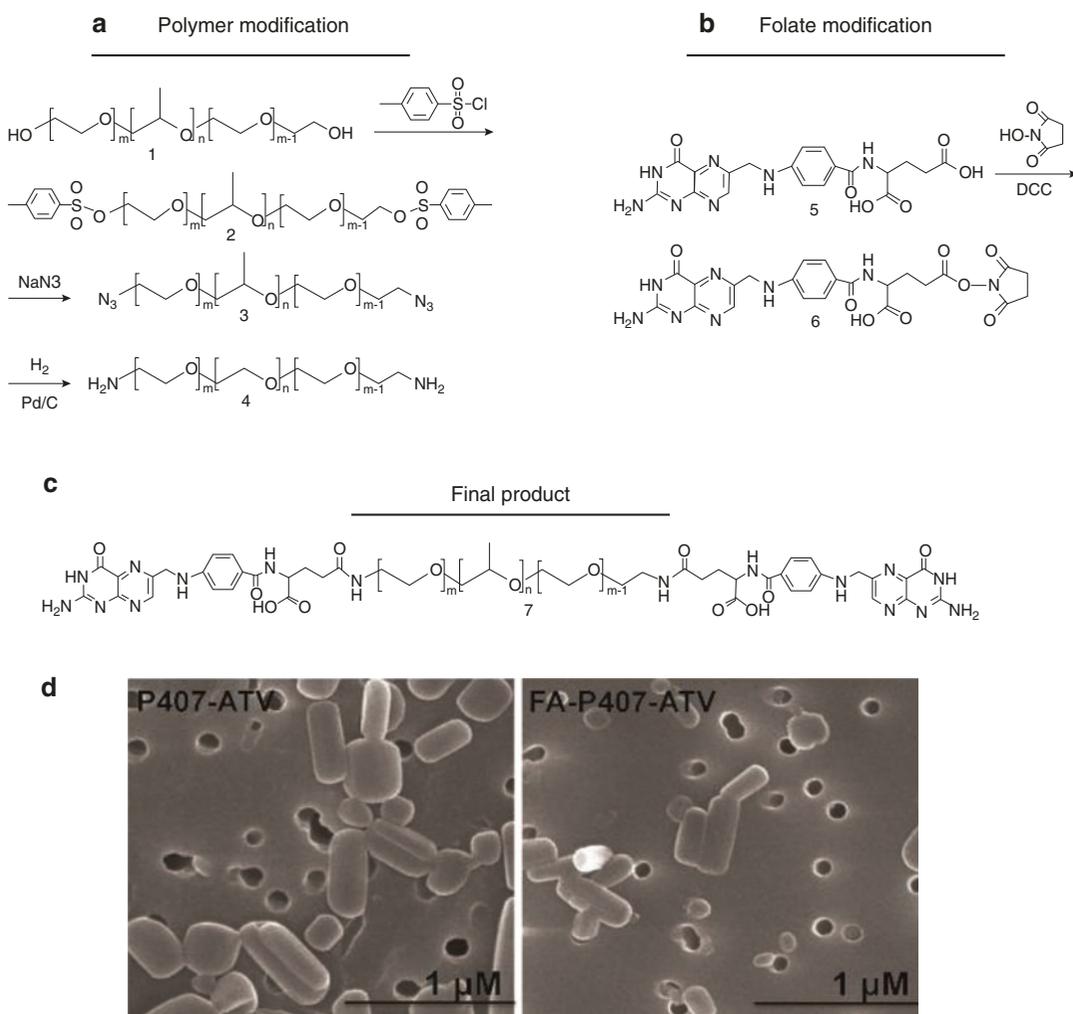

endolysosomal proteins. For example, in nanoATV-treated HIV-1-infected MDMs, Rab5 and Rab7 were downregulated, while upregulation of these proteins was observed in HIV-1-infected MDMs. DAVID and KEGG bioinformatics were used to analyze the proteomic data and the relationships between secretory, mobility, and phagocytic cell functions, and virus and particle trafficking was shown. In this study, a previously unknown mechanism for how long-acting nanoART provides a strategic advantage to combat viral infection was discovered.

Cell-Targeted NanoART

Macrophages, one of the cellular reservoirs of HIV, serve to disseminate virus and act as host cells for HIV infection and ongoing viral

replication. By definition, macrophage can be harnessed as a cell carrier for antiretroviral drugs, namely, cell-based drug delivery system. Because of its migratory function, macrophage can deliver drugs to areas of sustained viral growth and inflammation, which will otherwise be inaccessible due to either physical or biochemical barriers. Surface modification of nanoformulation can be employed to prepare cell-targeted nanoART for macrophage targeting, using ligands that will specifically bind to some surface receptors of macrophages and trigger the internalization of nanoparticles through phagocytosis or endocytosis. This strategy has been extensively studied in cancer treatment or other disease by targeting certain overexpressed receptors on the surface of target cells.

Based on published literature, it was proposed (Puligujja et al. 2013) that since activated

Long-Acting Nanoformulated Antiretroviral Therapy, Fig. 2 Synthesis of folate-conjugated poloxamer 407 (FA-P407). Schematic representation of the modifications for (a) poloxamer 407 and (b) folate and subsequent

reaction to yield (c) FA-P407. (d) Scanning electron micrographs of FA-P407-ATV and P407-ATV (Modified with permission from Puligujja et al. (2013))

macrophages express folate receptor 2 (FOLR2), its ligand folate-coated nanoART could facilitate macrophage uptake and increase cell retention of antiretroviral drugs. Folate-modified poloxamer 407 (FA-P407) was synthesized (Fig. 2), and free-base ATV nanosuspensions were prepared by high-pressure homogenization with or without using FA-P407. When MDM was treated with 100 μM FA-P407-ATV or P407-ATV, twofold greater cell uptake of nanoATV coated with 20% or 40% FA-P407 by MDM was observed, compared to nontargeted nanoATV. The antiretroviral

efficacy of targeted nanoATV was tested by first treating MDM with 100 μM FA-P407-ATV or P407-ATV for 8 h and then challenging treated MDM with HIV-1_{ADA} at 1, 5, 10, and 15 days later. FA-P407-ATV exhibited better antiretroviral activity than P407-ATV as HIV-1 replication was reduced by 87%, 80%, 82%, and 81% with FA-P407-ATV compared to 80%, 70%, 68%, and 64% with P407-ATV at days 1, 5, 10, and 15, respectively.

The pharmacokinetics, biodistribution, and pharmacodynamics of nanoART in vivo were

evaluated using Balb/cJ mice and HIV-1-infected hu-PBL-reconstituted NSG mice (Puligujja et al. 2015). The mice were injected with 50 or 100 mg/kg FA-coated or FA-uncoated nanoART, and the plasma and tissue ATV concentrations following FA-nanoART treatment were significantly higher than uncoated nanoART and were dose-dependent. The immune restoration after treatment represented by CD4:CD8 ratio was measured by flow cytometry. Compared to untreated controls, CD4:CD8 ratios were increased in tissues of HIV-1-infected mice. The antiretroviral activities of nanoART were also measured in the levels of HIV-1p24 antigen and HIV-1gag RNA, and the findings suggested that nanoART could effectively suppress viral replication. Interestingly, it was shown that the interaction between nanoART and macrophage increased the folate receptor expression, which further supported the rationale of using nanoART.

Limitations

Long-acting nanoART administered intramuscularly or subcutaneously has several disadvantages including limited injection volumes, painful nature of administration, considerable delay in onset of action compared to intravenous injection, and inability to withdraw drugs from circulation in the event of toxicity once the therapy starts. Additional limitations associate with the chemical and pharmacologic properties required for drugs, such as longer intrinsic half-life, higher protein binding, and satisfactory hydrophobicity capacities.

Ongoing and Future Perspective

GlaxoSmithKline is the leading pharmaceutical company for the development of long-acting nanoART for HIV treatment and prevention (Spreen et al. 2013). They developed a long-acting injectable nanosuspension that had 200 nm median particle size for cabotegravir (GSK1265744), an integrase inhibitor, by using wet milling technology. They reported that in the

phase I study of this nanoformulation, following single IM or SC injection, the mean plasma level concentration of cabotegravir remained well above the PA-IC₉₀ for about or longer than 24 weeks for dose of at least 200 mg. And cabotegravir was still detectable in plasma up to 48 weeks. A phase IIa clinical trial for the evaluation of the safety, tolerability, and acceptability of GSK1265744 long-acting injectable formulation (744 LA) in adult male subjects is ongoing. Long-acting injectable nanosuspension, called TMC278 LA, for rilpivirine (RPV), a non-nucleoside reverse transcriptase inhibitor (NNRTI), was also developed (Baert 2009). The free base of RPV is a stable crystalline polymorphic drug substance with very low water solubility. Its nanosuspensions can be easily manufactured by wet milling technology. The average particle sizes of nanosuspensions were 200, 400, and 800 nm, and all of them were stable over 6 months. Following a single-dose administration, the plasma concentration profiles showed sustained release of RPV over 3 months in dogs and 3 weeks in mice. Compared to 400 and 800 nm nanosuspensions, 200 nm nanosuspension achieved higher and more stable plasma concentration profiles, acted as long-acting injectable nanoformulation. In a further preclinical investigation (Hoeben et al. 2010), 200 nm nanosuspension of TMC278 was administered in rats and dogs as single IM or SC injection. RPV showed sustained and dose-dependent release over 2 months in rats and over 6 months in dogs. In the IM injection groups, the RPV concentrations in the lymph nodes exceeded the plasma concentrations by over 100-fold 1 month after administration and then decreased to three- to sixfold of the plasma concentrations 3 months after administration. It was suggested that such observation was due to the nanoparticle uptake by macrophages and then the establishment of secondary depots in lymph nodes. In the phase I study of TMC278 LA, single 400 and 600 mg doses, administered subcutaneously around the umbilicus or intramuscularly in the gluteus maximus muscle, gave prolonged RPV plasma exposure of approximately 20 ng/mL after 8 weeks without serious adverse events. The

combination use of 744 LA and TMC278 LA was also clinically evaluated. In the phase I clinical trial, pharmacokinetics, safety, and tolerability for the combination use of these two long-acting nanoART were assessed in healthy subjects. 744 plasma concentrations exceeded the protein-adjusted IC_{90} , and RPV plasma concentrations were comparable to steady-state oral RPV formulation (25 mg/day), with grade 1 injection site reactions being most commonly reported and without grade 3 or 4 adverse events. A phase IIb clinical trial of the combination use of 744 LA and TMC278 LA is ongoing.

By the end of 2013, 35 million people are living with HIV, while 1.5 million died due to AIDS-related symptoms globally. The introduction of ART successfully shifted HIV infection from a deadly disease to a chronic illness. Poor adherence is among the major issues facing life-long ART. It was estimated that the average rates of nonadherence to ART range from 50% to 70%. Poor adherence does not just lead to the loss of virologic control; it may also contribute to the development of drug-resistant strains of HIV. Drug-resistant strains of HIV can also be transmitted, leaving newly infected or treatment-naïve patients with fewer treatment options. One means to address this issue is through long-acting nanoART. These require only infrequent dosing and may improve long-term therapeutic responses by avoiding missing doses or treatment fatigue. In the last decades, institutions and companies have devoted to the development of long-acting nanoART with the following characteristics: comparable antiviral efficacy with existing oral ART, high drug-loading capacities and suitable pharmacokinetic characteristics allowing infrequent dosing at a practical injection volume, no or minimal incremental toxicity related to the method of administration, existence of corresponding oral formulations facilitating treatment initiation and discontinuation, feasibility of industrial production, and desirable stability for the distribution and storage of drug products (Spreen et al. 2013). Several qualified nanoformulations are already under evaluation in clinical trials (Spreen et al. 2013; Baert 2009; Hoeben et al. 2010).

Overall, it was shown that targeted delivery of nanoART to macrophages potentially improves antiretroviral efficacy, since macrophages can store nanoART for longer periods of time and disseminate the cargos to HIV sanctuary sites because of its migratory nature. It is possible by maintaining the optimal antiretroviral drug concentration in HIV cellular and anatomical reservoirs (CNS, GALT, lymphoid tissues), and macrophage-targeted nanoART will achieve the goal of HIV eradication. The development of next-generation cell-targeted long-acting nanoART should work as follows: with the advancement of technologies in cell membrane isolation and mass spectrum-based proteomics, more cell surface markers of specific type of cells, such as macrophages, can be identified. Some of them involved in phagocytosis or endocytosis function can be served as potential targets for the development of innovative delivery system. Ligands with high affinity and specificity to the chosen receptors can be identified by using a variety of techniques including, but not limited to, phage display, enzyme-linked immunosorbent assay (ELISA)-like high-throughput screening (HTS) assay, or computational design. The final stage is the manufacture of the decorated nanoART with the newly identified ligands and the *in vitro* and *in vivo* evaluation of this nanoART.

Conclusion

In summary, the long-acting nanoART possessed tremendous potential in the management of HIV infection as described here. Some of them already advanced to clinical trials with hope of success. And the next-generation cell-targeted long-acting nanoART with improved antiretroviral efficacy and diminished toxicity is on its way.

Long-Term Nonprogressors and Elite Controllers

Olivier Lambotte

Department of Clinical Immunology, Paris South University Hospitals, Le Kremlin Bicêtre, France

Definitions

Long-term nonprogressor (LTNP): a patient able to maintain a high CD4 T-cell count for unusually long periods of time in the absence of antiretroviral therapy (ART). This is an immunologic definition.

Elite controller (EC): a patient characterized by undetectable plasma viral loads for extended periods of time in the absence of ART. This is a virologic definition.

Posttreatment controller (PTC): a formerly viremic patient having received ART and in whom the viral load remains undetectable during a prolonged period after ART discontinuation.

In the absence of antiretroviral therapy (ART), HIV-1 infection in most patients is characterized by ongoing viral replication, progressive CD4 cell depletion, the development of AIDS, and death. Ever since the start of the AIDS pandemic, it has become clear that a small proportion of HIV-infected patients experience a mild course of infection. Patients with prolonged, AIDS-free survival in the absence of ART were termed long-term nonprogressors (LTNPs) (Gurdasani et al. 2014; Okulicz and Lambotte 2011). Once tests for viral load (VL) had become available, it became clear that (i) LTNPs were heterogeneous

and (ii) a subgroup was spontaneously able to control viral replication. At present, LTNPs are now usually defined as patients able to maintain a high CD4 T-cell count for unusually long periods of time in the absence of antiretroviral therapy. It should be noted that the VL is not taken into account in this definition. In contrast, elite controllers (ECs) are an uncommon subset of HIV-1-infected individuals with the ability to spontaneously control HIV loads for prolonged periods of time (Gurdasani et al. 2014; Okulicz and Lambotte 2011; Sáez-Cirión et al. 2012; Walker and Yu 2013). Again, it should be noted that the CD4 T-cell count is not taken into account in the definition of an EC. Although some patients are both LTNPs and ECs, the overlap is limited. Elite controllers have been extensively studied with a view to elucidating the mechanisms of spontaneous HIV control and thus facilitating the development of novel anti-HIV therapeutic approaches (including vaccines). However, there are probably several different mechanisms leading to virus control, and long-term outcomes in ECs have yet to be characterized. This entry will focus on the identification of ECs and the latter's epidemiological profile, clinical characteristics, and outcomes. It also gives an overview of the HIV control mechanisms that may be operating in these patients.

Recent observations have indicated that the initiation of a long-term course of treatment during the primary infection is associated with prolonged control of HIV viremia after ART withdrawal (Walker and Yu 2013). Accordingly, the few patients with lasting HIV control after ART withdrawal were referred to as posttreatment controllers (PTCs). These encouraging observations suggest that host responses can be manipulated and may lead to a functional cure.

The Differences Between Long-Term Nonprogressors and Elite Controllers

The first LTNPs were described in 1990–1995. Some were referred to as slow progressors. These patients are defined according to an immunologic parameter (the CD4 T-cell count). Various studies have shown that 2–15% of patients with

HIV can be classified as LTNPs (Okulicz and Lambotte 2011; Sáez-Cirión et al. 2012). Much research has since focused on determining the factors associated with nonprogression (Sáez-Cirión et al. 2012; Walker and Yu 2013). The presence of attenuated viruses such as the Nef-mutated viruses found in the Sydney cohort may explain some cases. Genetic factors (such as CCR5- Δ 32 polymorphisms and high frequency of B27 and B57 HLA class I alleles) have also been reported. In different groups of LTNPs, the immune response involves high titers of neutralizing antibodies, multifunctional, HIV-specific CD4 and CD8 T-cell responses, and the enhanced production of soluble antiviral factors. However, the data are heterogeneous, and a clear consensus on the most relevant mechanisms has not been reached.

This heterogeneity may be due (at least in part) to the fact that the exact definition of an LTNP (the CD4 T-cell count, the follow-up time, and the HIV load) differed from one study to another. These definitions were recently reviewed, and a common definition of an LTNP has been suggested: an asymptomatic individual infected for 8 or more years and with a CD4 T-cell count above 500 cells/ml in the absence of ART (Gurdasani et al. 2014). In fact, a large number of the individuals in LTNP cohorts eventually show a drop in their CD4 T-cell counts and progress to immunosuppression (Okulicz and Lambotte 2011). At present, most viremic LTNPs have received ART at some point. This explains probably the relatively low prevalence of LTNPs in recent studies (from 0.4% to 3.3%) (Okulicz and Lambotte 2011; Grabar et al. 2009).

A very small proportion of LTNPs are able to maintain low immune activation and asymptomatic infection despite an extremely high VL, a phenotype that resembles the nonpathogenic simian immunodeficiency virus infection in African nonhuman primates (Sáez-Cirión et al. 2012).

However, the LTNPs with high CD4 T-cell counts who remain asymptomatic are usually those with the lowest VLs. The availability of routine VL testing has made it possible to identify ECs (the definition of which is based on virologic criteria, in contrast to LTNPs). Since prolonged

virologic control (i.e., low VLs) is associated with elevated CD4 T-cell counts, there is nevertheless a limited degree of overlap between ECs and LTNPs. Two recent cohort studies have found between 4% and 12% of LTNPs meeting the criteria for ECs (Okulicz and Lambotte 2011; Grabar et al. 2009). This limited overlap strongly suggests that the determinants of viral control and CD4 T-cell homeostasis leading to slow progression phenotypes are distinct (Gurdasani et al. 2014). For instance, specific HLA class I alleles might be associated with the delayed loss of CD4 T cells but would not affect levels of HIV replication (Walker and Yu 2013) ► [Non pathogenic SIV infection of sooty Mangabeys](#).

Definitions of Elite Controllers

Elite controllers are typically defined by a series of VL test results below the limit of detection (in the absence of ART) (Gurdasani et al. 2014; Okulicz and Lambotte 2011; Sáez-Cirión et al. 2012; Walker and Yu 2013). These ECs have also been referred to as “elite suppressors,” “HIV controllers,” and “aviremic controllers” in the literature. A recent article reviewed all the definitions of extreme phenotypes related to HIV control and progression (Gurdasani et al. 2014). The definition of a “controller” has varied from one study to another, which may explain some of the differences in the patients’ immunologic and virologic characteristics. Three main parameters must be taken into account: (i) the period of sustained virologic suppression in the absence of ART, (ii) the VL threshold considered, and (iii) the allowance for some episodes of detectable VLs. These “blips” can be due to concomitant illnesses, vaccinations, variations in VL testing, or other unidentified factors. Most studies have used one of the three following definitions for ECs and/or controllers. Firstly, ECs are usually defined as having three or more VL determinations below the limit of assay detection (generally <50 copies/mL) over a period of at least 12 months in the absence of ART (Gurdasani et al. 2014; Walker and Yu 2013). Secondly, a stringent definition of an HIV controller is based on long follow-up data:

known HIV-1 infection for more than 10 years, with more than 90% of the VLs below the limit of detection (Gurdasani et al. 2014; Okulicz and Lambotte 2011; Sáez-Cirión and Pancino 2013). Patients fulfilling this criterion also fulfill the criterion for definition as an EC. The third definition is wider: HIV-infected individuals with at least three measurements of plasma HIV RNA (<2,000 copies/ml) over a period of at least 12 months in the absence of ART. This definition includes a separate group of patients with persistently low but detectable VLs in standard clinical assays (50–2,000 RNA copies/mL), termed viremic controllers. In the present review, ECs are defined according to the first and second definitions (Gurdasani et al. 2014; Walker and Yu 2013) ► [Viremic non progressors](#).

The Prevalence of Elite Controllers

Several studies have estimated the prevalence of ECs in the HIV-1-infected population. Transient control of viremia is not uncommon. For example, 6.7% of the patients in one study had two consecutive HIV RNA values below 500 copies/mL (Okulicz and Lambotte 2011). Prolonged control of viremia, however, is rare and generally occurs in less than 1% of patients. In several cohorts in France and in the USA, the reported prevalences range from 0.2% to 0.6% (Gurdasani et al. 2014; Okulicz and Lambotte 2011; Sáez-Cirión and Pancino 2013; Walker and Yu 2013).

Demographic Characteristics of Elite Controllers

The median age at HIV diagnosis is between 25 and 30, and the median age at enrolment is between 45 and 50 (Sáez-Cirión et al. 2012). These values highlight the long duration of HIV infection in ECs, with persistent, undetectable viremia and no disease progression for a median of 15–17 years of infection (Sáez-Cirión et al. 2012). Both male and female ECs are observed, but females seem to be more frequent in several cohorts (relative to age-matched general

populations of HIV-1-infected individuals). Studies of demographic characteristics have failed to reveal a preferential association with ethnic origin or the mode of HIV infection. Although there are few data on coinfection by other pathogens in ECs, at least some of these patients appear to be able to control or even clear hepatitis C infections (Okulicz and Lambotte 2011; Sáez-Cirión et al. 2012).

Similarly, there is little information on the natural history of HIV control post-seroconversion. However, several studies have shown that control occurs rapidly after seroconversion in most of these individuals. However, about a quarter of ECs require more than 3 years achieving control (Madec et al. 2013). The mechanisms influencing rapid control and delayed control are probably not the same.

The Mechanisms of HIV Control

The Virus

Although a range of HIV subtypes have been observed in ECs, subtype B appears to be over-represented. This may be due to the prevalence of subtype B in HIV-infected populations in the USA and Europe at the time when most ECs became infected with HIV.

Patients who become controllers may harbor viruses with reduced replication capacity during the early stages of infection; this is likely associated with transmitted or acquired cytotoxic T-cell escape mutations or transmitted drug resistance mutations (Walker and Yu 2013). However, the presence of defective HIV virus is not a common feature in ECs, since several studies have shown that replication-competent viruses can be recovered from CD4 T cells (Walker and Yu 2013; Sáez-Cirión and Pancino 2013). In a recent study, transmission of viruses from ECs to humanized mice confirmed the pathogenicity of these strains (Salgado et al. 2014).

In many ECs, ultrasensitive single-copy VL (usVL) assays can detect extremely low levels of viral replication in plasma. If usVL assays are repeated over time, the proportion of ECs with a detectable plasma usVL tend toward 100%, and

the level of viremia is often similar to that observed in ART-suppressed patients (Walker and Yu 2013; Sáez-Cirión and Pancino 2013). Although the origin of HIV RNA in the plasma of patients on ART remains elusive, continuous viral replication is present in ECs (albeit at extremely low levels). Indeed, the analysis of Gag and Nef sequences from the plasma of HLA-B*57- and/or HLA-B*27-positive ECs revealed a temporal evolution of the viral sequences over time (i.e., testifying to active viral replication) (Walker and Yu 2013; Sáez-Cirión and Pancino 2013; Bailey et al. 2006). Paradoxically, the virus is able to replicate but does so at low levels only.

Several explanations for this paradox have been put forward and are described in this entry. The immune system, especially the HIV-specific T-cell response, is involved. The fitness cost associated with some escape mutations (driven by the T-cell response) may limit viral replication. Indeed, various studies have suggested that B*57- and B*27-restricted CD8 T-cell responses target epitopes located within structurally important sequences of the virus, where variations would come at a cost to viral fitness (Walker and Yu 2013; Sáez-Cirión and Pancino 2013; Bailey et al. 2006). Viral restriction factors seem able also to limit viral replication (see below). These mechanisms could contribute to the small size of the HIV-1 reservoirs in ECs. ECs have much smaller amounts of HIV DNA in their peripheral blood mononuclear cells (PBMCs), when compared with other groups of HIV-infected patients (and especially patients on ART).

These data suggest that early, intense immune pressure affecting viral fitness (rather than the characteristics of the infecting virus per se) is a key factor in viral control in ECs. Other host factors also influence the control of viral replication. The observations of HIV-1 controller/chronic progressor transmission pairs (Walker and Yu 2013) provided strong evidence that host factors primarily explain elite control of HIV-1 replication.

The Genetic Characteristics of ECs

As in some LTNP cohorts, there is an overrepresentation of protective HLA alleles (HLA B57

and B27, which contain the Bw4 motif) in ECs (Walker and Yu 2013; Sáez-Cirión and Pancino 2013). These alleles are present in 45–86% of the patients, depending on the cohort in question. HLA B5701 is enriched in North American and European controller cohorts, whereas the HLA B5703 allele is enriched in African populations. Genome-wide association studies have confirmed this relationship; the single-nucleotide polymorphisms with the most significant associations were located close to the HLA-B and HLA-C genes (International HIV Controllers Study et al. 2010). The strong association with certain HLA class I alleles, the impact of the amino acid composition of the class I-binding groove on viral peptide-binding capacity, and HIV-1 control all point to the role of the immune response (and especially a specific cytotoxic T-cell (CTL) response) in ECs (Walker and Yu 2013; International HIV Controllers Study et al. 2010).

Other genetic associations have been evidenced in ECs. Killer-cell immunoglobulin-like receptors (KIRs) are expressed on natural killer (NK) cells and bind to HLA class I molecules. The KIR genes are polymorphic. Some genotypes of KIR3DL1 (KIR3DL1**h*/**y*) and KIR3DS1 are associated with better control of HIV-1 when present in patients harboring HLA-B alleles with Bw4 epitope specificity (namely, HLA-B*57/27/58) (Walker and Yu 2013). These data suggest that the mechanisms of protection in ECs bearing these alleles are due not only to CTL responses but also to NK cell responses.

However, it should be borne in mind that the HLA genetic associations as a whole only account for 19% of the variance in the host's viral control (Walker and Yu 2013).

Immune Responses

Adaptive Responses

CD8 T Cells The significant link between MHC class I loci and EC status indicates that an adaptive, MHC class I-restricted CD8 T-cell-mediated control is involved ► [HIV and SIV, CD8 T cell responses to](#).

A large proportion of ECs have strong HIV-specific CD8 T-cell responses (Walker and Yu 2013; Sáez-Cirión and Pancino 2013). The great magnitude of the HIV-specific CD8 T-cell response in ECs contrasts with the low response observed in patients receiving ART but who also have an undetectable VL. The detection of strong, HIV-specific CD8 T-cell responses in ECs could be related to the persistence of low-level viral replication described above. The frequency of HIV-specific CD8 T cells in these ECs is similar to that observed in viremic progressors.

However, the cells in ECs are qualitatively different from the functionally impaired, exhausted cells in viremic individuals. HIV-specific CD8 T cells in ECs have several specific properties, some of which may be surrogate markers of efficacy for HIV vaccines (Walker and Yu 2013; Sáez-Cirión and Pancino 2013; Migueles et al. 2008).

1. *Functions.* ECs have high numbers of multifunctional HIV-specific CD8 T cells, as defined by the ability to exert multiple effector functions (including the secretion of several cytokines, such as IFN- γ , TNF- α , MIP-1 β , CD107a, and interleukin (IL)-2) following antigenic stimulation. A major, unique characteristic of HIV-specific CD8 T cells in ECs is their ability to proliferate in response to antigen, rapidly upregulate granzyme and perforin, degranulate, and thus suppress HIV-1 infection of autologous CD4 T cells (Sáez-Cirión and Pancino 2013; Sáez-Cirión et al. 2007; Migueles et al. 2008). This ability to rapidly kill HIV-infected CD4 T cells in vitro is associated with high expression levels of the T-box transcription factor T-bet. There is a positive correlation between the frequency of Gag-specific CD8 T cells and the ability of CD8 T cells to block viral replication. The rapid elimination of infected cell targets by CD8 T cells is consistent with the higher numbers of differentiated effector CD8 T cells in ECs than in HIV-1 progressors. In ECs, HIV-specific CD8 T cells are activated. The frequency of CD38 + DR+ activated HIV-specific CD8 T cells is lower than in viremic progressors but higher than in healthy donors.

2. *Targets.* Strong responses to HIV Gag and (to a lesser extent) HIV Nef are predominant. This is important because Gag is one of the first viral antigens to be produced in infected cells. These data emphasize the involvement of an immune response targeting the first steps in the viral cycle.
3. *The T-cell receptor (TCR).* Gag-specific CTLs from ECs can mediate effective viral control because of their higher functional avidity (i.e., the ability to react to lower antigen concentrations and to recognize a wider range of epitope variants) relative to HIV progressors (International HIV Controllers Study et al. 2010). This point has been well evidenced in Gag-specific CD8 T cells in ECs bearing B27 and B57 HLA alleles. High avidity is associated with differences in the selection of epitope-specific TCR clonotypes during infection. When compared with TCR clonotypes in progressors, the high-avidity TCR clonotypes in ECs were better able to cross recognize naturally occurring viral variants and upregulate perforin and granzyme B (Walker and Yu 2013).

The selection and survival of these favorable TCR clonotypes might be due to several factors. The genetic background is likely to be especially important. Indeed, the peculiar amino acid composition of the protective HLA-B peptide-binding groove may favor optimal presentation of the viral peptide. HIV-specific CD8 T cells appear to cooperate more effectively with functional dendritic cells (Walker and Yu 2013). Indeed, myeloid dendritic cells (responsible for priming the T-specific response) have enhanced antigen-presenting capacities in ECs and do not produce the same set of cytokines as cells from progressors (Walker and Yu 2013). The low expression of negative immunomodulatory receptors (such as programmed death-1 (PD-1) and TIM3) may also favor the establishment and persistence of functional Gag-specific CD8 T cells (Walker and Yu 2013). The greater survival of HIV-specific CD8 T cells in ECs is also favored by the presence of functional central memory CD4 T cells (see below). The specific transcriptional profile of HIV-specific CD8 T cells of ECs also promotes

better survival. Upregulation of the genes involved in the heat shock response may regulate T-cell survival. In contrast, interferon-stimulated genes do not seem to be upregulated, as is also the case in models of nonpathogenic SIV infection in LTNPs and ECs (Peretz et al. 2012).

However, ECs are a heterogeneous population: high HIV-specific CD8 T-cell blood counts are not detected in about 50% of these individuals, and 20–60% of ECs lack protective B27 and B57 HLA alleles. However, two lines of evidence suggest that a potent HIV-specific CD8 T-cell response nevertheless has a role in some of these ECs. Firstly, multifunctional CD8 T-cell responses to HIV Gag are more intense in the rectal mucosa of ECs and are more closely correlated with controller status than peripheral blood responses are (Shacklett and Ferre 2011). Indeed, in some ECs, the majority of HIV-specific CD8 T cells appear to reside in the mucosa. Secondly, HIV-specific CD8 T cells with a virus-suppressing ability can be expanded upon in vitro stimulation with Gag peptides; this is consistent with the presence of HIV-specific CD8 T cells with a memory phenotype (Walker and Yu 2013) ► [HIV and SIV, CD4 T cell responses to](#).

CD4 T Cells The confirmed presence of functional HIV-specific CD8 T cells strongly suggests that HIV-specific CD4 T cells are likely to be present (Walker and Yu 2013; Sáez-Cirión and Pancino 2013; Porichis and Kaufmann 2011). This has been clearly demonstrated by the detection of multifunctional, Gag-specific CD4 T cells capable of producing many different cytokines in a high proportion of ECs. CD4 T cells in ECs share some characteristics with those found in patients on long-term ART. In the majority of ECs, the transcriptional profiles of CD4 T cells are similar to those in ART-treated patients but differ from those of healthy donors (except for a small subset). In both ECs and ART-treated patients, levels of DR+ activated CD4 T cells are higher than in healthy donors but are lower than in viremic subjects. It is known that CD4 T cells from both ECs and ART-treated patients can produce IL-2. Hence, these characteristics may merely reflect the achievement of viral control.

However, an increasing number of qualitative differences between HIV-specific CD4 T cells in controllers and progressors have been identified, and some of these differences are not fully corrected by viral control after the initiation of ART. This suggests that HIV-specific CD4 T cells from ECs have specific properties of relevance to HIV control and do not solely reflect low viremia. In ECs, central memory CD4 T (T_{CM}) cells are still present in the blood; they display high avidity for immunodominant Gag peptides and are capable of maintaining robust responses, despite the presence of low levels of viral antigen. Although the links between specific HLA Class II alleles and the characteristics of HIV-specific CD4 T-cell responses have yet to be investigated, the results of some studies suggest that ECs carrying the class II alleles HLA-DRB1*13 and/or HLA-DQB1*06 have the most robust HIV-specific CD4 T-cell responses (Shacklett and Ferre 2011).

It is known that there is attrition of the HIV-specific CD4 T-cell population in the gut mucosa in ART-treated subjects. This contrasts with the maintenance of a multifunctional response in ECs (Shacklett and Ferre 2011). Th17 cells (an IL-17-producing subset of CD4 T cells) have a major impact on the innate immune response and the regulation of inflammation in the mucosa. In HIV infection, depletion of these cells is associated with the dissemination of microbial products from the infected gut, increased systemic immune activation, and disease progression. In ECs, the blood Th17 count appears to be maintained (Hartigan-O'Connor et al. 2011).

In viremic patients, CD4 T-cell exhaustion is one of the mechanisms that lead to nonfunctional HIV-specific CD4 T-cell responses. This T-cell exhaustion is promoted by the expression of inhibitory receptors on CD4 T cells and the activation of inhibitory pathways. The CD4 T cells in ECs express lower levels of the negative immunoregulatory molecules PD-1 and cytotoxic T-cell-associated antigen 4 than the corresponding cells in ART-treated patients. This is consistent with the greater observed functionality of CD4 T cells in ECs. Regulatory T cells (Tregs) have also been linked to the suppression of antiviral

responses. Several researchers have reported that the Treg count in ECs is similar to or lower than that observed in uninfected individuals (Hartigan-O'Connor et al. 2011). This may contribute to the maintenance of high-quality, HIV-1-specific CD8 and CD4 T-cell responses in ECs. In addition, in contrast to the situation in ART-treated patients, HIV-specific CD4 T cells from ECs produce low amounts of IL-10 (a negative immunoregulatory cytokine). Another specific characteristic of CD4 T cells from ECs relates to their ability to maintain the production of IL-21. Several groups have shown that IL-21 secretion by HIV-specific CD4 T cells is higher in ECs than in individuals on ART, with the lowest levels detected in viremic subjects (Porichis and Kaufmann 2011). Interleukin-21 increases the expression of perforin, granzymes A and B, and the degranulation marker CD107 in HIV-specific CTLs – suggesting that HIV-specific IL-21⁺ CD4 T cells might help to control viral replication in humans. Interleukin-21 is produced by T follicular helper cells and has also an important role in B-cell differentiation (see below).

The survival of CD4 T cells is better in ECs than in other HIV-infected patients (Sáez-Cirión and Pancino 2013; Peretz et al. 2012; Porichis and Kaufmann 2011). T_{CM} cells and effector memory (T_{EM}) CD4 T cells from ECs are less susceptible to Fas- and TRAIL-mediated apoptosis and persist longer after multiple rounds of TCR triggering than cells from ART-treated patients. The survival of T_{CM} cells in ECs might be a consequence of inactivation of the FOXO3a pathway. CD4 T-cell homeostasis is also maintained because of optimal thymic output, homeostatic proliferation, and preserved lymphopoiesis (Walker and Yu 2013; Sáez-Cirión and Pancino 2013; Porichis and Kaufmann 2011).

B cells The extent of the humoral response's contribution to viral control in ECs is not clear because these individuals display a heterogeneous humoral immune response. Weakly reactive/partial Western blots have been reported for some ECs (Sáez-Cirión and Pancino 2013). The relatively low level of neutralizing antibodies in ECs emphasizes the positive correlation between viral

replication and the production of these antibodies. In contrast, antibody-dependent cell cytotoxicity (ADCC) and the antibody-dependent cell viral inhibition response (which are reportedly higher in ECs than in viremic patients) may have a role in virus control (Walker and Yu 2013; Sáez-Cirión and Pancino 2013). The higher ADCC levels found in B57-negative ECs require further investigation.

Innate Immunity

When HIV infects the host, an adaptive immune response is not present. During early infection, innate immune mechanisms may limit viral replication and enable the development of a strong, effective, HIV-specific CD4 and CD8 T-cell immune response. This hypothesis is supported by clinical data on the few early controllers described in European cohorts of primary infection. About 50% of patients who go on to become ECs will already have undetectable viremia when diagnosed during the primary infection (Madec et al. 2013). Both innate immune cells and cellular restriction factors might have a role in the context. Other evidences for a strong innate immune response relate to the fact that ECs appear to be able to spontaneously control other viral infections (such as hepatitis C virus) (Okulicz and Lambotte 2011).

Innate Immune Cells The data are limited: NK cells do not appear to have a major role in controlling HIV *ex vivo* – at least when ECs are studied years after the primary infection (Sáez-Cirión and Pancino 2013). In contrast, ECs maintain fully functional $\gamma\delta$ T-cell levels. This may well be one of the specific characteristics of ECs (Walker and Yu 2013). Dendritic cells also appear to be highly functional in ECs – in contrast to other groups of HIV-infected patients. The functional cooperation of myeloid dendritic cells with T cells has been described above. Plasmacytoid dendritic cells are present in ECs and are able to produce (i) normal amounts of IFN- α when exposed to HIV in contrast to viremic patients and (ii) higher amounts than healthy donors when exposed to influenza virus (Walker and Yu 2013).

Restriction Factors Innate immunity also relies on a number of intrinsic cellular antiviral defense mechanisms. In the setting of HIV infection, several proteins are involved in the restriction of HIV replication (including TRIM5a, APOBEC3G, tetherin, and SAMHD1). However, these proteins do not appear to have a special role in ECs. Some studies have failed to show reduced CD4 T-cell susceptibility to HIV. However, more recent studies of stringent HIV infection conditions clearly demonstrate reduced permissiveness to HIV-1 replication in CD4 T cells and monocytes/macrophages (Walker and Yu 2013; Sáez-Cirión and Pancino 2013). The mechanisms involved appear to be independent of the abovementioned restriction factors and might be related to the CDK inhibitor p21 pathway. Interestingly, the decreased susceptibility of CD4 T cells correlates with the level of viral DNA that these CD4 T cells carry *in vivo* – suggesting that the susceptibility may contribute to the decrease in the viral reservoir in ECs. After *ex vivo* superinfection of CD4 T cells from ECs, the low observed integration of HIV DNA indicates the presence of restriction factors that act on the HIV reservoir (Walker and Yu 2013). This finding implies that intrinsic cell resistance to infection may have an important role in controlling the size of the viral reservoir in ECs early in primary infection. Currently unidentified restriction factors may also have a role in limiting viral replication within latently infected CD4 T cells in ECs.

Long-Term Virologic Control and Clinical Outcomes

Elite controllers are heterogeneous. Viral “escape” appears to be rare in ECs and should prompt researchers to look for a superinfection (Okulicz and Lambotte 2011). In contrast, a slow, moderate decrease over time in the CD4 T-cell count is observed in most ECs. A few cases of severe CD4 T-cell depletion among ECs (below 350 cells/mm³ and even below 200 cells/mm³ in very rare cases) have been reported. AIDS events remain rare but have been described in a few ECS. The events are related to CD4 T-cell

criteria or to the development of hallmark features of AIDS (Okulicz and Lambotte 2011). Antiretroviral therapy is therefore prescribed in some ECs, although literature data are scarce. In a recent collaborative study of 34 ECs who had started combination ART, nearly all the patients recovered their CD4 T-cell counts. However, their gains were smaller than in patients with uncontrolled viremia at the start of therapy (Boufassa et al. 2014).

Several factors are involved in the decrease in the CD4 T-cell count ► **Chronic immune activation in HIV** (Sáez-Cirión and Pancino 2013). Low-grade HIV replication (with detectable “blips”) is associated with the CD4 T-cell decrease. Immune activation and chronic inflammation are probably also important factors. Despite controlled viremia in ECs, activation of blood CD4 and CD8 T-cell compartments is generally much the same as (or sometimes even greater than) those observed in ART-exposed patients. This activation is correlated with a decline in CD4 T-cell counts in these individuals. Blood levels of IP10 (a chemokine that mainly depends on the interferon pathways) are also higher in ECs than in healthy donors and are inversely correlated with the CD4 T-cell count. Hence, immune activation may be triggered by low-level residual HIV replication, an insufficient regulatory T-cell response and/or the translocation of bacterial products from the gut mucosa. Relative to noninfected individuals, ECs have higher blood levels of LPS and markers of monocyte activation (such as sCD14 and sCD163). These data recently prompted the performance of a pilot study in which ART was seen to be associated with a significant reduction in immune system activation in ECs (Walker and Yu 2013).

Immune activation and chronic inflammation might also cause the exhaustion of lymphopoiesis and impair the replenishment of the lost CD4 T cells. Alterations of the hematopoietic progenitor cells have been reported in ECs with decreasing CD4 T-cell counts (Sáez-Cirión and Pancino 2013).

The long-term consequences of this abnormal activation of the immune system in ECs have not been determined, although they possibly include

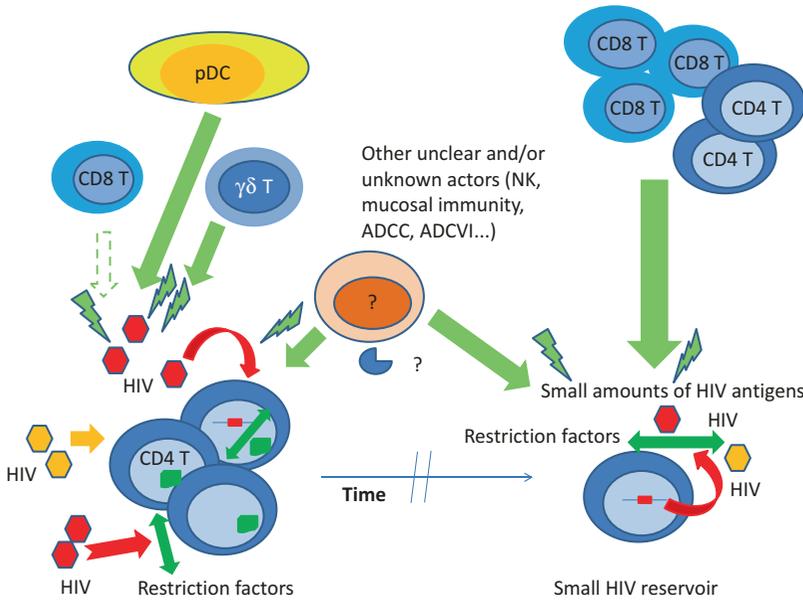

the loss of CD4 T cells and an increase in the cardiovascular risk. Given that ART reduces immune activation, ART might be useful in ECs. Indeed, the use of ART in ECs displaying a decrease in CD4 T-cell counts is now recommended in the official guidelines. The broader prescription of ART in ECs (i.e., those without a decrease in CD4 T-cell counts) remains subject to much debate ► **Post-treatment controllers**. The long-term clinical follow-up of ART-naïve ECs will be of paramount importance in identifying the long-term impact of HIV infection.

Posttreatment Controllers

In two recent studies (Walker and Yu 2013), viremic patients treated soon after the primary infection achieved an undetectable VL. The patients received ART for a median of 3 years and maintained an undetectable VL after treatment discontinuation (for a median period of 6 years). These PTCs do not seem to be ECs: they do not have a high frequency of HLA protective alleles, their CD8 T cells do not suppress HIV in CD4-CD8 T-cell cocultures, and their HIV-specific CD8 T-cell counts are low. However, PTCs have very low numbers of latently infected CD4 T cells (like ECs).

Conclusion

Although considerable progress has been made in understanding the factors and mechanisms associated with the spontaneous control of HIV-1 infection in ECs, many questions remain unanswered. Although ECs have specific transcriptomic, genomic, virologic, and immunologic features, they constitute a heterogeneous population. It is likely that spontaneous control of infection results from the concomitant operation of several of the mechanisms described above (Fig. 1). Although it is possible that several subgroups of HIC exist (depending on which mechanisms are involved in viral control), it is more likely that all the various mechanisms are interlinked and are regulated by factors such as residual viremia and immune activation. During

Long-Term Nonprogressors and Elite Controllers, Fig. 1 In primary infection, HIV infects only a limited number of CD4 T cells leading to a small HIV reservoir. Several factors contribute to control the extent of viral replication: HIV strains with reduced fitness (in orange), cell restriction factors limiting the infection of the target cells and the capacity of HIV to integrate, the innate immunity actors as $\gamma\delta$ T cells, plasmacytoid dendritic cells (pDC), and also the rapidly developing HIV-specific CD8 T cells. The limitation of viral replication allows the

development of functional HIV-specific CD4 and CD8 T-cell responses. In chronic infection, HLA class I-restricted HIV-specific CD8 and HIV-specific CD4 T cells are central components of HIV immune control. The CD8 selection pressure leads to reduced fitness of some HIV strains (in orange). Cell restriction factors still play a role in limiting viral replication in the long term. The role of many factors remains to be determined: NK cells, mucosal immunity (Th17 innate cells, cytokines), and humoral immunity especially ADCC and ADCVI

primary infection, cell restriction factors, innate immune components, and HIV strains with reduced fitness may all contribute to the small size of the HIV reservoir and the limited extent of viral replication. In PTCs, ART may have achieved the same result. A small viral reservoir may not only help to attenuate the dynamics of viral replication but may also favor the development and maturation of an optimal cellular immune response. In chronic infection, the combination of cell restriction factors and the pressure of functional HIV-specific CD8 and CD4 T-cell responses favor the achievement of viral control. However, residual viral replication is still present in ECs, most of whom show signs of mucosal damage, chronic immune activation, and inflammation. Although the maintenance of an optimally tuned immune response against HIV may have a cost, the latter is far outweighed by the benefits in the majority of ECs.

Studies of ECs have provided valuable information on vaccine strategies: limiting cell activation and obtaining high-avidity, anti-Gag HIV-specific CD4 and CD8 T cells appear to be important. The role of other factors (such as ADCC and the modulation of intrinsic restriction factors) requires further detailed investigation. Observations of PTCs are important because they show that the natural history of HIV infection can be modified by therapeutic intervention. Nevertheless, the underlying mechanisms remain to be characterized.

Lung Cancer

Deepthi Mani¹ and David M. Aboulafia^{2,3}

¹Division of Internal Medicine, Multicare Good Samaritan Hospital, Puyallup, WA, USA

²Division of Hematology and Oncology, Virginia Mason Medical Center, Seattle, WA, USA

³Division of Hematology, University of Washington, Seattle, WA, USA

Definition

The term lung cancer is usually used to describe any of several types of primary tumors arising in the lung; common histological types include adenocarcinoma, squamous cell carcinoma, large cell carcinoma, bronchoalveolar cancer, and small-cell lung cancer. Taken together, lung cancer is the most common non-AIDS-defining malignancy in HIV-infected individuals. Lung cancer risk appears to be two to five times greater in the HIV-infected persons compared to the general population, and most epidemiological studies find that the risk remains high even after adjusting for other factors like smoking intensity and duration. Often these patients present with advanced disease at a younger age but may have

comparable survival compared with similarly matched lung cancer patients without HIV infection. Smoking cessation is the most effective preventive strategy.

Introduction

The advent of highly active antiretroviral therapy (HAART) (► [Antiretroviral Medications, Care and Treatment](#)), consisting of multiclass antiretroviral drug regimens, has dramatically decreased HIV-associated morbidity and mortality in the economically developed world. As HIV infection has transformed from a fatal disease to a chronic condition, there has been renewed public and clinical interest in long-term morbidities, including malignancies (► [Cancers Related to HIV](#)) that occur disproportionately within this population. HIV-infected individuals have an increased propensity to develop both AIDS-defining malignancies (ADM) (► [Overview: AIDS-Related and Non-AIDS Related Cancers](#)), such as Kaposi's sarcoma (KS) (► [Presentation and Pathogenesis of Kaposi Sarcoma](#)), non-Hodgkin lymphoma (NHL), and ► [cervical cancer](#), and a number of non-AIDS-defining malignancies (NADM) (► [Overview: AIDS-Related and Non-AIDS Related Cancers](#)), including lung cancer, ► [anal cancer](#), liver cancer, and ► [Hodgkin's lymphoma](#). Lung cancer is the most common NADM and the leading source of NADM mortality among HIV-infected individuals. Lung cancer risk appears to be two to five times greater in the HIV-infected persons compared to the general population, and most studies show that the risk remains high even after adjusting for other factors, such as smoking intensity and duration (Kirk et al. 2011). Often these patients present with advanced disease at a younger age and yet may have a comparable survival compared with stage- and histology-matched lung cancer patients without HIV infection. This entry briefly describes the epidemiology, risk factors, clinical characteristics, treatment, and outcome of HIV-associated lung cancer, as well as potential approaches to decrease the burden of lung cancer through smoking cessation initiatives.

Epidemiology

Epidemiologic studies of lung cancer among the HIV population commonly involve linkage of HIV/AIDS registries, observational databases, or clinical HIV cohorts to cancer registries. The risk of lung cancer is estimated by calculating the standardized incidence ratio (SIR), resulting in comparisons of observed cases occurring among an HIV-infected study population to the expected number of estimated cases from general population rates. These analyses have primarily been conducted in the United States and Europe. In the majority of the registry studies, SIRs are in the range of a two- to fivefold increase in lung cancer associated with HIV infection (Kirk et al. 2011). Two meta-analytic studies estimated the increased risk for lung cancer with HIV infection to be 2.6-fold (Grulich et al. 2007; Shiels et al. 2009). The risk of lung cancer in the setting of HIV infection appears to have remained relatively stable in the pre-HAART and HAART era.

Risk Factors

Smoking

Although there is a clear and consistent demonstration of elevated lung cancer risk among HIV-infected individuals compared with the general population, it is difficult to determine whether this elevated risk is due solely to the increased incidence of cigarette smoking in the HIV-infected population. Among HIV-infected individuals living in the United States, prevalence estimates of smoking range from 35% to 70% compared to approximately 20% in the general population (Kirk et al. 2011; Rahmanian et al. 2011). Tobacco use may be even more common among HIV-seropositive intravenous drug users. Five studies directly accounted for individual smoking exposure among HIV-infected persons, and the risk for lung cancer associated with HIV infection was 1.2–3.6-fold higher compared to epidemiologically valid comparison populations who were not infected with HIV (Kirk et al. 2011). In four of the studies, the smoking-adjusted increase attributable to HIV infection was

statistically significant, although in one it was not. In the largest cohort study in the HAART era, with individual level smoking data involving greater than 110,000 US military veterans, the incident rate of lung cancer was 1.7 times higher in the HIV-infected veterans compared to uninfected veterans and remained significant after multivariable adjustment (Sigel et al. 2012). The true test of an independent effect of HIV infection on lung cancer risk would be to observe the effects of HIV among nonsmokers. Such an analysis may not be feasible due to the very low incidence of lung cancer among nonsmokers and the high prevalence of smoking among HIV-infected persons (Kirk et al. 2011).

HIV-Related Factors

Unlike the prototypical ADMs, KS, and NHL, where the risk increases as immunosuppression becomes more pronounced, lung cancer may occur at any point in the course of HIV infection. The risk of HIV-associated lung cancer generally is not closely linked to a low CD4+ cell count or to an elevated HIV viral load, although there is evidence that prolonged moderate immunosuppression as seen in the HAART era may contribute to the risk. Organ transplant recipients on immunosuppressive agents have a lung cancer incidence rate comparable to HIV-infected patients (Grulich et al. 2007).

HIV itself might have a direct oncogenic role. Though limited experimental data suggest that HIV *tat* (trans-activator of transcription) (► [Tat Expression and Function](#)) gene product may modulate the expression of proto-oncogenes and tumor suppressor genes, amplification of HIV sequences in lung carcinoma has not been demonstrated. Other potential mechanisms for the role of HIV in the pathogenesis of lung cancer includes accelerated lung damage through recurrent pulmonary infections and increased susceptibility to tobacco carcinogens through genomic instability (Kirk et al. 2011; Mani et al. 2012).

Clinical Characteristics

Lung cancer typically is diagnosed a decade or more earlier among HIV-infected persons

compared to those without HIV infection (Pakkala and Ramalingam 2010; Mani et al. 2012). However, after adjustment for difference in the age compositions of populations at risk, the difference in the age at diagnosis of lung cancer (50 vs. 54 years) was relatively modest between persons with AIDS and the general population (Shiels et al. 2010). The majority of patients with HIV-associated lung cancer are symptomatic at diagnosis (Mani et al. 2012). This is often due to the advanced stage of disease by the time lung cancer is diagnosed. Respiratory complaints are particularly frequent and most notably include cough (40–86%), chest pain (25–75%), and dyspnea (10–57%). Fatigue is ubiquitous, and as many as 10–30% of patients also will have hemoptysis. The signs and symptoms of lung cancer among HIV-infected persons mirror those of stage-matched lung cancer controls.

Non-small-cell lung cancer (NSCLC) represents 67–86% of primary lung cancers in patients with HIV; small-cell lung cancer comprises another 6–14% with unidentified subtypes accounting for the remaining percentage (Pakkala and Ramalingam 2010). Of the NSCLC, the most common histologic diagnosis is adenocarcinoma (30–67%) followed by squamous cell (17–39%), large cell (3–16%), and bronchoalveolar (2–3%) cancer in HIV-positive patients. The majority of patients present with either advanced stage III or IV disease. Recent HAART-era case series and cohort studies with morphology and stage data have described similar distributions of morphologic type and stage at presentation in HIV-infected lung cancer patients compared with HIV-indeterminate or uninfected patients (D'jaen et al. 2010; Sigel et al. 2012).

Radiological features of lung cancer in HIV-infected patients appear to be similar to those in HIV-negative patients and include a parenchymal mass, more often peripheral rather than central, mediastinal lymphadenopathy, and pleural effusions. A low clinical suspicion for malignancy, particularly in younger patients, and overreliance on nondiagnostic chest radiographs may result in delayed diagnosis of lung cancer in HIV-positive individuals (Brock et al. 2006).

Treatment and Outcome

Recommendations for the management of HIV-associated lung cancer are evolving. Historically, individuals with HIV-associated lung cancer have been excluded from participating in ► [clinical trials](#) (Persad et al. 2008). Surgery with curative intent remains the treatment of choice for localized disease, and there is increasing experience in using of radiation therapy and systemic chemotherapy for patients who do not have surgical options.

Data on the management of HIV-associated lung cancer are principally derived from uncontrolled retrospective analyses rather than prospective clinical trials. In a recent study, HIV-infected NSCLC patients who underwent surgery with curative intent were more likely to have pulmonary and extrapulmonary postoperative complications, more rapid progression to disease recurrence, and poorer postoperative survival when compared to HIV-indeterminate patients (Hooker et al. 2012). HIV-infected lung cancer patients with CD4 + counts less than 200 cells/mm³ had shortened median survival compared with patients with higher counts. This finding runs contrary to prior studies that advocated surgery for HIV-infected patients regardless of immune status (Cadranet et al. 2006). However, the lack of precision inherent in a small sample size precludes drawing any strong recommendations from these studies.

In the general population, patients with advanced NSCLC usually are treated with a combination of a platinum drug (cisplatin or carboplatin) and a third-generation, non-platinum drug (docetaxel, gemcitabine, irinotecan, paclitaxel, pemetrexed, or vinorelbine), resulting in a slight increase in survival and relief of cancer-related symptoms. Strategies to further improve survival of patients include the addition of targeted drugs to cytotoxic chemotherapy, such as epidermal growth factor receptor or anti-vascular endothelial growth factor monoclonal antibodies and receptor protein kinase inhibitors, and pursuing maintenance therapy with pemetrexed after first-line chemotherapy (Makinson et al. 2011). There are potential drug-drug interactions

and cumulative toxicity when HAART is combined with systemic chemotherapy (Rudek et al. 2011). Etoposide, taxanes, vinca alkaloids, and anilinoquinazolines erlotinib and gefitinib are metabolized by cytochrome P450. All protease inhibitors inhibit CYP4503A4, but ritonavir, even in low doses, is the most potent inhibitor in the class. Also, ritonavir inhibits the P-glycoprotein efflux pump protein, driving chemotherapeutic agents like vinca alkaloids and taxanes outside the tumor cells. Protease inhibitors may be associated with a greater incidence of grade 4 hematological toxicity when used in conjunction with the aforementioned chemotherapy regimens and, in the case of nelfinavir and lopinavir, a heightened risk of diarrhea (Makinson et al. 2011). The nucleoside analog zidovudine can exacerbate myelosuppression, while other drugs in this class (stavudine, zalcitabine, and didanosine) may aggravate peripheral neuropathy associated with cisplatin and taxane derivatives (Rudek et al. 2011).

In the HIV-infected population with NSCLC, the factors associated with increased survival include Eastern Cooperative Oncology Group Performance status less than 2, HAART during chemotherapy, and CD4+ count >200 cells/μl at NSCLC diagnosis (Lavole et al. 2009; Makinson et al. 2011). Initial studies of patients with HIV and lung cancer implied that they may have a shortened survival compared to HIV-negative lung cancer controls. During 1996 to 2000, 24-month survival with lung cancer was only 10% among people with AIDS, compared to 31% in the general population in New York (Biggar et al. 2005). In Italy during 1999–2006, the risk of death among patients with lung cancer and AIDS was sixfold higher when compared to the general population (Zucchetto et al. 2010). Recent studies in the HAART era have yielded variable results. In a retrospective study of HIV-infected lung cancer patients collected from several clinics with experience in taking care of this population, the median survival for those with advanced cancer was 9 months and was comparable to the median survival of Surveillance, Epidemiology, and End Results (SEER) lung cancer participants (D'jaen et al. 2010). A recent analysis of HIV-infected and HIV-negative lung cancer

patients collected from a SEER database between the years 2000 and 2005 showed no significant difference in clinical outcomes (Rengan et al. 2012). In addition, survival after curative resection in early stage patients was similar in HIV-infected individuals and uninfected controls. These data suggest that HIV status should not be the most important determinant in therapeutic decision-making in NSCLC.

Prevention

Smoking Cessation

As there are no unique clinical practice guidelines to implement smoking cessation efforts among HIV-positive persons, evidence-based treatments with demonstrated efficacy in the general population must be incorporated into the care of HIV-positive smokers.

There are a number of barriers and complicating factors that compromise the success of smoking cessation in the HIV-infected individuals. Smokers are more likely to be abusers of alcohol and illicit drugs, and tobacco use may increase when persons are under the influence of these substances; substance abuse (Substance use) also can be a risk factor for smoking cessation failure. HIV-infected individuals may have a number of psychological stresses and mental health challenges that contribute to smoking and make cessation more difficult. Some HIV-infected individuals may use tobacco to manage HIV-related symptoms and pain and perceive smoking as one way to cope with the stress of living with a difficult illness (Rahmanian et al. 2011; Lifson and Lando 2012). In addition, HIV-infected individuals may feel that they will ultimately die from AIDS, making smoking cessation less of a priority.

US Public Health Service guidelines recommend brief individual smoking cessation counseling with five components (known as the “5 As”) at each clinical encounter. Providers are advised to systematically *ask* about tobacco use, *advise* smokers to quit, *assess* willingness to quit, *assist* with quitting, and *arrange* follow-up. Smokers’ telephone quit lines are cost-effective

interventions with broad reach and demonstrated efficacy for long-term smoking cessation. Motivational interviewing is effective in increasing quit attempts. Cognitive behavioral interventions are additional strategies to help smokers quit or reduce cigarette smoking. These interventions are designed to modify critical cognitions and actions that maintain behaviors such as smoking by promoting the thoughts and skills necessary to create behavioral change. Given the widespread availability of cell phones throughout the world, delivery of interventions through cell phones may be feasible even in many resource-limited settings. When cell phone counseling is used in conjunction with nicotine replacement therapy, HIV-infected smokers were 3.6 times more likely to quit than those who received usual care with physician advice, written materials, and nicotine replacement therapy (Lifson and Lando 2012).

Medications approved by the US Food and Drug Administration for smoking cessation include nicotine replacement therapy (patch, lozenges, inhalers, gum, and nasal spray), bupropion, and varenicline. There are no known interactions between nicotine replacement therapy and HAART. Bupropion is metabolized by the hepatic cytochrome P450 CYP2B6 system, and its metabolism has been shown to be inhibited by protease inhibitors (nelfinavir, ritonavir) and a non-nucleoside reverse transcriptase inhibitor (efavirenz) in vitro. Short-term ritonavir administration does not significantly alter bupropion pharmacokinetics in healthy volunteers, and no medication-associated adverse events were observed in a case series of 10 HIV-positive persons using either ritonavir, nelfinavir, or efavirenz with bupropion (Nahvi and Cooperman 2009). The results and tolerance recorded for varenicline in HIV-positive individuals are similar to those published in relation to seronegative patients, and no drug interactions have been described to date with HAART and varenicline. Both bupropion and varenicline are associated with significant neuropsychiatric symptoms, including behavioral changes, hostility, agitation, depressed mood, suicidal ideation, and attempted suicide. These symptoms have occurred in patients without preexisting psychiatric illness.

Despite the high prevalence of smoking and significant barriers to quitting among those with HIV, 30–60% of HIV-positive smokers are contemplating quitting or preparing to quit smoking, and so the importance of stopping smoking needs to be an ever present message during our clinical encounters (Rahmanian et al. 2011; Lifson and Lando 2012).

Screening

Lung cancer screening is a rapidly evolving field that has the potential to significantly reduce the burden of lung cancer. Early randomized control trials in lung cancer screening evaluated chest radiography with or without sputum cytology and showed no reduction in lung cancer mortality.

The lack of a clear result from chest X-ray screening and the refinement of computerized tomographic (CT) scanning techniques led to the evaluation of CT scanning for lung cancer screening. The National Lung Screening Trial (NLST) compared the effects of low-dose helical CT and standard chest X-ray on lung cancer mortality. The randomized national trial involved more than 53,000 current and former US smokers between the ages of 55 and 74 years old who had at least a 30-pack per year smoking history. Among trial participants screened with low-dose helical CT, there were 20% fewer lung cancer deaths (National Lung Screening Trial Research Team et al. 2011). The possible disadvantages of helical CT include the cumulative effects of radiation from multiple CT scans, surgical and medical complications in patients who prove not to have lung cancer but who need additional testing to make that determination, and overdiagnosis from the detection of cancers that never would have become symptomatic.

At the time of this writing (August 2013), the American College of Chest Physicians, the American Society of Clinical Oncology, and the American Thoracic Society recommend screening for lung cancer using LDCT based primarily on results from NLST, with eligibility criteria that model closely on NLST (current or former smokers ages 55–74 years with a ≥ 30 pack-year

history of cigarette smoking and ≤ 15 years since quitting). The recommendations also stipulate that screening should be offered only in clinical settings similar to those in the trial. The US Preventive Services Task Force's final recommendations are pending, and its draft recommendation supports annual screening for lung cancer with LDCT in persons at high risk based on age and cumulative tobacco smoke exposure.

The high prevalence of infectious and inflammatory conditions in HIV-infected patients can generate suspicious findings and increase the false-positive rate, resulting in significant anxiety and expense. The NLST study population, while ethnically representative of the high-risk US population of smokers, was a highly motivated and primarily urban group that was screened at major medical centers. In part for these reasons, the results may not accurately predict the effects of recommending low-dose helical CT scanning for other populations, including HIV-infected individuals. Also, other lung pathologies are more common in HIV-infected individuals, and these may yield more false-positive scans and make it particularly hard to apply the results of the NLST population to HIV-infected patients. Additional studies are needed to address this issue, perhaps by modeling the findings using studies of helical CT scans in an HIV-infected population.

Conclusion

Lung cancer risk is about two to five times greater in HIV-infected persons than in the general population, even after adjusting for smoking intensity and duration. HIV-associated lung cancer typically is diagnosed a decade or more earlier among HIV-infected persons. Adenocarcinoma is the most common histological type, and the majority of patients are diagnosed with locally advanced or metastatic disease (stage IIIB or IV). As pulmonary infections are common among HIV-infected individuals, clinicians may not suspect lung cancer in this patient population, and this may lead to a delay in the cancer diagnosis. Surgery with curative intent remains the treatment of choice for localized disease, and there is

increasing experience in using radiation therapy and systemic chemotherapy for patients who do not have surgical options. Though retrospective studies conducted during the pre- and early HAART era reported shorter survival times among HIV-lung cancer patients than HIV-indeterminate or negative lung cancer patients, in the most recent of studies performed in the HAART era, these two groups appear to have comparable survival times. Screening with low-dose CT scans is not yet routine in this high-risk population. As smoking plays a significant role in the development of HIV-associated lung cancer, people with HIV should be reminded of the hazards of smoking and encouraged to stop. Smoking cessation strategies with demonstrated efficacy in the general population should when possible be routinely incorporated into the care of HIV-positive smokers.

Definition

Decades ago, when cell death was observed in cells or tissues, it was assumed that the cause was either toxic or traumatic and that there was little cellular control over whether a given cell or tissue would undergo death in response to a given stimulus. Consequently naïve terms such as cytotoxicity or necrosis were used. In the intervening years much has been learned, and it is now recognized that cell death is a tightly coordinated event that can proceed through distinct processes of apoptosis, autophagy, and necrosis and on occasion through mechanisms which share features of more than one process such as necroptosis which has characteristics of both apoptosis and necrosis.

In parallel, much has been learned about how cell death occurs during HIV infection, which, at its most fundamental of levels, causes a disease of dysregulated cell death. For example, it is now understood that HIV infection of CD4 T cells causes the death of most of the cells which are infected, but those cells which resist death become a long lived reservoir for HIV. In addition HIV infection causes polyclonal activation of both immune and nonimmune cells, and this activation in turn favors death of those uninfected cells – resulting in bystander death of CD4 and CD8 T cells, B cells, neurons, hepatocytes, and other cell types. Moreover every HIV-encoded protein impacts the cell death/survival balance, often in a situational-dependent manner; for example, Tat can favor or induce resistance to apoptosis depending upon concentration and cell type.

Understanding how cell death pathways are altered in HIV infection is of direct clinical relevance, as numerous correlations exist between rates of cell death and rates of either CD4 decline or outcome from HIV infection. Indeed, study of patients with slower rates of HIV disease progression (LTNP and/or elite controllers) has illuminated novel insights into control of the immune system and suggests novel therapeutic strategies aimed towards curing HIV infection.

Cell Death and Apoptosis Regulation

Cell death plays a critical role in human development and tissue homeostasis, but when dysregulated, both excessive and insufficient cell death favor the development of disease. Cell death in humans occurs by one of three main pathways: autophagy, necrosis, or apoptosis. Accelerated CD4 T-cell death by apoptosis is an example of excessive cell death which contributes to the immunodeficiency seen during human immunodeficiency virus (HIV) infection.

Autophagy plays a role in both the innate and adaptive immune responses. Autophagy results when a double-membrane vesicle engulfs part of the cytoplasm becoming an autophagosome, which then fuses with a lysosome. The components of the autophagosome are broken down in the acidic environment of the lysosome. In HIV infection, single-stranded viral RNA triggers toll-like receptors (TLR), which recruit adaptor proteins such as myeloid differentiation factor 88 and toll-interleukin-1 receptor domain-containing adaptor-inducing interferon- β (TRIF) resulting in Beclin being sequestered away from Bcl-2 and induction of autophagy. Key morphologic characteristics which distinguish an autophagic cell are an accumulation of double-membrane-lined vacuoles and an absence of chromatin condensation.

Necrosis involves cell swelling and rupturing of the plasma membrane, resulting in an inflammatory response. Classically necrosis is a traumatic or complement mediated death; however, some forms of necrosis are tightly regulated and termed necroptosis. Death receptors and toll-like

receptors can induce necroptosis, and such death is dependent on receptor-interacting protein 1 (RIP1). For example, tumor necrosis factor (TNF) ligation of the TNF receptor 1 recruits TNF receptor-associated death domain (TRADD) and Fas-associated death domain (FADD), which in the presence of a caspase 8 inhibitor (i.e., cFLIP), RIP1 and RIP3 are phosphorylated, resulting in necrosis. When RIP1 activity is blocked by necrostatin 1, necroptosis is blocked. RIP3 knockout mice have less tissue necrosis and inflammation following vaccinia virus infection than WT mice. In the context of HIV, Vpr interacts with RIP1, and both HIV-infected and bystander CD4 T cells undergo necroptosis in certain contexts as discussed in greater detail below.

Both HIV-infected and uninfected T cells also die by apoptosis in an HIV-infected individual. Apoptosis is a mechanism of programmed cell death wherein the cell is broken down in a tightly regulated and stepwise manner. The term was first coined in 1972 phenotypically as involving nuclear condensation and membrane blebbing. Excessive apoptosis can lead to tissue atrophy, while insufficient apoptosis favors malignancy formation and/or progression. Apoptosis is most often induced via one of two major pathways, (1) the intrinsic or mitochondrial pathway or (2) the extrinsic or death receptor pathway. Neither pathway is exclusive, with cross talk existing between both.

Caspases are cysteine proteases that cleave proteins at aspartic acid residues. The first caspase was described in the 1990s as cleaving interleukin-1- β . Since then, ten human caspases have been described and have been found to contribute to cell proliferation, inflammation, and apoptosis. Caspases are synthesized as inactive zymogens with an N-terminal prodomain, a large subunit which contains the active cysteine, and a smaller subunit. The N-terminal prodomain is responsible for protein-protein interactions with adaptor proteins (discussed more in depth later) and functions to connect the death stimulus to the caspase. Once a stimulus is detected, two sequential cleavage events occur, first cleaving and freeing the smaller subunit, followed by cleavage and release of the larger subunit. The

larger and smaller subunits heterodimerize and form an active tetramer. For a protein to be cleaved, it must contain an aspartic acid with three specific preceding amino acids; not all proteins containing this recognition site will be cleaved, indicating that the tertiary or quaternary structure of the target protein might also play a role. Caspases can be classified as either an initiator caspase, which most often cleaves other apoptosis regulatory proteins, or as an effector caspase which typically cleaves structural proteins.

Initiator caspases (such as caspase 8) cleave and activate effector caspases such as caspase 3 and/or activate Bcl-2 family members such as BID. They are activated either by receptor clustering or by specific cofactors. For example, cytochrome c is required for activating caspase 9, a mechanism that is discussed further in depth later. In a healthy cell, caspase 9 is found in the cytosol, and cytochrome c is localized to the mitochondria; however, cytochrome c is released into the cytosol after a death stimulus and its release activates caspase 9. Active caspase 9 then cleaves and activates the effector caspases. The effector caspases are responsible for the phenotypic changes of apoptosis by cleaving a wide range of proteins including structural proteins actin and laminin and tumor suppressor proteins like PTEN and amplifying the apoptotic signaling cascade with cleavage/activation of additional caspases or Bcl-2 family members. Regulation of effector caspases involves specific inhibitors such as IAPs (inhibitors of apoptosis). One IAP, x-linked IAP (XIAP), specifically inhibits caspase 3 and 7 through direct interaction.

The Bcl-2 family is a group of proteins involved in apoptosis regulation involving the mitochondria. The first Bcl-2 family member, B-cell lymphoma 2 (Bcl-2), was identified in the middle of the 1980s and was originally being investigated for its role in oncogenesis. Ultimately Bcl-2 does not promote cell growth but protects the cell from death. To date, over 15 Bcl2 family members have been identified on the basis of containing one or more alpha helical Bcl-2 homology (BH) domains. Bcl-2 family members can be subdivided based on their functional activities

into three groups: antiapoptotic, proapoptotic, or BH3 only.

Antiapoptotic Bcl-2 family members are Bcl-2, Bcl-xL, Bcl-w, A1, Mcl-1, Bcl-RAMBO, Diva, and Bcl-G and inhibit cell death, by either (1) binding BH3-only proteins, sequestering them away from the proapoptotic family members, or (2) directly binding proapoptotic family members, inhibiting BH3 proteins from docking and activating them. Antiapoptotic family members contain a hydrophobic groove that allows proteins containing BH3 domains to bind.

The proapoptotic Bcl-2 family member subgroup consists of Bax, Bak, and Bok. There are two theories on how Bak and Bax are activated: (1) direct activation by a BH3-only protein or (2) indirect activation through inhibition of antagonists. Once activated, Bax and Bak can hetero- or homo-oligomerize to form pores in the outer mitochondrial membrane. Through these pores, inter-mitochondrial proteins are released into the cytosol and the cell is destined to die. While no crystal structure of this pore has been made, crystal structures of individual Bak and Bax show that each has a BH1, BH2, and BH3 domain that forms a hydrophobic groove which allows BH3-only proteins to bind and activate Bak and Bax.

The BH3-only subgroup of apoptosis-inducing proteins includes: Bid, Bim, Bad, BMF, Noxa, HRK, Puma, Bik, and MULE, which share a common BH3 domain, which in the presence of Bcl-2 paralogs forms an alpha helix that binds pro- or antiapoptotic family members via their BH3 grooves. BH3-only proteins induce apoptosis either by binding antiapoptotic Bcl-2 family members, resulting in the release of activator proteins like Bid or Bim that activate Bak or Bax. Alternatively, BH3-only proteins may sequester antiapoptotic Bcl-2 family proteins away from Bak and Bax, allowing Bax/Bak then to become active.

The intrinsic apoptosis pathway involves mitochondrial outer membrane permeabilization (MOMP). There are two channels proposed to open to result in MOMP, the first being mitochondrial permeability transition pore (PTP) composed of voltage-dependent anion channel (VDAC) and adenosine nucleotide transporter (ANT) and hexokinase which opens in response to apoptotic

stimuli. Another proposed pore involves oligomerization of Bak and/or Bax. Bak is expressed on the mitochondria, while Bax is cytosolic and only translocates to the mitochondria once a death stimuli is present. When Bax/Bak are oligomerized and inserted into the mitochondrial outer membrane, MOMP occurs, and the inner mitochondrial proteins, cytochrome c and Smac/DIABLO, are released into the cytosol, where in the presence of ATP and cytochrome c apoptotic protease activating factor 1 (APAF-1) oligomerizes and activates caspase 9 to form the "apoptosome." In the apoptosome, caspase 9 becomes active and cleaves downstream caspase 3 and 7, while Smac/DIABLO bind IAPs, derepressing the inhibition exerted by IAPs.

Death receptor ligation also initiates apoptosis as well as proliferation and differentiation. Death receptors are type II transmembrane proteins with a conserved 80 amino acid cytosolic region deemed the death domain. There are three classical death receptor classes: tumor necrosis factor receptors (TNFR), Fas/CD95 receptor, or TNF-related apoptosis-inducing ligand (TRAIL) receptors. Following receptor binding to its cognate ligand, TNF for TNFR receptors, Fas for CD95 receptors, or TRAIL for TRAIL receptors, the receptor trimerizes and recruits proteins which constitute the death-inducing signaling complex (DISC). For Fas and TRAIL receptors, the DISC is composed of Fas-associated death domain (FADD) which in turn recruits and activates procaspase 8 binds via its death-effector domain (DED). TNFR differs slightly from this because first TNFR-associated death domain (TRADD), then FADD, and procaspase 8 bind. In type I cells, active caspase 8 directly cleaves caspase 3, initiating the caspase cascade and the cell dies. In type II cells, active caspase 8 cleaves BID to its active form, tBID, and induces death via the mitochondrial pathway.

Associations of Apoptosis with HIV Disease Progression

One hallmark of HIV infection is a depletion of CD4 T cells over the course of disease. However,

observations over the past three decades have shown that not all HIV-infected individuals decrease the CD4 T-cell counts and progress to the acquired immune deficiency syndrome (AIDS) at the same rate. A subset of untreated HIV-infected individuals will maintain normal CD4 T-cell counts over periods longer than 7 years and are referred to as long-term non-progressor (LTNP). These patients also have a relatively low but detectable HIV viral burden in the lymphoid tissue and in the peripheral blood. It is estimated that 2–5% of people living with HIV are LTNPs. Even smaller subsets of individuals (<1%) infected with HIV are able to maintain undetectable levels of HIV replication without antiretroviral therapy, are categorized as elite controllers (EC), and maintain normal CD4 T-cell counts as a result of their excellent HIV control. There are mechanisms by which some human hosts rapidly decrease CD4 T-cell counts, while others have a very long, slow decrease in CD4 T-cell counts, and still others maintain normal CD4 T-cell counts which is unclear and an area of active investigation.

Although the mechanisms by which CD4 T cells die during HIV infection are likely multifactorial, it is clear that the CD4 T cells are dying by accelerated apoptosis. Furthermore, there are lower levels of spontaneous CD4 T-cell apoptosis in LTNPs compared to normal progressors (NP) (Gougeon et al. 1996). More specifically, caspase 9 and caspase 3 activity in CD4 T cells is higher and caspase 9/bcl-2 ratios are higher in progressors compared to LTNPs and noninfected individuals (Gougeon et al. 1996). When CD4 T cells from LTNPs, with a normal CD4 T-cell counts for over 7 years, were compared to AIDS patients, the LTNPs had a lower frequency of apoptotic CD4 and CD8 T cells. The T cells of LTNPs also had lower expression of Fas and Fas L and, therefore, were less susceptible to Fas-mediated apoptosis. The patients with AIDS in this cohort also had greater spontaneous mitochondrial depolarization and generated greater reactive oxygen species compared to LTNPs. Interestingly, CD4 T cells from LTNPs have similar levels of apoptosis despite higher levels of markers of immune activation than HIV-negative

individuals, suggesting that LTNPs may have a factor protecting their CD4 T cells from activation-induced cell death (AICD), in which activation of T-cell receptors results in cell death.

PD-1 is a cell-surface marker which belongs to the CD28 family and is expressed on activated CD4 and CD8 T cells. When PD-1 is bound by its ligands PD-L1 or PD-L2 during chronic viral infection, an immunosuppressive pathway is activated that suppresses T-cell function, including effector T-cell function, and leads to exhaustion of virus-specific CD8 T cells. LTNPs exhibit lower levels of PD-1 on HIV-specific CD8 T cells than progressors, suggesting that progressors have greater levels of HIV-specific T-cell exhaustion. Since blocking the PD-1/PD-L1 binding can reverse cognate T-cell exhaustion, there is great interest in therapeutically inhibiting PD-1/PD-L1 signaling. This work hints that LTNPs may have more functional anti-HIV defenses and are able to maintain preserved immune numbers as well as function.

Although most work has looked to the host for an explanation of slowed disease progression, some evidence suggests that the virus may also be responsible. The (H[F/S]RIG)₂ domain of the viral protein R (Vpr) of HIV induces apoptosis by binding to the adenine nucleotide translocator (ANT) in CD4 T cells. Viruses isolated from LTNPs have a higher frequency of the *vpr* R77Q mutation than viruses isolated from progressors (Lum et al. 2003). Pseudotyped HIV containing *vpr* R77Q infection of CD4 T cells in vitro resulted in less T-cell apoptosis than wild-type virus. In a cohort of 19 LTNPs followed over 6 years, seven of the patients were infected with viruses with the *vpr* R77Q mutation, whereas none of the progressors were infected with viruses carrying this mutation. Therefore, naturally occurring viral mutations may create viruses that are less able to induce T-cell apoptosis, resulting in a slowed disease progression.

Decreased T-cell apoptosis in LTNPs compared to progressors may also be due to alterations in T-cell regulation. CD4⁺ CD25⁺ regulatory T cells (Treg) suppress T-cell responses and maintain immune tolerance in a healthy state. Early investigations into the role of Tregs in the

pathogenesis of HIV disease suggests that numbers and function of Tregs may influence the state of immune activation during HIV infection, dysfunction of HIV-specific T cells, and other host-specific immune responses (Eggena et al. 2005). Treg numbers decrease significantly in progressors during the course of their HIV infection but are maintained at near-normal levels for LTNPs. The progressive decline in Treg cells correlated with elevated markers of immune activation and increased levels of spontaneous CD8 T-cell apoptosis *in vitro*. Antiretroviral therapy reversed this, increased Treg cell numbers and decreased immune activation and anti-CD3-induced CD8 T-cell apoptosis.

With mounting evidence suggesting that host factors dictate the progression of HIV disease, genetic differences between LTNPs and progressors have been sought. Genetic variants of cytokines that modulate HIV disease progression and HIV replication have been identified to differ between LTNPs and progressors. The CCR5 $\Delta 32$ allele, TNF- α -238A, and noncoding proteins associated with HLA-B*-5701 were positively associated with LTNPs in an Italian cohort of HIV-infected individuals. Array analysis revealed overexpression of genes in LTNPs involved in cytokine interactions and negative control of apoptosis, whereas progressors had overexpression of CD38 which is associated with immune activation and cell death. Furthermore, genome-wide transcriptome analysis of primary CD4 and CD8 T cells isolated from progressors and LTNPs with HIV infection was analyzed by Illumina microarray. A gene set enrichment analysis (GSEA) demonstrated several signal transduction pathways enriched in progressors, including tricarboxylic acid cycle and oxidative phosphorylation, which represent mitochondrial energy and metabolism pathways as well mitochondrial-mediated apoptosis. In contrast, LTNPs gene sets were enriched with cell survival pathways such as mitogen-activated protein kinase (MAPK), WNT, and protein kinase B (AKT) pathways. Collectively, these results give insight into differences in cell types, cytokine milieu, and intracellular signal transduction pathways which result in variances in levels of apoptosis between people who

have a normal progression of HIV disease and that of LTNPs.

The majority of ECs maintain a normal CD4 T-cell counts as a result of complete viral suppression, despite similar reductions in naïve T-cell counts as seen in progressors. The ECs, however, are distinguished from progressors by preserved thymic function and extra-thymic production of recent thymic emigrants. Furthermore, HIV-specific CD8 T cells from ECs are more resistant to apoptosis than similar cells from progressors, as measured by cleaved caspase 3 after the CD 8 T cells underwent HIV cognate peptide stimulation. This was associated with significant upregulation of Bcl-2 in HIV-specific CD8 T cells in EC compared to progressors.

Ten to 15% of HIV-infected individuals progress rapidly to AIDS within 1 year. These rapid progressors (RP) have an earlier emergence of CXCR4-utilizing strains of HIV, higher concentrations of IP-10, and single nucleotide polymorphisms in toll-like receptors and IL-7R α . However, the mechanistic basis by which these individuals have a more rapid progression of disease has remained unknown. In PBMCs from a large prospective cohort in China, there was a distinct cluster of genes expressed in RPs, unique from progressors that were associated with cell survival and apoptosis pathways; for example, 5 miRNAs were upregulated in RPs which impacted mitochondrial transport or the proapoptotic proteins Bid, Bmf, and Bim. This data suggests that the RP phenotype is impacted by proapoptotic factors.

The treatment for HIV replication and disease progression is antiretroviral therapy (ART). After HIV-infected patients are treated with effective ART, there is a dramatic decrease in plasma viremia, an increase in CD4 T-cell counts, and a decrease in spontaneous CD4 and CD8 T-cell apoptosis. However, about 1 in 10 patients on ART will maintain a paradoxically high CD4 T-cell counts despite ongoing viral replication. The percent of CD4 T-cell apoptosis in this unique population is significantly less than patients with virologic and immunologic ART failure (Meroni et al. 2002). The decreased CD4 T-cell apoptosis despite HIV replication may be due to intrinsic

antiapoptotic features of the ART. HIV protease inhibitors, in particular, can bind to the adenine nucleotide translocator protein in the mitochondrial transmembrane and prevent cytochrome c release, thereby preserving the mitochondrial transmembrane potential and blocking apoptosis. It remains unclear whether using ART with intrinsic antiapoptotic properties affects long-term clinical outcomes.

Taken together, this data demonstrates that a greater apoptotic response to HIV results in a rapid decline in CD4 T cells and rapid progression of disease; a host protective, antiapoptotic response to HIV results in normal CD4 T-cell counts and a slower disease course. Although a small-number people possess genetic protective factors that guard them from progressive HIV disease, alterations in apoptotic signaling may be a therapeutic approach to HIV infection in the majority of individuals with a normal disease progression.

HIV Infection of Lymphocytes

With the advent of highly active antiretroviral therapy (HAART) in the mid-1990s, the morbidity and mortality of HIV infection dramatically decreased, and now HIV-infected individuals have lived for almost two decades with normal CD4 T-cell counts and minimal spontaneous CD4 T-cell apoptosis as a consequence of suppressed viral replication. Nonetheless, stopping antiretroviral therapy (ART) still results in a viral rebound within 3–4 weeks (Finzi et al. 1997), due to persistence of HIV within a viral reservoir where HIV remains latent. There are several immunologic reservoirs for persistent virus, including resting CD4 T cells, macrophages, follicular dendritic cells, and hematopoietic stem cells. There are also anatomic sites for HIV to evade ART such as the central nervous system and the male urogenital tract. It is unclear whether HIV persists in these hidden sanctuaries despite effective ART because of episodic reactivation of the reservoir or because of ongoing low-level replication within the reservoir. Some evidence and mathematical modeling suggests that current ART is

capable of completely blocking even low-level replication within the reservoir, and therefore intensification of ART using newer agents might be capable of eventually eliminating HIV. However, if the reservoir is stably integrated latent virus, novel approaches will be needed to target the residual virus in order to eliminate HIV.

HIV latency occurs when HIV DNA is inserted into the host genome and remains transcriptionally silent, with up to 1 per 10^6 cells isolated from the peripheral blood containing an integrated and transcriptionally silent HIV provirus (Finzi et al. 1997; Chun et al. 1997). These integrated proviruses do not show viral evolution, suggesting that much of the reservoir is seeded early in infection and also suggesting that proviral integration serves as a survival feature for the retrovirus to maintain replication-competent virus over time.

It remains unclear how latency is established. The two predominant hypotheses are that HIV infects either (1) resting CD4 T cells or (2) activated CD4 T cells which escape death or revert to a resting state. De novo infection of resting CD4 T cells is difficult and inefficient compared to infection of actively replicating cells. There is in vitro evidence that HIV-infected actively proliferating cells are able to revert to a latent state with integrated proviral DNA after treatment with selective cytokines. Once in a resting state, these HIV-infected cells can reactivate to produce replication-competent virus. Since proliferating CD4 T cells contain latent HIV provirus, the two hypotheses remain: (1) HIV infects and integrates into actively proliferating cells and then cells create transition into a resting state or (2) HIV directly infects resting cells.

In order to fully understand proviral latency, it must be determined whether the mechanism of establishing latency is due to cellular factors (*trans* effects), viral genetic defects (*cis* effects), or viral and host factors (*cis/trans* effects). A number of proposed mechanisms involve *trans*-acting factors. Since HIV transcription depends on several steps beginning with the HIV transcription factors SP-1, NFAT, and NF-KB, it is possible that there may not be sufficient nuclear concentration of these factors to support active replication of the HIV. In addition, there is

evidence that negative regulatory transcription factors such as YY1 can bind the HIV LTR and increase the number of cells that become inactive, resulting in latently infected cells. Transcript elongation is also required for HIV replication; therefore, insufficient amounts of elongation factors, including positive elongation factor b, may limit HIV replication and promote latency. Studies of CD4 T-cell clones that have a single integration demonstrate that integration site location may influence whether the virus becomes latent or transcriptionally active. The clones with proviruses in the same chromosomal region had similar silent or inducible gene status. Lastly, micro-RNAs, which target certain gene sequences and degrade the viral RNA by the RNA interference pathway, may be upregulated and act to prevent HIV replication in certain cells, thereby promoting a latent state (Huang et al. 2007).

Both cis- and trans-acting factors affect chromatin at the HIV promoter. There are significant differences in the chromatin organization in transcriptionally active versus inactive HIV promoters notably by epigenetic silencing. In vitro work in transformed T-cell lines has demonstrated that HIV provirus can integrate into the heterochromatin of actively transcribing genes as well as quiescent genes. Nucleosome modifications and site of binding can limit the access of transcription factors to HIV. Furthermore, DNA methylation is found in a large number of latently HIV-infected cells and can also alter viral promoter sequences. These mechanisms suggest that treating latently infected cells with small-molecule inhibitors of the family of histone-modifying enzymes (HDACs) would alter the chromatin formation at the HIV promoter, allow the provirus better access to transcription factors, and possibly reactivate HIV out of latency. When resting CD4 T cells from virologically suppressed HIV-infected patients were treated with the HDAC inhibitor, vorinostat, there was an increase in biomarkers of acetylation and a 4.8-fold increase in HIV RNA expression (Archin et al. 2012), providing a proof of concept that HDAC inhibitors can reactivate latent HIV infection.

Another possible mechanism of latency occurs by cis-acting mechanisms or mutations

of the virus. Viral proteins are required for HIV replication, such as the HIV protein Tat which acts by binding to an RNA stem-loop structure, the trans-activating response element (TAR) of the 5' end of the transcript before initiating transcription elongation. By Tat binding to HIV, it activates transcription by creating a transcriptionally active elongation complex. A mutation in the TAR motif inhibits HIV transcription and results in HIV proviruses carrying this mutation remaining transcriptionally inactive in resting CD4 T cells. In order for this mechanism to be responsible for establishing the viral reservoir, the viral mutations would need to be minimal in order to allow for replication-competent virus upon reactivation.

Viral and host cellular (*cis* and *trans*) factors in combination may also be responsible for establishing HIV latency. As an example, since HIV prefers to integrate into transcriptionally active genes, when an upstream host gene is being transcribed, its transcription may obstruct the HIV 5'LTR transcription if both transcription factors are initiating in the same direction. Furthermore, the antisense strand of siRNA may affect histone methylation and result in gene silencing by chromatin remodeling of the HIV 5'LTR promoter. Whatever the mechanism of establishing the reservoir, silencing transcription and maintaining viral latency, it is clear that latently HIV-infected cells are protected from HIV-induced apoptosis and remain stable for months to years.

Although latently HIV-infected cells are resistant to apoptosis, most transcriptionally active cells produce virions and die as a result of the replicating virus. There are three predominant theories as to how infected cells die during HIV infection. Firstly, a body of work in CD4 T cells shows that during productive and acute infection, the HIV protein protease cleaves the host protein caspase 8, creating a unique protein fragment called Cas8p41. Once produced, Cas8p41 translocates to the mitochondria where it activates NF- κ B and induces mitochondrial permeability which leads to apoptosis of the infected cell (Nie et al. 2007). Since transcriptionally inactive HIV-infected cells would not be producing the

HIV protease protein, the latently infected cells would not die. Furthermore, short-term antigen stimulation of a CD4 T cell results in host procaspase 8 upregulation, whereas chronically stimulated cells downregulate procaspase 8, acquire a memory phenotype, and become resistant to apoptosis, and this may explain how an activated infected cell is transformed into a resting latently infected cell. Secondly, HIV proviral integration can cause death of cells prior to replicating virus. Viral integration into the host genome involves activating the DNA damage response, including DNA-dependent protein kinase (DNA-PK), which phosphorylates p53 and histone H2AX. Blocking HIV integration with the integrase inhibitor raltegravir or infecting cells with an integrase-deficient mutant virus abrogated cell death, whereas replenishing HIV Integrase restored cell death. Furthermore, inhibiting DNA-PK resulted in HIV-infected cells that did not die, although it is unclear whether these cells exhibited a transcriptionally inactive resting state. Thirdly, accumulated unintegrated HIV provirus transcripts can induce HIV-infected cell death. Resting HIV-infected CD4 T cells have full-length unintegrated viral DNA that is distinct from the genome-integrated proviral DNA. Replication of limited numbers of virus from a resting CD4 T cell would result in only a few viral DNA molecules and would not be sufficient to cause apoptosis, whereas prolific viral replication (as seen in an activated cell) would be adequate to cause infected cell apoptosis.

Once HIV infects a cell, it can integrate into the host genome, kill the cell, and/or shift into a resting latent state. What determines how, whether, or when any of these steps occurs remains unknown, although convincing arguments suggest that actively replicating infected cells can be transformed into a resting latent state. Moreover, the presence of viral proteins, induced during viral replication, may result in HIV-infected CD4 T-cell death. Understanding these processes will direct approaches to reactivating HIV out of a latent state or prevent it from ever entering a latent state and allow for HIV-infected cell apoptosis as a means of eradicating HIV infection.

HIV Infection of Myeloid Cells

Myeloid cells, including monocytes, dendritic cells, and macrophages, play important roles in the adaptive and innate immune responses. They are some of the first cells to be exposed to HIV in the mucus membranes, and since they express CD4 receptors and the necessary chemokine coreceptors, they are vulnerable to infection. However, these cells are resistant to HIV-induced apoptosis but can induce death of bystander, infected, and uninfected cells.

When a monocyte differentiates into a macrophage, it becomes apoptosis resistant. This phenotype can be attributed to altered regulation of death receptors and the mitochondrial apoptotic regulators. At the cell membrane in macrophages, cFLIP, the inhibitor of caspase 8, is upregulated while caspase 8 expression is downregulated. This allows molecules of cFLIP to bind and sequester caspase 8 away from FADD, resulting in less DISC formation and downstream activation of caspase 3, whose levels are also decreased in macrophages. In order to inhibit mitochondrial depolarization and apoptosis, macrophages upregulate Bcl-xL, thereby inhibiting oligomerization and activation of Bak. Downstream of the mitochondria in macrophages, XIAP, a protein that binds and inhibits caspases 9, 3, and 7 activation, is upregulated while caspase 9 expression is decreased.

HIV infection of myeloid cells also induces an apoptotic resistant phenotype. Monocytes from HIV-1 infected patients express a differential gene signature than T cells from these same individuals resulting in death ligand resistance (Giri et al. 2009). This may be due to HIV infection of monocytes and macrophages causing NF- κ B activation. NF- κ B affects multiple pathways but in macrophages allows the cells to become resistant to TNF-induced apoptosis. In addition, HIV-infected macrophages are resistant to TRAIL; the HIV glycoprotein gp120 stimulates the production of macrophage colony-stimulating factor (M-CSF) which downregulates TRAIL receptor 1 and upregulates Mcl-1. Similarly, the HIV protein Tat upregulates Bcl-2 miRNA and protein

levels in a dose-dependent manner (Zheng et al. 2007). Furthermore, Nef causes Bad phosphorylation, thereby inhibiting the proapoptotic BH3 protein from binding Bcl-2 or Bcl-xL and sequestering them away from Bak and Bax (Wolf et al. 2001). These events, paired with those that already make myeloid cells resistant to cell death, help to establish an HIV reservoir which is difficult to eliminate.

As HIV-infected myeloid cells become resistant to apoptotic stimuli, they develop the ability to induce death of bystander cells by upregulating death receptor ligands, possibly explaining why noninfected T cells undergo apoptosis in an HIV-infected patient. Nef and Tat recruit T cells to antigen-presenting macrophages, whereupon the death ligands expressed by the infected macrophages interact with death receptors on activated T cells, thereby causing T-cell death. Nef expression in macrophages increases the production of macrophage inflammatory protein-1 (MIP-1), which is a T-cell chemotactic. Tat expression in dendritic cells drives production of other chemoattractants, interferon gamma-induced protein 10, and monocyte chemoattractant protein 2, luring T cells and macrophages closer to the infected myeloid cell. Additionally, Tat expression in macrophages increases expression of TRAIL. TNF- α production on macrophages is increased by gp120 or HIV infection, and following interaction with TNFR2 has been proposed to cause death of CD8 T cells in HIV-infected individuals. Furthermore, Monocyte-derived macrophages from healthy donors express more FasL upon infection with HIV. Inhibiting the interaction of FasL with its receptor decreases death of bystander T cells killed by those infected macrophages. This increase of FasL, and subsequent induction of apoptosis in bystander T cells, is specific to monocyte-derived macrophages as opposed to monocyte-derived dendritic cells. While infected macrophages and dendritic cells may recruit T cells, it is due to the increase in death receptor ligand expression on macrophages that attributes to their death. Therefore, as cells are lured to the infected macrophage, they are exposed to the death-stimulating ligands, resulting in their death.

HIV Proteins and Apoptosis

A number of HIV proteins have been directly or indirectly associated with regulation of apoptosis, particularly Gp120, Vpr, Tat, Nef, integrase, and protease. The purpose of this section is to review the reported mechanisms associated with HIV protein regulation of apoptosis, focusing mainly on lymphocyte death. However, several limitations in the relevant literature should be noted first. The use of immortalized cell lines is common but difficult to interpret, since they often have abnormal apoptosis regulatory mechanisms a priori. Single protein overexpression systems may not accurately reflect true in vivo intracellular protein concentrations, which are by and large unknown. Single- or multiple-gene deficient viral constructs may not replicate normally, which is important in accurately modeling in vivo infection. Furthermore, few observations have been rigorously replicated, and even fewer have been conclusively demonstrated in in vivo infection, so the reported effects may be model and context dependent. What remains, though, is a likely picture of pleiotropic and overlapping effects of HIV proteins on apoptosis, suggesting a complex regulatory system with inherent redundancies highlighting the importance of apoptosis in the survival and propagation of the HIV virus.

Gp120

The HIV-1 envelope protein Gp120 has been shown in numerous models and cell types to induce apoptosis. Gp120 exists in both a membrane-bound form, expressed on virions and the cell surface of infected cells, and insoluble form, which is detectable in plasma and tissues in vivo. As Gp120 engagement with the CD4 receptor and associated coreceptors is necessary for viral entry, Gp120-induced apoptosis has been mostly described as contributing to uninfected, so-called bystander, cell death, through direct cell-to-cell contact, syncytium formation, or trans-signaling events. For instance, exposure to exogenous Gp120 can increase lymphocyte susceptibility to apoptosis through upregulation of death receptor expression, such as Fas and

TRAIL receptors 1 and 2, or downregulation of Bcl-2 expression. Gp120 also induces cells to express death ligands, including Fas and TNF- α (154). Gp120-induced proapoptotic signaling through cellular protein kinases results in activation of MTOR and (Castedo et al. 2001; Perfettini et al. 2004) as well as. Other reported proapoptotic effects of Gp120 include induction of cell cycle arrest and generation of reactive oxygen species. In vitro and in some instances mouse models confirm Gp120-induced cytotoxicity in many cell types, including neurons, cardiomyocytes, vascular endothelial cells, hepatocytes, renal tubular epithelial cells, and osteoblasts, implicating this protein in the pathogenesis in many non-AIDS-associated morbidities.

Vpr

The accessory viral protein Vpr, contained within mature virions, infected cells and secreted into the extracellular space, has been reported to have both pro- and antiapoptotic effects. The main function of Vpr is to induce G(2)/M cell cycle arrest in infected cells, and the off-target effects likely differ before and after that important event in the viral life cycle. Early, low-level expression of Vpr results in suppression of NF- κ B-dependent cytokine induction, decreased Bax, and increased Bcl-2 expression, rendering cells resistant to death receptor-mediated apoptosis. Coincident with the G(2)/M arrest, VPR induces expression of other antiapoptotic molecules, including surviving. On the other hand, later in the viral life cycle, Vpr can directly induce apoptosis through mitochondrial depolarization by binding either Bax or ANT and VDAC. Others have shown that intracellular expression of Vpr in renal tubular epithelial cells results in sustained ERK activation and activation of procaspase 8, although this has not been demonstrated in lymphocytes.

Vpr is one of the few HIV proteins where the reported apoptotic regulatory effects have a direct correlation in human infection. As discussed above, a naturally occurring polymorphism in Vpr (R77Q) is overrepresented in long-term non-progressing patients compared to normal progressors; furthermore, this mutation is associated

with decreased apoptosis induction by Vpr in vitro (Lum et al. 2003).

Tat

The HIV-1 transactivator protein, Tat, has been described to have a number of pro- and antiapoptotic effects. Produced in infected cells, Tat is secreted into the extracellular environment and enters uninfected bystander cells through clathrin-mediated endocytosis. Low concentrations of exogenous Tat are generally antiapoptotic and result in resistance to death receptor-induced apoptosis, associated with increased expression of Bcl-2 and cFLIP. In fact, the C terminus of Tat has been shown to directly interact with the Bcl-2 promoter and induce transcription. However, higher concentrations of Tat can induce apoptotic sensitivity through increasing expression of FasL (Westendorp et al. 1995), caspase 8, and Bax. Some of these effects may be dependent on Tat-mediated activation of p53 through inhibition of SIRT1. Endogenous Tat expression generally results in an antiapoptotic phenotype. Therefore, Tat may have a role in bystander killing. In fact, exogenous treatment of monocytes and macrophages with Tat results in increased surface expression of TRAIL, which can then participate in killing of neighboring uninfected cells.

Nef

The net effect of Nef expression in HIV-infected cells on apoptosis regulation is unclear, as a number of quite varied functions have been attributed to this accessory protein. Intracellular expression of Nef has been associated with increased Fas and FasL expression, increased PD-1 expression, and decreased expression of antiapoptotic Bcl-2 proteins. Nef has also been shown to cause lysosomal permeabilization, releasing cathepsin D into the cytosol and thereby initiating mitochondrial-dependent cell death (70). However, a number of antiapoptotic functions have been described as well. Through direct interactions, Nef can inhibit the activity of both ASK-1 and, indirectly inhibit the function of Bad (Wolf et al. 2001). More recently, it has been shown that intracellular expression of Nef results in secretion of the protein in exosomes, which can then contribute

to activation-induced cell death in uninfected bystander cells.

Protease

Although the primary substrate for HIV-1 protease is the Gag/Pol polyprotein, the acute and significant cellular toxicity associated with endogenous overexpression of HIV-1 protease suggests significant degenerate substrate specificity. In fact, HIV-1 protease has been shown to specifically cleave Bcl-2 between phenylalanine 112 and alanine 113, inactivating Bcl-2 and resulting in apoptosis of protease-expressing cells. We have shown that HIV-1 protease also specifically cleaves procaspase 8 between phenylalanines at positions 355 and 356 resulting in a pro-apoptotic fragment called Casp8p41 (Nie et al. 2007). Casp8p41 interacts with the mitochondria resulting in depolarization and apoptosis that is dependent on Bax/Bak (Sainski et al. 2011).

HIV-1 protease is the other HIV protein where there is specific evidence of importance in apoptosis regulation in human infection. Two mutations in HIV-1 protease, I54V and V82A, are overrepresented in infected patients who are failing antiretroviral therapy but have sustained elevations in CD4 T-cell counts, suggesting impairment in HIV-induced cell death. We have shown that these mutations also impair the ability of HIV-1 protease to cleave procaspase 8 to generate Casp8p41, whereas they do not impair the ability of protease to cleave the Gag/Pol polyprotein (Natesampillai et al. 2010). Furthermore, higher levels of Casp8p41 expression in memory CD4 T cells in HIV-infected patients are associated with lower CD4 T-cell counts.

Integrase

A recent study implicates the activities of HIV integrase in HIV-induced lymphocyte apoptosis prior to progeny virus replication, as apoptosis failed to occur in cells infected with integrase-deficient virus or treated with the integrase inhibitor raltegravir. DNA breakage, as a necessary event for HIV proviral integration into the host genome, initiates a cellular DNA damage response, characterized by activation of DNA-dependent protein kinase (DNA-PK). DNA-PK-

dependent phosphorylation and activation of p53 was necessary for HIV-induced apoptosis in that particular *in vitro* model. However, it is clear that a substantial portion of infected cells must survive this toxic DNA damage response in order to establish both latent and productive infection. This suggests that additional events in the post-integration phase of the viral life cycle, such as those described above, also contribute to the lymphocyte apoptosis seen during productive HIV infection.

HIV-Mediated Apoptosis of Nonimmune Cells

With the advent of HAART, people infected with HIV are living longer, have healthier lives, and are no longer suffering from opportunistic infections and cancers. For reasons that are not entirely clear, effectively treated HIV-infected individuals are now experiencing non-AIDS-related causes of morbidity and mortality at an accelerated rate (Deeks et al. 2013). Most of these are a result of end-organ diseases such as liver disease, kidney disease, and neurocognitive disease. Accumulating evidence suggests that HIV may directly or indirectly cause apoptosis of end-organ, non-immune cells, contributing to the disease of the organ.

Liver Disease

End-stage liver disease is one of the most common causes of hospitalized death of HIV-infected individuals in the United States. Because hepatocyte apoptosis will eventually lead to cell repair, inflammation, and ultimately fibrosis of the liver, understanding hepatocyte cell death during HIV infection is critical. Although liver disease is more common in HIV-infected individuals with viral coinfections such as hepatitis B and hepatitis C, there is evidence that HIV alone can cause liver damage. Early work has shown histologic damage to the liver during HIV infection and the presence of HIV p24 and HIV cDNA in liver tissue. Mechanistically, the X4 HIV gp120 can bind to CXCR4 receptors on human hepatocytes and induce a low level of transformed or primary hepatocyte

apoptosis, without infecting the cell, since the CD4 T-cell receptors are not expressed on non-immune cells. When the chemokine receptor-linked G_i protein was inhibited, HIV/CXCR4-mediated hepatocyte apoptosis was abrogated; however, caspase inhibition did not affect this low-level direct HIV-hepatocyte death. Thus, HIV proteins may be directly cytopathic to hepatocytes.

HIV causes chronic activation of the immune system, which contributes to the increased T-cell turnover and the pathogenesis of HIV. Therefore, it is possible that increased activation of intrahepatic circulating immune cells may contribute to liver damage and hepatocyte apoptosis. Liver biopsies from HIV/HBV-coinfected patients were compared to liver biopsies from HBV mono-infected patients and analyzed for markers of T cell, monocyte, natural killer cells, and hepatic stellate cell (HSC) activation before and after ART. Compared to HBV mono-infected samples, the HIV/HBV-coinfected samples had significantly increased hepatocyte apoptosis but fewer intrahepatic T cells, Kupffer cells, and HSC as well as lower levels of immune cell activation. These results were not altered by ART. Therefore, HIV-mediated liver disease appears to occur independent of the presence of immune cells or their activation state.

Tumor necrosis factor apoptosis-inducing ligand (TRAIL) and its receptors TRAIL-R1 and TRAIL-R2 are members of the tumor necrosis receptor (TNF) death receptor family. When TRAIL binds TRAIL-R1 or TRAIL-R2, a death-inducing signaling complex (DISC) forms which contains the death receptor and adaptor proteins which in turn signal a caspase-dependent cell death. HIV gp120 signals through CXCR4 on hepatocytes which upregulates TRAIL-R2 expression, making the previously TRAIL-resistant hepatocytes susceptible to TRAIL-mediated killing. Moreover, HCV upregulates TRAIL expression. Therefore, the accelerated hepatocyte apoptosis found during HIV/HCV coinfection might be due to a TRAIL-dependent death process. When HIV gp120 primed hepatocytes were co-incubated with hepatocytes expressing HCV core, there was selective

apoptosis in the HIV-primed hepatocytes which was inhibited by blocking TRAIL-R2. This was correlated with liver biopsy samples from HIV and HCV mono- or coinfecting patients which showed higher TRAIL expression in HCV-infected livers, greater TRAIL-R2 expression in HIV-infected livers, and higher levels of apoptosis in HIV/HCV coinfecting livers than either mono-infected liver. Additional work showed increased caspase 3/7 activity in HCV-infected hepatocyte cell lines after treatment with heat-inactivated HIV that was abrogated by pharmacologic caspase inhibition. These findings suggest that HIV-mediated hepatocyte apoptosis during states of increased TRAIL production, such as HCV coinfection, is due to a TRAIL-mediated apoptosis.

Kidney Disease

End-stage renal disease (ESRD) occurs in approximately 1% of HIV-infected individuals in the United States with 10–15% of those infected experiencing some form of renal disease. In fact, HIV-associated kidney disease is now the third leading cause of ESRD in African Americans in the United States. The majority of this kidney disease is due to HIV-associated nephropathy (HIVAN) which is characterized by focal glomerulosclerosis and tubulointerstitial lesions that occur with tubular epithelial cell injury as a result of apoptosis. HIV RNA has been isolated from human kidney samples; however, the mechanism of by which HIV causes apoptosis in the renal cells remains under investigation.

In one model of HIV-associated renal cell apoptosis, lentiviral expression of X4 HIV gp120 caused apoptosis of transformed human proximal tubular cell lines that was associated with an increase in Fas and FasL expression on the tubular cells, after HIV gp120 treatment. The HIV gp120/renal cell death was inhibited by pretreating the cells with antagonistic-FasL antibody or caspase 8 inhibitor. Additionally, soluble HIV gp120 causes renal tubular cell apoptosis that was inhibited by blocking gp120 binding to the cell and by pharmacologically inhibiting p38 kinase phosphorylation. Together, this work alludes to possible signaling mechanisms for the HIV

gp120-dependent renal tubular apoptosis, including signaling which occurs through the Fas/FasL and/or p38 signaling. Transcription of Fas and FasL is regulated by NF- κ B, yet NF- κ B also transcribes a number of genes that mediate immune and inflammatory processes. HIV transgenic mice with HIVAN had higher expression of the FasL promoter than transgenic mice with normal renal architecture. In addition, p65-containing (RelA) complexes were bound to the FasL promoter in HIVAN cells and NF- κ B decreased FasL RNA levels in the same cells. This data indicates that the HIV-mediated apoptosis of renal tubular cells can result from signaling through Fas/FasL binding and is controlled by NF- κ B transcription regulation.

In addition to HIV gp120, other HIV proteins have also been reported to signal renal cell apoptosis. HIV Vpr inhibits cell division of proximal tubule cells and induces renal tubular apoptosis. Human renal tubular epithelial cells (RTEC) undergo apoptosis after treatment with lentiviral vectors expressing HIV Vpr but not control lentiviruses, manifested by caspase 3/7 activation, PARP-1 cleavage, and mitochondrial injury. Vpr also induced ERK phosphorylation and activation, which can be associated with cell cycle arrest in certain cell types, as well as cleavage of BID to tBID and caspase 8 activation; all indicators of an extrinsic pathway apoptosis (Snyder et al. 2010). These results have been confirmed by evidence of tubular apoptosis, increased Fas levels, and ERK phosphorylation in human biopsy tissue from patients with HIVAN compared to HIV-infected individuals without kidney disease. With a better understanding of HIV-mediated apoptosis of renal tubular cells, interventions can be designed to prevent HIVAN and ESRD in HIV-infected individuals.

Neurologic Disease

HIV-infected individuals often experience neurocognitive decline which is referred to as HIV-associated neurocognitive disorders (HAND). Clinically, these neurocognitive findings can range from subclinical changes to HIV-associated dementia (HAD). Before effective ART, the prevalence of HAD was 20–30% in

some populations, but with HAART, the incidence is closer to 1%. However, less severe forms of HAND such as minor cognitive-motor disorder (MCMD) have been reported in as high as 37% of infected individuals even after ART. Autopsy specimens from HIV patients with neurologic changes have shown apoptosis of central nervous system neuronal and nonneuronal cells in excess of control specimens. This was associated with damage to synapses and death of hippocampal and basal ganglion neurons, suggesting that neuronal apoptosis may be contributing to HAND. The mechanism of HIV-mediated neuronal apoptosis is likely multifactorial with HIV directly and indirectly triggering neuronal damage.

Similar to HIV-induced liver and kidney disease, HIV-caused apoptosis in neurons is due in part to direct effects of HIV proteins (Singh 2004, p. 141). HIV gp120, in particular, induces neuronal apoptosis in cell culture, ex vivo in hippocampal slice preparations and in mouse models including direct stereotactic intracranial injection of HIV gp120 (Toggas et al. 1994). The apoptosis was dependent on surface expression of CXCR4 and protein kinase C activation. Because K⁺ channel blockade has prevented neuronal death in other models of apoptosis, and since HAND may be partially reversible with ART, the role of K⁺ channels in HIV-mediated neuronal death has been under investigation. Work thus far has demonstrated that treating cortical neurons with HIV gp120 resulted in enhancement of A-type transient outward K⁺ currents and eventually in neuronal apoptosis. It is unclear whether this occurred as a result of indirect activation of bystander glial cells which produced a soluble substance that signaled cell death or via direct mechanisms. Furthermore, prolonged HIV gp120 or SDF-1 α /CXCR4 binding also altered neuronal K⁺ channel efflux and induced apoptosis; however, in this rat model of neuronal damage, the channel effects were also blocked by p38 kinase inhibition.

In addition to HIV gp120, the HIV Tat protein also causes alterations in K⁺ channel efflux and neuronal apoptosis. Rat microglial cells treated with HIV Tat resulted in the release of TNF- α ,

IL-1 β , and ROS, suggesting a state of microglial activation, which was coincident with an enhanced outward K⁺ channel current. Altogether, this work suggests that controlling K⁺ channel activity may alter HIV-associated neuronal apoptosis.

Other indirect mechanisms of HIV-associated neuronal damage have been proposed that involved astrocytes which can maintain low levels of infection. Astrocyte infection with X4 HIV results in inositol triphosphate-regulated calcium release which signals apoptosis in neighboring astrocytes, but the HIV-infected astrocytes themselves did not die. In this system, HIV infection conferred a protective antiapoptotic state to the actively infected cells, caused surrounding bystander cell death, and enabled the astrocytes to serve as sanctuary for the HIV reservoir. The same may be true in other myeloid cells.

Altering Apoptosis Pathways and the HIV Cure Initiative

Over recent years, spurred by the report of one and possibly other HIV “cures,” much attention has been devoted to understanding ways in which HIV might be eradicated. Careful examination of how cure was affected in those cases may provide guidance as to how this might be recapitulated on a broader scale.

In the initial report, an HIV-infected patient with long-term antiretroviral-mediated HIV suppression was treated for AML with chemotherapy, followed by auto- then allogeneic bone marrow transplantation using a donor with CCR5delta 32 mutation. Several years following treatment there is no detectable replication-competent HIV despite cessation of antiretroviral therapy (Allers et al. 2011). There has been much speculation as to why HIV was cleared in this case, with the predominant theories being that either (i) the cytotoxic chemotherapy eradicated cells harboring HIV, and ARV prevented repopulation of the HIV reservoir, (ii) the transplanted allogeneic bone marrow mediated a graft versus HIV, (iii) the transplanted CCR5delta 32 cells precluded productive infection posttransplant, thereby

preventing reestablishment of the HIV reservoir, or (iv) a combination of these effects.

Considering these possibilities on a mechanistic basis, cytotoxic chemotherapy (in particular using the agents used in the Berlin patient – i.e., fludarabine, amsacrine, and ara-C with anti-Thymoglobulin (ATG) GVHD prophylaxis) causes the death of both cancerous and non-cancerous cells including lymphoid and myeloid subsets by induction of mitochondrial-dependent apoptosis in the case of the chemotherapeutics and by combination of complement-dependent lysis and caspase-mediated apoptosis in the case of ATG. Moreover recent evidence implicates TRAIL as a critical effector mechanism involved in graft versus tumor effects, raising the possibility that any graft versus HIV effect might be mediated by TRAIL as well. Furthermore TRAIL-mediated immune control by CD8 T cells has been described in the case of influenza infection (Brincks et al. 2008), suggesting that it may be important as well during HIV infection. As outlined above, TRAIL has also been implicated in the immunopathogenesis of HIV.

The concept that inducing apoptosis in cells from HIV-infected patients can cause eradication or at least reduction in viral burden is not new. Spurred by initial observations that inhibiting apoptosis in HIV-infected cells increase HIV replication (Chinnaiyan et al. 1997) and the corollary that inducing apoptosis by cytotoxic chemotherapy can reduce HIV replication, we tested the hypothesis that apoptosis induction in HIV-infected cells might reduce viral burden by killing those cells which produce the virus. Indeed, more than a decade ago we reported that exogenous treatment of cells from HIV-infected patients with recombinant TRAIL caused a reduction in viral burden, often to undetectable levels (Lum et al. 2001), without negative quantitative or qualitative effects on bystander cells. At the time this was an attractive and promising preclinical strategy as a variety of clinical grade compounds were being developed as therapy for a variety of cancers; however, in the interim the development of these compounds have suffered from weak delivery, the recognition of TRAIL-resistant cancers, and disappointing early phase clinical trial results.

Conclusion

Looking to the future, how can the premise that inducing apoptosis in HIV-infected cells reduce HIV burden be exploited towards the goal of achieving a cure for HIV?

- (i) **Apoptosis-inducing agents to reduce the burden of HIV-infected cells.** In the early 1990s there was interest in evaluating OKT3 (an apoptosis-inducing anti-CD3 antibody) in the setting of IL-2 to reactivate HIV expression along with antiretroviral therapy. This treatment resulted in decreased HIV RNA levels and undetectable HIV on viral outgrowth assays from CD4 T cells in a proportion of patients. This proof of concept study demonstrates the ability of anti-cellular therapies to impact HIV burden. It would be of interest to study the anti-HIV effect of other anti-cellular therapies – such as traditional chemotherapeutic agents. Alternately ATG which was used in the Berlin patient and which targets numerous epitopes including CD2, CD3, CD4, CD8, CD11a, CD28, and, CD45 might reduce cellular reservoirs of HIV occurring in both CD3 T cells and CD4⁺ monocytes/macrophages and DC. This is particularly appealing today given the superiority of current antiretroviral agents over those used in the 1990s, which may prevent repopulation of the viral reservoir during cytotoxic treatment.
- (ii) **Apoptosis sensitizers to enhance the likelihood of HIV dying in response to expressing HIV proteins.** Latently infected resting memory CD4 T cells are proving to be difficult to eliminate because they are resistant to the cytotoxic and proapoptotic effects of viral reactivation (Shan et al. 2012). In latently infected CD4 T cells which have been induced to reactivate virus, there are a wide variety of proapoptotic stimuli expressed intracellularly including Tat, Nef, Env, Vpr, and HIV protease. In the different settings of acute infection of an activated CD4 T cell, these stimuli are sufficient

to contribute to the death of infected cells. However, in the setting of HIV reactivation, these stimuli are insufficient to cause the death of cells which express these proteins. Therefore, we have proposed the model of using chemosensitizing drugs that have been tested in oncology to alter the susceptibility of a latently HIV-infected CD4 T cell that has become resistant to the proapoptotic effects of intracellular HIV replication, so that the latently infected resting memory CD4 T cell becomes susceptible again to the proapoptotic effects of productive HIV replication. This novel paradigm of “**prime, shock, and kill**” involves chemosensitization to render latently infected cells susceptible to the cytotoxic effects of proapoptotic HIV proteins and viral reactivation with agents that do not cause immune activation (e.g., vorinostat), in order to cause intracellular expression of the proapoptotic HIV proteins Tat, Nef, Env, Vpr, and protease. While this model has yet to be fully tested, it may explain observations that agents such as auranofin which is a cancer-chemosensitizing agent may have anti-SIV effect in chronically SIVmac251-infected macaques under highly intensified ART

At the most fundamental of levels, HIV infection is a disease of altered cell death, with too many acutely infected and bystander CD4 T cells dying leading to immunodeficiency and too few latently infected cells dying allowing persistence of the infection. Therefore, enhanced understanding of the death pathways that occur in HIV, as well as the counter regulatory mechanisms which are induced to prevent death of cells destined to become the reservoir of HIV, will offer insights towards death-modifying treatment approaches to eradicate HIV.

Medicine, The University of California, San
Diego, CA, USA

***Mycobacterium avium* Complex**

Definition

Mycobacterium avium complex (MAC) comprises two closely related acid-fast bacteria, *M. avium* and *M. intracellulare*. The most common clinical presentation of disease due to these organisms in adults is infection of the respiratory tract, primarily seen in immunocompetent individuals with underlying chronic pulmonary disease, while disseminated infection is primarily a complication of advanced human immunodeficiency virus (HIV) infection. Although the incidence of disseminated MAC infection (dMAC) has declined significantly with the widespread use of potent combination antiretroviral therapy (ART), it still remains an important complication of advanced HIV infection.

Epidemiology

Mycobacterium avium complex organisms are thought to have little virulence in the normal host, and prior to the onset of the HIV epidemic

had mostly been recognized as a cause of localized pneumonia in persons with chronic pulmonary disease. Reports of dMAC infection were extremely rare prior to 1980, when there were only 24 cases reported in the literature (Horsburgh 1991). After the onset of the HIV epidemic, MAC infection became increasingly recognized as a cause of illness in individuals with advanced HIV, as defined by a CD4 T cell count of less than 100 cells/mm³, and the incidence of dMAC infection increased as the HIV epidemic worsened. MAC typically presents as disseminated disease in HIV-infected individuals not on ART, although localized MAC disease can occur in HIV-infected individuals on ART, presenting as localized lymphadenitis, pericarditis, osteomyelitis, skin and soft tissue infection, or central nervous system infection.

MAC has been isolated from water, soil, foods, and a variety of animal species, and is thought to be ubiquitous in the environment (Gordin and Horsburgh 2005). Water is the main source for infection and MAC has been isolated from tap drinking water, ice machines, swimming pools, hot tubs, and spas (Corti and Palmero 2008). The ubiquitous nature of MAC in the environment has made infection difficult to prevent. It is estimated that 7–12% of adults have been previously infected with MAC (Benson 1994b), and before the widespread availability of ART up to 40% of patients with acquired immune deficiency syndrome (AIDS) developed dMAC. With the widespread availability of ART and MAC

prophylaxis, the incidence of dMAC has significantly decreased and occurs rarely in those on ART even with low CD4 T cell counts.

The most significant risk factor for dMAC is a CD4 cell count less than 50 cells/mm³. No environmental exposure or specific behavior has consistently been associated as a risk factor (Karakousis et al. 2004). Prior opportunistic infections including *Pneumocystis jirovecii* pneumonia (PJP), severe anemia, and interruptions in antiretroviral therapy may increase the risk for dMAC (Benson 1994b), as do high plasma HIV RNA levels (>100,000 copies/mL) and previous colonization of the respiratory or gastrointestinal (GI) tract with MAC (Benson 1994b). Neither gender nor racial/ethnic group appears to be associated with dMAC (Benson 1994b). It should be noted that assessment of risk has largely been done prior to the availability of effective ART, and most risk factors were evaluated in individuals not receiving effective ART.

Pathogenesis

MAC is made up of two closely related organisms, *M. avium* and *M. intracellulare*, which can be distinguished by polymerase chain reaction (PCR) and other molecular testing. *M. avium* complex bacilli are acid-fast, slowly growing bacteria that are comprised of 28 serogroups, with serogroups 4 and 8 most frequently isolated from HIV-infected persons. *M. avium* appears to be a more important pathogen in disseminated disease, while *M. intracellulare* is a more important pathogen in causing respiratory disease (Guthertz et al. 1989; Han et al. 2005). There is no difference in treatment of these two organisms, so they are not routinely differentiated at diagnosis. MAC isolates from individuals with advanced HIV differ from both isolates in individuals without HIV and isolates from environmental sources, and have been shown to be more virulent in vitro and in animal models (Horsburgh 1991).

Person-to-person transmission of MAC does not appear likely, and those living in the same household or close contacts of those with MAC disease do not appear to be at increased risk for infection (Horsburgh 1999). The primary mode of transmission is via inhalation,

ingestion, or inoculation with bacilli via the respiratory or GI tract, with the GI tract being the most common portal of entry (Corti and Palmero 2008). In individuals with intact immune systems, asymptomatic colonization of the respiratory or GI tract can occur without further dissemination.

In individuals with advanced HIV, after MAC exposure and mucosal entry, transient MAC bacteremia occurs, followed by tissue invasion and colonization. Bacteria are taken up by polymorphonuclear leukocytes (PMNs), mononuclear phagocytes, fibroblasts, and endothelial cells and disseminated primarily to reticuloendothelial organs such as the liver, spleen, and bone marrow (Karakousis et al. 2004). In the absence of an effective immune response, persistent bacteremia occurs with ongoing mycobacterial replication and increasing tissue infiltration (Corti and Palmero 2008).

Disseminated MAC may be secondary to primary infection and subsequent dissemination in an immunocompromised host, or secondary to reactivation of MAC acquired previously, followed by dissemination (Gordin and Masur 1994). Cell-mediated immunity is probably the most important factor in immunological control of MAC and protection from infection. In a prospective study of individuals with HIV and CD4 cell counts less than 50 cells/mm³, the risk of developing MAC bacteremia within 1 year was 60% in those colonized with MAC in the respiratory or GI tract, with a greater risk in those with colonization of the GI tract (Corti and Palmero 2008).

Clinical Manifestations

In individuals not infected with HIV, MAC is most commonly a localized infection of the respiratory tract and causes pneumonia in individuals with chronic lung disease from etiologies such as chronic obstructive pulmonary disorders (COPD) and silicosis. In individuals infected with HIV who are not on effective ART, disseminated disease is most common, although localized disease of the pulmonary system can occur, presenting as pulmonary nodules, infiltrates, or cavities. Localized MAC can also present as isolated pericarditis,

intra-abdominal or soft tissue abscesses, skin lesions, osteomyelitis, or central nervous system (CNS) lesions (Benson 1994b). MAC can also present as a syndrome resembling Whipple's disease with localized involvement of the small intestine, although this is likely a localized manifestation of disseminated disease (Corti and Palmero 2008). Thus, in HIV-infected individuals not receiving effective ART, MAC is classically a disseminated disease that involves multiple organ systems.

Clinical symptoms generally precede bacteremia by a number of weeks and are nonspecific but include fever, night sweats, weight loss, fatigue, abdominal pain, and diarrhea (Horsburgh 1991; Corti and Palmero 2008; Benson 1994b). All of these symptoms are nonspecific and can occur with other opportunistic infections or advanced HIV disease. Approximately 40% of individuals with HIV and MAC have diarrhea and 20% intractable abdominal pain, which although nonspecific may point toward a diagnosis of dMAC (Corti and Palmero 2008). Other signs of dMAC on physical exam include lymphadenopathy and hepatosplenomegaly. Significant anemia, neutropenia from bone marrow infiltration, elevated alkaline phosphatase levels, and increased lactate dehydrogenase (LDH) levels offer evidence of dMAC infection on laboratory analysis (Corti and Palmero 2008; Benson 1994b).

Distinguishing dMAC infection from other opportunistic infections, particularly *Mycobacterium tuberculosis* (MTB) infection, can be challenging. Although MAC is ubiquitous in the environment, there is an inverse geographical relationship between MTB prevalence and MAC prevalence (Corti and Palmero 2008), which may aid in differentiating these two pathogens. In addition, night sweats, significant peripheral lymphadenopathy, and lung involvement are more common signs and symptoms of disseminated MTB infection, while leukopenia, elevated alkaline phosphatase levels, and hepatosplenomegaly are more common in dMAC (Corti and Palmero 2008).

In individuals with HIV on ART with good immunological and virological response to therapy, the most common presentation of dMAC

infection is “unmasking” immune reconstitution inflammatory syndrome (IRIS) from a previously undiagnosed infection. Previously diagnosed or treated dMAC can also worsen after ART initiation, termed “paradoxical” IRIS. IRIS secondary to underlying MAC disease is clinically indistinguishable from active MAC disease, although the temporal association of signs and symptoms compatible with dMAC after the introduction of ART points toward a diagnosis of MAC IRIS (Corti and Palmero 2008). IRIS from underlying MAC disease may be relatively benign and self-limiting, or may result in severe symptoms necessitating treatment with anti-inflammatory therapy or corticosteroids at doses similar to the treatment of IRIS secondary to MTB (Phillips et al. 2005). IRIS associated with MAC typically presents with localized lymphadenitis or soft tissue abscess, so any abscess associated with IRIS should prompt consideration for underlying MAC infection. Treatment of both “unmasking” and “paradoxical” IRIS should include continuation of ART, treatment of underlying MAC infection, and if needed symptomatic treatment with anti-inflammatory therapy or corticosteroids (Corti and Palmero 2008).

Diagnosis

The clinical presentation of dMAC infection can closely resemble disseminated MTB infection, so careful consideration and workup for disseminated MTB is critical, as the treatment of MAC and MTB differ considerably.

Diagnosis of dMAC infection is based on consistent clinical signs and symptoms, along with isolation of MAC from blood, lymph node aspirate, bone marrow aspirate, or cultures from other normally sterile sites (Benson 1994a). Within 14 days of the onset of symptoms, MAC bacteremia occurs in 86–98% of individuals with dMAC (Corti and Palmero 2008), so isolation of MAC from blood cultures is typically the easiest and least invasive way to diagnosis dMAC. Patients with dMAC often have continuous, high-grade bacteremia with high colony counts, making one or two blood cultures usually adequate for diagnosis (Woods 1994).

Hepatomegaly, splenomegaly, paratracheal, retroperitoneal, para-aortic, or peripheral lymphadenopathy may be found with dMAC disease and is often easily visualized by computed tomography (CT) scan. In cases of negative blood cultures or when further workup of lymphadenopathy is warranted, enlarged lymph nodes are potential sites for biopsy. Except for peripheral blood culture, all specimens obtained should be prepared for acid-fast bacilli (AFB) smear prior to submission for mycobacterial culture (Woods 1994). Since the GI tract is the most frequent anatomical site involved, duodenal or mucosal biopsies can be diagnostic as well, with white mucosal lesions visualized in the duodenum in about 80% of individuals with GI involvement on endoscopy (Corti and Palmero 2008). MAC can also be found on liver biopsy with disseminated disease. In one retrospective study, 501 HIV-infected individuals with either abnormal liver function tests, fever greater than 2 weeks, or hepatomegaly underwent percutaneous liver biopsy. The most common diagnosis on biopsy was MAC, seen in over 17% of biopsies (Poles et al. 1996).

Isolation of MAC by conventional mycobacterial culture on solid medium generally takes 3–4 weeks, but can be decreased to 5–12 days with culture on liquid media, such as with the radiometric BACTEC TB system. It is generally recommended that specimens be sent for culture on both liquid and solid media. Solid media allow for visualization of colony morphology, growth rates, and quantification, while liquid media allow for a higher mycobacterial yield and quicker diagnosis. In addition, commercial DNA probes are now available for confirmation of MAC within hours.

Since MAC often colonizes the respiratory and GI tract, sputum and stool cultures can represent colonization rather than true infection; positive cultures may be difficult to interpret. While colonization with MAC can be predictive of future dMAC infection, routine screening with GI or respiratory tract cultures is not recommended as there is a lack of data supporting prophylaxis for asymptomatic patients harboring MAC at these sites.

Prevention of MAC Infection

Because individuals who are profoundly immunosuppressed are at significantly increased risk for developing dMAC infection, primary prophylaxis is indicated in adults and adolescents infected with HIV who have a CD4 cell count less than 50 cells/mm³. Before initiating primary prophylaxis for MAC disease, both dMAC and MTB infection should be ruled out. In some settings routine primary prophylaxis is not initiated if ART is started immediately, even in cases where the CD4 cell count is less than 50 cells/mm³, as the risk of dMAC is thought to be minimal in patients with rapid immune reconstitution to ART (Lange et al. 2004). There is currently no evidence to support this strategy and the recommendation is still to initiate primary prophylaxis if indicated based on CD4 cell count.

Rifabutin, a rifamycin that has activity both in vitro and in animal models against MAC and MTB, was among the first antimycobacterial agents to be evaluated in individuals with HIV/AIDS. Two randomized, double-blind, placebo-controlled trials of rifabutin 300 mg daily versus placebo for prevention of dMAC disease in persons with HIV demonstrated decreased incidence of MAC in the rifabutin arms, although there was no significant difference in survival compared to placebo (Nightingale et al. 1993). However, potential drug interactions, high cost, limited availability, potential for development of cross-resistance in individuals coinfecting with MTB, and requirement for daily dosing prompted the investigation of other alternatives to rifabutin, including macrolide and azalide antibiotics also shown to have in vitro and in vivo activity against MAC.

A randomized, double-blind trial compared azithromycin 1200 mg weekly, rifabutin 300 mg daily, and azithromycin 1200 mg weekly plus rifabutin 300 mg daily. After 1 year of follow-up the risk of MAC was reduced in the azithromycin arm by almost 50% (MAC incidence rate of 15.3% in the rifabutin arm compared to 7.6% in the azithromycin arm). The azithromycin plus rifabutin combination arm had the greatest efficacy in preventing MAC with a MAC rate of 2.8% at 1 year of follow-up, but dose-limiting toxicity

was significantly more common in the combination arm (Havlir et al. 1996).

Another randomized, double-blind, placebo-controlled trial compared clarithromycin 500 mg twice daily, rifabutin 450 mg daily, and clarithromycin 500 mg twice daily plus rifabutin 450 mg daily. After a median follow-up of almost 2 years, 9% of individuals developed MAC in the clarithromycin arm versus 15% in the rifabutin arm and 7% in the combination therapy arm. While there was an increased risk of developing MAC in the rifabutin arm, there was no significant difference in MAC incidence between the clarithromycin and combination clarithromycin and rifabutin arms (Benson et al. 2000).

Thus, the preferred prophylactic regimen includes either azithromycin 1200 mg weekly or clarithromycin 500 mg twice daily (or 1000 mg extended-release tablets) in patients with a CD4 cell count less than 50 cells/mm³ (Table 1). Azithromycin has the advantage of weekly dosing rather than daily dosing and fewer drug-drug interactions than clarithromycin and rifabutin. In patients who cannot tolerate either azithromycin or clarithromycin, rifabutin 300 mg daily is the recommended alternative. Clarithromycin is associated with an increased risk of birth defects in animal studies and miscarriage in humans (Anderson et al. 2013), so azithromycin

is recommended for primary prophylaxis in pregnant women.

MAC prophylaxis can be safely discontinued for patients on effective ART once they have achieved viral load suppression and immune reconstitution. A randomized, double-blind, placebo-controlled trial of 520 individuals found no cases of MAC in either the placebo arm or the azithromycin 1200 mg weekly arm after 12 months in individuals who had an increase in CD4 cell count to above 100 cells/mm³ for greater than 3 months on ART (El-Sadr et al. 2000). A similar randomized, placebo-controlled trial of azithromycin 1200 mg weekly versus placebo found that after 16 months of follow-up, there were only 2 cases of dMAC out of 321 in the placebo group versus 0 cases out of 322 in the continued azithromycin group, with no statistically significant difference between the two groups (Currier et al. 2000). Thus, it appears safe to discontinue MAC prophylaxis once the CD4 cell count has increased above 100 cells/mm³ for greater than 3 months. Primary prophylaxis should be reintroduced if the CD4 cell count decreases to less than 50 cells/mm³.

M. avium Complex and Other Nontuberculous Mycobacteria and HIV, Table 1

Recommendations for primary and secondary prophylaxis of disseminated MAC disease in HIV infection

<p><i>Indications for initiating primary prophylaxis:</i> If the CD4 cell count is <50 cells/mm³, after ruling out disseminated MAC and <i>Mycobacterium tuberculosis</i> infection</p>	<p><i>Preferred therapy:</i> Azithromycin 1200 mg PO once weekly, <i>or</i> Clarithromycin 500 mg PO BID</p> <p><i>Alternative therapy:</i> Rifabutin 300 mg PO daily</p> <p><i>In pregnancy:</i> Azithromycin 1200 mg PO once weekly</p>
<p><i>Indications for discontinuing primary prophylaxis:</i> If on effective ART, once the CD4 cell count is >100 cells/mm³ for greater than 3 months</p>	
<p><i>Indications for restarting primary prophylaxis:</i> If the CD4 cell count decreases to <50 cells/mm³</p>	

Treatment of MAC Infection

Given the risk for the development of resistance and subsequent relapse with monotherapy, initial treatment of MAC disease should consist of two or more antimicrobial drugs. It is recommended that MAC isolates be tested for clarithromycin or azithromycin susceptibility in all patients (Griffith et al. 2007).

In a randomized, double-blind study investigating clarithromycin for treatment of MAC bacteremia in HIV-infected individuals, clarithromycin 500 mg twice daily had equivalent efficacy toward clearance of bacteremia and decreased mortality rates at 6 weeks compared to higher clarithromycin doses (1000 mg and 2000 mg twice daily). The lower-dose clarithromycin arm was also better tolerated; there was a statistically significant increase in adverse effects with the 2000 mg twice daily dose. Emergence of clarithromycin-resistant strains was a significant problem with all doses and occurred in 46% of subjects at 16 weeks (Chaisson et al. 1994).

In another randomized, open-labeled trial, individuals with dMAC were randomized to receive either clarithromycin 500 mg twice daily or 1000 mg twice daily plus weight-based ethambutol, plus either rifabutin 300 mg daily or clofazimine 100 mg daily. After a mean follow-up of 4.5 months, 22% of patients receiving low-dose clarithromycin died compared to 43% of those receiving high-dose clarithromycin, leading to the discontinuation of the high-dose clarithromycin arms. There were no differences in clinical or bacterial outcomes between the remaining arms. Thus, clarithromycin doses greater than 1000 mg/day should be avoided due to increased mortality risk (Cohn et al. 1999).

In a small randomized, open-labeled trial comparing azithromycin 600 mg daily plus weight-based ethambutol and clarithromycin 500 mg twice daily plus weight-based ethambutol for the treatment of MAC bacteremia, at 16 weeks the clarithromycin-ethambutol regimen cleared bacteremia in 86% of patients versus 38% of patients in the azithromycin-ethambutol arm. There was no statistically significant difference in resolution of symptoms, laboratory abnormalities, or adverse events between the two regimens (Ward et al. 1998).

Another randomized, double-blind study investigated the treatment of MAC bacteremia in HIV-infected individuals with weight-based ethambutol plus either azithromycin 250 mg daily, azithromycin 600 mg daily plus, or clarithromycin 500 mg twice daily. After 24 weeks of therapy there was no significant difference in clearance of bacteremia, relapse, or mortality rates between the high-dose azithromycin arm and the clarithromycin arm, although the trend favored clarithromycin. The low-dose azithromycin arm had poor clearance of bacteremia and was dropped midway through the study (Dunne et al. 2000).

Lastly, in a multicenter, randomized, open-label trial of patients with AIDS and MAC bacteremia, individuals were randomized to either clarithromycin 500 mg twice daily plus ethambutol 15 mg/kg/day, clarithromycin 500 mg twice daily plus rifabutin 450 mg daily, or clarithromycin 500 mg twice daily plus

ethambutol 15 mg/kg/day plus rifabutin 450 mg daily. After 12 weeks of follow-up there was no significant difference in microbiological response between the three arms, although there was a higher relapse rate in the clarithromycin plus rifabutin arm compared to the other two arms. There was improved survival and a lower relapse rate in the three-drug arm, and no significant difference in adverse events among the three arms (Benson et al. 2003).

Based on the aggregate of these data, the treatment recommendation for dMAC is either clarithromycin 500 mg twice daily plus ethambutol 15 mg/kg day, or azithromycin 500 mg daily plus ethambutol 15 mg/kg daily (Table 2). Rifabutin 300–450 mg daily is the recommended agent if a third drug is to be added. The addition of a third or fourth agent should be considered in patients with advanced immunosuppression (CD4 cell count less than 50 cells/mm³), high mycobacterial loads (>2 log₁₀ colony-forming units/mL of blood), absence of effective ART, or where emergence of drug resistance is likely. Other alternative agents including amikacin, streptomycin, or a

***M. avium* Complex and Other Nontuberculous Mycobacteria and HIV, Table 2** Recommendations for the treatment of disseminated MAC disease in HIV infection

Testing for drug susceptibility to clarithromycin or azithromycin is recommended Standard therapy should include at least two drugs, with consideration for a third or fourth agent with: Advanced immunosuppression (CD4 count <50 cells/mm ³) High mycobacterial loads (>2 log ₁₀ colony-forming units/mL of blood) Absence of effective ART If the emergence of drug resistance is likely	<i>Preferred therapy:</i> Clarithromycin 500 mg PO BID <i>plus</i> ethambutol 15 mg/kg PO daily, <i>or</i> Azithromycin 500 mg PO daily <i>plus</i> ethambutol 15 mg/kg PO daily <i>Recommended third agent:</i> Rifabutin 300–450 mg PO daily
<i>Other agents:</i> Use should be based on drug susceptibility testing	Amikacin, streptomycin, levofloxacin, or moxifloxacin

fluoroquinolone such as levofloxacin or moxifloxacin may be considered, although randomized clinical trials evaluating these agents are lacking. To minimize the occurrence of drug reactions and treatment-associated IRIS, in most cases ART and antimycobacterial therapy should not be initiated concurrently. ART should be initiated as soon as possible following the first 2 weeks of dMAC treatment to reduce the occurrence of other opportunistic infections.

For clarithromycin-resistant MAC, the recommendation is to treat with a fluoroquinolone such as moxifloxacin or levofloxacin plus ethambutol plus rifabutin. Multiple studies looking at clofazimine have not demonstrated improved microbiological response and its use has been associated with increased mortality, so it is not recommended in the treatment of MAC infection (Karakousis et al. 2004). Treatment with azithromycin and ethambutol is the preferred regimen for pregnant women, given the association of birth defects in mice and rats with clarithromycin (Corti and Palmero 2008).

An improvement in fever curve should be expected within 2 to 4 weeks after starting treatment, although in very extensive disease or advanced immunosuppression clinical response may be delayed. Repeat blood cultures for MAC should be obtained 4–8 weeks after initiating therapy in patients who fail to have an adequate clinical response to treatment. It is reasonable to discontinue therapy after individuals have completed at least 12 months of therapy, have no signs or symptoms of MAC, and have sustained a CD4 cell count greater than 100 cells/mm³ for 6 months after ART initiation (Aberg et al. 2003).

If individuals have a poor clinical response and persistent mycobacteremia after 4–8 weeks of treatment, repeating susceptibility testing for azithromycin and clarithromycin is recommended. Treatment regimens should be based on repeat susceptibility testing, and should consist of antimicrobials from at least two new drug categories not previously used. Whether or not continuing clarithromycin or azithromycin despite proven resistance is of additional benefit is unknown.

Other Nontuberculous Mycobacteria (NTM) and HIV

Mycobacterium kansasii

M. kansasii is the second most common cause of nontuberculous mycobacterial disease in the United States, and after MAC, the second most common cause in individuals with advanced HIV. Like MAC, it is primarily an environmental pathogen and tap water is likely its primary reservoir (Griffith et al. 2007).

M. kansasii is a slow-growing NTM that causes pulmonary disease in geographic clusters around the world, including the south and central United States. Risk factors for pulmonary disease include underlying chronic lung disease, malignancy, and alcoholism. In individuals with advanced HIV, *M. kansasii* can present as disseminated disease, typically in individuals with a CD4 cell count less than 50 cells/mm³. Unlike with dMAC infection, pulmonary disease is also seen in over 50% of individuals with disseminated disease, and bacteremia is uncommon, found in only 25% of individuals (Griffith et al. 2007). *M. kansasii* is typically considered one of the most pathogenic NTM, and represents true infection in 50% of patients with positive respiratory cultures (Marras and Daley 2004).

Treatment for pulmonary and disseminated disease should involve three agents, including rifampin 10 mg/kg/day, ethambutol 15 mg/kg/day, and isoniazid 5 mg/kg/day (maximum 300 mg daily), along with pyridoxine 50 mg daily. In patients with rifampin-resistant disease, a three-drug regimen is recommended based on drug susceptibility testing, but should include a macrolide (clarithromycin or azithromycin), moxifloxacin, ethambutol, sulfamethoxazole, or streptomycin. In pulmonary disease, treatment duration should entail 12 months of therapy after conversion of sputum cultures to negative. The treatment duration for disseminated *M. kansasii* disease is similar to that of disseminated MAC and includes at least 12 months of therapy if signs or symptoms have resolved and sustained immune reconstitution has occurred on ART (Griffith et al. 2007).

Mycobacterium chelonae

M. chelonae is a rapidly growing environmental mycobacterium that can cause isolated skin, soft tissue, and bone infections, and has been implicated as a cause of keratitis in contact lens wearers and those that have undergone ocular surgery. It can also present as disseminated disease in individuals with advanced HIV (Kunin et al. 2014).

An open-labeled, single-arm study of 14 patients with *M. chelonae* infection investigated monotherapy with clarithromycin 500 mg twice daily. Ten patients had disseminated disease, and eleven patients completed at least 6 months of therapy. Clarithromycin was subsequently discontinued in 9 of the 14, with no evidence of relapse. Two other patients died of causes unrelated to infection and one self-discontinued therapy after 3.5 months with subsequent relapse (Wallace et al. 1993).

For significant skin, soft tissue, bone, or pulmonary disease, combination therapy with clarithromycin plus another agent is recommended to minimize selection for clarithromycin-resistant organisms. Antimicrobial choice should be guided by drug susceptibility testing. At least 4 months of treatment is recommended for skin and soft tissue infections, 6 months for bone infection, and 12 months from sputum culture conversion for pulmonary infection. Surgery may be indicated as an adjunct for skin, soft tissue, or bone infection if disease is extensive or when antimicrobials alone fail; removal of involved foreign bodies or prosthetic devices is crucial for cure (Griffith et al. 2007).

Mycobacterium genavense

M. genavense is a slow-growing NTM that causes both localized and disseminated disease in HIV-infected individuals (Bottger et al. 1992). It has been isolated from the cervical lymph node of a dog as well as a number of pet birds, including psittacine birds (Kiehn et al. 1996). Disseminated disease has been noted in individuals with advanced HIV, and *M. genavense* has been recovered from multiple reticuloendothelial sites including blood, bone marrow, liver, and spleen. *M. genavense* is likely acquired through ingestion

and appears to have a predilection for colonizing the GI tract (Doggett and Strasfield 2011).

Optimal treatment of *M. genavense* infections is unknown, but multidrug regimens that include clarithromycin are recommended. Most isolates are susceptible to amikacin, rifamycins, fluoroquinolones, macrolides, and streptomycin. Ethambutol has poor activity against *M. genavense* (Griffith et al. 2007). Studies evaluating outcomes of therapy in HIV-infected individuals are limited.

Mycobacterium gordonae

M. gordonae is a slow-growing, environmental NTM that is ubiquitous in the environment and frequently recovered from freshwater sources, soil, and tap water, including water from hospitals. When found in cultures it is typically considered a nonpathogenic contaminant, as it can easily be introduced into clinical specimens during collection and processing (Weinberger et al. 1992) and can colonize the GI and respiratory tract (Mizoshita et al. 2011). All of these factors may make it difficult to differentiate as a contaminant or true pathogen.

Occasionally *M. gordonae* has been associated with clinically significant infections and has been associated with disseminated disease, pulmonary infection, keratitis, peritonitis, and skin and soft tissue infections, as well as in individuals with underlying immunosuppression such as advanced HIV. Infections have also been associated with foreign bodies, which may even have been the portal for infection (Weinberger et al. 1992).

There is a paucity of data available on optimal treatment regimens. Ethambutol, rifabutin, clarithromycin, linezolid, and the fluoroquinolones most consistently have in vitro activity against *M. gordonae* (Griffith et al. 2007).

Conclusion

Disseminated *Mycobacterium avium* complex (dMAC) infection is primarily a complication of advanced HIV infection in the absence of effective ART. More common prior to the advent and widespread use of potent combination ART, the

incidence of dMAC has declined considerably over the past two decades, although individuals with very low CD4 cell counts still remain at risk.

MAC is ubiquitous in the environment, and a CD4 cell count less than 50 cells/mm³ is the most significant risk factor for disseminated infection. Prophylaxis with azithromycin or clarithromycin is recommended in persons with a CD4 cell count less than 50 cells/mm³ and should be continued until the CD4 cell count is maintained above 100 cells/mm³ for greater than 3 months. Optimum treatment for dMAC includes treatment with at least two agents including clarithromycin or azithromycin plus ethambutol, with the addition of rifabutin as a third agent for those with more extensive disease. Although the incidence of dMAC has declined significantly with the widespread use of effective ART, it still remains an important complication of advanced HIV infection.

Environmental mycobacteria other than *M. tuberculosis* and *M. avium* complex can cause infection in humans. For many of these NTM, chronic pulmonary disease is a risk factor for infection of the respiratory system, although immunodeficiency from advanced HIV infection is a risk factor for a number of NTM as well. Treatment differs based on the pathogen and in some cases has not been well elucidated or studied, making accurate diagnosis crucial and treatment challenging.

Macrophages in HIV Immunopathogenesis

Awatef Allouch¹ and Gianfranco Pancino²
¹INSERM U1030 – LabEx LERMIT, Institut Gustave Roussy, Villejuif, France
²Institut Pasteur and INSERM, Paris, France

Definition

Blood monocytes and tissue macrophages are professional phagocytic cells that play important roles in tissue homeostasis and the innate defense against microbial infections. Along with CD4⁺ T cells, monocytes and macrophages are a major target for HIV-1 infection. These cells play crucial roles in viral transmission and spread to body tissues, in the persistence of HIV-1 infection, and in HIV-1 immunopathogenesis and neuropathogenesis.

Monocyte and Macrophages: Origin, Heterogeneity, and Functions

Monocytes (Mos) and macrophages (Mφs) are myeloid cells that belong to the mononuclear phagocytic system (Murray and Wynn (2011) and references herein). Monocytes are generated in the bone marrow from hematopoietic stem cell precursors. It is generally believed that tissue Mφs originate from circulating monocytes that mature and differentiate after being recruited into tissues. However, recent studies in mice, supported by studies of patients affected by congenital monocytopenia, have challenged this paradigm. Indeed, tissue-resident Mφs have been shown to renew locally during adult life, thus suggesting that resident Mφs do not derive from blood monocytes, at least in some tissues, but can self-maintain and repopulate locally. Mos/Mφs are professional phagocytic cells that play crucial roles both in tissue homeostasis and in innate defenses against bacterial, viral, and parasitic infections. Mos/Mφs are extremely sensitive to any stress, malfunction, or danger signals due to the expression of numerous receptors on their surfaces, including toll-like receptors (TLR), scavenger receptors, and receptors for the Fc segment of immunoglobulins (FcR).

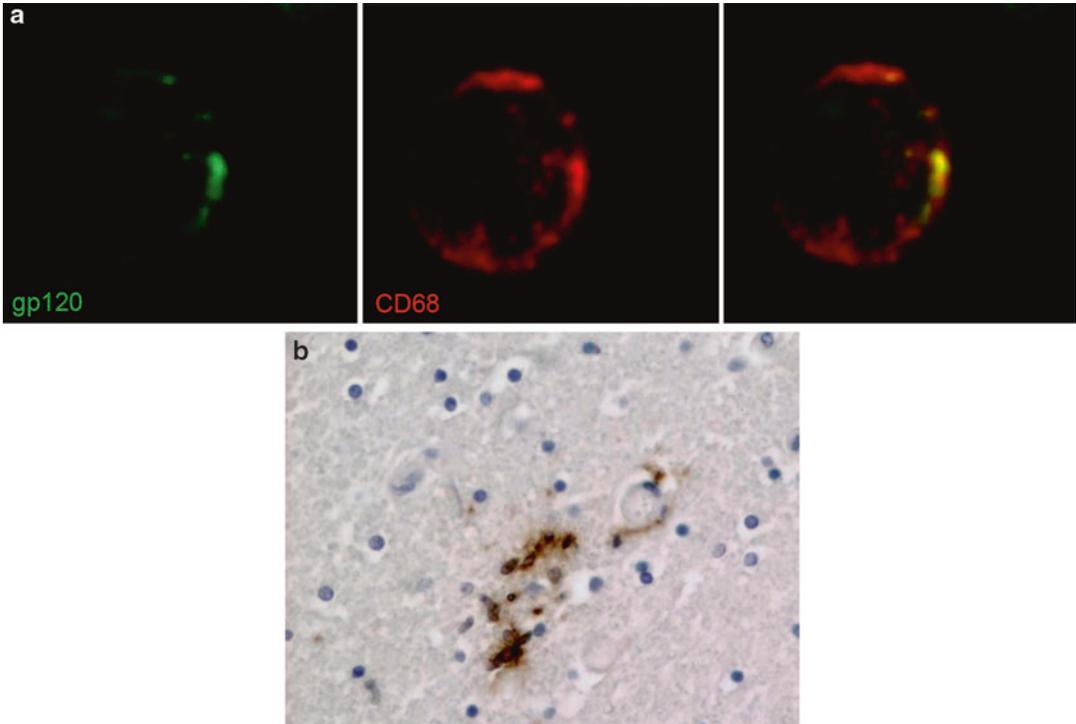

Mos circulate in the blood for several days and can extravasate into tissues, where they differentiate into Mφs in situations of inflammation and tissue injury. Three subsets of blood Mos can be distinguished phenotypically based on the differential expression of two surface molecules: the coreceptor to bacterial lipopolysaccharides (LPS) CD14 and the FcR for IgG₃ (FcγIII_R) CD16. Classical monocytes are CD14⁺⁺CD16⁻, intermediate monocytes are CD14⁺⁺CD16⁺, and nonclassical monocytes are CD14⁺CD16⁺⁺ (Ziegler-Heitbrock et al. 2010). In particular, nonclassical CD14⁺CD16⁺⁺ monocytes patrol blood vessels and respond to viral infections by producing proinflammatory cytokines such as TNFα and IL-1 via the activation of TLR7 and TLR8 (Cros et al. 2010).

Mφs are highly plastic cells that can acquire distinct phenotypes and functions based on the neighboring microenvironment. Tissue-resident Mφs, such as Kupffer cells in the liver, microglia in the brain, and alveolar Mφs in the lung,

differentiate and exert specialized functions according to their tissue localization. Infiltrating Mφs are derived from inflammatory Mos that extravasate to sites of inflammation or infection, and their accumulation in tissues is associated with the increased turnover of circulating monocytes. Mφs contribute to the first line of defense against pathogens either by phagocytizing and degrading them or by secreting chemokines and cytokines. These soluble molecules either exert direct antimicrobial effects or serve to recruit and activate other innate and adaptive immune cells. Based on their phenotype and effector functions, by analogy with the T helper type 1 and T helper type 2 (T_H1-T_H2) polarization, Mφs have been further classified as classically activated Mφs (M1 Mφs), which exhibit microbicidal properties and secrete proinflammatory cytokines and alternatively activated Mφs (M2 Mφs), which play a crucial role in resolving inflammation.

General Considerations for Monocytes and Macrophages in HIV Infection

Mos and Mφs are, along with CD4⁺ T cells, major cell targets for HIV-1 infection. Unlike T cells, Mos/Mφs are relatively resistant to the cytopathic effects of HIV-1 infection and can survive for long periods of time following infection. Although Mos isolated from the blood do not support productive HIV infection *in vitro*, due to the blocking of early steps in the viral replication cycle before the integration of proviral DNA, Mos-bearing HIV-1 DNA and RNA have been detected in the blood of HIV-1-infected patients, and HIV-1 variants distinct from those present in CD4⁺ T lymphocytes have been found in circulating Mos (Bergamaschi and Pancino (2010) and references herein). In addition, HIV-1 transcripts and signatures of viral evolution in viral genome sequences have been described in monocytes of patients undergoing effective combined antiretroviral therapy (cART). Monocytes harboring HIV-1 proteins can be detected in peripheral blood mononuclear cells (PBMC) (Fig. 1a). Altogether, these data indicate that infected Mos in HIV-1-infected patients can participate in viral dissemination into tissues.

Macrophages in HIV Immunopathogenesis, Fig. 1 HIV-1 infected monocytes and macrophages from HIV-1 infected patients. (a) Confocal microscopy immunolocalization of the HIV-1 protein gp120 (green) and the macrophages marker CD68 (red) in PBMC from HIV-1-infected patient. Original magnification: 63 \times .

(b) Immunohistochemical analysis of HIV-1 p24 protein expression (brown precipitate) on frontal cortex sections from patient with HIV-1-related encephalitis. Original magnification: 20 \times (Images kindly provided by Dr. Roberta Nardacci, National Institute for Infectious Diseases, IRCCS “L. Spallanzani.” Rome, Italy)

In particular, the magnitude of the nonclassical CD14⁺CD16⁺⁺ Mo subset, which comprises less than 10% of blood Mos in healthy individuals, is increased with HIV infection and can expand to 40% of Mos in AIDS patients (Thieblemont et al. 1995). CD14⁺CD16⁺⁺ Mos express higher levels of the HIV-1 coreceptor C-C chemokine receptor type 5 (CCR5) than other Mo subsets and have been reported to be more prone to HIV infection.

In contrast to Mos, M ϕ s are permissive to HIV-1 infection *in vitro*. For *in vitro* studies, M ϕ s are differentiated from blood monocytes by culturing for 6–7 days in the presence of macrophage colony-stimulating factor (M-CSF) or human serum. Monocyte-derived macrophages (MDMs) have been a valuable model for studies of the HIV-1 replication cycle and interactions between viral determinants and cellular factors. However, MDMs are not representative of the

heterogeneity of M ϕ s in body compartments. Unfortunately, *in vivo* studies in humans have been dampened by the fact that tissue M ϕ s are difficult to isolate from solid organs. However, immunohistochemistry and *in situ* hybridization studies have provided evidence for the infection of resident M ϕ s in different organs, including the brain, lymph nodes, liver, and lungs of HIV-1 patients (Fig. 1b) (Koenig et al. 1986). Valuable information regarding Mo and M ϕ infection *in vivo* and their role in pathogenesis has been obtained from nonhuman primate (NHP) models. Infection of Asian macaques with pathogenic SIVmac results in a disease similar to HIV-1 infection in humans. Together with macaque infections by SHIVs, which are chimeric SIV viruses bearing HIV envelope (Env) glycoproteins, this model recapitulates key features of human HIV infection. In particular, SIV-NHP

infection has been the best model for AIDS and neuroAIDS.

The following sections will address specific aspects of the HIV-1 replication cycle in Mφs and the role of Mφs in virus transmission and spread and in the immunopathology of the disease.

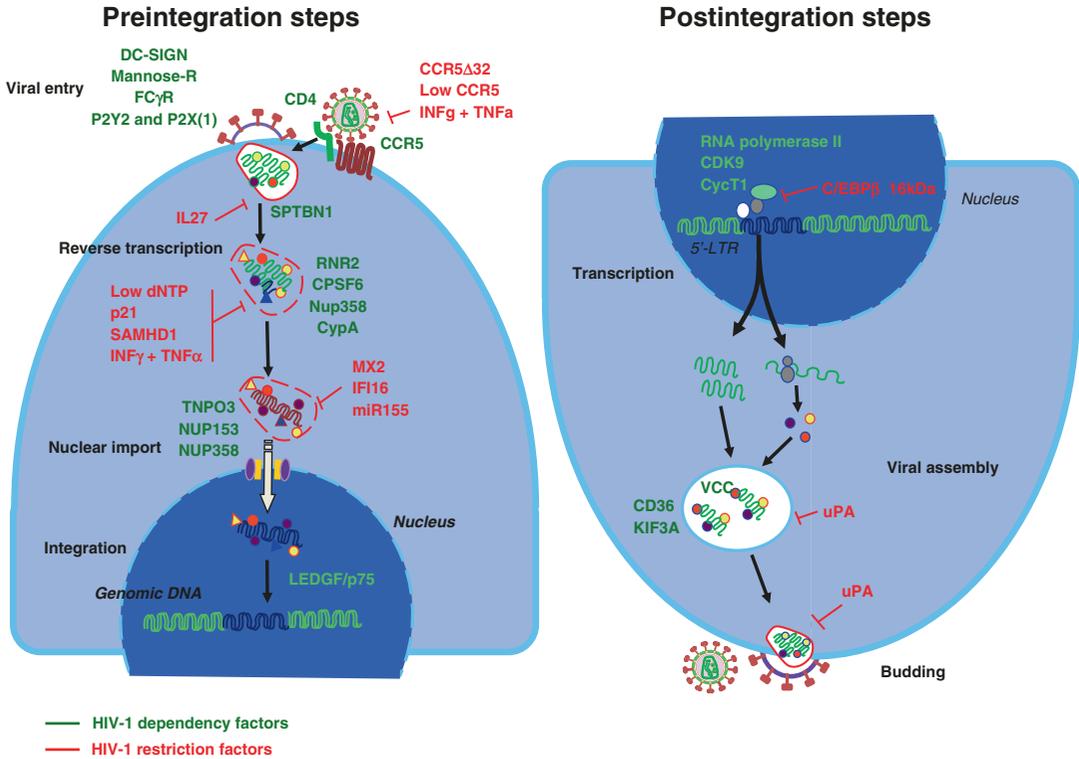

HIV Replication Cycle in Macrophages

HIV-1 tropism is determined at the level of viral entry via interactions between the gp120 envelope glycoprotein (Env) and receptors expressed on the cell surface, including the primary receptor CD4 and coreceptors that are strain and target specific (► [Tropism and Properties of the HIV-1 Envelope Glycoprotein in Transmission; CXCR4, Co-receptors](#)). R5 strains of HIV-1 use C-C chemokine receptor 5 (CCR5) as their coreceptor, whereas X4 strains of HIV-1 use CXCR4 coreceptors. R5/X4 HIV-1 isolates have dual tropisms and use both CCR5 and CXCR4 coreceptors. Macrophage-tropic (M-tropic) viruses can infect Mφs and CD4⁺ T lymphocytes and primarily use CCR5, T-cell-line-tropic (T-tropic) viruses can infect CD4⁺ T lymphocytes and T-cell lines using CXCR4, and dual-tropic viruses can infect both CD4⁺ T cells and Mφs. However, not all R5 HIV-1 strains are M-tropic, and some X4 viruses can efficiently infect Mφs, indicating that cellular tropism involves Env-coreceptor interactions that are not completely determined by coreceptor specificity. In particular, Mφs express lower CD4 levels than T lymphocytes, and it has been reported that M-tropic viruses isolated from the brain demonstrate lower CD4 dependence for entry, possibly due to higher Env affinity for CD4. In addition, gp120 Envs from some M-tropic viruses also appear to have higher affinities for the CCR5 coreceptor. Other molecules expressed on the Mo/Mφ surface, including heparan sulfate proteoglycans, mannose receptors, and FcRs, can serve as attachment receptors for HIV-1, therefore increasing virus binding to the cells and favoring interactions between viral Env, CD4, and coreceptors and consequently viral entry (Fig. 2 for a schematic

representation of HIV-1 replication cycle in Mφ and (Bergamaschi and Pancino 2010) for review).

The HIV-1 replication cycle begins with the binding of the viral envelope glycoprotein (Env) gp120 to the primary receptor CD4 and to the coreceptor CCR5 (► [HIV Life Cycle: Overview](#)). These interactions trigger conformational changes that lead to the fusion of the cellular and viral membranes and the delivery of the viral core into the cytoplasm. Recent reports have shed the light on the role of purinergic receptors in HIV-1 entry into CD4 T cells and Mφs (Paoletti et al. 2012). It has been shown that the binding of the gp120 viral envelope to the CD4 receptor leads to rapid cellular ATP release. ATP then acts on purinergic receptors, including P2Y2 and P2X (1), to induce transient plasma membrane depolarization through proline-rich kinase 2 (pyk2) activation and stimulate fusion between viral and cellular membranes. Immunohistochemical analyses of frontal brain sections containing microglial cells from HIV-infected, untreated patients and from patients with HIV-associated encephalitis showed that P2Y2 and phosphorylated pyk2 were expressed at higher levels compared to uninfected donors, supporting a role for this signaling pathway in HIV pathogenesis.

Following entry, the viral core is partially disassembled, and viral RNA is reverse-transcribed into DNA inside nucleoprotein complexes formed by viral and host cell proteins called the reverse transcription complex (RTC) and pre-integration complex (PIC). Reverse transcription, a hallmark step of retroviruses, converts the HIV-1 RNA genome into double-stranded DNA and is catalyzed by the reverse transcriptase enzyme; reverse transcription requires the availability of an intracellular pool of deoxynucleoside triphosphates (dNTP) (► [Uncoating and Nuclear Entry](#)). The reverse transcription process appears to be a limiting step in HIV-1 replication in Mφs (► [Reverse Transcriptase-Catalyzed HIV-1 DNA Synthesis](#)). Although the reverse transcriptase of lentiviruses is able to catalyze DNA synthesis, even at low dNTP concentrations, HIV-1 reverse transcription in Mφs exhibits slow kinetics compared to activated CD4⁺ T cells. This is attributed to the limited availability of dNTP in Mφs.

Macrophages in HIV Immunopathogenesis, Fig. 2 HIV-1 replication in macrophages. The virus can be captured on macrophage surface by different attachment receptors, including FcγR, mannose receptor, or DC-SIGN. The viral envelope protein (Env) of M-tropic HIV-1 binds the primary receptor CD4, undergoes a conformational change, then binds the chemokine receptors CCR5, and enters cells by fusion of the viral and cellular membranes. The viral entry is promoted by purinergic receptors (P2Y2 and P2X (1)) activation. Viral reverse transcription, which has slow kinetics due to the low dNTP intracellular levels, is affected by p21 and SAMHD1 restriction factors. Viral pre-integrative steps are also counteracted by IL27, INFγ + TNFα, MX2, IFI16, and miR155. HIV-1 capsid recruits cellular factors (CPSF6, Nup358, and CypA) to avoid activation of

immune sensors. The HIV-1 PIC then enters the nucleus of nondividing cells through the help of cellular proteins (TNPO3, Nup153, Nup358). Integrase catalyzes the insertion of the viral cDNA into the host genome. Provirus transcription to viral mRNAs, which is stimulated by the viral protein Tat and cellular factors (CycT1, CDK9, RNA polymerase II) is inhibited by C/EBPβ small isoform. The viral protein Rev transports partially spliced and unspliced genomic transcripts from the nucleus to the cytoplasm. Viral structural and enzymatic proteins are synthesized and assembled at the level of macrophage-specific compartments (VCCs) with the help of CD36 and KIF3A. Viral particles bud into VCCs where they are stored and released in the extracellular macrophage milieu through a yet unclear mechanism. Viral assembly and release can be counteracted by uPA

Indeed, the average dNTP concentration (26 nM) in MDMs is approximately 200 times lower than in PHA-activated T cells. Recent reports indicated that the anabolic and catabolic dNTP cellular pathways in MDMs are regulated by two cellular proteins, p21 and the SAM domain and HD domain, 1 (SAMHD1), respectively, leading to the inhibition of HIV-1 reverse transcription in these cells (see below). Importantly, HIV-1 is

able to replicate in primary human Mφs without stimulating the innate immune response despite reverse transcription of genomic RNA into double-stranded DNA, an activity that might be expected to trigger innate pattern recognition receptors. In an attempt to understand the mechanisms involved in this process, a recent study demonstrated that HIV-1 recruits the cellular factors CPSF6 and cyclophilins Nup358 and CypA

to cloak its replication via its capsid, permitting evasion of innate immune sensors in macrophages (Rasaiyaah et al. 2013). The authors found that capsid mutant viruses defective for the binding of CPSF6 and cyclophilins cannot replicate in MDMs because their reverse transcripts trigger innate sensors, leading to the production of type I interferons (IFN) and the induction of an antiviral state.

Lentiviruses, including HIV-1, are the only retroviruses able to infect nondividing cells such as Mφs, dendritic cells, and resting CD4⁺ T cells; this has been attributed to the ability of their cDNA to enter nuclei through an intact nuclear membrane. HIV-1 capsid is thought to be the major determinant of HIV-1 nuclear import in nonproliferating cells, interacting with several cellular proteins, including transportin 3 (TNPO3) and the nucleoporins NUP153 and NUP358 (Matreyek and Engelman 2013) (► [Role of Transportin-SR2 \(Transportin-3, TRN-SR2, TNPO3\) in HIV Replication](#)).

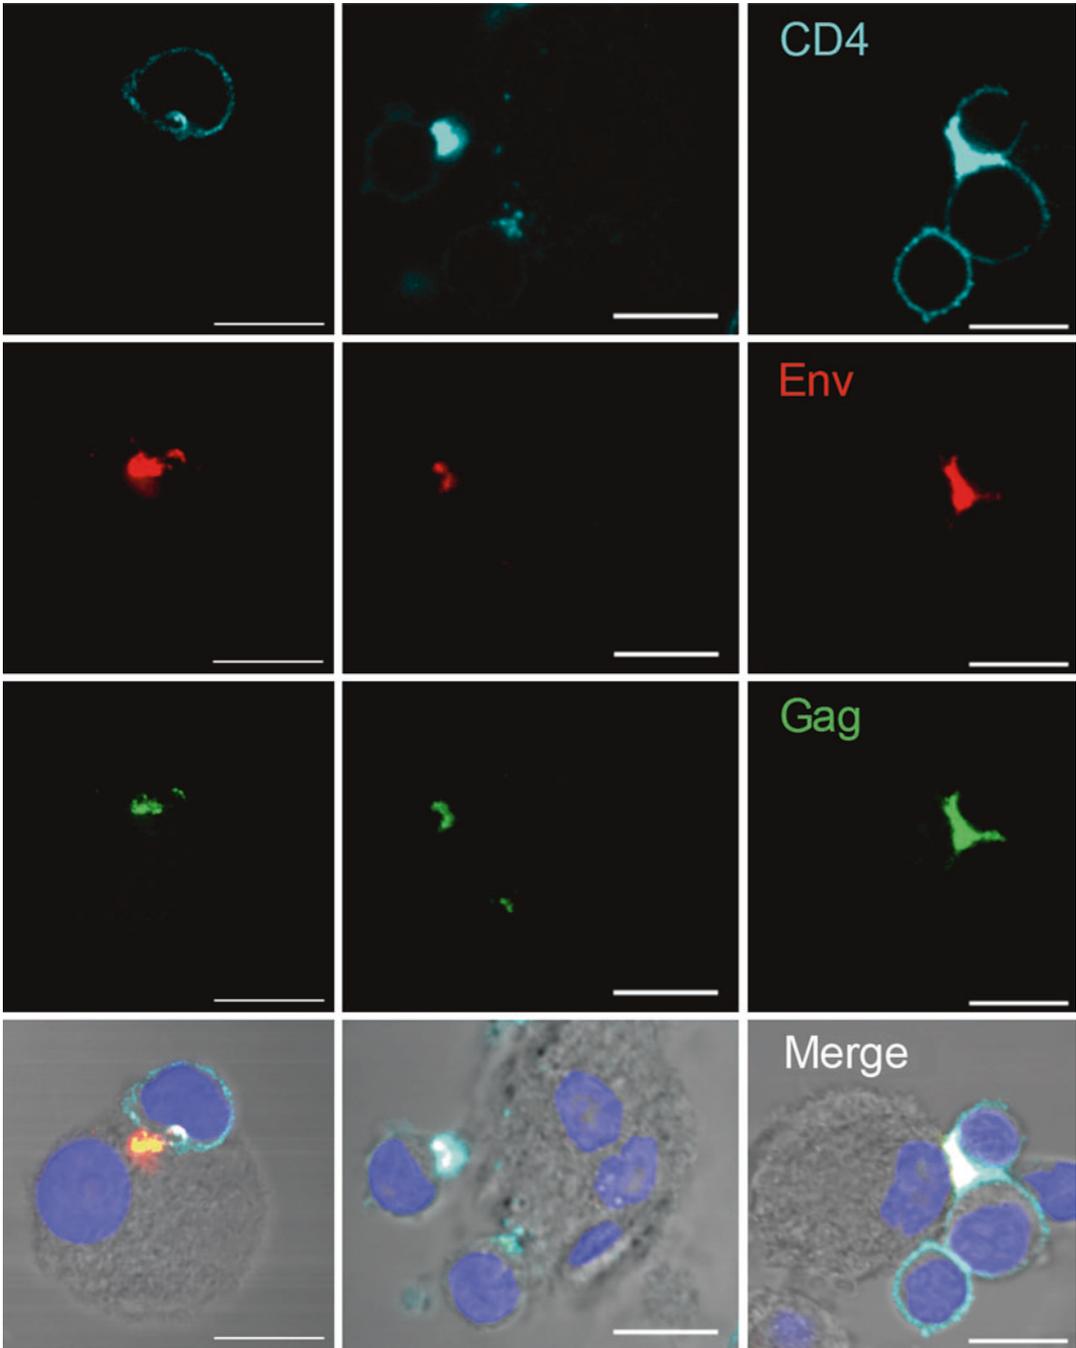

Following nuclear import of the viral PIC, HIV-1 integrase preferentially catalyzes the insertion of the linear double-stranded viral DNA into the host cell chromosome in transcribed genes, although not in close proximity to the start of transcriptional units, which is different than oncogenic retroviruses (► [Nuclear Import: HIV-1 Goes NUPs](#)).

Once integrated into the host genome, the provirus behaves like any human gene, with transcription being initiated at the 5' end and terminating at the 3' end. The 5' LTR contains enhancer and promoter sequences, with binding sites for several transcription factors (NFκB sites, C/EBP sites, SP1 sites, and a TATA cassette) (► [Integration; Transcription \(Initiation, Regulation, Elongation\)](#)). These transcription factors position RNA polymerase II at the 5' LTR to initiate transcription. The viral Tat is then indispensable for transcription elongation, recruiting the positive elongation transcription factor b (P-TEFb) complex, which contains cyclin T1 (CycT1) and a cyclin-dependent kinase 9 (CDK9) heterodimer, resulting in the phosphorylation of the carboxy-terminal domain of RNA polymerase II by CDK9 and a dramatic

stimulation of transcription elongation. In Mo, CycT1 is not expressed, and enhanced permissivity to HIV-1 infection was found to be associated with the increased expression of CycT1 during Mo differentiation into Mφs. Although CycT1 expression is later down-regulated in differentiated Mφs, its expression is enhanced by HIV-1 infection.

Synthesized viral RNAs are then exported from the nucleus to the cytoplasm for translation and packaging. The Env glycoprotein precursor, gp160, is synthesized in the endoplasmic reticulum and transported to the plasma membrane via the secretory pathway. In contrast, Gag and Gag-Pol polyprotein precursors are synthesized on free ribosomes in the cytosol and are targeted to the plasma membrane. HIV-1 assembly in CD4⁺ T cells takes place at the plasma membrane, and nascent viral particles bud off from the cell surface, facilitated by cellular endosomal sorting machinery complexes (ESCRTs), which normally function to promote the budding of vesicles into late endosomes to form multivesicular bodies (► [HIV-1 Assembly Cofactors](#)). Concomitant with virus release, the viral protease cleaves the Gag and Gag-Pol precursors into their respective protein domains, leading to virion maturation.

In contrast to T lymphocytes, where HIV-1 assembly occurs exclusively at the plasma membrane, in macrophages, newly formed virions are also assembled at the membrane of preexisting cytoplasmic compartments called virus-containing compartments (VCCs) (Tan and Sattentau 2013) and references herein) (Fig. 3) (► [Virus Assembly](#)). HIV-1 assembled virions then bud into VCCs, which may facilitate their protection from the immune response and antiviral drug treatments and contribute to the establishment of a viral reservoir in macrophages (discussed below). The VCCs appear to be macrophage-specific compartments and are clearly distinct from the endocytic pathway, as they have a neutral pH in contrast to endosomes, which are strongly acidic. VCCs share similar expression levels of the membrane marker CD44 with the plasma membrane, suggesting their cell surface origin, while endosomes have virtually no CD44. Further supporting their plasma membrane

Macrophages in HIV Immunopathogenesis, Fig. 3 HIV-1 transmission from infected MDMs to CD4⁺ T cells. Laser scanning confocal microscopy of HIV-1_{BaL}-infected MDM co-cultured for 3 hours with autologous CD4⁺ T cells preincubated for 30 min with non-blocking anti-CD4 (L120, mouse IgG₁), permeabilized, and stained for HIV-1 Gag (KC57-FITC) and Env (2G12-biotin) +/- appropriate secondary

antibodies. Nuclei were stained with Hoechst and images acquired using an Olympus FV1000 microscope with 60× oil-immersion objective lens. Scale bars represent 10 μm (Images kindly provided by Dr. Christopher Duncan at the Sir William Dunn School of Pathology, The University of Oxford, UK. Dr. Duncan was supported by the Wellcome Trust (094449/Z/10/Z)

origin, VCCs can remain accessible to the external medium via conduits or narrow microchannels; however, such connections are transient, and the dynamics of formation generate enclosed VCCs. A recent study showed that CD36, a scavenger receptor that is not expressed in lymphocytes, is localized to the VCC membrane and is essential for the recruitment of newly synthesized Gag to VCCs for viral assembly (Berre et al. 2013). Interestingly, anti-CD36 antibodies inhibited the extracellular release of HIV-1 virions from infected MDMs and the transmission of the virus to CD4⁺ T cells via the retention of HIV-1 virions within VCCs. A role for the kinesin KIF3A, a molecular motor that propels cargo along microtubules, in the translocation of VCCs at the macrophage surface and virus release was described (Tan and Sattentau 2013). The migration of VCCs to the virological synapses of infected macrophages with T cells has been reported, suggesting a role for VCCs in cell-to-cell transmission of HIV-1. However, other studies have suggested that the assembly and release of HIV-1 into macrophages may occur primarily at the plasma membrane. In particular, the analysis of macrophages in various organs from HIV-1-infected patients by electron microscopy suggested that a majority of virions use the plasma membrane rather than internal VCCs for budding (Tan and Sattentau 2013).

Restriction Mechanisms of HIV-1 Replication in M ϕ s

As described in previous sections, M ϕ s are permissive to HIV-1 infection both in vitro and in vivo. However, several factors, including the cytokine environment and exogenous stimuli, modulate their capacity to support HIV-1 replication. Furthermore, several host factors constituting an innate intracellular defense against the virus, called intrinsic immunity (► [Cell Intrinsic Immunity; Cellular Restriction Factors](#)), contribute to limit HIV-1 replication, affecting different steps of the viral life cycle (Fig. 2 and (Bergamaschi and Pancino 2010) references herein).

Differential Restriction of HIV-1 in M1- and M2a-Polarized M ϕ s

The polarization of MDMs into M1 cells, which are involved in the Th1 immune response, by interferon- γ (IFN- γ) and tumor necrosis factor- α (TNF- α) stimulation leads to the inhibition of HIV-1 entry, impaired viral cDNA synthesis, delayed viral cDNA integration, and reduced proviral transcription. M1 polarization was found to be associated with the downregulation of CD4 receptors and increased secretion of CCR5-binding chemokines (CCL3, CCL4, and CCL5). In contrast, the polarization of MDMs into anti-inflammatory M2a, which is involved in the Th2 response, via exposure to IL-4 inhibits HIV-1 infection at a late post-integration step. The removal of the polarization stimulus was associated with a renewed capacity to support HIV-1 infection, suggesting that M1/M2a polarization may represent a mechanism that permits macrophages to cycle between latent and productive HIV-1 infection (Cassol et al. 2010).

Restriction of HIV-1 Viral Entry

The absence of the expression of the CCR5 molecule on the cell surface, linked to the homozygous CCR5 Δ 32 mutation, blocks the entry of R5 HIV-1 into both M ϕ s and CD4⁺ T cells. Stimulation with lipopolysaccharide (LPS), a major constituent of gram-negative bacteria, activates MDMs and strongly inhibits HIV-1 infection. Viral entry restriction by LPS was correlated with the downregulation of CCR5 expression due to a defect in its recycling. In vivo exposure of macrophages to LPS might limit HIV-1 infection, as suggested by the observation that M ϕ s from the mucosa of the gastrointestinal tract, which is exposed to gram-negative bacteria and LPS, do not express CCR5 on their surface and are resistant to HIV-1 infection.

Restriction of HIV-1 Pre-integration Steps

IL-27, a cytokine that belongs to the IL-12 family, is mainly produced by activated antigen-presenting cells, including dendritic cells (DCs), Mos, and M ϕ s. IL-27 was recently shown to induce Mo differentiation into MDMs that are resistant to HIV-1 replication, due to a post-entry

block (Dai et al. 2013). IL-27 specifically confers HIV resistance to M ϕ s by downregulating the expression of the protein spectrin β non-erythrocyte 1 (SPTBN1), an HIV-dependent host factor that binds viral Gag and is required for an early step in HIV-1 replication.

SAMHD1 is a restriction factor that inhibits HIV-1 reverse transcription in DCs, M ϕ s, and resting CD4⁺ T cells by degrading dNTPs (Laguette et al. 2011) (► [SAMHD1](#)). Indeed, SAMHD1 is a dGTP-stimulated triphosphohydrolase that converts dNTPs into their constituent deoxynucleosides and inorganic triphosphates. SAMHD1 exerts its antiviral activity only in non-dividing cells. The most recent studies have shown that the restriction activity of SAMHD1 is lost upon its phosphorylation at residue T592 by specific cyclin-dependent kinases in activated and proliferating cells. However, SAMHD1's dNTPase activity is not affected by its phosphorylation. These data challenge the role of the dNTPase activity of SAMHD1 in the restriction of HIV-1 in M ϕ s. Recently, SAMHD1 has been found to have RNA exonuclease activity and it has been proposed that it restricts HIV-1 by degrading the viral genomic RNA as it is reverse transcribed (Ryoo et al. 2014). The relative contribution of the two mechanisms is still debated. Primate lentiviruses that express the accessory protein Vpx, such as HIV-2 and SIV, are able to escape this restriction, as Vpx targets SAMHD1 to the degradation machinery.

The M ϕ intracellular dNTP pool is also the target of viral restriction mediated by p21, an inhibitor of cyclin-dependent kinases, which inhibits HIV-1 reverse transcription in MDMs by suppressing the expression of ribonucleotide reductase subunit 2, RNR2, an enzyme indispensable for dNTP de novo biosynthesis in MDMs (Allouch et al. 2013). p21 also restricts lentiviruses expressing Vpx (HIV-2 and SIV), which is able to degrade SAMHD1. Interestingly, Fc γ R engagement on the MDM surface strongly inhibits HIV-1 reverse transcription by upregulating p21 expression.

Type I interferons can inhibit HIV-1 replication at different steps. MX2 is a recently described restriction factor of HIV-1 and related primate

lentiviruses (Goujon et al. 2013) (IFN Signalling and Induction of Restriction Factors). MX2 is inducible in MDMs and other cell types (CD4⁺ T cells, THP1 monocytic cell lines, and the glioblastoma line U87-MG) by IFN- α stimulation. MX2 did not affect HIV-1 reverse transcription but strongly reduced levels of 2-long terminal repeat circular DNA (2-LTR circles), a marker for HIV-1 cDNA nuclear localization, and of integrated proviruses, indicating a blockade of HIV-1 nuclear import or the degradation of viral cDNA. Susceptibility to MX2 restriction appears to be determined by the HIV-1 capsid. IFI16 (IFN-inducible protein 16) was recently described as an innate immune response inhibitor of HIV-1 replication in MDMs (Jakobsen et al. 2013). IFI16 senses HIV-1 reverse-transcribed cDNA and stimulates the innate immune response via a pathway that is dependent on stimulator of IFN genes (STING). The activated antiviral state stimulated by IFI16 targets a step after HIV-1 entry but prior to HIV-1 integration.

miR-155 is a microRNA induced in MDMs following stimulation of TLR3 and TLR4 by poly I:C (a synthetic analog of dsRNA) or LPS, respectively, and inhibits HIV-1 replication at post-entry, pre-integration events (Swaminathan et al. 2012). Overexpression of miR-155 in MDMs induces downregulation of the expression of mRNA and proteins involved in trafficking and/or nuclear import of PIC (ADAM10, TNPO3, Nup153, LEDGF/p75), suggesting that miR-155 antiviral activity targets HIV-1 cofactor mRNA for degradation.

Restriction of HIV-1 Post-integration Steps

The C/EBP binding sites in the HIV-1 LTR promoter recruit the C/EBP β transcription factor and are required for HIV-1 replication in macrophages but not in T cells. However, C/EBP β has two isoforms: a large isoform of 30–37 KDa that stimulates gene transcription and a small isoform of 16–21 KDa that exerts repressive activity. In HIV-1-infected patients, lung alveolar macrophages do not exhibit active viral replication, whereas they represent a major source of virus in pulmonary tuberculosis coinfection. The viral latency of HIV-1 in alveolar macrophages was

correlated with upregulated expression of the small inhibitory isoform of C/EBP β , which is suppressed after *Mycobacterium tuberculosis* infection. Furthermore, IFN- β , a cytokine that is produced in the brain and lung tissues during acute HIV/SIV infection, was shown to enhance the expression of the inhibitory isoform of C/EBP β and suppress SIV replication in macrophages of rhesus macaques.

Urokinase-type plasminogen activator (uPA) signaling has been shown to inhibit a late step in HIV-1 assembly, affecting the maturation and release of HIV-1 from infected MDMs and monocyte cell lines. uPA is a serine protease that interacts with a specific GPI-anchored receptor, uPAR (CD87), at the cell surface. uPAR is expressed by inflammatory cells, including macrophages. The uPA-uPAR interaction, involving the engagement of β 1, β 2, and Mac-1 integrins, was found to mediate uPA antiviral effects on HIV-1 release in macrophages, activated PBMCs, and ex vivo cultures of lymphoid tissues that were infected in vitro. Importantly, the loss of control of HIV-1 in the central nervous system (CNS) was correlated with deregulation of uPA and uPAR expression. These studies suggested that HIV-1 infection induces the overexpression of uPAR and consequently the overproduction of soluble uPAR (suPAR) in cerebrospinal fluid (CSF). The excess suPAR in the CSF binds most of the extracellular uPA, preventing it from binding to cell surface-associated uPAR and consequently inhibiting HIV-1.

Free-Virus and Cell-to-Cell HIV Transmission

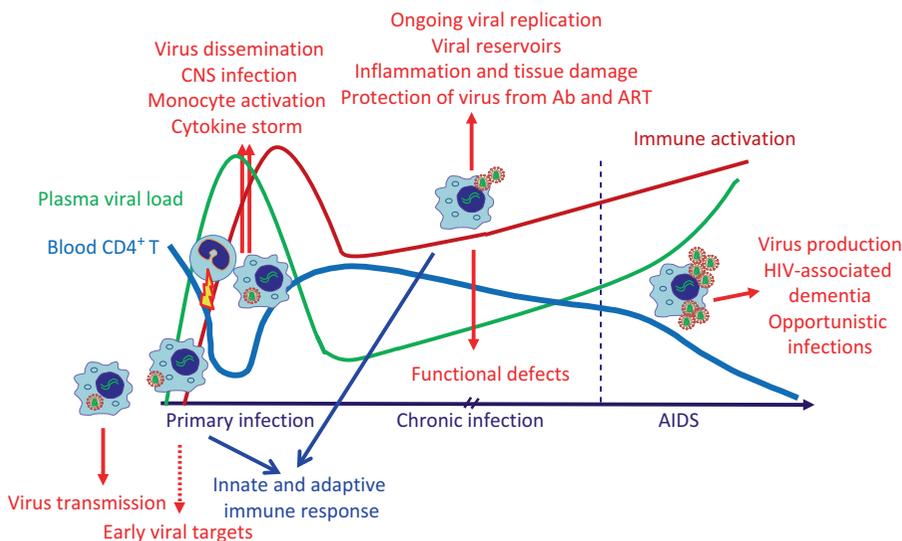

The free-virus transmission mode of HIV-1 was the first to be studied; however, it does not appear to be the most efficient mode of virus transmission. Indeed, following the fusion of HIV-1 Env from an infected cell with the receptors of a target cell, the formation of a cellular junction triggers the formation of membrane nanotubes, and the juxtaposition of the same HIV-1 Env molecular complex with the engaged receptors (CD4, CXCR4, CCR5), integrins (such as integrin

α 4 β 7), tetraspanins (such as CD81), adhesion proteins such as LFA1, ICAM-1, ICAM-3 and tubulin, and the actin cytoskeleton results in the formation of the virological synapse. This membrane structure mediates the cell-to-cell transmission of the virus to target cells (► [HIV-1 Transmission; Cell-Types Associated with](#)). HIV-1 transmission from infected MDMs to uninfected activated CD4 T cells through virological synapses (Fig. 3) (Groot et al. 2008) has been shown to be 20–250 times more efficient than cell-free infection. The formation of the virological synapse between infected MDMs and CD4 T cells occurs via the binding of viral gp120 Env with CD4 on target cells, a process that is dependent on actin and is facilitated by interactions between ICAM-1 and LFA-1. Whereas in cell-to-cell transmission between CD4 T cells, the microtubule-organizing center (MTOC) plays an important role in the formation of the virological synapse, in MDMs the actin cytoskeleton appears to have a more important role in the formation of these cellular junctions. Live fluorescence imaging has revealed that filopodia, which are long membrane projections produced by Mos/M ϕ s and other myeloid cells to probe their environment, protruding from infected MDMs are rich in HIV-1 Gag proteins and likely permit the virus to reach and be disseminated into neighboring cells. Cell-to-cell transmission of HIV-1 from HIV-1-infected MDMs to CD4 T cells is susceptible to epitope-specific broadly neutralizing monoclonal antibodies (bNmAbs) targeting the CD4 binding site (CD4bs) and glycans or glycopeptides but demonstrates resistance to bNmAbs targeting the Env gp41 subunit. In addition, whereas cell-free infection from HIV-1-infected MDMs to autologous CD4 T cells is efficiently inhibited by antiretroviral drugs, corresponding cell-to-cell transmission was reported to be resistant to the action of these drugs. This resistance has been attributed to the high multiplicity of infection of the target CD4 T cells via the cell-to-cell transmission mode. These findings suggest that in tissues where M ϕ s and CD4⁺ T cells are densely packed, antiretroviral penetrance might be reduced due to the increased probability of HIV cell-to-cell transmission.

Monocytes and Macrophages in HIV-1 Pathogenesis

Mos and Mφs are involved in various stages of HIV-1 infection (Fig. 4). They likely contribute to virus transmission via the mucosal route. Indeed, although less frequently infected than CD4⁺ T cells, Mφs account for 20–30% of leukocytes in semen, whereas T lymphocytes comprise only 5%. Semen Mφs may transmit infection at the mucosal surface by different mechanisms. Infected Mφs produce free viruses that may be transmitted to target cells in the lamina propria by crossing the epithelial barrier through breaks in the epithelium. Infected Mφs may also transmit virus to epithelial cells that permit the virus to cross the epithelial barrier via a mechanism called transcytosis, without being directly infected

themselves. Infected Mφs can also migrate through intact mucosa to the lamina propria, where they encounter CD4⁺ T cells and dendritic cells. Mφs are localized to mucosal sites of exposure to HIV-1 during sexual intercourse and may be early targets for the virus. However, the question of whether Mφs are among the first cells infected by the incoming virus is controversial. While some studies suggest that resident macrophages in the female genital mucosa or in the male urethra may serve as early targets for HIV-1, studies in macaque models suggest that the first targets during SIV exposure are primarily CD4⁺ T cells and DCs. Nevertheless, Mφs throughout the body are exposed to HIV-1 very early during infection. In infected macaques, macrophages accounted for 10–12% of SIV-infected lymph node cells 7–12 days after infection (Zhang et al. 1999).

Macrophages in HIV Immunopathogenesis, Fig. 4 Monocytes/macrophages in HIV-1 pathogenesis. Mos and Mφs are involved in all the stages of HIV-1 infection. They likely contribute to virus transmission via the mucosal route. Mφs are localized to mucosal sites of exposure to HIV-1 during sexual intercourse and may be early targets for the virus. Mos/Mφs play a crucial role in viral dissemination to body tissues and transmission to adjacent CD4⁺ T cells. Activated Mos crossing the blood-brain barrier are probably the main vehicles for HIV infection of the central nervous system. Perivascular Mφs and resident microglia are likely responsible for the persistence of low levels of viral replication and abnormal levels of

immune activation in the brain favoring HAND in HIV-infected patients and HAD in the late stages of the disease. Infected Mφs could serve as reservoirs of infectious virus. In addition, Mφs can survive for long periods of time and may be a source of viral rebound after therapy interruption. Mos/Mφs also play an important role in HIV/SIV immunopathogenesis, strongly contributing to immune activation and tissue damage. The defective phagocytic capacity of Mφs in HIV-1-infected patients favors opportunistic infections that are common at the AIDS stage of HIV infection. HIV-1 infection also affects the capacity of Mos/Mφs to induce adaptive responses and their adjuvant functions for adaptive immune cells

Mos/M ϕ s play a crucial role in viral dissemination to body tissues and transmission to adjacent CD4⁺ T cells. Indeed, infected M ϕ s store replication-competent HIV-1 in VCCs for the long term and can efficiently transmit virus to adjacent CD4⁺ T cells and other susceptible target cells (Sharova et al. 2005). Activated Mos crossing the blood-brain barrier have been suggested to be the main vehicles for HIV infection of the central nervous system. Mos in blood and M ϕ s in lymph nodes rapidly increase after SIV infection. Increased trafficking of Mos to the gut occurs in HIV infection and is associated with enhanced expression of homing molecules (Integrin β 7) and chemokine receptors (CCR2/CCL2 axis) (Acute HIV Infection and the CNS). Accordingly, M ϕ number is increased in the goat mucosa of untreated HIV-1-infected patients.

Mos/M ϕ s also play an important role in HIV/SIV immunopathogenesis, strongly contributing to immune activation and tissue damage. During SIV infection of macaques (► [Overview: Immunopathogenesis](#)), the rate of monocyte turnover increases, which suggests tissue infiltration and replacement of damaged M ϕ s. The levels of monocyte turnover in the acute phase of SIV infection predict disease progression (Hasegawa et al. 2009). In the late stages of disease, when CD4⁺ T cells are deeply depleted, HIV-1 can be detected in association with M ϕ s in nonlymphoid organs such as lung, colon, brain, liver, and kidney (Donaldson et al. 1994). When opportunistic coinfections occur, M ϕ s can produce huge amounts of virus and sustain high levels of viremia (Orenstein et al. 1997) (Opportunistic Infections of Global Significance). In macaques infected with a highly pathogenic SHIV that causes a rapid loss of CD4⁺ T cells, long-lived infected resident M ϕ s in tissues sustained high levels of virus production for months. In addition, chronically infected tissue M ϕ s were refractory to treatment with RT inhibitors (Igarashi et al. 2001). Depletion of CD4⁺ T cells before infection of rhesus macaques with SIV increased viral replication in M ϕ s and favored the emergence of SIV viruses harboring envelopes that were able to infect CCR5⁺ cells independently of the CD4 receptor (Ortiz et al. 2011).

M ϕ Dysfunction in HIV Infection

HIV-1 infection provokes functional defects and the destruction of M ϕ s, with consequent impact on innate defenses against microbes, including phagocytosis and the intracellular lysis of pathogens. In vitro HIV-1 infection of MDMs affects FcR-mediated phagocytosis by interfering with FcR signaling. In addition, impaired phagocytosis by Mos and mucosal M ϕ s was described in untreated HIV-1 patients. Similarly, SIV-infected monkeys exhibit gut mucosal M ϕ s with deficient bacterial clearance functions. The defective phagocytic capacity of M ϕ s likely favors opportunistic infections that are common at the AIDS stage of HIV infection. HIV-1 infection also affects the capacity of Mos/M ϕ s to induce adaptive responses and their adjuvant functions for adaptive immune cells. Indeed, defects in antigen uptake and presentation as well as the altered production of cytokines by Mos/M ϕ s have been reported in HIV-1-infected patients.

Relatively few studies have addressed the effects of HIV infection on Mo/M ϕ metabolic activity. It has been shown that HIV-1 affects cholesterol metabolism by Mos/M ϕ s, resulting in the presence of fatty M ϕ s in vessels and likely contributing to cardiovascular disease in HIV-infected patients. Interestingly, accumulation of CD68⁺CD163⁺-activated M ϕ s and high levels of sCD163 (see below) has been described in cardiac tissues of HIV-infected humans with coronary atherosclerosis.

Role of Mos/M ϕ s in Inflammation and Immune Activation in HIV Infection

Primary HIV-1 acute infection causes a strong cytokine storm and high levels of generalized immune activation. Levels of T-cell immune activation following primary infection are stronger predictors of disease progression than plasma viral load (Acute HIV Infection and the CNS). Mos/M ϕ s exert effector functions on the inflammatory response to viruses and nucleic acids and play a key role in driving immune activation in HIV-1-infected patients and SIV-infected macaques. Viral Env binding to the CD4 receptor and viral RNA sensing by TLRs 7 and 8 after viral entry resulted in the secretion of inflammatory

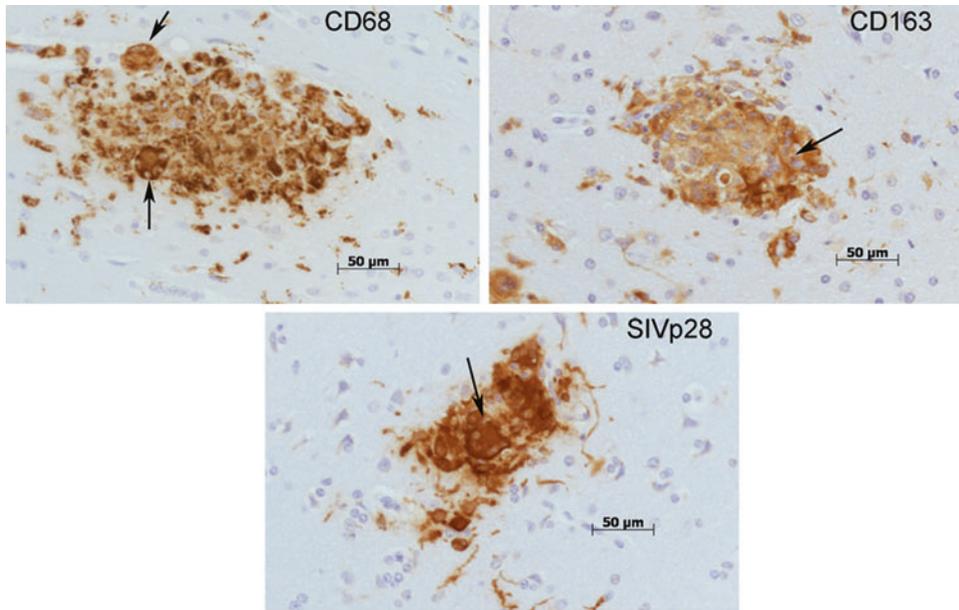

cytokines such as IL-1 and TNF- α . The expansion of monocytes exhibiting a skewed profile toward activated subsets (CD14⁺CD16⁺/CD14⁺CD16⁺⁺) in acute HIV-1 infection was documented long ago (Thieblemont et al. 1995) and has been confirmed by numerous studies. It has recently been shown that levels of the monocyte activation markers IL1RA and sCD14 in plasma are increased during primary infection and that early levels of IL1RA are strong predictors of a T-cell activation set point (Chevalier et al. 2013). Early immune activation in HIV patients and SIV-infected macaques has been proposed to be driven by an early disruption in intestinal epithelial barrier function associated with the massive depletion of intestinal CD4⁺ T cells and microbial translocation. However, using a mutated SIV virus that caused neither CD4⁺ depletion in the gut lamina propria nor microbial translocation (► [Microbial Translocation](#)), levels of immune activation equivalent to those induced by infection with the wild-type virus were detected. Viral replication itself is likely driving Mo/M ϕ activation in primary HIV-1 infection, and Mo/M ϕ activation may contribute to generalized T-cell activation at this early stage. Microbial translocation, favored by intestinal M ϕ destruction and dysfunction, later fuels further activation of the immune system.

A subset of nonclassical CD14⁺CD16⁺⁺ Mos expressing the M-DC8⁺ marker was found to be significantly expanded during chronic HIV infection with active viral replication (Dutertre et al. 2012). M-DC8⁺CD14⁺CD16⁺⁺ Mos express CX3CR1 and CCR2 chemokine receptors and are able to migrate and traffic between body compartments in response to chemokines. These cells are able to secrete TNF α in response to bacterial LPS and may play a major role in the maintenance of chronic immune activation in the gut mucosa.

Role of Mos/M ϕ s in Neuropathogenesis

HIV-1 infection of the central nervous system (CNS) can lead to neurological disease, causing cognitive impairments and eventually leading to HIV-1-associated dementia (HAD) in untreated patients (for review see Burdo et al. (2013) and references herein) (► [HIV-2 Transmission](#)).

Despite the fact that neurons are not directly infected, neuronal damage occurs early in the infected CNS, as indicated by the decreased levels of the CNS metabolite N-acetylaspartate, which is indicative of neuronal loss or dysfunction within weeks of HIV and SIV infection. Diverse factors have been implicated as causes of neuronal damage, including viral proteins such as the gp120 envelope glycoprotein or Tat, proinflammatory cytokines such as TNF- α , which is released by activated Mos/M ϕ s, and microglial activation and the subsequent release of neurotoxins. Although HAD has almost disappeared since the introduction of cART, a substantial proportion of treated patients still exhibit HIV-associated neurocognitive disorders (HAND) despite effective viral suppression. Among the potential causes of HAND, early CNS damage prior to therapy (► [HAND in the Pre-ART and Post-ART Eras](#)), the persistence of low levels of viral replication in the brain, and abnormal levels of immune activation have been suggested. HIV-1 replication in the CNS occurs in perivascular M ϕ s and resident microglia (Fig. 5). Microglia constitutes the stable resident population, and perivascular M ϕ s are repopulated from the bone marrow. Perivascular macrophages expressing the scavenger receptor CD163 are the primary cell type that is productively infected by SIV in the brain. Administering the thymidine analog bromodeoxyuridine (BrdU) to monkeys permits the monitoring of lymphocyte and Mo/M ϕ proliferation and traffic in vivo. It has been shown that BrdU is taken up by monocyte precursors in the bone marrow and is then found in blood monocytes. In monkeys that demonstrated a rapid progression toward AIDS, BrdU⁺ monocyte numbers increased by 8 days post-infection. A second wave of activated monocytes in the blood was detected preceding immunodeficiency and AIDS. Earlier work had shown a correlation between the magnitude of circulating CD14⁺CD16⁺ monocyte subsets and HAD. In the macaque model, soluble CD163 (sCD163) released from activated Mos/M ϕ s and particularly CD14⁺CD16^{+/+++} Mos was highly associated with an increased number of BrdU⁺ monocytes. In addition, levels of sCD163 are elevated in the plasma of HIV-infected patients in the early stages

Macrophages in HIV Immunopathogenesis, Fig. 5 SIV encephalitic lesions in the frontal cortex of an SIV-infected CD8-depleted rhesus macaque: SIVE lesions contain infected macrophages and multinucleated giant cells (*arrows*). Resident (CD68⁺) and perivascular

(CD163⁺) macrophages are present in SIVE lesions and are active sites of productive viral replication (SIVp28⁺) (These images were kindly provided by Drs. Tricia Burdo and Kenneth Williams. TB and KW are supported by NIH grants R01NS082116 (TB) and R01NS040237 (KW))

M

of infection and remain high in chronically infected patients, while they decrease in cART-treated patients. However, plasma sCD163 levels were found to be associated with neuropsychological impairment in HIV-1-infected patients under cART. Plasma sCD163 has been proposed to be an early marker of Mo/M ϕ activation that correlates with HIV replication and pathogenesis.

Macrophages as Viral Reservoirs

Despite the paramount success of cART in containing HIV-1 infection and disease, HIV-1 cannot be cured. Abnormal levels of immune activation and HAND persist under cART. The principal obstacle to HIV-1 eradication by cART is the establishment of viral reservoirs, where the virus is not reachable by antiretroviral drugs. Quiescently infected CD4⁺ T memory cells, in which the integrated provirus remains latent and does not express viral proteins, are considered the major HIV-1 reservoir. However, infected M ϕ s could serve as reservoirs of infectious virus. M ϕ s can survive for long periods of time and may be a

source of viral rebound after therapy interruption. Accordingly, macrophage-tropic HIV-1 populations were found to be compartmentalized in cerebrospinal fluid (CSF) and have been associated with the slow decay of virus in the CSF after the initiation of cART, suggesting residual viral replication in long-lived cells, such as M ϕ s. The persistence of infected M ϕ s harboring infectious virus under cART may be attributable to different mechanisms. At the cellular level, as described above, HIV-1 accumulates in VCCs, where it may be protected not only from Abs but also from antiretroviral molecules. Macrophages can transmit the virus directly from VCCs to adjacent cells, and it has been reported that antiretrovirals exhibit reduced inhibitory effects on cell-to-cell transmission (Sigal et al. 2011). It is noteworthy that the activity of antiretroviral drugs, such as nucleoside RT inhibitors or HIV-1 protease inhibitors, was strongly reduced in persistently infected MDMs compared with their activity in acutely infected MDMs (Perno et al. 1988). At the tissue level, viral persistence may rely on ongoing viral

replication in M ϕ s at anatomical sites where the penetrance of antiretroviral molecules may be suboptimal (sanctuaries), as has been reported for the brain, semen, and the gut.

Conclusions

HIV-1 infection subverts the natural roles of Mos/M ϕ s in innate defenses and tissue homeostasis, transforming them into vehicles for dissemination and shelters for persistence. Infection of Mos/M ϕ s affects their functions and thus contributes to HIV-1-associated morbidity, including cardiac and CNS diseases. Overall, together with CD4⁺ T-cell depletion, Mo/M ϕ infection drives the progression of HIV-1 infection to AIDS. Therapeutic strategies for the treatment of HIV-1 infection should improve the focus on Mos/M ϕ s as fundamental targets.

Macrophage-Specific Aspects of HIV-1 Infection

Nicholas Francella, Sarah T. Elliot and Ronald G. Collman

Perelman School of Medicine, Department of Medicine, Division of Pulmonary, Allergy and Critical Care, University of Pennsylvania, Philadelphia, PA, USA

Definition

Macrophages are a heterogeneous population of myeloid leukocytes that perform diverse innate and adaptive functions of the vertebrate immune system. They are principally defined as being differentiated, tissue-resident forms of monocytes, with a phagocytic capacity, relatively large size, and expression of various functional markers on their cell surface. Notably, macrophages express the HIV/SIV entry receptors CD4 and CCR5/CXCR4 and have long been known as *in vivo* and *in vitro* targets of infection. However, HIV and SIV that infect CD4⁺ T cells vary in their capacity to infect macrophages (macrophage

tropism). This variability can be attributed to macrophage-specific characteristics and differences among virus variant, principally in the ability to enter macrophages, as well various levels of restriction outlined in this entry and adaptations that the virus uses to overcome these restrictions.

Introduction

While CD4⁺ T cells constitute the majority of infected cells during *in vivo* HIV infection, other important targets of infection are myeloid cells, predominantly macrophages. T cells and macrophages are vastly different in morphology, proliferative capacity, gene expression profile, and interaction with HIV, yet both can become infected and support viral replication.

In the central nervous system (CNS), the majority of infected cells are myeloid cells (macrophages and microglia), and these are responsible for neurological aspects of disease. Outside the CNS, macrophages are involved in events at mucosal surfaces during transmission, can serve as long-lived reservoirs, and may contribute substantially to virus production especially in late-stage disease when CD4⁺ T cells are largely depleted (Blankson et al. 2002). Thus, comparative studies of HIV infection of macrophages versus T cells continue to be of great interest. Much of the current understanding of HIV molecular pathogenesis comes from studies using tissue culture-adapted viruses and transformed cell lines that resemble neither T cells nor macrophages. It is therefore essential to consider the HIV life cycle in the context of the very different primary cell types these viruses can infect. While the primary focus of this review is HIV-1, critical insights have been gained through studies of SIV, and so we will indicate where data is extrapolated from SIV to the context of HIV-1.

Macrophage Models Used to Study HIV/SIV

Much of the understanding of HIV biology has been generated through studies in transformed

cell lines, but while useful they do not always reflect unique features of HIV/primary cell interactions. Monocyte-/macrophage-like cell lines exist that are sometimes used for HIV infection studies (U937, THP-1, MonoMac, HL60), but since they may not faithfully recapitulate primary cell interactions with the virus, primary cells are often used. As cell-specific experimental targets for HIV, monocyte-derived macrophages (MDMs) are most often generated by *ex vivo* culture and differentiation of blood-derived monocytes. In addition, more physiologic and phenotypically diverse tissue-associated macrophages can be isolated directly from human and nonhuman primate mucosal regions such as the gut, lung, and vaginal tract, as well as from the secondary lymphoid organs, liver, kidneys and central nervous system (Cassol et al. 2006).

Phenotypically, macrophages are distinguished from other leukocytes by their propensity to adhere to culture surfaces, their large irregular morphology, and surface expression of MHC (major histocompatibility complex) class II as well as myeloid markers such as CD14, CD16, CD68, and CD156. Functionally, macrophages are highly diverse, with important roles ranging from innate immune control, inflammation, phagocytosis, and antigen presentation to anti-parasitic and wound healing.

Traditionally, HIV-1 isolates have been phenotypically classified as macrophage tropic (capable of infecting primary macrophages and primary CD4⁺ T cells but not transformed T-cell lines), T-cell-line tropic (capable of infecting primary CD4⁺ T cells and transformed T-cell lines but not primary macrophages), or dual tropic (capable of infecting all three target cell types *in vitro*). The term “macrophage tropic” was formerly used interchangeably with “CCR5 tropic” in reference to HIV entry receptors, a correlation that is now recognized to be highly imperfect, as will be discussed in detail below (Goodenow and Collman 2006). Today, “macrophage tropism” in the context of lentiviral infection generally refers to the ability of a virus to infect and replicate in *ex vivo* cultured macrophages and/or the ability of viral components (such as the envelope glycoprotein) to mediate

infection of macrophages in a single-round assay (Duncan and Sattentau 2011).

Interestingly, monocytes are much more resistant to HIV-1 infection *in vitro* than differentiated macrophages. *In vivo*, HIV DNA can be found in circulating CD14⁺ monocytes, although typically at levels considerably lower than CD4⁺ T cells. Monocytes impact HIV pathogenesis partially because they are directly infected by the virus and may be involved in trafficking virus into tissues such as the brain, and partially through bystander and indirect effects associated with immune activation (Kuroda 2010).

Macrophage-Specific HIV Entry

The viral envelope (Env) glycoprotein of HIV-1 (as well as HIV-2 and SIV) is comprised of the surface subunit gp120 and transmembrane subunit gp41, which are organized as trimeric units (trimer of heterodimers) on the virus surface. Entry is mediated by gp120 engagement of cellular CD4, which results in structural changes to gp120 that enable interactions with one of two principal cellular coreceptors, CCR5 or CXCR4. Further structural changes in gp41 then lead to ► [fusion](#) of the viral and cellular membranes and viral entry (Wilens et al. 2012).

Entry Receptor Use as Determinant of Macrophage Tropism

Early studies on HIV-1 suggested that macrophage-tropic viral isolates used CCR5 as a coreceptor, whereas viruses that could not infect macrophages used CXCR4. However, it is now recognized that CCR5 is the principal coreceptor for most HIV-1 strains, and a gradation of macrophage tropism exists among them that is determined by the ability to utilize CCR5/CD4 in the context of their expression levels on the surface of primary cells. Conversely, macrophages also express low levels of CXCR4, and while T-cell-line-tropic HIV-1 strains that use CXCR4 for entry are usually not able to enter macrophages efficiently, some primary isolates that use CXCR4 for entry can use macrophage CXCR4. Dual-tropic HIV-1 variants, which use both CCR5 and

CXCR4, may enter macrophages through either or both pathways. Despite this plasticity in macrophage coreceptor use, however, it is true that most macrophage-tropic HIV variants studied use CCR5. In contrast, non-macrophage-tropic variants may use CCR5, CXCR4, or both (Goodenow and Collman 2006).

Among CCR5-using viral variants, efficiency of CD4 use is a major entry determinant of macrophage tropism. Macrophages express less CD4 on their cell surface than CD4⁺ T cells, and most macrophage-tropic viral variants are capable of infecting cells expressing little CD4. The viral Env determinants of coreceptor usage (CCR5 versus CXCR4) map in large part although not exclusively to the third hypervariable (V3) domain (Dragic 2001). Among R5 variants, the viral Env determinates that regulate the efficiency of CD4 use and thus macrophage tropism are more varied and include changes in the first and second variable loops (V1/V2) as well as loss of glycosylation in the CD4-binding site and second constant domain (C2) (Duncan and Sattentau 2011).

Of note, different tissue macrophages vary in their expression of CCR5 and thus permissiveness to HIV-1 infection. For example, vaginal mucosal macrophages are susceptible to infection *in vitro* and in the rhesus macaque/SIV model *in vivo*, whereas small intestinal mucosal macrophages are reported to lack entry coreceptors and resist infection (Hladik and McElrath 2008).

Endocytosis in Macrophage Entry

HIV entry occurs predominantly at the plasma membrane surface, in contrast to viruses that enter via endocytic pathways. However, some models suggest that HIV entry into macrophages (and some cell lines) may involve endocytic pathways, although its relative importance remains to be fully defined (Wilén et al. 2012).

Immunological Correlates of Macrophage Tropism

Macrophage-tropic HIV-1 strains are generally more sensitive to neutralization by HIV⁺ serum and monoclonal antibodies than non-macrophage-tropic variants. At least one explanation for this is that these variants exhibit increased

constitutive exposure of regions within Env, such as the coreceptor interacting domains, that enable viral entry in the presence of reduced CD4 levels. These regions are highly vulnerable targets of neutralizing antibodies. In contrast, variants that are not macrophage tropic normally shield such epitopes until entry is triggered by CD4 (Bhattacharya et al. 2003). Macrophage-tropic variants are able to tolerate this enhanced sensitivity to neutralization because they typically reside in immune-privileged compartments like the CNS, emerge in late-stage disease, or possibly avoid antibodies by infecting new target cells via cell-to-cell spread.

Anatomic Compartmentalization of Macrophage Infection and Macrophage Tropism

The neutralization sensitivity of macrophage-tropic viral variants has implications reflected in observations of HIV infection *in vivo*. While infected macrophages can be found in the gut, vaginal tract, and lungs, infected macrophages and highly macrophage-tropic viral variants are most abundant in the CNS. In patients with AIDS-associated neurological disorders, microglia and perivascular macrophages are the principal infected cells and viral reservoir in the CNS, rather than T cells. The propensity of macrophage-tropic HIV-1 to preferentially emerge in the CNS is likely due to both the abundance of myeloid cells and paucity of T cells in this compartment and the relative shelter from peripheral immune pressure that allows the low-CD4-using, neutralization-sensitive variants to exist (Bhattacharya et al. 2003).

Viral RNA can be detected in the cerebrospinal fluid in most HIV-infected individuals who are not on antiretroviral treatment (ART) (Churchill and Nath 2013), and as many as 40–70% of untreated individuals experience some form of HIV-associated neurological disorder (Yadav and Collman 2009). However, productive infection of macrophages in the CNS may be less common, as infected CNS-resident cells have been detected in approximately 20% of patients when examined during autopsy (Churchill and Nath 2013). Based on decay rate following ART initiation,

CSF virus appears to be derived from a combination of short-lived and long-lived cells, with the former likely reflecting virus originating from blood T cells and the latter likely originating from brain macrophages and more dominant in individuals with more severe neurological disease.

While non-CNS HIV-1 variants are typically poorly macrophage tropic, macrophage-tropic variants may be more often isolated from the blood and lymph nodes of late-stage and highly immunodeficient AIDS patients. Like the immune-privileged CNS, emergence of macrophage-tropic viral variants in late-stage disease with advanced T-cell loss may also reflect a setting in which there are limiting numbers of T-cell targets combined with diminished immune pressure. Consistent with this notion, studies in the rhesus macaque model infected with SIV or SHIV (SIV/HIV chimeras) show that macrophages may be an important, or even principal, reservoir in very-late-stage disease when nearly all detectable CD4⁺ T cells have been depleted or following experimental CD4⁺ T-cell depletion (Blankson et al. 2002).

Postentry Early Events in Replication Cycle

Following fusion and entry, the viral genome is reverse transcribed from RNA into DNA and transported into the nucleus within a structure known as the pre-integration complex, comprised largely of viral capsid proteins.

Cellular Restriction Factors

Mammalian cells have a variety of intrinsic proteins that have, as major (if not exclusive) functions, the ability to restrict incoming retroviruses, including among them lentiviruses such as HIV and SIV. In cases where virus successfully establishes infection in target cells, it either has evolved to avoid these restriction factors or has acquired specific genes to impede their function. These restriction factors are typically interferon stimulated, contributing to innate

immunity augmenting intrinsic cellular resistance to infection.

A cellular restriction factor that has a unique role in macrophages is SAMHD1, which impedes HIV-1 reverse transcription by hydrolyzing deoxynucleosides in the cytoplasm. As nondividing cells, macrophages have lower pools compared to T cells of deoxynucleoside precursors required for reverse transcription of viral RNA into DNA (Gavegnano et al. 2012). HIV-2 and most SIVs encode a *vpx* gene, whose gene product interferes with SAMHD1 and enhances viral permissiveness in macrophages. In some SIVs lacking *vpx*, a similar function is ascribed to Vpr, but HIV-1 lacks both the *vpx* gene and any as-yet-identified gene with equivalent function. Nevertheless, HIV-1 does infect macrophages in vitro and in vivo, and macrophage-tropic Env allows productive infection of macrophages in vitro, despite the absence of Vpx, relatively high levels of SAMHD1 and low levels of nucleotides in the cytoplasm. This suggests that SAMHD1 restriction of HIV-1 modulates but is not sufficient to fully block infection of macrophages.

The APOBEC3 family of proteins restricts virus replication by multiple mechanisms, the most well defined of which is cytosine deamination during reverse transcription that leads to G-to-A hypermutation, unless countered in the virus-producer cell by the virally encoded Vif protein. While APOBEC3 proteins are not known to differentially restrict HIV infection in T cells versus macrophages, it has been suggested that APOBEC3 expression in immature blood monocytes contributes to their resistance to infection relative to differentiated macrophages, but this line of evidence is not yet conclusive. TRIM5 α and related members of the TRIM family are intrinsic cellular resistance factors that target the capsid of incoming viruses for degradation. While simian TRIM proteins block efficient HIV-1 infection, HIV-1 has evolved to avoid targeting by human TRIM proteins. TRIM proteins are expressed in both macrophages and T cells, and some evidences suggest that different members of the large TRIM are differentially expressed in

macrophages compared to T cells, although they likely function similarly in the different cell types (Bergamaschi and Pancino 2010).

Antiviral restriction factors place HIV and SIV under continuous evolutionary pressure to avoid triggering innate host immune signaling while maximizing replication and target cell tropism. For example, the cellular DNase TREX1 degrades cytoplasmic viral DNA, but rather than acting as an antiviral mechanism, this process actually enhances HIV infection because the virus hijacks the TREX1 system in order to prevent self-integration and reduce the risk of triggering an interferon response, particularly in T cells. In contrast, viral genomes persist for a longer time in myeloid cells and thus are more prone to detection by innate immune sensors. One current hypothesis is that the inability of HIV-1 to antagonize myeloid-specific restriction factors leads to reduced infection of macrophages and dendritic cells and, consequently, only weak triggering of the interferon response in these cells. In contrast, HIV-2 and various SIVs, which possess Vpx and Vpr proteins that overcome restriction in these cells, may then trigger a robust interferon response that in turn reduces viral replication across multiple cell types (Yan and Lieberman 2011). However, despite this intriguing and plausible hypothesis, there is as yet no evidence that in vivo macrophage infection is greater in SIV compared to HIV or that the viruses elicit distinct interferon responses in vivo (Mashiba and Collins 2013).

Nuclear Migration and Integration

Macrophages differ from activated CD4⁺ T-cell targets of infection in that they are terminally differentiated nondividing cells. In contrast to other retroviruses, which are unable to enter the nucleus of nondividing cells, lentiviruses including HIV have the ability to efficiently enter the nucleus of nondividing cells and establish ► [integration](#). The viral Vpr protein plays a major role in enabling nuclear migration in nondividing cells, interacting with cellular proteins to allow nuclear entry without disruption of the nuclear envelope, and thus is an important factor for efficient

macrophage infection. In addition to Vpr, the viral matrix, capsid, and integrase proteins also contribute to efficient nuclear migration in nondividing cells. On the other hand, Vpr plays an important role during infection of proliferating activated CD4⁺ T cells by inducing cell cycle arrest, a function that is not operative in nondividing macrophages (Kogan and Rappaport 2011).

HIV-1 has a distinct predilection for integration into genes and especially into transcriptionally active genes. This is a feature common to both macrophages and CD4⁺ T cells. One difference between cell types, however, is that while integration is considered essential for efficient viral gene expression in CD4⁺ T cells, some models suggest that low levels of transcription from unintegrated viral DNA may occur in macrophages, driven by Vpr and enabled by the non-proliferating nature of macrophages that allows persistence of unintegrated genomes (Le Douce et al. 2010).

Viral Expression: Transcription, RNA Processing, and Translation

Key factors that determine whether an integrated virus is productively expressed or latent include the complement of cellular transcription factors present and state of cellular activation. In macrophages in particular, the relatively quiescent activation state compared to activated CD4⁺ T cells and distinct transcription factor patterns are associated with generally lower levels of viral gene expression. Compared to CD4⁺ T cells, macrophages possess higher ratios of repressive forms of transcription factors such as C/EBP β , Sp3, and OKT18. In addition, macrophage-specific chromatin conformations and recruitment of histone deacetylases to the HIV-1 promoter may also contribute to relative transcriptional quiescence. Together, these factors contribute to overall lower viral expression in macrophages compared to T cells and may also contribute to the potential for long-term survival of infected cells via decreased direct cytopathogenicity or immune recognition in vivo (Le Douce et al. 2010).

Viral Assembly and Release

Following structural gene expression, the virus is assembled and is released from the cell, either as cell-free virus at the plasma membrane or, perhaps especially in the case of macrophages, via cell-to-cell transfer through viral synapses. Differences in viral assembly and release between macrophages and T cells are a dynamic area of research.

Budding Versus Exocytosis

In macrophages, mature HIV-1 virions have been observed in large vesicular structures within cells. There is long-standing debate as to whether this reflects budding into intracellular multivesicular body-like structures or into deep invaginated pockets of the cell membrane. Thus, it is also unclear whether HIV-1 is released from macrophages following fusion of these multivesicular bodies with the plasma membrane (exocytosis), or if the virus buds from the cell surface as it does other target cells, only into these invaginated pockets (Carter and Ehrlich 2008). In either model, the nature of the budding site is believed to provide a mechanism shielding virions from immune surveillance.

Tetherin

The host cell restriction factor tetherin inhibits release from the cell surface of HIV-1 virions (as well as many other enveloped viruses). The HIV-1 viral protein Vpu counteracts tetherin by promoting its degradation, enabling release of virus from the cell surface. Macrophages express high levels of tetherin relative to primary T cells. Release of virus carrying mutant Vpu is more attenuated in macrophages *in vitro* than in CD4 lymphocytes, which have lower levels of tetherin. This implies that tetherin may play a particularly significant role in viral restriction in macrophages relative to other target cell types (Dube et al. 2010).

Cytopathicity and Reservoir Function

Macrophages are relatively resistant to the cytopathic effects of HIV-1 infection *in vitro* and are

able to produce virus for prolonged periods of time, in contrast to productively infected CD4+ T cells that are rapidly killed following infection. The *in vivo* half-life of tissue macrophages is estimated to be approximately 2 weeks in healthy individuals. *In vitro*, the lifespan of macrophages is not reduced by HIV infection, and current dogma that the same is true *in vivo* (Blankson et al. 2002), although this remains an active area of research (Cassol et al. 2006; Kuroda 2010).

In Vivo Reservoir

Infected individuals receiving antiretroviral therapy, even those with viral loads below the limit of detection for many years, experience viral rebound after termination of therapy. In addition, even when antiretroviral therapy reduces plasma viremia below the threshold of clinical assays, most patients maintain very low levels of plasma virus that can be detected with ultrasensitive methods. The source of both persistent low-level plasma virus on treatment and rebound virus when therapy is stopped is a key area of current investigation. While productively infected activated CD4+ T cells survive for only a short time *in vitro* and *in vivo*, resting CD4+ T cells that are latently infected are one important reservoir for long-term persistence. In addition, because of their resistance to viral cytopathicity and long natural lifespan, macrophages have the potential to serve as another long-lived HIV-1 reservoir in patients treated with antiretroviral therapy (Le Douce et al. 2010). Because macrophages penetrate and reside deep within tissues, they may be particularly shielded from antiretroviral drugs due to their anatomic localization.

Brain macrophages are an especially important current focus of interest as a long-term reservoir, given the low tissue-specific bioavailability of many antiretroviral drugs in the CNS. Although infected macrophages have been found in many tissues, they are the predominant infected cell type in the brain. In addition to their role in viral persistence, they are the source of viral expression and inflammation contributing to HIV-1-associated neurological disorders, even in infected individuals with undetectable peripheral viral loads on long-term antiretroviral therapy

(Yadav and Collman 2009). Furthermore, CNS viral load exhibits slower decay kinetics than does plasma viral load following antiretroviral therapy, although viral RNA is generally undetectable in the CNS in long-term-treated patients (Blankson et al. 2002).

Consequences of HIV-1 Infection for Macrophage Function

In contrast to the clear evidence that HIV-induced CD4+ T-cell loss and dysfunction lead to immune dysfunction and AIDS, it is not clear whether there is substantial macrophage immune dysfunction induced by HIV infection that directly contributes to immunodeficiency. On the other hand, monocyte-macrophage activation induced by HIV-1 binding and/or infection, or by other consequences of infection such as gastrointestinal tract mucosal damage and chronic microbial translocation, clearly contributes to disease pathogenesis. Generalized immune activation is a central feature of HIV pathogenesis, and levels of the monocyte activation marker soluble CD14 are strongly linked to disease. In HIV-infected people, blood monocytes show changes in transcriptomic profiles, and in SIV infection monocyte turnover is linked to rapid disease progression (Kuroda 2010).

Unlike most neurotropic or neurovirulent viruses, HIV does not directly infect neurons, and HIV-associated neurological disorders result from indirect effects mediated by glial cells, primarily infected or activated brain macrophages and microglia. Viral Env binding to the CD4/chemokine coreceptor complex triggers intracellular signaling cascades, which lead to release of cytokines, chemokines, and other mediators that augment inflammation. In addition, productive macrophage infection leads to release of neurotoxic cytokines and small-molecule mediators that injure neurons. Thus, HIV-induced activation and infection of macrophages are responsible for the indirect neuronal injury seen in HIV-associated neurological disorders, which persist albeit at lesser degrees of severity even in people on antiretroviral therapy (Yadav and Collman 2009).

Conclusion

HIV-1 infects macrophages both in vitro and in vivo. Several aspects of HIV-1 infection in macrophages distinguish infection of these cells from other HIV-1 target cells. HIV-1 viruses that infect macrophages are primarily CCR5 tropic and generally neutralization sensitive given their adaptation to low levels of CD4 expressed on these cells. A number of host restriction factors and other cellular proteins dictate unique aspects of HIV-1 entry, reverse transcription, nuclear migration, and egress in macrophages relative to HIV-1 infection of CD4 T cells. HIV-1 infection of macrophages in the CNS has a well-defined role in AIDS-associated neurological disorders and an likely albeit less clear role in other tissues. Importantly, macrophages may be a reservoir of persistent infection in patients treated with antiretroviral therapy. Defining the specific role of macrophages in disease progression, understanding mechanisms of macrophage HIV-1 infection, controlling HIV-1-triggered macrophage immune activation, and finding ways to successfully eliminate persistent macrophage reservoirs will be central to developing successful therapies to treat and perhaps block HIV-1 infection.

Male Condoms

Jeffrey E. Korte

Department of Public Health Sciences, College of Medicine, Medical University of South Carolina, Charleston, SC, USA

Definition

The male condom is a barrier method for the prevention of HIV and sexually transmitted infections (see entries “► [Immunopathogenesis of HIV Coinfections](#),” “► [Risk of Sexual HIV-1 Transmission: Coinfections Associated with Risk](#),”

“► [Immunopathogenesis of HIV Coinfections](#)”) and for the prevention of pregnancy (see entries “► [Pregnant Women: Care and Treatment](#),” “► [Preventing Mother-to-Child Transmission of HIV-1](#),” and “► [Behavioral Aspects of HIV Mother-to-Child Transmission](#)”). When placed over a man’s erect penis, it is designed to cover the penis during sexual intercourse and physically block ejaculatory fluids, sperm cells, and infectious agents from entering the sexual partner’s body. The male condom is designed to cover both the glans and shaft of the penis and may have a reservoir tip to provide space for the ejaculate. For effective use, the condom must be placed over the penis before genital contact. Modern condoms are manufactured from a variety of materials including natural latex, synthetic materials such as polyurethane and polyisoprene, and natural membranes including sheep intestine (“lambskin”).

Introduction

Male condoms appear to have been the first barrier contraceptive designed for male use. Evidence from ancient artwork and the written record suggests that condoms may have been used for contraception thousands of years ago: a 12,000-year-old example of cave art discovered in France depicts a man and woman engaging in sexual intercourse with the penis covered (Collier 2007). In addition, over 3,000 years ago in Egypt, written records describe men wearing a sheath covering only the glans of the penis, made of oiled animal intestines or bladders. It is possible that these sheaths were intended for use during sexual intercourse to prevent pregnancy or infection. However, the earliest unambiguous description of a condom to be used specifically during sexual intercourse, developed for protection against syphilis, was made in the 1500s by the Italian anatomist and physician Gabriello Fallopio (Youssef 1993).

Currently, the male condom is a popular form of birth control and protection from HIV and other sexually transmitted infections. Condoms are safe, easy to use, and widely available. Condoms can increase sexual pleasure for some couples by

prolonging an erection and preventing premature ejaculation. Additionally, containment of semen within the condom may decrease the messiness of sexual intercourse. However, the male condom also has several disadvantages. Many men report a decrease in sensitivity and sensation during sexual intercourse with condom use. In addition, placement of a condom on the erect penis may interrupt sexual intercourse.

Many of the possible disadvantages of condom use may be overcome through technical advances and behavioral shifts. For example, one brand of condom has been introduced with a design innovation meant to address complaints about reduced sensitivity and sensation. Instead of the typical tubular form, the condom is manufactured with more room at the tip of the condom so that it fits snug at the base of the penis, but loose around the glans. This design is intended to provide more sensation during sexual intercourse by allowing the loose material to move more, providing more friction. As a second example, some safe-sex interventions (see entries “► Behavioral Science Highlights of Evidence and Research,” “► HIV Prevention and Women,” “► HIV Prevention for Serodiscordant Couples,” “► HIV Prevention in Youth” “► HIV Prevention for MSM,” “► HIV-1 Transmission: Influence of Bodily Secretions,” “► HIV-2 Transmission,” “► Prevention of Alcohol-related HIV Risk Behavior,” and “► Risk of Sexual HIV-1 Transmission: Coinfections Associated with Risk”) have specifically addressed complaints about interrupting sexual intercourse to place a condom (Shain et al. 2004). If the receptive partner or both partners erotically incorporate the placement of the condom into sexual foreplay, then the perception of condom use as interrupting sexual activity may be reduced or eliminated.

Effectiveness of Condoms in Preventing Pregnancy and Sexually Transmitted Infections

It is important to distinguish between the efficacy of the male condom, which refers to the protection that the male condom affords when used perfectly,

and the effectiveness of the condom, which refers to the protection actually afforded by the condoms when used in the real world. The effectiveness of male condoms in preventing pregnancy and sexually transmitted infections is dependent on correct and consistent use. For correct use of the condom, several guidelines must be followed. First, the condom must be placed on the penis before genital contact begins. Pre-ejaculatory fluid may contain viable sperm cells and infectious agents; in addition, penile skin may harbor mucosal viruses such as the ► [human papillomavirus \(HPV\)](#). Second, the condom must remain intact and covering the penis throughout sexual intercourse. If the condom breaks, the sexual partners should cease genital contact, and a new condom should be placed on the penis before resumption of genital contact. Third, after ejaculation, the condom should be held at the base and the penis should be withdrawn while it is still erect, to prevent leakage or spillage of semen. A new condom should be used for each act of sexual intercourse.

With correct and consistent use, the male condom has been shown to prevent pregnancy, HIV, and many other sexually transmitted infections with high efficacy. Laboratory studies have clearly shown that the latex condom is an impervious barrier to sperm cells and sexually transmitted bacteria and viruses, including HIV. Clinical studies have shown that the condom protects the user and the partner against sexually transmitted infections, including HIV, gonorrhea, chlamydia, ureaplasma, trichomoniasis, and herpes simplex virus. The data on protection from HIV is more comprehensive than for other sexually transmitted infections. For HIV, studies of serodiscordant couples (see entry “► HIV Prevention for Serodiscordant Couples”) followed over time have shown that latex condoms are highly effective in protecting against HIV: in two large studies of serodiscordant couples, researchers found that between 0 and 2% of consistent condom users seroconverted over a 2-year period, versus 10–12% of couples who were not using condoms consistently (Saracco et al. 1993; de Vincenzi 1994).

The effectiveness of condoms in preventing human papillomavirus infections (HPV) is

reduced in comparison with other sexually transmitted infections. This is thought to be because the human papillomavirus may be resident on the skin in areas not covered by the condom. Research on human papillomavirus infection in men has shown that HPV can be detected in a variety of anatomic sites including the glans of the penis and the shaft of the penis and on other areas of the skin surrounding the genitals.

Latex Condoms

Most modern condoms are manufactured from latex, due to the material's strength, elastic properties, and impermeability to sperm, viruses, and bacteria. Latex condoms can be stretched to over 800% before breaking and have been shown to far exceed the minimum strength required for effective use. During the manufacturing process, latex condoms are tested for holes using an electric current. Latex condoms deteriorate when exposed to ultraviolet light and therefore should be packaged in foil or with opaque packaging on both sides. Material degradation over time is a concern with extended storage of condoms. Extended storage before distribution is less likely to occur in highly developed countries; however, longer supply chains may exist in some countries with the greatest burden of HIV/AIDS. Extended storage and unpredictable distribution of condoms, notably in developing countries with tropical or desert climates, may increase the rate of condom deterioration. Nevertheless, research on condom testing after extended storage has demonstrated that stored condoms may still be uniform in strength and therefore suitable for use.

The characteristics of latex have made it the most popular material for condom manufacture. However, a significant drawback of this material is that the latex is damaged by oil-based lubricants such as petroleum jelly, mineral oil, and other substances. These oils, and lubricants based on these oils, result in a loss of elasticity in the latex, leading to condom breakage as well as slippage during sexual intercourse. Therefore, if lubricants are used with latex condoms, water-based lubricants or other non-oil-based lubricants should be used to avoid material degradation.

Approximately 1–5% of the general population around the world is sensitive to latex, with increased prevalences of latex allergy among highly exposed occupational groups, including health care workers and rubber industry workers. Latex allergic reactions make the use of latex condoms problematic for these individuals. Condoms manufactured from different materials are available, including natural membranes and non-latex synthetic materials such as polyurethane and polyisoprene.

Natural Membrane Condoms

Natural membrane or “lambskin” condoms, typically manufactured from sheep intestine, are one alternative for people with sensitivity to latex. Natural membrane condoms offer protection against pregnancy similar to the protection offered by the latex condom. However, the porous nature of the intestinal membrane results in reduced protection against many sexually transmitted infections. While sperm cells are too large to pass through the pores of the membrane, the pores have been shown to be large enough to allow the passage of viruses including HIV, herpes, and HPV. The natural membrane used in the manufacture of these condoms is considerably stronger, but less elastic than latex, and reportedly transmits more body heat and a more natural sensation during sexual intercourse. Natural membrane condoms are significantly more expensive than latex condoms.

Synthetic Condoms

Condoms are currently manufactured using several synthetic materials as alternatives to latex or natural membranes. Polyurethane condoms are thinner than latex condoms, allowing greater sensitivity and more transmittal of body heat. They are odorless and colorless, reportedly twice as strong as latex, and unlike latex condoms, they can be used with oil-based lubricants. In comparison with latex condoms, polyurethane condoms are less sensitive to ultraviolet light and

temperature and are therefore more resistant to deterioration in storage. However, polyurethane condoms may be noisy during sexual intercourse and may require more lubricant than latex condoms. Laboratory tests have found polyurethane condoms to be as effective as latex condoms in preventing the transmission of sperm and sexually transmitted infections including HIV. However, polyurethane condoms may be less elastic than latex condoms, resulting in a looser fit, higher potential for breakage and slippage, and therefore potentially reduced real-world efficacy against pregnancy and sexually transmitted infections.

Other synthetic materials used in the manufacture of condoms include AT-10 resin and polyisoprene. Polyisoprene condoms cannot be used with an oil-based lubricant but are softer and more elastic than polyurethane condoms.

Spermicidal Lubricants

Surveys have shown that a majority of condom users prefer lubricated condoms. Lubricants may contain spermicidal agents or antimicrobial agents, potentially increasing the efficacy of condoms for pregnancy prevention as well as prevention of sexually transmitted infections. One type of spermicidal lubricant, nonoxynol-9 (N-9), is a surfactant that causes damage to sperm membranes. Results of HIV studies using N-9 have provided evidence suggesting that N-9 may increase the risk of HIV infection. One prominent study found approximately 50% more HIV infections among sex workers using N-9 versus placebo. If N-9 increases the risk of HIV, this effect may be due to increased vaginal irritation and mucosal inflammation (see entry “► [Inflammatory Cytokines](#)”), potentially decreasing the body’s defense against HIV. For example, increased mucosal inflammation may result in recruitment of HIV-target immune cells to the sites of virus entry. Concerns about the possible adverse effects of N-9 have led to condom manufacturers including alternative lubricants in condoms.

Conclusion

The basic form and function of the male condom has been in place for at least 450 years and perhaps much longer. Modern materials and manufacturing technology have improved the male condom and reduced the cost to the point that it is a widespread and effective public health tool for the prevention of HIV, other sexually transmitted disease, and pregnancy in developed and undeveloped countries around the world. When used correctly and consistently, it is a highly effective tool to prevent the sexual transmission of HIV.

Malignancies in Children with HIV Infection

D. Cristina Stefan

Department of Paediatrics and Child Health,
Tygerberg Hospital and Stellenbosch University,
Tygerberg, Cape Town, South Africa

Definitions

Children with HIV infection have an increased incidence of malignancies. A number of them are similar to those tumors that are associated with HIV infection in adults, such as Kaposi

sarcoma (KS), aggressive non-Hodgkin lymphoma (NHL), and ► [cervical cancer](#). Additionally, HIV-infected children have a higher risk than older patients of developing leiomyomas and leiomyosarcomas associated with ► [Epstein-Barr virus](#). The overall incidence of malignancies in HIV-infected children is smaller than in HIV-infected adults, but children's relative risk is higher because the incidence of cancer is usually low in this age group. HIV-associated cancers in children are now a health problem especially in Africa, because of the high incidence of pediatric HIV infection and the high prevalence of infections with oncogenic viruses responsible for many of these tumors.

Changes in the Incidence of Childhood Cancers Associated with the HIV Epidemic

In the adult population subgroup infected with HIV, the lifetime incidence of cancer has been found to be as high as 40% (Flint et al. 2009). Certain tumors, such as Kaposi sarcoma (KS), or non-Hodgkin lymphomas (NHL) are much more frequently encountered in the adult HIV-positive population subgroup and for this reason have been identified as AIDS-defining cancers. Invasive ► [cervical cancer](#) is also considered AIDS-defining. However, besides these three, numerous other malignancies are found more frequently in HIV-infected adults: the list includes ► [Hodgkin lymphoma](#), anal cancer, lung cancer, liver cancer, nonmelanocytic skin cancer, myeloma, leukemia, and conjunctival tumors (Engels et al. 2008).

Similarly, the HIV epidemic in children (0–14 years) was associated with an increase in the incidence of certain cancers, especially non-Hodgkin lymphomas, soft tissue tumors, cancer of the uterine cervix in adolescent girls, as well as thyroid and pulmonary neoplasms. It is estimated that about 2% of children with HIV will develop a cancer as their AIDS-defining disease, as compared to an incidence of malignant disease in the general pediatric population of around 0.0013% (Mueller 1999). The highest incidence increase with AIDS in the United States and Europe was

observed for NHL, followed by leiomyomas and leiomyosarcomas, associated with ► [Epstein-Barr virus \(EBV\)](#) infection. Kaposi sarcoma remained, in these regions, rare by comparison with adults living with HIV. It should be noted that while the incidence of NHL in children with AIDS in the United States is substantially lower than in adults, the standardized incidence ratio of NHL is higher in children because the background rate in the general population is substantially lower.

With the development of tests to screen blood products for HIV and the use of antiviral drugs to prevent maternal-child transmission during birth, the incidence of HIV infection in children has fallen dramatically in the United States and Europe, and it is now very unusual to see HIV-associated tumors in children. By contrast, the incidence of HIV infection remains high in Africa and other resource-limited regions, and HIV-associated malignancies are an important clinical problem. In African children, the incidence of Kaposi sarcoma and, to a lesser extent, that of ► [Burkitt lymphoma \(BL\)](#) soared after the onset of the AIDS epidemic. This has been attributed to the fact that in Central Africa, as far as Cameroun in the west and Malawi in the south, KS was already endemic, with incidence rates greater than 6/1,000, before the advent of AIDS. In these regions, the prevalence of infection with the causative agent of KS, ► [human herpesvirus-8 \(HHV-8\)](#), also known as [Kaposi sarcoma-associated herpesvirus \(KSHV\)](#) is relatively high in children. At the same time, high rates of BL of 4 to 5/1,000 existed in parts of Uganda and Tanzania before the AIDS epidemic; in other parts of Central Africa the rates were lower: 0.2/1,000 in males and 0.04/1,000 in females. Even the smaller rates of BL appear huge when compared with European standardized incidence rates, which, during the AIDS epidemic, did not rise over 3.94/million. The ways in which the AIDS epidemic exacerbated the endemic rates of these cancers will be discussed in the next section.

There are no epidemiologic data on HIV-associated tumors for the whole African continent and in fact, collecting more complete and accurate epidemiologic data would help substantially by informing further research which could

lead to clinical advances in this area. This said, statistics that are available from various countries exemplify the changes in the incidence of cancers in HIV-positive children. In Uganda it was found that the probability of acquiring KS was 95 times higher in children with HIV while the probability of developing BL was 7.5 times higher, but no increase in risk was seen for other cancers (Newton et al. 2001). In Zambia, beside the clear increase in the incidence of KS, several other cancers were noted more frequently after the onset of the AIDS epidemic: non-Hodgkin lymphoma, nasopharyngeal carcinoma, rhabdomyosarcoma, and retinoblastoma (Chintu et al. 1995). In South Africa, the probability of developing BL was found to be over 46 times higher in children living with HIV than in the general pediatric population (Stefan et al. 2011).

Oncogenesis in HIV Infection

The list of malignancies that appear more frequently in people infected with HIV is extensive. However, only a few cancers are highly prevalent in this population group: KS, non-Hodgkin lymphomas (NHL), and invasive cancer of the uterine cervix. They are considered to be AIDS-defining conditions, together with infections like tuberculosis, candidiasis, *Pneumocystis jiroveci* pneumonia, and others. It is significant that with the exception of a large subset of NHL, the above cancers are also, almost always, caused by infections. KS is the result of infection with human herpesvirus 8 ▶ [HHV-8/KSHV](#). Burkitt's lymphoma and other AIDS-associated lymphomas (primary central nervous system lymphomas, diffuse large cell lymphomas, ▶ [Hodgkin lymphoma](#), and primary effusion lymphomas) as well as leiomyomas and leiomyosarcomas are caused mainly by ▶ [EBV](#). Cancer of the uterine cervix is caused by high-risk strains of ▶ [human papilloma virus \(HPV\)](#) (Flint et al. 2009).

Smooth muscle tumors – leiomyoma and leiomyosarcoma – are also encountered in children with HIV; in one study in the United States, they represented the second most common tumor (Mueller 1999). The presence of EBV, in latent

form, in these tumors was signaled initially by McClain et al. in 1995. Jenson et al. (1997) have observed a high presence of the virus in these neoplasms, averaging 4.5 viral genomes per cell. Additionally, the monoclonality of EBV within a given tumor is interpreted as evidence of its involvement in the oncogenetic process. It remains, however, unclear how the abnormal cell division is induced by EBV. It was suggested that certain viral proteins, which continue to be produced by the virus in its latent state, may interfere with the mTOR system, which regulates cell division (Purgina et al. 2011).

It is generally accepted that HIV does not have any intrinsic oncogenic activity, but instead promotes the oncogenesis induced by the viruses mentioned above. This effect is caused, on the one hand, by an inefficient immune surveillance against both oncogenic viral agents and the tumor cells they may produce. On the other hand, the HIV-associated chronic hyperactivity of the immune system mediated by cytokines, stimulates the immune cells' proliferation, which in turn enhances the replication of oncogenic viruses within those cells. Secondly, the cytokines promote the growth of blood vessels in the tumor tissue. The inefficient immune surveillance may also explain why other cancers, not known to be associated with infectious agents, appear slightly more frequently in HIV-infected children (Flint et al. 2009).

The Influence of the HIV Infection on the Clinical Presentation of Malignancies in Children

The immunodeficiency in AIDS might result, in theory, in faster progression of the malignant disease. This could be expressed by more advanced or widespread cancers at the first presentation, a poorer response to treatment and a reduced survival rate. It is also possible that the symptoms and signs of the cancer would be altered by the immune suppression, as the immune response is often contributing to generating the signs and symptoms of a disease. There is a dearth of information in the literature on these aspects, due to the relative rarity of cancer in children coupled with a

relative rarity of HIV in this age group in resource-rich regions, with the resulting difficulty of finding enough cases to comply with the power requirements of the studies. Africa offers a unique opportunity of comparing the clinical presentation of KS and BL, which remain endemic in HIV-negative children, alongside to the epidemic form, which is associated with AIDS.

With regard to KS, there is evidence pointing to a more disseminated disease at presentation in HIV-infected versus noninfected children, including more frequent visceral involvement. There is more frequent lymph node involvement than skin involvement by KS in children with HIV (Gantt et al. 2010). The epidemic has been associated with an increase of the incidence of KS in females, who are also comparatively more often infected with HIV at birth than males are.

In BL, the most frequent localization of the tumor is facial, irrespective of the HIV status (71.4% in HIV-positive, 76.6% in HIV-negative); however, children with retroviral infection have significantly more frequent liver and thoracic involvement, as well as lymphadenopathy. As a consequence, there are significantly more children presenting in advanced stage (stage D) in the HIV-positive subgroup compared with the HIV-negative (37.15 vs. 20.3%, respectively), with the corresponding effect on the survival rates (Orem et al. 2009).

In conclusion, KS and BL, whose endemic variants coexist, in Africa, with their epidemic variants associated with AIDS, offer an opportunity to assess the effect of HIV infection on the clinical manifestations and course of cancers. Retrospective studies of these two diseases, in children with and without HIV, point to a faster progression of the malignancies in the presence of immune deficiency, with more disseminated forms involving more often thoracic or abdominal organs. The consequence of this negative influence is a poorer prognosis.

The literature on smooth muscle tumors and HIV was reviewed by Purgina et al. (2011). Out of the 64 cases published worldwide, only 19 were under 10 years of age and a further 3 were aged between 10 and 20 years. They found that the most frequent localization (but

without a breakdown on age groups) was the central nervous system, followed by the lung and gastrointestinal tract. Other sites involved were bones, serosa and genito-urinary tract. In one-third of cases the tumors were either multiple or recurrent. The clinical progression appeared to be slow, with most of the deaths reported being due to other causes than tumor growth or dissemination.

Particularities of the Management of Malignant Disease in Children with HIV and Cancer

While studies conducted in NHL before the development of HAART suggested that AIDS-associated NHL was best treated with low-dose chemotherapy regimens, there is increasing evidence that standard cytostatic or radiotherapy protocols are preferred instead of low-dose protocols. Cancer chemotherapy is associated with a severe immune suppression due to the destruction of leucocytes. In children with a healthy immune system, the leucopaenia induced by cytostatics is transient and will redress itself during the intervals between therapeutic doses. They are, however, susceptible to severe infections during the neutropenic spells. In contrast, prior to the development of HAART, children with an already compromised immunity by HIV would often not recover but would develop a progressive neutropaenia during the course of their treatment (Chanock and Pizzo 1995). They were thus even more prone to developing infection during cancer chemotherapy. The answer to this complication, however, does not consist in using a low-dose cytostatic protocol but rather in efficient infection prevention by controlling the child's environment, by applying strict hygiene measures and using well-planned prophylactic antibiotherapy, guided by the oncology unit's cumulative antibiogram and by the knowledge of the infectious agents that are usually being encountered in AIDS (Chanock and Pizzo 1995). Excessive neutropenia is less of a problem in patients who are receiving HAART, but can still pose difficulties in patients who have very low nadir CD4 counts.

There is evidence that peripheral stem cell transplantation, which assists with the reconstitution of the immune system, can be of use in the treatment of children with HIV-associated malignancies. Should a bone marrow transplant be indicated, the child may possibly benefit from receiving HIV-resistant (naturally resistant or genetically modified) bone marrow cells, in an attempt to cure the retroviral infection (Krishnan and Forman 2010). This is an area of ongoing research.

Most specialists with experience in the field now feel that radiotherapy should be given in standard doses (and not in reduced doses) irrespective of the HIV status of the patient. There is evidence that in HIV-positive children the toxicity of irradiation is higher, mainly for the mucosa of the digestive tract. Further, radiotherapy was clearly shown to reduce the CD4+ cell counts, both in HIV-negative and positive patients. This reduction is persistent over several years. There are no published data yet to document the extent of the potential increase in risk for opportunistic infections in HIV positive patients who receive irradiation. While there is no evidence to support the initiation of highly active antiretroviral therapy (HAART) at the onset of radiotherapy or before it in such cases, the use of prophylactic antibiotics is common.

Leiomyomas and leiomyosarcomas are most often treated by surgical resection. They are not sensitive to chemotherapy, but radiotherapy has been used in conjunction with surgery (Purgina et al. 2011).

There is convincing evidence that HAART has a beneficial role in the management of AIDS malignancies. Antiretroviral therapy reduces the HIV viral load and allows for restoration of the depleted CD4+ lymphocytes and, consequently, the immunity of the patient improves. Kaposi sarcoma can undergo complete or partial remission after initiation of HAART even without other specific therapy. This has been best studied in adults but can also occur in children (Niehues et al. 1999), to the extent where it appears logical to consider HAART as a first line of treatment in childhood KS, while cytotoxic drugs constitute the second line or agents to be used in patients with extensive disease. Caution should be used, however, in conducting antiretroviral therapy on

patient with KS, as a substantial increase in the volume of the lesions may occur after a few weeks or months of treatment due to the immune reconstitution inflammatory syndrome (IRIS). In this condition, the reconstitution of the CD4+ cell number stimulates the immune system and leads to additional inflammatory reaction around the cancerous lesions. Depending on the localization of these lesions (for instance close to the airways), the IRIS may be fatal; the addition of chemotherapy may control the process.

The effect of antiretroviral treatment in NHL, including BL, is not as well defined, but it is thought to be beneficial: HAART can potentially make patients better tolerate standard-dose chemotherapy and thus improve considerably the prognosis of the patients. An analysis of 87 patients treated for NHL in the same institution found that only 14.3% of the subjects not receiving HAART achieved complete response to chemotherapy, compared with 57.6% of those taking antiretrovirals ($p \leq 0.0001$). The mean survival time was similarly extended from 4.8 to 14 months respectively ($p = 0.01$) (Cornejo-Juárez et al. 2008). This was not, however, a randomized trial and it is possible that HAART administered prior to treatment also affected the type and extent of lymphoma over and above any effect seen during treatment.

While there is an increase of cervical intraepithelial lesions incidence in people infected with HIV, and while cervical cancer is an AIDS-defining disease, the evidence accumulated so far does not find a clear effect of HAART on the incidence of cervical pre-cancerous lesions or on the course of the cervical cancer once it develops, with or without treatment (Adler 2010). Also, HAART is not, by itself, effective treatment for non-AIDS-defining cancers. These appear in individuals who are infected with HIV but are not necessarily immunocompromised and may not have an indication for HAART. These cancers remain relatively rare in children, although their incidence increased slightly.

There are too few cases of use of HAART in smooth muscle tumors, but the data accumulated so far point to a stabilizing effect on the course of the malignancy (Purgina et al. 2011).

Finally, the use of HAART in conjunction with cancer chemotherapy calls for careful planning and close monitoring, due to possible drug interactions, as both cytotoxic agents and antivirals may be metabolized by the same hepatic enzymes (cytochrome P450 group), with consequent increase or decrease in the actions of some of the agents involved (Mounier et al. 2009). More research is needed to define such interactions.

Tuberculosis, malaria, and malnutrition are frequently seen in children with malignancies and AIDS, especially in low-income countries. Irrespective of the potential influence of the HIV epidemic, studies have reported a high incidence of tuberculosis in children with cancer (Stefan et al. 2008). The association of tuberculosis, HIV, and malignant tumors in children creates difficulties in diagnosis and impacts on the survival rate.

There is substantial evidence that the co-operation of malaria and Epstein-Barr virus is important in the pathogenesis of BL; however, the mechanisms involved are still unclear. For instance, it has been shown that during malarial infection the replication of EBV is enhanced, and the treatment of malaria is significantly reducing the EBV viral load (Donati et al. 2006). It is hypothesized that HIV contributes to the pathogenesis by inducing immunodeficiency, but these interactions are incompletely understood at this time.

Malnutrition in children with cancer is frequently seen and not necessarily related to AIDS. During cytotoxic therapy, malnourished children have a higher rate of profound neutropaenia, resulting in a higher risk of severe infections and death (Israëls et al. 2009). A thorough evaluation of the nutritional status of children with cancer on admission – even more so if they are infected with HIV – and a nutrition plan established by a dietician with experience in cancer management would be very useful in these cases.

Conclusion

In conclusion, although HIV does not cause cancer by itself, it strongly facilitates the oncogenetic action of other viruses: HHV-8, EBV, and HPV. This explains the significant increase of the

incidence of malignancies known to be induced by the above agents. Other cancers were also observed more frequently in children with HIV, probably due to inefficient immune surveillance against malignant cells. The infection with HIV worsens the prognosis of cancers. A contributor to this is the relatively more severe and prolonged neutropenia during the treatment with cytotoxic drugs, which opens the gate to potentially lethal infections. There is evidence that HAART aids in the recovery from neutropenia, thus facilitating the administration of standard chemotherapy protocols. Coexistent tuberculosis, malaria, and malnutrition, much more prevalent in low-income countries, add to the complexity of cancer management in children with HIV.

Management of AIDS-Related Kaposi's Sarcoma

Susan E. Krown
AIDS Malignancy Consortium, New York, NY,
USA

Definition

Kaposi's sarcoma (KS) (► [Overview: Aids-Related and Non-aids-Related Cancers](#); ► [Cancers Related to HIV](#)) is a multifocal angiogenic neoplasm whose development requires systemic infection with a human herpesvirus, known as human herpesvirus-

8 (HHV-8) or the KS-associated herpesvirus (KSHV) (► [Kaposi's Sarcoma-Associated Herpesvirus](#)). KSHV infection is required for the development of this neoplasm, but KS occurs in only a fraction of KSHV-infected individuals. Although KS lesions may arise in the absence of overt immunodeficiency, defects in endogenous viral control mechanisms increase the likelihood that KS will develop (► [Epidemiology of AIDS-Related Malignancies](#)). KS is thus more frequently observed among individuals with underlying conditions, such as HIV infection, which impair antiviral immune responses, and is considered an AIDS-defining condition when it occurs in an HIV-infected person. In formulating a management strategy for KS in HIV-infected individuals, two main aspects of the disease need to be considered: (1) the extent of dissemination of KS and the extent to which it impairs the functional status and quality of life of the affected individual and (2) the degree to which HIV infection is suppressed and the options available for improving HIV control and immune function.

Introduction

KSHV, like other human herpesviruses, persists in host cells in a latent form. Available treatments are not able to eradicate human herpesvirus reservoirs, so any therapeutic approaches – either directed at KSHV or at the resulting KS lesions – must currently be considered palliative. There are, however, treatments that can be successfully utilized to control KS tumors either via direct effects on tumor cell growth or indirectly, by stimulating host anti-tumor and antiviral defenses, and in some instances it is possible to eradicate all discernable disease. In AIDS-associated KS, combining both therapeutic approaches is often the best way to manage tumor-associated morbidity.

Evaluation of the Patient

Diagnostic Tests

A definitive diagnosis of KS requires biopsy and pathological examination of a suspected lesion.

Although an experienced clinician may diagnose KS presumptively based on the appearance of typical red or violaceous skin or mucous membrane plaques, patches, or nodules, other pigmented vascular lesions (e.g., bacillary angiomatosis, pyogenic granuloma) may look similar to KS, particularly in darker-skinned individuals, so biopsy is indicated in all cases of suspected KS. Immunohistochemistry using antibodies to KSHV-associated proteins (e.g., latency-associated nuclear antigen, LANA-1) and/or antibodies to endothelial cell proteins (e.g., CD-31) can help confirm the diagnosis of KS and is particularly useful for determining the nature of vascular lesions showing atypical histopathology (O'Donnell et al. 2010).

Documenting the extent of disease (► [Presentation and Pathogenesis of Kaposi's Sarcoma](#)) is required for KS staging and monitoring the response to treatment. The extent of KS varies widely; some individuals may present with a few, inconspicuous skin lesions and show minimal or no progression over time, whereas others may show widespread skin and/or visceral disease and rapid development of new lesions. Evaluation includes a medical history; review of systems (including functional impairments related to the presence of edema, oral lesions, ulcerated skin lesions, pulmonary and/or gastrointestinal lesions) and careful examination of the entire skin surface, including the feet, the external genitalia, the scalp, and the ears; documentation of lesional ulceration; examination of the oral cavity; assessment of lymph node enlargement and edema; and a rectal examination, including testing of a stool specimen for the presence of occult blood. KS-associated edema is typically non-pitting; edema is most common on the lower extremities but may involve the genitals, the periorbital area (with resulting visual impairment), the upper extremities, and the trunk. A chest x-ray should be performed in all patients to evaluate for parenchymal lesions or effusions. Computerized tomography (CT) or magnetic resonance imaging (MRI) of the chest may provide better definition of parenchymal KS lesions. In some cases where pulmonary symptoms are prominent but the results of radiographic studies

are normal or equivocal, bronchoscopy may disclose endobronchial KS lesions. Bronchoscopy may also be helpful in diagnostically challenging situations where pulmonary KS and opportunistic infections coexist or when imaging of the lung is suggestive of KS in a patient who does not have other evidences for KS. Patients should be questioned about the presence of gastrointestinal symptoms (pain, dysphagia, symptoms of obstruction or bleeding). If positive, or if the stool shows the presence of occult blood, upper and/or lower gastrointestinal endoscopy may demonstrate typical KS lesions. Such lesions may be submucosal and difficult to biopsy, but some lesions, particularly superficial or ulcerated lesions, may show KS on histopathologic examination. Routine gastrointestinal endoscopy in the absence of gastrointestinal signs or symptoms is not indicated. As a rule, contrast-enhanced plain radiographs or scans are not useful in evaluating and managing gastrointestinal KS.

Unless lymph node enlargement is particularly prominent or asymmetric, biopsy of lymph nodes to diagnose KS is not indicated, as the finding of incidental KS in lymph nodes has no bearing on prognosis. Even in the presence of proven lymph node KS, regional lymph node dissection is not indicated. Similarly, wide surgical excision of cutaneous KS lesions is not indicated as it does not prevent local or distant KS spread, and surgical excision should be reserved for diagnostic purposes or for the rare isolated lesion that is either cosmetically disfiguring or causing local symptoms (e.g., an isolated, pedunculated lesion of the foot that is bleeding).

Staging

Several staging classifications have been proposed for KS in the presence and absence of HIV infection. The classification used most commonly to describe HIV-infected individuals was described by the AIDS Clinical Trials Group in 1989 (Table 1) and subsequently validated as a predictor of survival based on data obtained in the "pre-HAART" era between 1989 and 1995 (Krown et al. 1997). The staging system, often referred to as the TIS (for tumor/immune system/systemic illness) or ACTG classification,

Management of AIDS-Related Kaposi's Sarcoma, Table 1 Kaposi sarcoma staging classification

	Good risk (0) (all of the following)	Poor risk (1) (any of the following)
Tumor (T)	Confined to skin and/or lymph nodes and/or minimal oral disease ^a	Tumor-associated edema or ulceration Extensive oral KS Gastrointestinal KS KS in other non-nodal viscera
Immune system (I)	CD4 cells $\geq 200/\mu\text{L}$	CD4 cells $< 200/\mu\text{L}$
Systemic illness (S)	No history of opportunistic infection (OI) or thrush	History of OI and/or thrush
	No "B" symptoms ^b	"B" symptoms present
	Performance status ≥ 70 (Karnofsky)	Performance status < 70 Other HIV-related illness (e.g., neurological disease, lymphoma)

^aMinimal oral disease is non-nodular KS confined to the palate

^b"B" symptoms are unexplained fever, night sweats, $>10\%$ involuntary weight loss, or diarrhea persisting more than 2 weeks

categorizes the disease as "good risk" (denoted by subscript 0) or "poor risk" (denoted by subscript 1) based on tumor extent, CD4 count as a measure of immune system function, and the presence or absence of systemic manifestations of HIV infection. A subsequent analysis of the utility of the TIS classification in predicting survival in the "post-HAART" era (Nasti et al. 2003) showed that the presence of poor-risk tumor features, particularly the presence of pulmonary KS, in combination with poor-risk HIV-related symptoms (i.e., low performance status, history of other AIDS-defining illness, unexplained night sweats, fever, weight loss, diarrhea) (T_1S_1), defined an especially poor-risk group of patients with a significantly shorter survival than those patients with good-risk tumor features and/or absence of poor-risk HIV-related symptoms (T_0S_0 , T_1S_0 , or T_0S_1).

Response Assessment

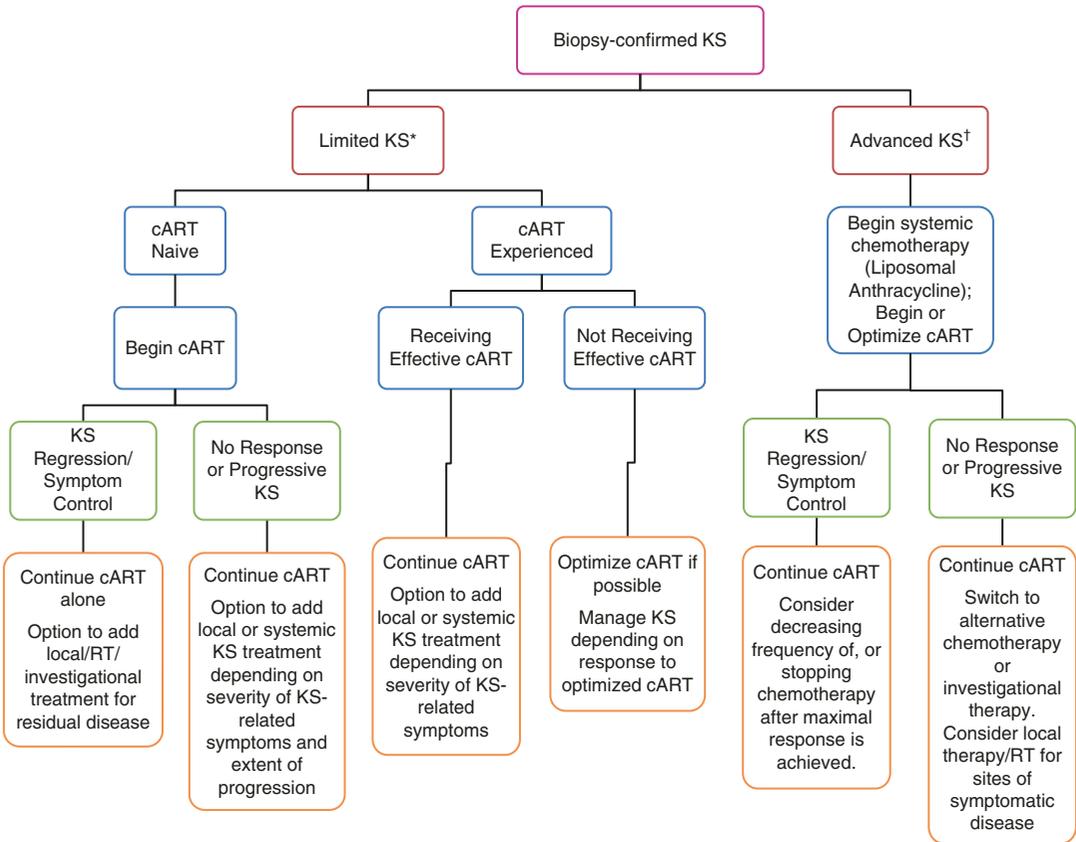

Evaluating the efficacy of treatments for KS presents unique challenges. Cutaneous KS lesions are often multiple, closely spaced or confluent, and irregularly shaped and show varying degrees of nodularity, making accurate assessments of tumor size difficult. Lung lesions are often irregular and poorly defined. Gastrointestinal lesions often require invasive procedures, such as endoscopy, for detection and evaluation, and assessments of lesion numbers and size are only semiquantitative. Tools that attempt to assess

patient benefit with respect to relief of KS-related symptoms (e.g., pain, edema, respiratory symptoms) have been developed but thus far have not been validated as surrogates for objective response or survival. In fact, the results of some studies have suggested that even among individuals not meeting the criteria for objective tumor response, chemotherapy may provide clinical benefits with respect to KS-related symptoms, although symptomatic improvement may also reflect the long-term benefits of coadministered cART (Cianfrocca et al. 2010).

Therapeutic Options

Developing an Overall Treatment Strategy

The extent and rate of progression of KS lesions (► [Presentation and Pathogenesis of Kaposi's Sarcoma](#)) is quite variable, as is the severity of tumor-related symptoms, organ dysfunction, and quality of life. The presence of KS may, by itself, be life threatening (e.g., when there is extensive lung involvement or gastrointestinal bleeding). More commonly, however, KS contributes to morbidity by way of physical manifestations (e.g., by causing pain, difficulty walking, or predisposing to cellulitis of edematous extremities) or by the emotional distress and social stigma occasioned by the presence of highly visible or disfiguring lesions. In some cases, KS may be

Management of AIDS-Related Kaposi's Sarcoma, Fig. 1 KS therapeutic strategy decision tree. *Limited KS is KS confined to the skin and/or lymph nodes and/or non-nodular palatal KS, not causing significant disfigurement or interfering with function and without symptomatic tumor-associated lymphedema, tumor ulceration,

pulmonary KS, or other symptomatic visceral KS. †Advanced KS includes cutaneous KS that is ulcerated, disfiguring, or rapidly progressive; oral KS that is nodular or involves structures other than the palate; symptomatic tumor-associated lymphedema; any pulmonary KS; symptomatic or bulky KS in other visceral sites

an incidental finding that contributes to neither mortality nor morbidity. In individuals with HIV-associated KS, there is also variation in the severity of immunosuppression, the degree to which HIV replication is controlled, and the presence and severity of HIV-related symptoms and other comorbid conditions, including opportunistic infections, wasting, cytopenias, and HIV-related or HIV-unrelated organ (e.g., heart, kidney, liver, lung) dysfunction that may influence the available therapeutic options and overall prognosis. Thus, treatment for AIDS-associated KS must be individualized according to the specific disease features in a given individual. In addition, because there is no treatment for KS

that can be said to be curative, and because a variety of potential management options with different side effects and therapeutic potential may be available for a given patient, the patient's personal goals must be considered in devising a course of treatment. A basic overall schema for developing a therapeutic approach for AIDS-associated KS is outlined in Fig. 1.

HIV Management

The widespread introduction in 1996 of combination antiretroviral therapy (cART) capable of inducing long-term suppression of HIV replication and restoration of immune function was associated with a marked reduction in the incidence of

opportunistic diseases including KS. In addition to its well-established role in KS prevention, cART, often referred to as highly active antiretroviral therapy (HAART) (► [Antiretroviral Medications, Adult Care and Treatment](#)), is considered a critical component of the effective management of HIV-infected patients with an established KS diagnosis. In some cases, particularly when KS is diagnosed in antiretroviral-naïve patients or when it occurs in the setting of suboptimal HIV suppression and immune reconstitution by ART, initiating effective cART or optimizing the cART regimen may, by itself, lead to KS regression. The decision of whether to attempt to treat KS in such individuals with cART alone, or to use cART together with other KS-directed treatments (e.g., chemotherapy), depends on how widely disseminated the KS lesions are and the degree to which they impair function and quality of life. HIV-infected patients diagnosed with or suspected to have KS should be evaluated by an oncologist, preferably one familiar with KS evaluation and management options, very early in the course of the disease, to facilitate treatment planning and follow-up. There is general consensus that attempts to manage KS with cART alone should be confined to individuals with limited, asymptomatic, or minimally symptomatic KS that does not involve visceral organs. Among patients with advanced KS, there is evidence that the combination of cART with cytotoxic chemotherapy results in a higher rate of KS regression and a longer response duration than that afforded by cytotoxic chemotherapy alone (Bower et al. 1999).

Several mechanisms may be involved in cART-induced KS control, but their relative contributions are unknown. These include overall improvements in immune function leading to generation of specific anti-KS responses and inhibition of HIV-1 proteins, angiogenic growth factors, and cytokines (► [Inflammatory Cytokines](#)) that are thought to be important in KS development and progression (Stebbing et al. 2003). In addition, there is *in vitro* evidence that several HIV protease inhibitors may interfere with tumor growth and angiogenesis through mechanisms that are independent of their effects on HIV

infection. One protease inhibitor, nelfinavir, has also been shown to directly inhibit KSHV replication *in vitro* (Gantt et al. 2011). However, the extent, if any, to which HIV protease inhibitors provide benefit to KS patients over and beyond their effect on HIV is not yet known.

Local Treatments

Several methods that aim to control individual KS lesions by the topical application or intralesional injection of antineoplastic agents may be considered for the management of selected patients with limited, non-bulky, slowly progressive cutaneous KS. Local treatments avoid many of the side effects associated with systemically administered therapy and often provide acceptable cosmetic results, sometimes after single or short-term treatment courses. However, these approaches may be associated with local inflammatory skin reactions, pain, and changes in skin pigmentation, prolonged treatment or re-treatment may be required, and there is no expectation that local lesion control will impede the development of new KS lesions in untreated areas.

Of the available local treatment options for KS, only alitretinoin 0.1% gel, applied to cutaneous KS lesions two to four times daily, has been specifically approved by the US Food and Drug Administration (FDA) for this purpose. Although improvement of treated lesions has been observed as early as 2 weeks after starting alitretinoin, much longer treatment courses may be required and treatment durations of up to 96 weeks have been described. Other commonly used local approaches include liquid nitrogen cryotherapy and intralesional injections of vinblastine. The results of several other intralesional treatments have been described in small clinical trials, including recombinant interferon alfa, granulocyte-macrophage colony-stimulating factor and platelet factor 4, and human chorionic gonadotropin, but none of these has been widely adopted in clinical practice. Photodynamic therapy, in which photosensitization of KS lesions is achieved using topical or systemically administered photosensitizers and tumor cell killing is achieved by subsequent irradiation with light from a laser, has also been reported to induce local KS lesion regression, as

has the topical administration of imiquimod 5% cream.

Radiation Therapy

KS lesions are highly radiosensitive. Radiation therapy (RT) has most often been used to treat cutaneous or oral KS lesions but has also been used rarely in the past to palliate complications of advanced, visceral KS, including bleeding gastrointestinal lesions and extensive pulmonary lesions. Although small-field, single-fraction or multi-fraction irradiation with superficial electron beams has been used as a local approach to treat individual KS skin lesions, photon beam RT is more commonly used in the management of more widespread disease such as extensively involved lower extremities, with or without associated lymphedema. Although often effective in achieving local lesion control, patients frequently develop long-term cutaneous changes including a woody appearance and pigmentation changes, and as with other local approaches to therapy, there is no expectation that control of individually treated lesions impedes the development of new KS lesions in untreated areas. An increased risk of mucosal radiation toxicity was described in the era before the introduction of cART, but there is scant recent data on the subject.

With the introduction of cART and the subsequently reduced incidence of advanced KS, the need for RT has declined. In addition, since other systemic treatments, including chemotherapy, are well tolerated and highly effective for treating widespread KS, RT is now generally used only as palliative treatment in individuals with KS that is limited in extent but causing local symptoms (Housri et al. 2010) or in those in whom other treatment alternatives have failed or are not appropriate because of poor performance status or comorbidities.

Systemic Chemotherapy

Systemic chemotherapy is indicated for the management of advanced KS. Advanced KS can be broadly defined as encompassing widespread, symptomatic, and/or rapidly progressive cutaneous KS, including (but not limited to) fungating and/or ulcerated lesions and lesions that cause

pain or disfigurement; extensive, nodular oral KS; symptomatic KS-associated lymphedema; pulmonary KS, including endobronchial or parenchymal lesions, and tumor-associated pleural effusion; and symptomatic gastrointestinal KS, causing pain, obstruction, and/or bleeding. The successful and safe treatment of KS in the HIV-infected patient requires cognizance of and careful monitoring for the multiple overlapping toxicities and potential drug-drug interactions between chemotherapy drugs, antiretroviral agents, and drugs used to treat other HIV-related complications and close cooperation between the primary HIV care provider and the oncologist (Rudek et al. 2011).

KS is highly sensitive to multiple chemotherapeutic agents, many of which were shown to induce regression of classic KS and/or African endemic KS long before AIDS-associated KS was first described. However, only three chemotherapeutic agents have been approved by the United States FDA specifically for use in AIDS-associated KS. These include two liposomal anthracyclines (pegylated liposomal doxorubicin and liposomal daunorubicin) and paclitaxel (Krown 2008). Most oncologists experienced with treating AIDS-associated KS have favored pegylated liposomal doxorubicin as first-line chemotherapy based on observed rates of tumor regression and symptom palliation, good tolerance over long treatment courses, and convenient treatment schedule (one dose every 3 weeks). Paclitaxel is also highly effective (Krown 2008), but is more frequently associated with peripheral neuropathy, asthenia, and alopecia than liposomal anthracyclines and is primarily used as second-line therapy after anthracycline failure or anthracycline-related toxicity.

Although not specifically FDA approved for KS treatment, activity against AIDS-associated KS has been reported for various other chemotherapy drugs used alone (bleomycin, docetaxel, doxorubicin, epirubicin, etoposide, gemcitabine, vinblastine, vincristine, and vinorelbine) or in combination (e.g., the ABV regimen in which doxorubicin (Adriamycin) is combined with bleomycin and vincristine, bleomycin and vincristine without doxorubicin, alternating cycles of

vincristine and vinblastine). Of these agents, only etoposide has shown anti-KS activity when administered by the oral route. The relative efficacy of these drugs in KS is difficult to estimate because they were studied primarily in the pre-cART era in uncontrolled, nonrandomized trials that employed different methods to document the extent of disease and in which response definitions were sometimes ambiguous and inconsistently applied.

The optimal duration of chemotherapy has not been well defined. In advanced KS, durable tumor control usually is dependent not only on the achievement of cytoreduction with chemotherapy but also on the extent to which immunocompetence is restored with antiretroviral therapy. Prior to the availability of cART, significant tumor regression was often observed after chemotherapy for AIDS-associated KS, but the duration of remission was usually short after chemotherapy was stopped. Once effective cART became available, however, it was often possible to discontinue chemotherapy after achieving KS regression without the rapid regrowth of the KS lesions. In some cases, tumor regression continues after chemotherapy is discontinued. These observations support the concept that cytotoxic chemotherapy is not expected, by itself, to cure KS and support the practice of stopping or decreasing the frequency of chemotherapy after stabilization of the lesions, control of tumor-related symptoms, and improvement in quality of life, rather than continuing cytotoxic treatment indefinitely and on a pre-defined schedule until complete tumor regression is achieved. Although KS may subsequently progress after stopping chemotherapy, it is not uncommon for tumors to regress again when chemotherapy (often with the same drug that initially induced tumor regression) is reinstated; this suggests that tumor progression does not result from the acquisition of mutations that confer chemotherapy resistance.

Interferon Alfa

Recombinant interferon alfa (IFN- α) preparations were the first agents specifically tested and FDA approved for the treatment of AIDS-associated KS in the 1980s, on the basis of studies performed

prior to the availability of cART (Krown 2007). Although infrequently used to treat KS for the past decade or more, primarily because of its side effects, the need for frequent parenteral administration, and the introduction of other, easier to administer, and more highly effective agents like liposomal doxorubicin, the sometimes remarkable activity of IFN- α against KS is noteworthy and probably reflects the net result of its multiple potential effects on this neoplasm, which include inhibitory effects on viruses (including HIV and KSHV) and on cell growth and function, including abnormal angiogenesis. Many of these potential mechanisms of IFN action are being investigated in studies of investigational agents that more narrowly target proteins and signaling pathways that are overexpressed or activated in KS.

Investigational Approaches

The growing knowledge of KS pathobiology has provided multiple opportunities to evaluate rational targeted therapies using novel agents. Several preliminary studies have shown the potential promise of this approach. Among the agents for which there is preliminary evidence for anti-KS activity are drugs such as imatinib that interfere with tyrosine kinase-mediated transmembrane receptor signals for angiogenic growth factors that are overexpressed in KS lesions (Koon et al. 2005); mTOR inhibitors, such as rapamycin (sirolimus), that target the constitutively activated Akt/mTOR signaling pathway in KS (Krown et al. 2012); and interleukin-12, a cytokine that enhances type 1 immunity, mediates antiangiogenic effects, and downregulates a constitutively active G-protein-coupled receptor that is encoded by KSHV (Yarchoan et al. 2007). These and other agents, such as those that can reverse KSHV latency and induce apoptosis of infected cells and immunomodulators such as thalidomide and its derivatives, require further formal testing.

Diagnosis and Management of KS-IRIS

Starting cART in the setting of advanced HIV infection has been associated, in some cases, with an apparently paradoxical appearance or worsening of various opportunistic diseases,

including KS, during immune system recovery. This process, known as immune reconstitution inflammatory syndrome (IRIS), has been reported to occur in a variable proportion of patients with KS. The frequency with which KS-IRIS develops is the subject of some debate and may vary in different patient populations. Estimates for the frequency of KS-IRIS have been much higher, for example, in sub-Saharan Africa than in the USA. One difficulty in interpreting the literature on the frequency of KS-IRIS is the lack of a consistent, predefined case definition (Letang et al. 2012). Reports of KS-IRIS have not used standard, rigorously defined criteria for KS progression, and the time interval after initiation of cART during which progression occurred and the degree to which CD4 counts must have increased and to which HIV viral load must have been suppressed has not been uniform.

The optimal management of patients suspected to have KS-IRIS has not been well studied. As a general rule, cART should be continued, and the patient should be evaluated for the presence of opportunistic infections that may have precipitated worsening of KS. Institution of nonsteroidal anti-inflammatory agents may be considered, but there is general consensus that the use of corticosteroids should be avoided whenever possible because they may exacerbate KS progression. The decision to institute or modify systemic chemotherapy in patients with suspected KS-IRIS needs to be individualized. In some cases, KS has been reported to stabilize and eventually regress with continued cART treatment, without addition or modification of KS-specific therapy. In other cases, however, KS may rapidly progress with symptomatic edema and life-threatening involvement of vital visceral organs. In such individuals, prompt institution of systemic chemotherapy may be lifesaving.

KS Management in Resource-Limited Settings: Special Considerations

The foregoing remarks on KS management apply to the experience in well-resourced settings where both cART and large numbers of cancer therapeutic agents have been widely available for many years, rates of KSHV infection and KS tumors are

relatively low, and many patients present with KS of limited extent. By contrast, the vast majority of AIDS-associated KS cases worldwide occur in low-resource settings, primarily in sub-Saharan Africa (► [Sub-Saharan Africa, Specific Characteristics of HIV/AIDS Epidemic](#); ► [HIV Cancers in the Developing World](#)), where rates of KSHV infection are much higher than in the USA and Europe, access to cART is more restricted, the diagnostic and therapeutic armamentaria and the options for supportive care for treatment-related complications are constrained, and comorbid conditions, such as tuberculosis, are common. These factors may affect the choice and tolerance of KS therapy. Moreover, in such settings, KS often is diagnosed at an advanced tumor stage.

Although much has been published on the epidemiology of KS in HIV-infected adults and children in sub-Saharan Africa, there have been few prospective studies to assess KS management strategies in this setting. Some initial reports suggest that chemotherapy with agents commonly available in this setting (i.e., bleomycin and vincristine, with or without concomitant, non-liposomal doxorubicin) provides benefit to patients receiving concomitant cART (Borok et al. 2010; Mosam et al. 2012). Studies to compare the ability of different treatments to induce KS regression, the impact of therapy on survival and quality of life (including effects on KS-associated signs and symptoms, the frequency of drug-related toxicities, and effects on HIV control), prognostic factors, ease of administration of therapy (which may have an impact on therapeutic adherence), and cost-effectiveness are needed to address these important management issues.

Conclusion

KS is the most common HIV-associated malignancy worldwide. In high-resource settings, its incidence has declined since the widespread availability of cART, but KS still represents a therapeutic challenge in a subset of individuals, including some with well-controlled HIV infection. A variety of strategies that include cART, either alone or in combination with other

therapeutic modalities, are available for the management of such patients and in many cases can control lesion growth and KS-related symptoms. However, currently available treatments must be considered palliative, as none have been shown to eradicate KSHV, the causal virus required for KS development. In lower-resource settings, in particular sub-Saharan Africa, the incidence of HIV-associated KS remains high. Although many of the same considerations that figure in developing an approach to the management of KS in well-resourced settings apply to management decisions in lower-resource areas, the availability of therapeutic agents and supportive care is more limited, the incidence of other comorbid illnesses is higher, and the tumor itself may be intrinsically more aggressive in African patients, so the optimal therapeutic approach may be different in this setting.

Definition

Mass media. “A medium of communication (as newspapers, radio, or television) that is designed to reach the mass of the people” (Merriam Webster’s Collegiate Dictionary 1993, p. 715).

Mass media interventions use various mediums of communication – such as television, radio, newspapers, and websites – to deliver HIV prevention messages to large numbers of people with the intention of educating, changing attitudes, or influencing behavior. Ideally, mass media interventions in the prevention of HIV are thoughtfully designed and built upon formative research and sound media and behavior change theory. Mass media interventions are messages or interactive interventions delivered through multiple media formats. Mass media interventions may be implemented or delivered by different sources (commercial, nonprofit, or governmental). Specific messages and desired effects can vary significantly between different campaigns. Mass media interventions in HIV prevention have been proven to be valuable and effective.

This brief entry discusses the use of mass media in HIV preventive interventions. Mass media are briefly defined and delineated. The entry reviews the advantages of using mass media and describes ways to use mass media effectively in HIV prevention. Evaluations of mass media HIV prevention interventions are reviewed, and the entry closes with future implications for mass media in preventing HIV infection.

Why Mass Media?

Mass media interventions can reach many people at a low rate of cost per person reached and can be cost-effective in preventing new HIV infections even among populations that are relatively low risk for HIV (Cohen et al. 2005). Mass media also have the potential to reach many different groups including people that may not be reached through conventional HIV prevention interventions. For instance, in China, knowledge about HIV has been slow to circulate through interpersonal channels, so mass media are one way to reach people who otherwise may not have any/accurate knowledge about HIV (Li et al. 2009).

Types of Media in HIV Prevention Campaigns

Determining what type of media is appropriate to use in a mass media HIV prevention campaign depends upon the location and target of the specific campaign. Campaigns can include more traditional forms of mass media such as print materials, billboards, and television or radio ads, or newer forms of mass media such as Internet advertising, smartphone applications (apps), or video games. At times, novel media interventions have been used to reach otherwise difficult-to-reach populations or to work within budgetary constraints. Examples of novel media campaigns include: a television soap opera portraying a family with HIV designed to increase HIV knowledge in the Ivory Coast (Shapiro et al. 2003), an audio drama broadcast over loudspeakers in Thailand (Elkins et al. 1997), and live plays performed in communities in Sri Lanka (McGill and Joseph 1996). In the era of Internet and smartphones, social media sites such as Facebook or Twitter are becoming targets for mass media campaigns, as are integrated smartphone apps. For instance, a program promoting testing for sexually transmitted infections (STIs) included the use of multiple social media sites to encourage individuals to seek STI testing as well as short message service (SMS or text messages) to inform them of STI testing

sites near their current location (Friedman et al. 2014). Mass media campaigns which use multiple forms of media are recommended due to the likelihood of increased exposure and increased effects of the messages; however, the cost of media campaigns may prohibit this multiple delivery method (Bertrand and Anhang 2006). An example of a campaign using multiple forms of mass media is a recent program targeting increased safe sex among men who have sex with men in Scotland, which utilized a campaign website, targeted online advertising, a smartphone app, as well as print materials such as posters and leaflets (Flowers et al. 2013).

Designing Effective Campaigns

For mass media campaigns to be effective in preventing HIV, they must be effectively designed. Effective mass media campaigns require careful planning, including the following steps (as delineated by Noar 2006): (1) research prior to forming the campaign to increase knowledge about the target audience, (2) rooting the campaign in sound theoretical concepts (e.g., behavior change theory), (3) defining a specific target audience, (4) designing a message that is specific to that target audience, (5) using media that is most likely to reach the target audience, and (6) evaluating the media campaign. Understanding the target audience is a very important component of designing media campaigns; formative research such as focus groups or analysis of trends within a community can help contribute to understanding the target audience and aid in intervention design.

While targeting one specific group is often the strategy of mass media campaigns, some particularly ingenious campaigns have targeted multiple groups with messages that evoke different meanings depending on the consumer's group membership by using "strategic ambiguity," wherein components of the message may remain ambiguous to target multiple groups simultaneously (DeJong et al. 2001). For example, a message may be ambiguous enough about race or gender to allow the viewer to believe that he or she is

watching someone within the message who is of a race or gender that is similar to his or her own race or gender. Creating mass media messages that target multiple groups allows the campaign to be delivered to an increased target audience, thereby reducing the cost of the media per targeted viewer.

Special care must be taken in targeting specific populations for HIV prevention, as an iatrogenic effect (an unintended harm caused by the message) could occur if the mass media consumer believes that he or she is not part of the targeted population and therefore is not at risk for HIV (Palmgreen et al. 2008). Alternatively, targeted prevention efforts may inaccurately stereotype the populations being targeted (Palmgreen et al. 2008). For instance, early mass media campaigns often inaccurately portrayed injection drug users as African American (Dejong et al. 2001), promoting an inaccurate association between this specific racial group and injection drug use. Similarly, members of a group may reject HIV prevention messages if they feel that their group is being unfairly stigmatized.

Initial comprehensive evaluations of mass media HIV prevention campaigns indicated a need for improvement in evaluation of the campaigns and increased theoretical rationale for campaigns (Myhre et al. 2000). Early HIV prevention mass media campaigns in the USA (created and/or broadcast from 1987 to 1994) were often poorly designed and were problematic due to shortcomings that included failure to target high-risk groups, failure to promote HIV testing, and failure to address barriers to safe sex (Dejong et al. 2001). More recently, mass media campaigns appear to have improved as they often have included elements of effective campaign design (Noar et al. 2009) or have been created through careful evaluation processes (as in Noar et al. 2014).

Implementation of Mass Media Campaigns

Mass media campaigns can be implemented by several sources, including government, not for profit or community-based organizations or for

profit businesses. Media time may be donated by a commercial media venue or may be paid for by a government or other vested organization. Alternatively, businesses that stand to profit from HIV prevention (for instance, condom manufacturing companies) may combine HIV prevention messages with advertisements for their product. Some organizations have experimented with innovative and comprehensive mass media dissemination of HIV prevention messages. The Kaiser Family Foundation, for instance, engaged media partners (such as popular television networks) to donate television time for public service announcements and to integrate HIV prevention messages into the storylines of popular television shows (Hoff et al. 2009). This kind of comprehensive approach seamlessly integrates HIV prevention messages into entertainment programming, which is reinforced by multiple media sources.

Mass Media Messages in HIV Prevention

HIV prevention messages in mass media can have several different goals. Messages may aim to educate individuals about HIV or HIV risk or encourage individuals to engage in a specific behavior (e.g., risk reduction, HIV testing). Research on the target population is vital to effectively developing and delivering a message. For example, one mass media campaign targeting African American adolescents designed messages to target beliefs in this community that condom use made sexual intercourse less pleasurable (Romer et al. 2009). Romer et al. (2009) targeted this belief by promoting the idea that intercourse with a condom can be more pleasurable because there is less associated concern about safety and STIs and found differences in this core belief among adolescents exposed to these targeted messages. Identifying core beliefs which may be barriers and/or assets to HIV prevention efforts allows the message content to be individualized to the target community and can result in a culturally relevant message. Targeted messages should take into account the characteristics of the community being targeted. For instance, within communities with high HIV rates, prevention campaigns may

encourage use of antiretroviral medications in order to lower rates of disease transmission, while in communities with low HIV rates, this would be an ineffective and inappropriate intervention. Customizing prevention messages to the needs of target audiences is vital in creating effective mass media campaigns.

Effectiveness of Mass Media Campaigns

Mass media campaigns have been shown to be effective in HIV prevention, including the following outcomes: increased knowledge and reduced HIV/AIDS-related stigma (Li et al. 2009), increased rates of voluntary HIV testing (Vidanapathirana et al. 2005), and increased rates of safer sex (Agha 2003). In some cases, mass media campaigns have been shown to be increasingly effective with increased exposure to the campaigns, thereby exhibiting a dose–response relationship, (Agha 2003). Mass media campaigns have also been shown to primarily effect short-term (rather than long-term) behavior change (Vidanapathirana et al. 2005) and thus should be considered part of an ongoing prevention effort rather than a one-time intervention. Taken together, these findings implicate the utility of using mass media campaigns in an ongoing basis.

Future Directions in HIV Mass Media Campaigns

Media usage patterns are continually changing as new technologies become available and go in or out of vogue. Newer trends away from traditional television watching and toward Internet-delivered programming have already and will continue to increase the need for adaptive and creative ways to reach target audiences. Internet television in its various forms, including video sharing websites, is one way to deliver HIV prevention messages. Sharing media through and advertising on social networking sites are other ways to deliver HIV prevention messages to targeted communities. Video games or smartphone apps can be

interactive ways to encourage behaviors that would prevent HIV. Newer mass media programs can include billboards or other media that direct consumers to use their smartphones to scan barcodes, which direct them to other media on their phone or direct them to websites to play HIV prevention games. As technologies continue to develop, novel means of using mass media will continue. Future research could identify successful components (i.e., by using dismantling) of mass media interventions so that these specific components could be used to target specific communities in culturally appropriate ways.

Conclusion

Mass media can be an affordable and effective tool in HIV prevention efforts. It can also be used in novel ways to reach otherwise difficult-to-reach populations. Mass media HIV prevention efforts will continue to adapt to new technologies to reach contemporary audiences.

Maturation Inhibitor

Shashi Kapadia and Marshall J. Glesby
Division of Infectious Diseases, Department of
Medicine, Weill Cornell Medical College,
New York, NY, USA

Definition

Maturation inhibitors are a class of HIV antiretroviral agents currently in development. They act at the viral maturation step, which involves cleavage of the structural protein “Gag,” resulting in the development of an infective viral particle. These agents aim to stop viral maturation by inhibiting Gag cleavage. While not currently in clinical use, they represent a promising new therapeutic class for HIV infection.

Introduction

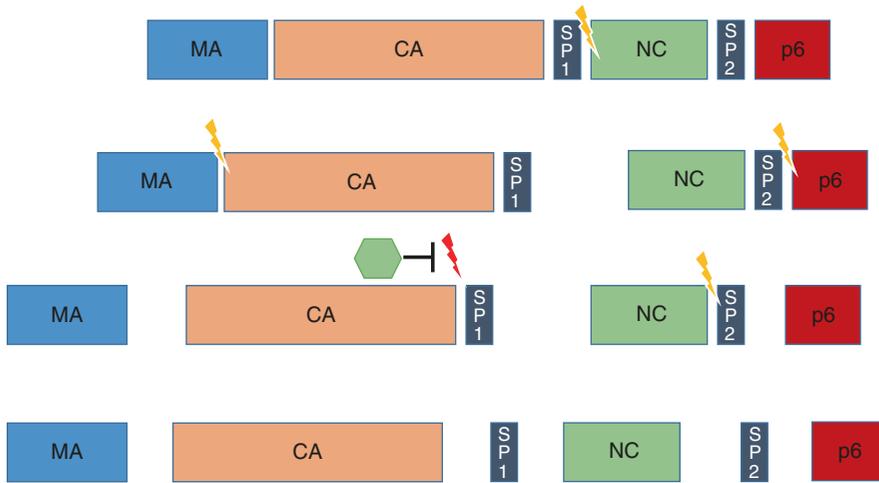

Combination antiretroviral agents with distinct mechanisms have become the mainstay of therapy for HIV infection. A variety of drug classes are available for use, as discussed elsewhere in this text, targeting viral enzymes including reverse transcriptase (RT), protease (PR), and integrase (IN). All currently recommended antiretroviral regimens use a combination of the above classes to provide therapeutic effect (Panel on Antiretroviral Guidelines for Adults and Adolescents 2014; Gunthard et al. 2014). The rationale for a combination approach to therapy is largely based on the ability of HIV-1 to rapidly acquire drug resistance when exposed to single agents (Simon et al. 2006; Temesgen et al. 2006).

Additional drug classes have been developed and are continuously being sought, with examples including inhibition of viral entry by targeting the gp41 envelope protein or by targeting the CCR5 coreceptor (Haqqani and Tilton 2013). Both of the above drug classes are in limited use, often reserved for therapy when resistance has developed to first-line or subsequent regimens (Haqqani and Tilton 2013; Llibre et al. 2015).

A recently discovered approach to HIV therapy, maturation inhibitors target proteolytic cleavage of the precursor Gag polyprotein (Pr55^{Gag}). The precursor Gag polyprotein is one of the three polyproteins that are eventually cleaved into the composite proteins making the structure of the complete virion, the other two being the precursors to Gag-Pro-Pol (Pr160^{Gag-Pol}) and to Env (Swanstrom and Wills 1997). As an initial step in assembly, the Gag and Gag-Pro-Pol polyproteins migrate to the host cell plasma membrane, where they undergo multimerization, and facilitate assembly of the immature virion via protein-RNA interactions, protein-protein interactions, and interaction with host motor proteins and cellular transport machinery (Sundquist and Krausslich 2012). Ultimately, Gag is necessary for a number of important steps in virion assembly: initiation of the budding process, control of virion size, and directing and packaging the components of the developing virion (Swanstrom and Wills 1997).

As they arrive at the plasma membrane, both the Gag and Gag-Pro-Pol precursors undergo cleavage by viral protease into their component proteins (Adamson and Freed 2007). The Pro-Pol component of Gag-Pro-Pol is cleaved into the viral reverse transcriptase, protease, and integrase. The Gag component is cleaved into a set of structurally important proteins: matrix protein (MA), capsid (CA), nucleocapsid (NC), the p6 protein, and the spacer peptides SP1 and SP2 (Sundquist and Krausslich 2012). This cleavage induces structural changes in the developing virion, resulting in assembly of the conical capsid lattice needed for a mature virus (Ganser-Pornillos et al. 2008). Gag processing is highly ordered. Differential rates of cleavage by the PR protein result in a specific sequence to processing: First, the precursor protein is separated into the NC-SP2-p6 and MA-CA-SP1 fragments. Next, PR cleaves the MA-CA site and the SP2-p6 site and then finally the NC-SP2 site and the CA-SP1 site (Adamson and Freed 2007; Erickson-Viitanen et al. 1989; Krausslich et al. 1988; Wiegers et al. 1998) (Fig. 1).

It is this final step, the cleavage between CA and SP1, that is the target of the drug class

Maturation Inhibitor, Fig. 1 The Gag polyprotein with stepwise cleavage by protease. The cleavage between CA and SP1 is blocked by the action of bevirimat

described here. This class of drug has been termed “maturation inhibitors.”

Maturation Inhibitors

Bevirimat

The story of maturation inhibitors begins with 3-*O*-(3',3'-dimethylsuccinyl)-betulinic acid, later named bevirimat (BVM), which was studied for clinical use between 2003 and 2010.

Initially developed as PA-457, the compound was derived from betulinic acid based on a mechanism-blind screening assay. After development of the compound, it was determined that the mechanism was disruption of the PR-mediated cleavage of the Gag precursor protein (Li et al. 2003; Kanamoto et al. 2001; Zhou et al. 2003). Specifically, bevirimat acts near the cleavage site between CA and SP1, preventing the conversion of the CA-SP1 precursor to the mature CA protein (Li et al. 2006). Even a transient, subtle disruption in the highly regulated mechanism of Gag cleavage can be sufficient, as uncleaved CA-SP1 present during assembly can interfere markedly with maturation (Checkley et al. 2010; Muller et al. 2009). The presence of bevirimat has been shown to stabilize the immature, noninfective capsid lattice, rather than allowing the formation

of the conical capsid necessary for infectivity (Keller et al. 2011).

The conservation of the CA-SP1 cleavage site sequence is essential to the action of bevirimat: viruses with divergent CA-SP1 sequences such as SIV and HIV-2 did not show response to the drug (Zhou et al. 2003). Further work identified specific amino acid polymorphisms resulting in decreased antiviral activity of the drug (Zhou et al. 2006; Adamson et al. 2006; Lu et al. 2011).

Phase 1 and phase 2a studies of bevirimat showed promise, with safety and efficacy in small numbers of patients studied without apparent development of resistance (Smith et al. 2007; Yebra and Holguin 2008; Martin et al. 2007a, b). Further studies showed safe coadministration with protease inhibitors without apparent interaction (Martin et al. 2008). However, phase 2b clinical trials found that about half the patients given bevirimat did not show clinical response despite adequate levels because of CA-SP1 site polymorphisms predisposing to resistance (McCallister et al. 2008; Van Baelen et al. 2009; Adamson et al. 2010). The prevalence of naturally occurring polymorphisms conferring reduced susceptibility or resistance to bevirimat was found to be unacceptably high: between a third and half of treatment-naïve viruses tested (Seclen et al. 2010; Verheyen et al. 2010; Margot et al. 2010).

Development on bevirimat was stopped in 2010. However, interest in the Gag processing pathway as a therapeutic target remains, and new investigational medications in this class continue to be studied.

MPC-9055

A second maturation inhibitor named MPC-9055 had also started development in 2009. It too showed similar limitations with the development of polymorphisms conferring resistance, and development was halted in 2010 (Baichwal et al. 2009).

BMS-955176

As of this writing, a second-generation maturation inhibitor is currently under development. Known as BMS-955176, the phase 2a clinical data were presented in 2015. Like bevirimat, BMS-955176 also targets the cleavage of the CA-SP1 precursor but unlike its predecessor seems to offer improved binding to Gag polymorphs. Monotherapy for 10 days was well tolerated and resulted in dose-dependent declines in HIV viral load, with a median reduction of 1.64 log₁₀ copies/ml. The study showed similar declines in HIV-1 viral load among wild-type Gag proteins and proteins with baseline polymorphisms that may have conferred resistance to bevirimat (Hwang et al. 2015). Another study presented on the same year showed activity and safety of the drug in combination with atazanavir and ritonavir (Hwang et al. 2015). Further studies to assess the role of BMS-955176 remain underway.

Conclusions

While the strides in controlling HIV through antiretroviral therapy have been massive, the continued problem of evolving drug resistance shows the need for continued development of new, safe, and effective antiviral agents. Our improving knowledge of the HIV life cycle makes novel therapeutic targets a possibility. The HIV Gag polyprotein, essential for virus assembly and

maturation, provides one such target. While drugs targeting Gag processing are not yet ready for clinical use, our preliminary understanding of this mechanism leads to hope that they will one day be an additional armament in the battle against the HIV epidemic.

Definition/Introduction

Among persons living with HIV infection, adherence to antiretroviral therapy (ART) and other prescribed medications is the critical factor associated with reductions in morbidity and mortality. As a result, HIV is often considered a chronic illness. There have been several advancements in ART medication development, formulation, and administration that have increased the ease of ART adherence as compared to the early years of the epidemic. Specifically, side effect profiles have improved medication tolerability, and there are newer combination medications that allow for most regimens to be between one to three pills per day. Along with the view that HIV has become a chronic illness, however, is the observation that the number of chronic comorbidities among those with HIV has grown. Thus, pill burden remains high among HIV-infected persons as compared to the general population, although many of the medications are for the treatment of HIV-related conditions (e.g., neuropathy, chronic pain) and associated comorbidities (e.g., increased rates of cardiovascular disease). A recent meta-analysis showed that only 62% of HIV+ individuals are $\geq 90\%$ adherent to their ART (Ortego et al. 2011).

Several factors have been consistently shown to be associated with nonadherence to ART and include mood disorders, substance abuse, and

lack of social support, among others. Pertinent to this chapter, neurocognitive impairment is also a strong predictor of ART adherence. Even in this era of effective ART, HIV-associated neurocognitive disorders (HAND) persist in up to half of HIV+ individuals (Heaton et al. 2010). Critical to the diagnostic criteria for HAND is whether neurocognitive impairment impacts everyday functioning and the severity of the daily functioning problems. Interestingly, there may be a bidirectional relationship between cognition and medication adherence, that is, poor neurocognition may lead to medication nonadherence and subsequently worse medication adherence leads to less controlled HIV disease, which confers risk for worse neurocognitive functioning. Although effective interventions have been developed for improving ART adherence, few interventions consider how neurocognition may complicate treatment implementation.

Given the prevalence of HAND and the importance of medication adherence, this chapter will (1) broadly review HAND and its association with daily functioning, (2) discuss medication adherence among HIV-infected persons, (3) assess the relationship between HAND and medication adherence, and (4) discuss HAND remediation efforts. It is important to note that we will be using a broad definition of medication adherence to include all medications and not exclusively ART; however, the great majority of studies relating HAND to medication adherence have focused fully on adherence to ART.

What Is HAND?

In the current era of ART, the profile of HAND is typically one of mild-to-moderate neurocognitive impairment with either the absence (asymptomatic neurocognitive impairment, ANI) or presence of daily functioning difficulties (mild neurocognitive disorder, MND), rather than the more severe presentation of HAND (i.e., HIV-associated dementia, HAD). The profile of ANI and MND is somewhat variable given that HIV infection is associated with damage to both cortical and subcortical structures (fronto-striato-

thalamic circuits appear particularly susceptible). As a result, the most commonly observed neurocognitive deficits are in learning (e.g., ability to encode new information over repeated exposures), episodic memory (e.g., ability to retain both verbal and nonverbal information over a delay, e.g., at least 30 min), executive functions (e.g., a broad term associated with frontal lobe functioning, posited to include problem solving, abstraction, planning, cognitive flexibility, and inhibition), and working memory (e.g., ability to maintain and manipulate information “online”) (Heaton et al. 2011). Certain neurocognitive functions tend to be unaffected, such as naming abilities, simple attention, and somatosensory functions, which distinguishes ANI and MND from more severe dementing conditions.

Of ecological relevance to the present chapter, such HIV-related neurocognitive impairment is reliably associated with everyday functioning declines in this population. Although neurocognitive deficits are largely “mild” in nature (meaning that performances typically fall just below one standard deviation below the expected mean of healthy comparison participants), up to 60% of HIV+ individuals with HAND demonstrate difficulties on functional outcomes. Most commonly, the effects of HIV-associated neurocognitive impairment are observed on instrumental activities of daily living and other more complex daily living tasks (e.g., financial management, driving, unemployment) rather than basic activities of daily living (e.g., dressing and bathing). Impairments on basic activities of daily living remain largely intact and are more strongly related to physical symptoms due to advanced HIV disease progression (Blackstone et al. 2013a).

Medication Adherence in HIV-Infected Persons

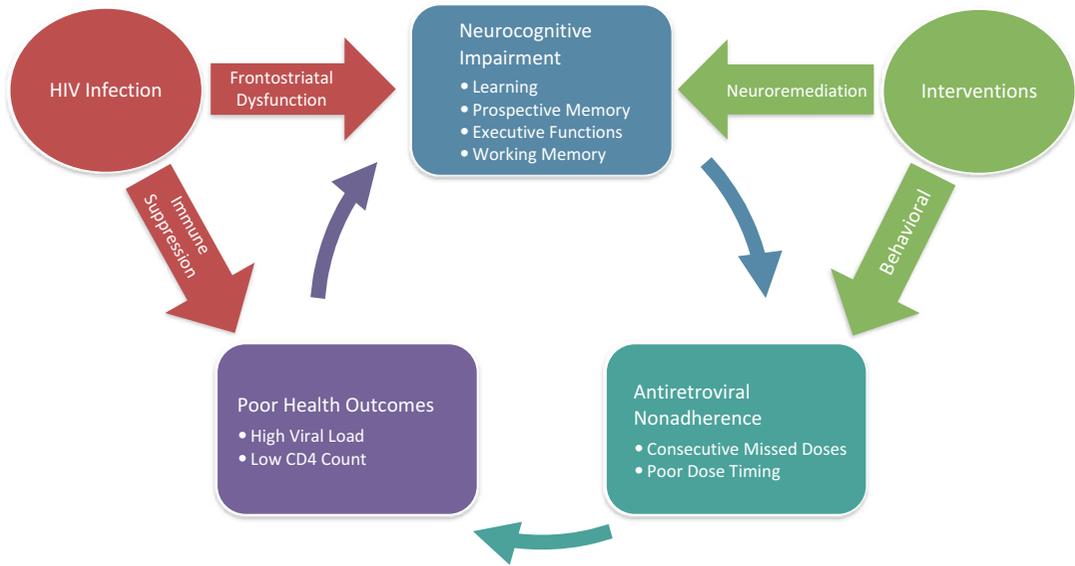

Without effective ART treatment, HIV infection leads to a progressive failure of the body’s immune system. Once an individual is infected with HIV, the virus fuses to the surface of the host cell (e.g., CD4 lymphocyte), which permits HIV to enter the cell. Once inside, HIV releases an

enzyme called reverse transcriptase to convert its genetic material (i.e., HIV RNA) into HIV DNA. HIV then produces another enzyme called integrase that allows HIV DNA to be integrated with the cell DNA. HIV then uses the machinery of the host cell to create long chains of HIV proteins that are the building blocks for more HIV. An HIV enzyme called protease cuts up the long chains of HIV proteins, and the smaller HIV proteins combine with HIV RNA to form a new virus, which then bud from the host cell. The life cycle of HIV is important to consider because antiretroviral medications used for the management of HIV infection act to interrupt the HIV replication cycle.

Antiretroviral medications used in the treatment of HIV infection protect the immune system by blocking HIV at different stages of the HIV replication cycle. The initial antiretroviral medications were nucleoside reverse transcriptase inhibitors (NRTIs), which block reverse transcriptase from converting HIV RNA into HIV DNA. Subsequently, nonnucleoside reverse transcriptase inhibitors (NNRTIs), which bind and inhibit reverse transcriptase, and the viral protease inhibitors (PIs), which block protease, were introduced. Agents targeting other phases of the HIV life cycle, including inhibition of the fusion peptide chemokine receptor 5 (CCR5) and viral integrase, have recently become part of “the cocktail” of drugs available for the treatment of HIV.

Combination ART, which combines two drugs that target reverse transcriptase (i.e., NRTIs and/or NNRTIs) with drugs that target the viral protease, is now the standard treatment approach. At the beginning of modern ART, regimens were notable for frequent dosing (i.e., high “pill burden”) and significant adverse effects, which negatively affected ART adherence. Current combination ART regimes and drug formulations reduce pill burden and dosing complexity as well as adverse effects, all of which provide greater opportunities for successful ART adherence. Consequently, combination ART regimens have reduced disease progression and mortality substantially compared to regimens using agents targeting only one aspect of the HIV life cycle (Fig. 1).

Adherence to ART is key to deriving therapeutic benefit. Although ART has led to

Medication Adherence and HIV-Associated Neurocognitive Disorders (HAND), Fig. 1 A model illustrating the hypothesized mechanisms by which HIV infection detrimentally impacts antiretroviral (ART) adherence and neurocognitive functioning, as well as potential

points for intervention. Of note, several other factors are known to confer risk for suboptimal adherence to ART and to impact performance on neurocognitive tasks (e.g., mood disorders and substance abuse); however, these factors are not the primary focus of this chapter

improvements in clinical outcomes, antiretrovirals need to be taken with consistency to work effectively. Although extremely high ART adherence (i.e., greater than 95% adherent) was initially considered necessary to optimize viral suppression, poor ART adherence does not necessarily lead to a complete lack of therapeutic benefit. Recent research indicates that patterns of adherence have different impact on the risk of detectable HIV RNA levels. Specifically, missing days of medication consecutively may have a greater impact on the efficacy of ART than missing the same amount of time in a nonconsecutive manner (Genberg et al. 2012). Furthermore, the efficacy of some combination ART regimens may be less affected by patterns of adherence due to longer half-lives of agents (e.g., NNRTIs and boosted PIs). Although perfect adherence to ART may not be necessary to achieve positive clinical outcomes, limited ART adherence may lead to poor virologic control and death and create treatment-resistant HIV strains.

Despite the abundance of empirical evidence supporting the therapeutic benefit of ART adherence, the most valid and reliable measure of

medication adherence is a topic of ongoing deliberation. Selection of the best strategy for assessing medication adherence requires consideration of the advantages and disadvantages of the various assessment tools. Multiple methodologies have been employed to assess medication adherence, which include direct and indirect measures. Direct methods may involve the collection of biological assays of active drug, metabolite, or other markers in bodily fluids to confirm active drug ingestion. Indirect methods, which do not directly measure the presence of the drug in an individual, include self-report, clinician assessment, medical chart review, clinic attendance, behavioral observation (e.g., directly observed therapy, pill count, pharmacy refill records, medication event monitoring system), and therapeutic impact (e.g., HIV RNA viral load, CD4 lymphocyte count, Centers for Disease Control-defined stage of disease progression, and mortality). Each assessment method has advantages and disadvantages to consider, including financial and logistical cost, as well as issues of psychometric and epidemiologic validity and reliability.

Intersection of HAND, Adherence, and ART

Neurocognitive Impairment and Adherence in HIV

Numerous studies have shown that worse neurocognitive functioning is associated with poorer medication adherence. Specifically, HAND has been found to confer up to a 2.5-fold increased risk for nonadherence (e.g., Hinkin et al. 2004). Broadly, cross-sectional studies have shown that better higher-order executive functions, as well as learning and working memory abilities, are particularly important for optimal medication adherence among HIV-infected persons.

Longitudinal studies have also examined the temporal relationship between ART adherence and HAND. In one such study, it was found that among neurocognitively impaired persons with HIV infection, ART adherence decreased significantly on weekend days as compared to weekdays. The authors hypothesized that the weekend-related adherence decrease was driven by a lack of structured schedules on the weekends compared to the weekdays. Importantly, there appears to be a reciprocal relationship between HAND and adherence such that as one worsens, the other worsens (Ettenhofer et al. 2010). A recent longitudinal analysis showed that over a 6-month period, individuals with declines in neurocognitive performance were more likely to evidence worsening adherence. Worse learning, memory, and executive dysfunction predicted poorer adherence; not surprisingly, on the other hand, higher levels of adherence were associated with more intact broad frontostriatal abilities, including better processing speed, attention, executive functions, and motor functioning.

More research, however, needs to be conducted, particularly with regard to relationships between neurocognitive function, daily adherence (e.g., the proportion of doses taken on a given day), and duration and frequency of frank interruptions in treatment. It is important for such research to include representation of both genders and vulnerable populations that face difficulties in consistently sustaining access to treatment (e.g., seriously mentally ill, drug abusing, homeless, or

incarcerated populations, and those in resource-limited settings). Cysique and Brew (2009) list some of the remaining challenges for those living with HAND.

One neurocognitive ability that may be especially germane to medication adherence in among people with HIV infection is prospective memory (i.e., “remembering to remember”). Given that one of the necessary neurocognitive components of successful adherence is remembering to take one’s medication at the designated time, the role of prospective memory in medication-taking behaviors is particularly face-valid and ecologically relevant. Additionally, prospective memory draws upon prefrontal and hippocampal neural systems and necessitates aspects of both episodic memory (e.g., retrospective recall) and executive functioning skills (e.g., self-monitoring), all of which are susceptible to disruption following HIV infection. In fact, HIV+ individuals evidence large effect size decrements in prospective memory performance compared to their seronegative counterparts (i.e., Cohen’s $d = -0.92$).

Not surprisingly, deficits in prospective memory are linked to worse self-reported ART management skills (e.g., “I am less efficient at adhering to my regimen than I used to be”), independent of other important factors known to predict medication management (e.g., mood, attitudes toward medications, relationship with medical providers, and worse performance on traditional neurocognitive batteries) and beyond frequency of implementation of behavioral ART adherence strategies (e.g., using an alarm). Additionally, global prospective memory abilities demonstrate medium effect sizes with ART adherence (i.e., Woods et al. 2009), and appear to be particularly driven by time-based prospective memory abilities (i.e., remembering to complete a future intention at a particular time), which exhibit large effect sizes with ART adherence (i.e., Cohen’s $d = 0.60$; Woods et al. 2009). In fact, Poquette et al. (2013) recently demonstrated that it may be HIV-related difficulties in executing intentions across longer delays (i.e., 15 min) but not shorter delays (i.e., 2 min) that are most strongly tied with ART nonadherence. Counterintuitively, increased implementation of memory-based adherence strategies

is associated with poorer event-based prospective memory abilities and worse ART adherence, as measured by the medication event monitoring system (Blackstone et al. 2013b). Although the mechanisms behind this finding are not yet clear, these results may indicate that although individuals with HIV-associated prospective memory deficits tend to report using more memory-based adherence strategies, such strategies are not completely successful at bolstering ART adherence in the context of prospective memory deficits.

ART Efficacy

Given the persistence of HAND in the context of ART adherence, research is under way to develop more effective antiretroviral agents capable of penetrating the central nervous system (CNS). Antiretroviral agents vary in their ability to penetrate the blood-brain barrier and enter the CNS, depending on their protein binding, molecular size, and lipophilicity. This variability has been quantified by a metric termed the CNS penetration effectiveness (CPE) ranking system. Better penetrating (i.e., higher CPE) regimens, with presumed better CNS effectiveness, have been shown to better suppress viral loads in the cerebrospinal fluid. Longitudinal investigations have documented that patients with HAND demonstrate better improvement with initiation of higher CPE regimens; however, results of cross-sectional studies have been discrepant. These cross-sectional results may reflect the possibility that higher-CPE regimens were selected to treat more medically ill patients, who have a higher likelihood of neurocognitive impairment. As the HIV-infected population continues to age, it will be important to determine if certain ART agents require dosing modifications based on increased blood-brain permeability experienced late in life.

In addition to the issue of CNS penetration, treatment initiation may influence neurocognitive outcomes. Both low CD4+ nadir and the inadequate suppression of peripheral viral load are consistently associated with worse neurocognitive performance in the presence of adequate ART adherence. Given that neurocognitive impairment may be detectable shortly after infection with

HIV, initiation of ART before damage to the immune system occurs, and viral control is lost and is recommended to improve neurocognitive outcomes. A recent report documented similar rates of neurocognitive impairment between early-treated HIV patients and uninfected persons, suggesting that initiation of ART shortly after infection may protect the CNS, thereby preserving neurocognitive function (Crum-Cianflone et al. 2013). Earlier initiation of ART may prevent individuals from obtaining a low nadir CD4+ lymphocyte count, thereby eliminating a risk factor for poor neurocognitive outcomes. Additionally, earlier initiation of ART may allow individuals to benefit from the effects of ART on neurocognitive function at an earlier stage of HIV disease (Winston and Vera 2014).

ART Neurotoxicity

Although some research indicates that ART regimens with relatively high CPE ranking result in better neurocognitive outcomes, the toxicity of various antiretroviral compounds to neurons in the CNS has not been well described. ART neurotoxicity is plausible, based on our knowledge of its adverse systemic effects on the peripheral nervous system and evidence from studies using magnetic resonance spectroscopy of the brain. A recent *in vitro* study using measures of neuronal dysfunction sensitive to the earliest forms of HIV-associated damage found a wide range of neurotoxic potencies (e.g., CNS damage involving beading, simplification of the dendritic processes, and neuronal shrinkage) among antiretroviral agents in current clinical use, with no additive effects observed for antiretroviral combinations. As ART continues to be developed, protection of the brain and elimination of the CNS viral reservoir are high priorities in the treatment of HIV.

The interplay between potential neurotoxic effects and ART intolerability plays an important role in ART adherence. ART intolerability is a significant driving factor for treatment switches and interruptions. In addition to peripheral CNS side effects (e.g., gastrointestinal intolerance and skin rashes), neurotoxic effects may prompt changes to patients' ART regimens, potentially

at the expense of switching to a combination ART regimen with a lower CNS penetration. However, based on current evidence, the benefits conferred by ART in protecting the CNS likely outweigh risk of any chronic neurotoxic effects.

Remediation

Despite over 20 years of literature exploring the detrimental effects of HIV infection on the CNS system resulting in neurocognitive deficits and, subsequently, medication nonadherence, very little is known regarding the remediation of such impairments. Given the established relationship between HAND and ART nonadherence, neuro-rehabilitation approaches to improve HAND may additionally result in improved adherence. To date, there have been several pharmacological and cognitive/behavioral approaches to remediate HAND with mixed to promising results.

Some non-ART adjunctive pharmacological approaches to manage HAND, including lithium and serotonin reuptake inhibitors (i.e., citalopram, sertraline, or trazodone), were associated with restoration of global neurocognitive functioning and decreased detectable CSF viral load among small samples of HIV+ individuals (e.g., $n = 21$; Letendre et al. 2006). However, other neuro-enhancing drugs (e.g., methylphenidate) demonstrated limited success, with negligible improvement relative to placebo, poor generalizability in larger longitudinal cohorts, or effects limited to psychological symptoms (e.g., depression). Of note, the intrinsic problem with use of pharmacological approaches to improve HAND is the cyclical relationship between neurocognitive impairment and medication adherence among HIV+ individuals, that is, those individuals who are most impaired (and are therefore in greatest need of treatment) are also the least likely to be able to successfully adhere to the treatment regimen, potentially resulting in limited success of such approaches.

Given the inherent real-world difficulties with pharmacological techniques, alternatives, such as cognitive and behavioral strategies, have begun to be explored. For instance, several computerized

cognitive remediation techniques have shown proof-of-concept feasibility and acceptability among HIV+ individuals and show encouraging results (e.g., increased speed of information processing abilities). However, these preliminary studies are still limited in their conclusions due to poor specificity (e.g., did not use HAND as inclusion criteria), lack of control comparisons, lack of long-term follow-up, and small sample sizes. On the other hand, experimental approaches to improve HAND are also under way, including self-generation techniques (e.g., asking participants to actively generate information, rather than passively listen, in order to deepen encoding and long-term memory) and cuing approaches (e.g., providing category cuing to improve verbal fluency), which have shown positive results among HIV+ individuals in the laboratory. Additionally, cognitive-behavioral techniques, such as compensatory mechanisms (e.g., alarms), which target everyday functioning directly, may be useful for HAND rehabilitation. For example, older HIV+ adults who reported regularly using compensatory strategies in daily life were more likely to successfully perform a naturalistic prospective memory task (i.e., remembering to call the examiner) compared to non-strategy users. Future research is needed to expand our understanding of neurorehabilitation approaches to HAND at both the cognitive mechanistic and the behavioral levels and determine how these improvements impact ART adherence. Although not yet tested from an interventional standpoint, physical activity has been associated with less neurocognitive impairment and may provide another alternative to HAND amelioration.

Importantly, an alternative approach to HAND remediation as a mechanism to improve ART adherence is to simply target adherence behaviors directly. Incorporation of technological approaches, such as text messaging, as means of “real-time” behavioral intervention is on the rise and shows promise for improved ART adherence, but these technological interventions are in the early stages of development (Finitsis et al. 2014). Given the increasing ubiquity of cell phones, mobile health interventions have the potential to decrease traditional treatment barriers, such as transportation,

insurance, and physical limitations, allowing providers to reach difficult-to-track populations. Further exploration of such “real-time” behavioral interventions to improve ART adherence are therefore warranted as our understanding of HAND and adherence moves forward.

Conclusion

Both HAND and ART adherence difficulties persist even in the current ART era that has evolved HIV into a chronic illness. Certain medication classes are more impervious to nonadherence, and consecutive missed doses appear to be worse for HIV outcomes, as compared to sporadic single-missed doses. In addition, while there is evidence that those medications with the greatest ability to cross into the CNS may reduce HAND symptoms, there is also some evidence on neurotoxicity. Thus, a balance needs to be struck between getting drugs into the nervous system and modulating levels of these drugs to avoid neurotoxicity. Notably, ART adherence and HAND are intertwined in a complex, bidirectional interplay, such that worse adherence may lead to greater immunosuppression and risk for HAND. Alternatively, those with existing neurocognitive impairments may be at greater risk for worse adherence and subsequent disease progression. Interventions designed to improve HAND and those designed to improve adherence must recognize the importance of the complex, bidirectional interplay of ART adherence and HAND for successful patient outcomes.

Merkel Cell Carcinoma and Other HIV-Associated Skin Cancers

Nathalie C. Zeitouni and Bethany Lema
Department of Dermatology, Roswell Park
Cancer Institute, Buffalo, NY, USA

Definition

Cutaneous neoplasms are cancers that originate from the skin and are the most common malignancies in the United States. Patients with HIV and other immunocompromised diseases have not only a greater risk of developing common skin cancers such as basal cell carcinoma (BCC), squamous cell carcinoma (SCC), and melanoma but also more unusual cutaneous tumors such as Merkel cell carcinoma (MCC), Kaposi sarcoma (KS), and certain lymphomas.

Merkel cell carcinoma (MCC) is a rare and aggressive cutaneous neoplasm of neuroendocrine origin, most commonly associated with increased ultraviolet radiation. A recently described polyomavirus (MCPyV) has been found present in the majority of MCC suggesting an oncogenic viral role in tumorigenesis. Immunosuppression may also contribute to MCC development given the tumor's increased incidence in patients with HIV and hematologic malignancies and in those who have undergone solid organ transplantation.

Merkel Cell Carcinoma

Introduction

Merkel cell carcinoma (MCC) is a rare and aggressive neuroendocrine cutaneous tumor. MCC was first described in 1972 by Toker as "trabecular carcinoma" due to its histologic latticelike structure (Izickson and Zeitouni 2011). With the discovery of the tumor's neuroendocrine origin, it was renamed Merkel cell carcinoma. Merkel cells are the only skin cells with neuroendocrine function and are specialized touch receptors found in the basal layer of the epidermis. However, despite similarities in name, morphology, and ultrastructural

appearance between Merkel cells and MCC, there is lack of evidence to support a direct relationship between Merkel cells and the development of Merkel cell carcinoma. In fact, recent evidence suggests that MCC may instead arise from less differentiated stem cells in the skin (Izickson and Zeitouni 2011).

Given its aggressive nature, the timely diagnosis of MCC is necessary, and management is often approached in a multidisciplinary fashion (Izickson and Zeitouni 2011).

Epidemiology

Parallel to other rare cutaneous malignancies, the incidence of MCC is low but is rapidly increasing. Currently, there are approximately 1,500 newly diagnosed cases each year in the United States. The incidence has tripled from 0.15 cases per 100,000 in 1986 to 0.44 cases per 100,000 in 2001 and is now estimated at 0.50/100,000 (Heath et al. 2008; Wieland et al. 2011; Fields et al. 2011a). Interestingly, the incidence of MCC now exceeds that of cutaneous T-cell lymphoma but is still 100 times as rare as melanoma.

The risk of development of MCC in patients with HIV is about 13 times that of the normal population (Heath et al. 2008). In one study there was an increased risk of MCC in HIV patients (OR 2.65), and a substantial risk in AIDS patients (SIR 11) was also documented (Lanoy et al. 2010). In the HIV population, there is an earlier age of disease onset compared to immunocompetent persons (Izickson et al. 2011). The risk of MCC is also increased in other immunosuppressed populations and, for reasons that are not yet clear, appears to be particularly increased in patients with chronic lymphocytic leukemia (Heath et al. 2008; Paulson et al. 2013). Currently, there is no documented correlation between the CD4 count and the onset of MCC (Izickson et al. 2011). MCC may occur before or after a diagnosis of AIDS. There is a slight male predominance seen in both the general population and those with HIV. In immunocompetent patients, MCC occurs more commonly in fair-skinned Caucasian individuals. MCC however can arise in sun-protected non-head-and-neck areas in HIV patients, suggesting that ultraviolet

radiation may play less of a role in this population. The median age of onset in immunocompetent patients is 69 years old, while in the HIV population, it was found to be 49 years old (Izickson et al. 2011). Time to diagnosis from HIV to MCC was 9.5 years in one study, which is longer than reported for other non-AIDS-defining malignancies (Izickson et al. 2011).

Pathogenesis

The exact etiology of MCC is unknown and is most likely multifactorial. The immune system clearly plays a role as demonstrated by the increased risk of development of MCC in patients with HIV or other immunodeficient conditions. In one study of 195 cases of MCC, 7.8% had some form of immunosuppression, including bone marrow transplantation, HIV, organ transplantation, or leukemia/lymphoma (Heath et al. 2008). Furthermore, it was reported that 14.5% of 1,024 persons with MCC were receiving or had received an immunosuppressant agent (Qian Zhan et al. 2009).

Chronic ultraviolet radiation contributes to the etiology as demonstrated by the high incidence of development of MCC on the head/neck and sun-exposed areas. Reportedly, there is a 100-fold increase in occurrence of MCC in patients who received UVA for psoriasis (Izickson and Zeitouni 2011). Concurrences of MCC with SCC and BCCs have also been reported (Izickson and Zeitouni 2011).

In 2008, Feng and colleagues from the University of Pittsburgh discovered a novel polyomavirus, which they called Merkel cell polyomavirus (MCPyV). Of 437 MCC tumors, 72% demonstrated positivity for MCPyV, and in some reports, ~80% of tumors were positive (Izickson and Zeitouni 2011). In a recent study, using monoclonal antibody to large T antigen, MCPyV was found in 97% of MCC (Rodig et al. 2012). The MCPyV harbors a genomic mutation that allows it to integrate in infected cells; this occurs prior to the clonal expansion of MCC. MCPyV expresses both large and small T antigen as well as viral structural proteins in cells. In over 2,000 tissue samples of other malignant and premalignant tissue analyzed for the MCPyV, only a subset of

small cell lung carcinoma samples showed abundant positivity. This finding suggests that at least one other neuroendocrine tumor besides MCC is associated with this virus (Fukumoto et al. 2013). MCPyV genomes have frequently been found in normal skin and other body sites and fluids, such as tonsillar tissue and respiratory secretions. In MCCs, however, the levels of MCPyV are over 60 times higher than the highest values of other tissues (Koljonen 2010).

In HIV-positive men, there is an increased prevalence of cutaneous MCPyV. Also, the MCPyV viral DNA load is significantly higher in patients with poorly controlled HIV infection (Wieland et al. 2011). In a recent study, MCPyV DNA was detected more frequently in the sera of HIV patients than in the sera of non-HIV patients (Fukumoto et al. 2013), suggesting that viremia is associated with host immunity.

The exact role of MCPyV in the pathogenesis of MCC is actively being researched.

Clinical Presentation

MCC typically presents as a solitary, rapidly growing, non-tender erythematous/pink nodule located frequently on the head and neck region (20% periorbital), followed by the trunk and extremities. Ulceration may be present. Most tumors show rapid growth within the first 3 months, which is the average time from initial presentation to diagnosis. At time of consultation, the size of the primary tumor is usually less than 1 cm in ~20%, between 1 and 2 cm in 40%, and greater than 2 cm in 35% (Qian Zhan et al. 2009). The median size is between 1.8 and 2.1 cm at the time of diagnosis (Koljonen 2010).

Given the nonspecific nature of MCCs, it can often be confused with benign conditions, such as cysts, lipomas, dermatofibromas, or vascular lesions. It may also be confused with other malignant tumors, such as nonmelanoma skin cancer, lymphoma, or sarcoma. The acronym AEIOU was developed to aid in the clinical diagnosis of MCC and stands for Asymptomatic/lack of tenderness, Expanding rapidly, Immune suppression, Older than 50 years old, and Ultraviolet-exposed site on person with fair skin. Heath et al. found that 89% of 195 cases demonstrated three or more of

these features (Heath et al. 2008). MCCs can frequently be associated with other types of cutaneous carcinomas on actinically damaged skin (Izikson and Zeitouni 2011; Qian Zhan et al. 2009). Metastatic MCC may present cutaneously as a 1–3 cm skin-colored or red nodules or indurated subcutaneous tumor that grows rapidly over 2–4 weeks (Izikson and Zeitouni 2011; Zeitouni et al. 2000). If metastases occur, the most common sites are the skin, lymph nodes, liver, lung, and bone.

Histopathology

Histology and immunohistochemistry help to confirm the clinical diagnosis. Pathologically, the tumor consists of sheets of dermal small round blue cells with scant cytoplasm and medium-sized nuclei. Mitoses are abundant and chromatin is typically in a salt and pepper pattern. It is an ill-defined tumor which frequently extends into subcutaneous fat and/or muscle. Necrosis, vascular invasion, and perineural invasion are common features. Most MCC stain positive with cytokeratin 20 (CK 20), neuron-specific enolase, epithelial membrane antigen neurofilaments, CAM 5.2, and synaptophysin. CK 20 stains in a characteristic paranuclear dot pattern which is virtually pathognomonic for MCC (Izikson and Zeitouni 2011). MCC also stains positive for MCV large T antigen.

There are three main histologic types: intermediate (80%), trabecular (10%), and small cell type (10%). The small cell pattern is difficult to distinguish from other blue cell carcinomas, particularly small cell lung cancer. Differentiation may be made based on thyroid transcription factor-1 and CK7 positivity in small cell lung carcinoma compared to negative staining for MCC (Merkel Cell Carcinoma 2010). Furthermore, it is not uncommon to diagnose a collision tumor histologically, consisting of a BCC or SCC in combination with a MCC (Izikson and Zeitouni 2011; Qian Zhan et al. 2009).

Staging

In 2010, the American Joint Committee on Cancer (AJCC) published the new MCC consensus staging system (Table 1) that replaced several

previous systems (Merkel Cell Carcinoma 2010). The current system, which incorporates an assessment of tumor (T), lymph nodes (N), and metastases (M), is based on prognostic analysis of 5,823 MCC cases from the National Cancer Data Base (Lemos et al. 2010). Both primary tumor site and pathological nodal status are now incorporated in staging and prognosis of MCC patients (Lemos et al. 2010).

Management

A multidisciplinary approach is often necessary for the treatment of MCC and may include radiological imaging, surgery, radiation therapy, and chemotherapy. The use of radiographic imaging such as magnetic resonance imaging (MRI), CT scan, and PET scan may be indicated for staging patients. PET scan has been shown to be more sensitive and as specific as CT scan for nodal evaluation. In a retrospective study PET/CT resulted in an increase in stage in 16% of cases at baseline and identified metastatic disease (bone–bone marrow) better than CT at follow-up (Hawryluk et al. 2012).

Treatment of the primary tumor is surgical, with either wide local excision or Mohs micrographic surgery. Wide local excision with 1–2 cm margins to investing fascia of muscle or pericranium is generally needed. Mohs micrographic surgery (MMS) has been shown to be effective in achieving tumor-free margin control and may be especially useful where tissue sparing is critical (Izikson and Zeitouni 2011).

At presentation, 27–30% of patients will have clinical positive nodal disease (Lemos et al. 2010). Management of regional disease includes lymph node dissection and/or radiation therapy and possible chemotherapy. Patients with clinically negative nodes can be offered sentinel lymph node biopsy (SLNB), elective lymph node dissection, radiotherapy, or observation. The rate of positive SLNB is between 19% and 38% (Fields et al. 2011a) and is recommended for most Stage I patients. Routine use of immunohistochemistry on SLN is highly suggested in order to more accurately identify micrometastases. SLNB has been shown as important for staging, prognosis, and for determining therapy; however,

Merkel Cell Carcinoma and Other HIV-Associated Skin Cancers, Table 1 TNM criteria and stage groupings of the new AJCC staging system for Merkel cell carcinoma

T	N	M	Survival
Tx , primary tumor cannot be assessed	Nx , regional nodes cannot be assessed	Mx , distant metastasis cannot be assessed	
T0 , no primary tumor	N0 , no regional node metastasis ^a	M0 , no distant metastasis	
Tis , in situ primary tumor	cN0 , nodes not clinically detectable ^a	M1 , distant metastasis ^c	
T1 , primary tumor ≤2 cm	cN1 , nodes clinically detectable ^a	M1a , distant skin, distant subcutaneous tissues or distant lymph nodes	
T2 , primary tumor >2 but ≤5 cm	pN0 , nodes negative by pathologic exam	M1b , lung	
T3 , primary tumor >5 cm	pNx , nodes not examined pathologically N1a , micrometastasis ^b	M1c , all other visceral sites	
T4 , primary tumor invades bone, muscle, fascia, or cartilage	N1b , macrometastasis ^c		
	N2 , in-transit metastasis ^d		
Stage		Stage Grouping	
0	Tis	N0	M0
IA	T1	pN0	M0
IB	T1	cN0	M0
IIA	T2/T3	pN0	M0
IIB	T2/T3	cN0	M0
IIC	T4	N0	M0
IIIA	Any T	N1a	M0
IIIB	Any T	N1b/N2	M0
IV	Any T	Any N	M1

^a“N0” denotes negative nodes by clinical, pathologic, or both types of exam. Clinical detection of nodal disease may be via inspection, palpation, and/or imaging; cN0 is used only for patients who did not undergo pathologic node staging

^bMicrometastases are diagnosed after sentinel or elective lymphadenectomy

^cMacrometastases are defined as clinically detectable nodal metastases confirmed pathologically by biopsy or therapeutic lymphadenectomy

^dIn-transit metastasis is a tumor distinct from the primary lesion and located either (1) between the primary lesion and the draining regional lymph nodes or (2) distal to the primary lesion

^eBecause there are no data to suggest a significant effect of M categories on survival in MCC, M1a–M1c are included in the same stage grouping

its impact on recurrence or survival remains unknown.

MCC is a radiosensitive tumor with both adjuvant and definite radiation therapy (RT) playing a role in its management. Numerous studies, mostly retrospective, have investigated the use of adjuvant radiation therapy and have found that it may improve locoregional disease (Rush et al. 2011). It has an unclear effect on distant recurrences or disease-specific survival. There are few studies assessing the use of RT alone for microscopic

disease found on SLNB, but it appears that RT may offer similar local control as compared to complete lymph dissection (Fields et al. 2011a). Definitive radiation therapy has been shown to achieve good in-field control rates and can be offered to patients with inoperable disease or used in selected cases of residual disease post-surgery (Rush et al. 2011).

Systemic chemotherapy is recommended for patients with distant metastatic disease either at presentation (7%) or at relapse time following

therapy. No standard chemotherapy regimen has been established for treating metastatic MCC, but generally platinum-based combination therapy or etoposide has been used. Chemotherapy may carry substantial toxicity risk. Overall, two-thirds of patients may respond to chemotherapy, but response rates are short and recurrences are quite frequent. Chemotherapy has not been shown to increase survival (Izickson and Zeitouni 2011; Qian Zhan et al. 2009). Due to its similarities to small cell lung carcinoma, the same chemotherapy regimens are used for MCC, including anti-metabolites, bleomycin, cyclophosphamide, anthracyclines, and platinum derivatives (Izickson and Zeitouni 2011; Qian Zhan et al. 2009).

Chemotherapy can be used for locally advanced disease and recurrence, as well as for therapy of *in-transit* metastases with isolated limb perfusion or limb infusion methods (Zeitouni et al. 2011). *In-transit* metastases refer to metastases located in subcutaneous or intradermal tissue and deep lymphatics, manifesting as multiple subcutaneous nodules. *In-transit* metastases usually occur after surgical resection of the primary tumor. Isolated limb perfusion or infusion allows for high-dose chemotherapy, such as melphalan, to be administered to an extremity while reducing systemic toxicities (Zeitouni et al. 2011). By isolating the extremity, the dosage of chemotherapy may be increased leading to more effective tumor targeting and may prevent amputation (Zeitouni et al. 2011).

In HIV patients, studies on the effect of antiretroviral therapy on MCC progression are lacking. Because of the association of MCC with immunosuppression, it is possible that initiation or adjustment of antiviral therapy could be beneficial in selected patients, although it is not clear that it would be effective once the tumor has developed (Wieland et al. 2011). Reducing iatrogenic immunosuppression should be attempted when clinically feasible.

In summary, the recommended treatment of MCC:

- Surgical resection with either wide local excision with 1–2 cm margins or MMS of the primary tumor

- Consideration of sentinel lymph node biopsy for patients with clinically negative nodal disease; regional lymph node dissection and/or radiation therapy for those with positive nodal disease
- Adjuvant radiation therapy for local or regional control in lymph node-positive cases, locally advanced disease, or local recurrence following surgery
- Definitive radiation therapy for inoperable cases
- Consideration of systemic chemotherapy for selected locally advanced disease, recurrence, and distant metastases
- Consideration of antiretroviral therapy in HIV patients
- Consideration of decreasing iatrogenic immunosuppression

Prognosis

MCC is associated with both a high morbidity and mortality rate. Following initial therapy, patients may develop local recurrence (25–30%), regional disease (52–59%), or distant metastatic disease (30–36%). The median time to recurrence is about 8 months, with 90% of recurrences developing within 2–3 years of diagnosis. Lemos et al. found a 5-year overall survival of 40% and relative survival of 54% (Lemos et al. 2010). According to the new staging system, primary tumor size (≤ 2 , > 2 cm) and pathological nodal status both affect prognosis (Lemos et al. 2010). Estimation of 5-year survival varies from 18% to 64% depending on stage of disease. Immunosuppressed patients have a poorer MCC-specific survival (Paulson et al. 2013).

In a recent study, microscopic nodal status was not associated with recurrence or survival; rather clinically positive nodes increased the risk of death, and lymphovascular invasion was strongly associated with disease-specific mortality (Fields et al. 2011b). Patients with occult primary tumor (Stage IIIB) appear to have a more favorable outcome than patients with known primary tumor of similar stage (Lemos et al. 2010). In one study, there was no correlation between Breslow thickness of the primary biopsied MCC and clinical stage of disease or survival

(Izikson et al. 2012), while another study found that increasing tumor thickness was associated with poor disease survival (Lim et al. 2012).

Tumors on the lip carry a worse prognosis, and location may be an independent prognostic factor in head and neck MCC. In regard to HIV patients with MCC, the average survival after MCC diagnosis in a recent study was 18 months (Izikson et al. 2011).

Follow-Up

Patients should be monitored closely with full skin exams and lymph node evaluation every 1–3 months for the first year, then every 3–6 months for the second year, and then followed on a yearly basis. Patients should also be encouraged to perform monthly complete skin exams. Imaging with PET/CT may be valuable as a restaging tool.

Key Points for Persons with MCC and HIV

- MCC is more commonly seen on non-sun-exposed areas compared to immunocompetent patients.
- Increased risk of development of MCC in HIV patients when compared to immunocompetent population.
- Age of diagnosis approximately 20 years earlier; average age of 49 years compared to 69 years for immunocompetent patients.
- Average length of time between diagnosis of HIV and development of MCC: 9.5 years.
- No clear relationship between CD4 count and MCC development and/or survival rates established.
- Need for aggressive management, possible antiretroviral therapy.
- Survival rates decreased when compared to immunocompetent patients.

Kaposi Sarcoma (KS) (See Separate Section on Kaposi Sarcoma)

Kaposi sarcoma was the most common skin cancer seen in HIV-infected patients during the first years of the AIDS epidemic. With the introduction of HAART, the incidence of KS has greatly

decreased but there is still a substantially increased risk (OR 21.58) (Lanoy et al. 2009). In the United States, it is still the second most common tumor in HIV-infected patients after lymphoma. Its incidence varies considerably in different regions, and in some countries in Africa, it is the most common tumor overall. (Crum-Cianflone et al. 2009; Jessop 2006).

Squamous and Basal Cell Carcinomas

Squamous cell carcinoma (SCC) is a type of skin cancer derived from the squamous epithelial cell of the epidermis, whereas basal cell carcinoma (BCC) is derived from the basal cell layer of the epidermis. They are the most common types of skin cancer, with approximately three million cases of BCC and 700,000 cases of SCC diagnosed yearly (Skin Cancer Foundation). While they are both associated with chronic actinic damage, SCC also can be associated with the human papillomavirus (see ► [Human Papillomavirus \(HPV\)](#)). The rate of development of non-melanoma skin cancers in the HIV population is about three to five times that of the general population (Rieger et al. 2008). Further, they tend to develop at a younger age in the HIV population and are less frequently located on sun-protected areas when compared to the general population. In the HIV population, SCCs tend to be more aggressive in terms of recurrence and risk of metastases, whereas basal cell carcinomas have not been shown to behave differently when compared to the general population (Rieger et al. 2008). Lastly, due to the increased incidence of high-risk HPV in the HIV population, SCCs in the anogenital, mucosal, and digital areas are more prevalent.

Clinically, SCC appears as erythematous keratotic papules or plaques which may be eroded. They are most commonly seen on the sun-exposed areas including the head, neck, dorsal arms, and upper chest in the immunocompetent population. They are associated with chronic daily sun exposure. Basal cell carcinomas are described as pearly papules or nodules with telangiectasias on sun-exposed areas. They are associated with intermittent sunburns and sun exposure.

Histopathology can confirm the suspected clinical diagnosis of BCC/SCC. Treatment approaches for these carcinomas include surgical excision, Mohs micrographic surgery, topical immunomodulators, cryotherapy, electrical dissection and curettage, photodynamic therapy, chemotherapy, and radiation therapy.

Lymphomas (See Other Sections on Lymphomas)

Non-Hodgkin B-cell lymphoma (NHL) is more prevalent in the HIV population (OR 2.41), particularly in patients with <200 CD4 cells/mm³ (Fields et al. 2011b; Rieger et al. 2008) and is considered an AIDS-defining illness (Silverberg et al. 2011). Cutaneous T-cell lymphoma (CTCL) and Sezary syndrome may also be increased in the HIV population. Various forms of B-cell NHL may involve the skin. Clinically, cutaneous NHL often presents as erythematous, indurated nodules that may ulcerate. A high percentage of cases of B-cell NHL are associated with an Epstein-Barr virus, especially in HIV individuals; the percentage involvement varies among different forms of lymphoma (Rieger et al. 2008). CTCL presents as erythematous scaly plaques in sun-protected areas. However, in HIV, these plaques may be seen in atypical locations and present at an earlier age of onset compared to the general population (Rieger et al. 2008). The incidence of B-cell NHL has decreased in HIV patients since the advent of HAART therapy.

Melanoma

Melanoma is an aggressive malignant tumor of melanocytes. There are approximately 120,000–150,000 new cases diagnosed worldwide annually (Skin Cancer Foundation). Clinically, melanoma presents as an irregular dark brown to black macule, papule, plaque, or nodule. However, melanoma may also present as a red or skin-colored tumor. It most commonly appears on the back of men and the lower extremities of women but may present anywhere where there

are melanocytes including mucosal surfaces and nail beds. When diagnosed early, melanoma is curable. Invasive disease may require surgery, sentinel lymph node biopsy, lymph node dissection, radiation, or chemotherapy. Some epidemiologic studies have found an increased incidence of melanoma in HIV-infected patients, while other studies have not found an increase (Lanoy et al. 2009). However, melanoma was found to be more aggressive in this population, presumably due to the immunosuppression. The disease-free and overall survival rate of HIV persons with melanoma is decreased (Silverberg et al. 2011; Rodrigues et al. 2002).

Conclusion

Patients with HIV are at a high risk for developing a number of cutaneous carcinomas such as MCC, Kaposi sarcoma, lymphoma, BCC, and SCC; melanoma is elevated in some but not other studies. All these tumors may also be more aggressive in HIV-infected patients necessitating timely diagnosis. HIV patients should have regular full-body skin exams in order to assess, promptly diagnose, and treat any skin cancers.

²Heinrich Pette Institute, Leibniz Institute for Experimental Virology, Hamburg, Germany

Definition

Merkel cell polyomavirus (MCV) is a recently discovered member of the *Polyomaviridae*, a family of small DNA viruses that replicate in the

nucleus of their host cell. MCV is one of the ten identified polyomaviruses that naturally infect humans and furthermore one of four polyomaviruses that are known to cause severe human disease, predominantly in immunosuppressed or immunodeficient individuals. Of these, MCV is of particular interest since it presently is the only human polyomavirus known to be involved in tumorigenesis. The virus was first identified in 2008 in tissue from ► [Merkel Cell Carcinoma and Other HIV-associated Skin Cancers](#) by high-throughput sequencing (Feng et al. 2008). Considerable evidence suggests that MCV is causally linked to MCC pathogenesis: Viral DNA is monoclonally integrated into the genome of the tumor cells in up to 90% of all MCV cases, and the integrated MCV genomes furthermore harbor signature mutations that selectively abrogate viral replication while preserving cell cycle deregulating functions of the virus (Chang and Moore 2012). Nonetheless, the development of MCC is doubtless a very rare complication of MCV infection, given that MCV is highly prevalent in the general population, with 44–80% of adults displaying serum reactivity against viral antigens. What cells represent the natural reservoir of MCV infection in healthy individuals, whether the virus is potentially linked to human diseases other than MCC, and how precisely MCV infection contributes to cellular transformation during MCC pathogenesis are unresolved issues that are the subject of current research efforts.

Introduction

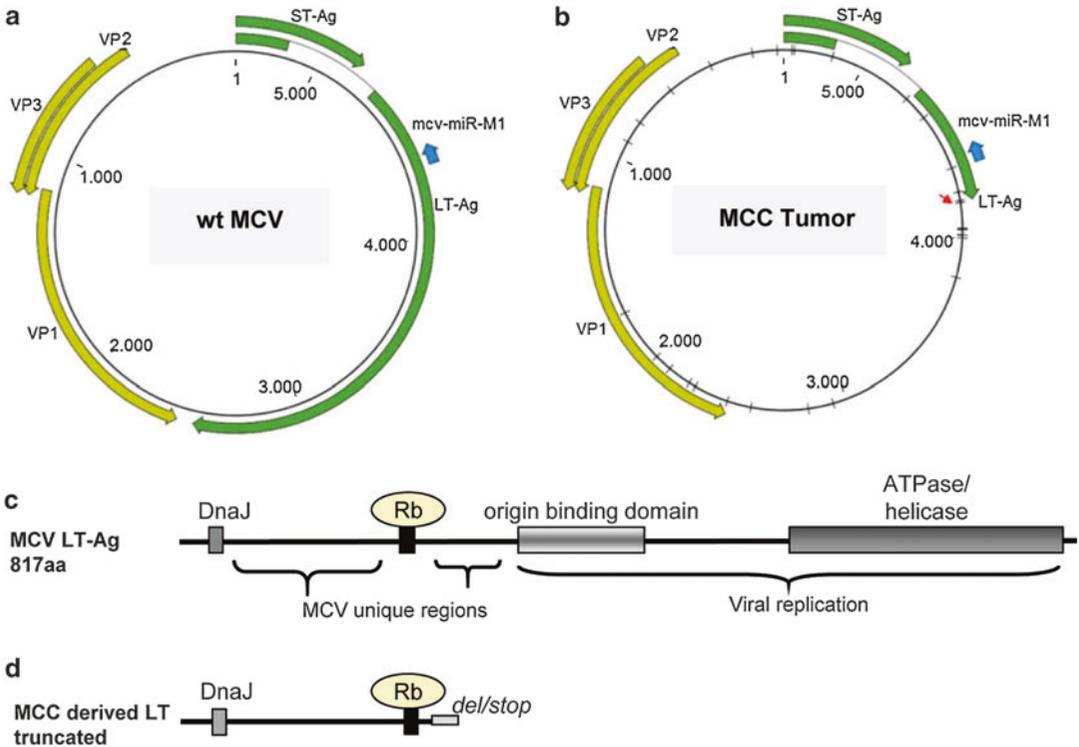

Merkel cell carcinoma (MCC) is a rare but highly aggressive skin cancer which predominantly arises in elderly and immunosuppressed patients. The risk to develop MCC is 10- to 15-fold increased in patients undergoing solid organ transplantation (SOT) and HIV patients. This, together with occasional reports of spontaneous regression of MCC after reconstitution of the immune system, strongly suggests an infectious etiology of the disease (Schrama et al. 2012). In 2008, high-throughput sequencing of RNA derived from MCC tissue successfully identified a novel

human polyomavirus (Feng et al. 2008). Subsequent studies from different laboratories worldwide confirmed the frequent detection of viral DNA in MCC; hence the virus was named Merkel cell polyomavirus (MCV) (Chang and Moore 2012). Due to the considerable molecular and serological evidence that argues for a causative link between MCV and MCC pathogenesis (see section “[MCV Epidemiology](#)” below), MCV has been classified by the WHO International Agency for Research on Cancer (IARC) as a group 2A carcinogen (Chang and Moore 2012).

Polyomaviruses and other small DNA viruses (adenoviruses and papillomaviruses) have long been known to induce malignant transformation of cells *in vitro* or *in vivo*. This ability is closely linked to the replication strategy of these viruses: Upon entry in the host cell nucleus, they rapidly express early genes that mediate aberrant S-phase entry and inhibit apoptosis, e.g., by inhibiting pRb and p53. These manipulations serve to create an environment supportive of massive replication of viral DNA and subsequent production of viral progeny, a process that usually results in the death of the host cell, or its clearance by the immune system. However, if viral DNA replication is blocked (e.g., due to the infection of a nonpermissive species or cell type) and if the viral genome additionally integrates in the cellular genome and hence is stably propagated upon host cell division, constitutive low-level expression of early viral gene products may promote cellular transformation. Many polyomaviruses can cause tumors under experimental conditions, e.g., when introduced into tissues or animal species in which the virus normally does not replicate. However, in their natural host, polyomaviruses only very rarely induce tumors. Indeed, MCV is one of only two members of the family (the other being African green monkey polyomavirus) that has been reported to contribute to neoplastic disease of its natural host.

MCV Genome Organization

MCV is a non-enveloped virus with a circular DNA of 5,386 bp. Its genome shows the typical

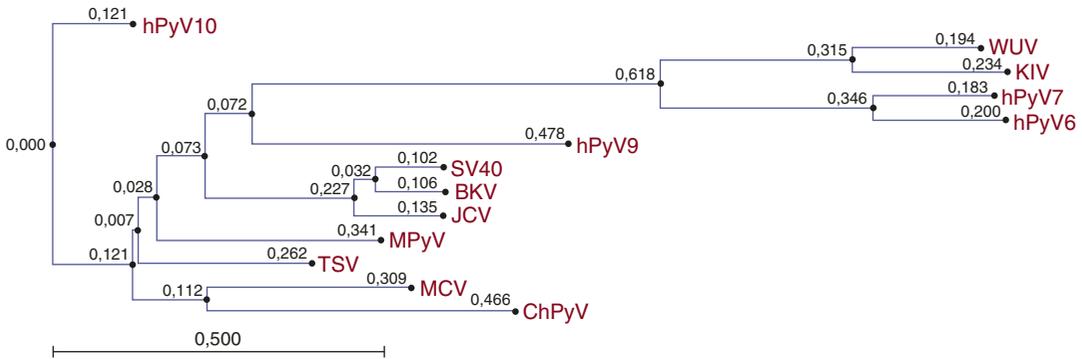

Merkel Cell Polyomavirus (MCV), Fig. 1 MCV genome organization. (a) The genome is divided in three regions: the early gene region illustrated in *green*; the late gene region, counterclockwise to the early transcripts, pictured in *yellow*; and the noncoding control region. MCV is one out of few polyomaviruses encoding for a viral microRNA (MCV miR-M1) (shown in *blue*), located antisense to the LT transcripts. (b) Sequences identified in MCC tissue. LT sequences carry point mutations, frameshift mutations, or small deletions all resulting in

premature stop codon. In the MCC tumor, only the N-terminal region encompassing the retinoblastoma protein-binding region of LT (labeled Rb in the figure) is expressed. The C-terminus containing the origin binding domain as well as the helicase is not expressed. (c+d) Schematic drawing of MCV LT protein domains. (c) MCV LT full-length protein as identified in wild type strains isolated from healthy skin and (d) MCC-derived truncated LT protein

organization of polyomaviruses and can be divided into three regions (Fig. 1): (i) the noncoding control region (NCCR) encompassing the origin of replication as well as the promoters for early and late gene expression, (ii) the early gene region that produces alternatively spliced early transcripts encoding large T antigen (LT), small T antigen (ST), and a 57 kD antigen, and (iii) in reverse orientation relative to the early transcripts, the late genes that encode the structural proteins VP1, VP2, and probably VP3. Whether MCV indeed expresses a VP3 structural protein is still under discussion, given that the amino acid motif Met-Ala-Leu that initiates VP3 translation in other polyomaviruses is not present (An et al.

2012; Chang and Moore 2012). Like certain other polyomaviruses, the MCV genome also harbors a viral microRNA located antisense to the early transcripts. However, it lacks middle T antigen (MT) as seen in mouse polyomavirus and also does not encode an agnoprotein as in SV40.

Phylogenetically, the MCV LT-Ag possesses closest homology to chimpanzee polyomavirus (ChPyV) (Fig. 2). Among the human polyomaviruses (hPyV), MCV is most closely related to trichodysplasia spinulosa-associated virus (TSV), a virus that causes a rare (non-neoplastic) skin disease in immunocompromised individuals. The two remaining polyomaviruses associated

Merkel Cell Polyomavirus (MCV), Fig. 2 Phylogenetic analysis of large T antigen aa sequence from human polyomaviruses (hPyV), SV40, mouse polyomavirus (MPyV), and chimpanzee PyV (ChPyV). Large T antigen sequences from SV40, ChPyV, and ten hPyV were aligned using CLC workbench 6.6.1, and the phylogenetic tree was generated using neighbor-joining method.

Specific viruses studied were BK virus (BKV), NC_001538.1; JC virus (JCV), NC_001699.1; WUV, NC_009539.1; KIV, NC_009238.1; hPyV6, NC_014406.1; hPyV7, NC_014407.1; MCV, JN707599.1; TSV, NC_014361.1; hPyV9, HQ696593.1; hPyV10, JX262162.1; MPyV, NC_001515.1; ChPyV, NC_014743.1; and SV40, NC_001669.1

with major diseases in humans are JC virus and BK virus. These two viruses cause a usually fatal demyelinating or severe renal disease, respectively, and are more closely related to the simian virus 40 (SV40), the prototypical member of the polyomavirus family, than to MCV. BKV and SV40 LT-Ag share more than 75% amino acid (aa) sequence similarity, whereas the LT-Ags of BKV and MCV are only 55% homologous.

MCV Replication and Persistence

A fully permissive *in vitro* replication system for MCV does not yet exist, a fact which severely hampers studies of the viral life cycle. The absence of such a system may be explained by the fact that polyomaviruses often exhibit a highly restricted tissue tropism and only replicate in specific cell types. At present, the authentic cell type in which MCV replicates *in vivo* is unknown. This is true for most human polyomavirus; in fact, the full viral life cycle can so far be only studied for two human polyomaviruses, and in both cases a particular cell system is required (primary human renal proximal tubule epithelial cells (RPTE) for BK virus, and human glial cells for JC virus). In contrast, simian virus 40 can successfully be cultured in monkey cell lines (Vero, CV1).

Consequently, most information about the polyomavirus life cycle is derived from the study of SV40 replication (An et al. 2012).

Attempts to recapitulate the MCV life cycle by transfection of episomal DNA into cultured cells have so far not identified a cell type that allows the efficient production infectious virions. However, the initial phase of the life cycle (receptor binding, entry, and viral DNA replication) can be studied in some established cell lines (Chang and Moore 2012; Neumann et al. 2011; Schowalter et al. 2011). Viral entry is a sequential process that involves attachment of MCV particles to large linear polysaccharides (glycosaminoglycans), and a subsequent post attachment step that requires the presence of sialic acid (Schowalter et al. 2011).

Although not studied in authentic MCV infection, the subsequent steps are likely to be similar to those observed during SV40 infection: after virion uptake by endocytosis, the viral genome is delivered to the nucleus where early gene transcription immediately starts. Polyomaviruses infect quiescent cells and do not encode their own DNA polymerase; they thus need to induce the cell cycle to be able to replicate their DNA. Induction of S phase is achieved by LT-Ag binding to the Rb protein and subsequent inactivation of p53. Late gene transcription is

concomitantly initiated with viral DNA replication, and translation of the structural antigens is followed by virion assembly and egress of viral particles.

Upon transfection of MCV genomes, expression of T antigens and efficient replication of viral episomes have been observed in some, but not all of the tested cell types (Chang and Moore 2012; Neumann et al. 2011), indicating that cell type-dependent postentry blocks to early gene expression or DNA replication may exist. Another block that limits the MCV life cycle appears to be on the level of late gene expression and/or virion assembly, as all cell systems studied so far (including those that permit DNA replication) fail to efficiently produce viral particles. The molecular nature of the mechanisms that hinder viral replication in above models is unknown. Likewise, it remains an open question whether similar mechanisms contribute to a replication block that may precede integration and mutagenesis of MCV genomes during MCC pathogenesis.

MCV and MCC Pathogenesis

Several observations support the notion that MCV infection plays a causative role in MCC tumorigenesis. Firstly, MCV genomes can be detected with high frequency in MCC, with 80–90% of all MCC tumors being positive for MCV DNA. Secondly, the tumor cells express early viral gene products and contain the viral DNA monoclally integrated in the host genome. The fact that integration sites are always identical within a given tumor and its metastases strongly suggests that viral infection must precede tumorigenesis. At the same time, integration sites vary among tumors from different patients, indicating that integration is likely to reflect a selection pressure to maintain viral DNA and expression of early antigens, rather than a proliferative advantage gained by changes in expression or structure of flanking cellular chromatin. Thirdly, all integrated viral genomes harbor signature mutations that are absent from viral episomes residing in tissues in which the virus is thought to replicate (Chang and Moore 2012; Schrama et al. 2012).

Strikingly, although these mutations are diverse among different tumors, they unequivocally occur in the form of point mutations or small deletions that lead to the disruption of the LT-Ag coding region between the sequences that code for the Rb-binding motif and those that encode the origin binding and ATPase/helicase domains (see Fig. 1c, d). Hence, the resulting truncated LT-Ags are unable to support viral DNA replication but retain their ability to bind to and sequester Rb. It is therefore likely that the mutations represent the result of a dual selection pressure: the need to prevent the untimely firing of integrated viral replication origins outside of S phase (which would result in the death of the host cell), while simultaneously preserving cell cycle deregulatory functions of early antigens.

Besides LT-Ag, sT-Ag may also play a critical role during MCC pathogenesis. Indeed, the sT-Ag (which is expressed in MCC tumors and is not affected by the LT-Ag mutations) was found to induce loss of contact inhibition and permit anchorage independent growth of rodent fibroblasts. In contrast to other polyomaviruses (SV40, MPyV), the mechanism by which sT-Ag influences proliferation does not involve PP2A inhibition but appears to act downstream within the Akt-mTOR pathway, ultimately resulting in 4E-BP1 inhibition and stimulation of cap-dependent mRNA translation (Chang and Moore 2012). Experiments using siRNAs to selectively inhibit either sT-Ag expression alone or sT- and LT-Ag expression in MCV-positive MCC cell lines have indeed shown that both early antigens contribute to cell survival (Chang and Moore 2012; Schrama et al. 2012), making them attractive targets for potential future therapeutic approaches.

MCV Epidemiology

Capsid epitope immunoassays demonstrate a high prevalence of MCV (up to 80%) in healthy adults, similar to rates that have been previously described for other human polyomaviruses (Chang and Moore 2012). Fifty percent of children younger than 15 years are seropositive for MCV antibodies, indicating a common infection

that already occurs at young age and that only in very rare cases leads to the development of a tumor. Although antibody titers against viral capsid protein can be detected in the majority of adults, MCC patients with MCV-positive tumors demonstrate higher antibody titers compared to patients with MCV-negative tumors (Chang and Moore 2012). This observation suggests that such patients may be unable to efficiently control MCV replication and supports the notion of a causative role of MCV in MCC. In contrast to seroreactivity against viral capsid proteins, antibodies against the early T antigens are only sparsely detectable in the general population or are only detected at very low titers. However, patients with MCV-positive MCC demonstrate high LT antibody titers. Interestingly, LT antibody titers fluctuate during disease progression with high titers in patients with recurring disease and progressing metastasis and decreased titers in patients in which the tumor did not recur.

In addition to seroprevalence studies, the presence of MCV DNA on the skin of healthy patients has also been analyzed, using swab samples from different body sites and subsequent qualitative as well as quantitative PCR (Wieland et al. 2009). Wild-type MCV genomes that carry no premature stop codons in the early region were successfully isolated from healthy persons, again supporting the hypothesis that MCV is part of the normal skin flora (Schowalter et al. 2010; Wieland et al. 2009). Furthermore, a recent study demonstrated that the amount of viral DNA shedded correlates with serum antibody responsiveness, suggesting that the skin is a major site of MCV replication (Pastrana et al. 2012). Nonetheless, as indicated above, the specific cell type in which MCV may replicate has not been identified yet. MCV may also reside in other tissues, as viral sequences can be detected by PCR in the respiratory tract, saliva, gut, urine, lymphoid tissue, and whole blood from healthy patients. However, compared to the skin viral copy numbers are much lower in these tissues (Chang and Moore 2012). Whether they only represent secondary sites of replication or play other important roles during MCV infection, for example, as long-term reservoirs of infection, is currently unknown.

MCV Infection in HIV Patients

HIV patients show an increased rate of neoplastic diseases, with Kaposi sarcoma (KS) and large B-cell non-Hodgkin lymphomas representing the most common virally induced AIDS-defining cancers. With the widespread use of HAART for more than a decade, the population of HIV-infected patients is increasing, and this population is becoming older. Along with these changes, the number of HIV-infected patients developing non-AIDS-defining cancers is increasing, and the repertoire of these cancers is expanding. MCC is increasingly being appreciated as an HIV-associated cancer. In addition, the sites at which MCC occurs are more diverse in location in AIDS patients compared to HIV-negative patients, and, in HIV-infected patients, it frequently develops on non-sun-exposed body parts. This observation suggests that UV mutagenesis might be lesser important in MCC development in AIDS patients as compared to other patients (Wieland and Kreuter 2011).

Although MCC occurrence in AIDS patients is increased up to 15-fold, studies evaluating the seroprevalence of antibodies against MCV capsid protein have not found a correlation between MCV infection and HIV status or AIDS progression (Tolstov et al. 2011). However, MCV-specific PCR performed with forehead skin swabs of 210 HIV-positive men demonstrated that individuals with poorly controlled HIV infection are more than twice as frequently positive for MCV DNA and also exhibit significantly higher viral loads than a control cohort (Wieland and Kreuter 2011).

MCV in Diseases Other Than MCC

The potential association of MCV with neoplasia other than MCC has been extensively studied in the years since the identification of the virus. Mostly PCR but to some extent also LT immunohistochemistry techniques have been used to detect MCV sequences and/or Ag expression in tumor tissues. So far, MCV has only rarely been detected (and if so, only in low copy numbers) in, e.g., neuroendocrine tumors from different

anatomical sites, mesotheliomas, different skin cancers (BCC, SCC, melanoma, and Kaposi Sarcoma), breast cancer, prostate cancer, and ovarian cancer, suggesting no direct association of MCV with these diseases (Chang and Moore 2012).

Since patients with MCC have an increased risk of developing chronic lymphocytic leukemia (CLL) and vice versa, the association of MCV and CLL was analyzed in particular detail. Two independent studies lead to contradictory results (Chang and Moore 2012): One study detected MCV DNA in 27% of CLL samples and 13% of control samples by PCR, FISH, as well as IHC, whereas another study investigated CLL cases with and without concurrent MCC and has not found MCV sequences or LT-Ag expression in CLL tissues. Based on these findings, it may be reasonable to conclude, at least for the moment, that MCV represents a passenger virus in CLL, perhaps being a result of increased viral replication rates due to decreased immunity. However, at present a contribution of MCV infection to CLL disease cannot be categorically ruled out.

Diagnostic and Prognostic Value of MCV Detection in MCC

Immunohistochemistry (IHC) of MCV antigen expression (LT and sT) is useful to discriminate between virus-positive and virus-negative tumors. IHC staining of MCC tissue with a monoclonal antibody against LT (Cm2B4) has been applied by several studies, and reliable IHC protocols for the diagnostic use have been established. Staining of viral antigens is generally restricted to MCC tumor cells and has not been described for healthy tissue surrounding or interspersed within the tumor. However, some MCV-positive MCC cases that are negative for IHC staining with the Cm2B4 antibody directed against LT-Ag but positive when tested with an antibody that detects sT-Ag have been reported. As sT-Ag expression is detectable in all MCV-positive MCC tumors tested so far, IHC for this viral antigen would be superior to LT-Ag staining. Unfortunately, no antibody against sT antigen is commercially available thus far. Therefore, LT-Ag IHC is routinely

employed to complement the panel of non-viral marker proteins (CK20, CK18, neuron-specific enolase, chromogranin A, synaptophysin) used to diagnose MCC.

The use of LT antigen IHC staining (and/or MCV DNA load) as a prognostic marker is still under discussion, with conflicting reports about MCV status and MCC recurrence. While a Finnish study reported a correlation of LT antigen expression and MCV DNA load with survival rates, with patients with MCV-positive tumors having prolonged survival rates (Sihto et al. 2011), a German study that included MCC cases from Germany and Australia found no direct association between MCV status and MCC recurrence (Schrama et al. 2011).

More recent studies are encouraging with regard to using the immune status of MCC patients as a potential prognostic marker. Several reports indicate that an increased number of CD8⁺ T-cells in MCC tumors are associated with longer disease-free survival. MCV-positive tumors often contain high numbers of infiltrating immune cells. Interestingly, MCV-negative tumors with high numbers of immune cells also have a better disease outcome, so the relationship of these immune cells to a viral antigen is unclear (Paulson et al. 2011; Sihto et al. 2012).

Conclusion

MCV is the first polyomavirus with convincing evidence of an etiological role in human cancer formation. This evidence includes high association (up to 90%) of MCV with the tumor in which the virus was identified, monoclonal genomic integration of viral DNA carrying signature mutations in the cells of primary tumors and subsequent metastases, expression of viral oncoproteins in the tumor tissue, and significantly increased viral titers in patients with disease.

Since the discovery of MCV, significant progress has been made with regard to the understanding of MCV biology and its role in MCC pathogenesis. Even so, the precise mechanisms that lead to virally induced transformation *in vivo* remain to be unraveled. It is to be expected

that future studies of the viral life cycle and its role in cellular transformation will provide not only important information for the diagnosis and prognosis of MCC but may also allow novel therapeutic approaches that directly target viral antigens required for the survival and continued proliferation of the tumor cells.

Definition

The major histocompatibility complex (*MHC*) on the short arm of chromosome 6 contains over 120 expressed genes, 40% of which contribute to immune responses. The classical *HLA* class I (*HLA-A*, *HLA-B*, and *HLA-C*) and class II (*HLA-DR*, *HLA-DQ*, and *HLA-DP*) genes within the *MHC* are the most diversified loci in the human genome. *HLA* genes maintain extensive diversity primarily in the gene segments encoding the peptide-binding domains. The number of *HLA* alleles is in the range of thousands, though only

less than one fifth are defined as common and well-documented (CWD) alleles, which more truly reflect the level of *HLA* polymorphism in populations. It is generally agreed that the extraordinary diversity of *HLA* is generated and maintained by balancing selection through interactions between the host and infectious pathogens.

The products of *HLA* genes are fundamentally important to acquired as well as innate immune responses. The class I loci encode molecules that bind antigenic epitopes usually derived from intracellular pathogens and present them to CD8⁺ T cells, thereby initiating a cytotoxic T-cell response. In addition to their role in acquired immunity, class I HLA molecules also serve as ligands for killer cell immunoglobulin-like receptors (KIR) (“► [KIR Locus Variation](#)”), thereby participating in the regulation of natural killer (NK) cell activity.

HLA and AIDS

HIV/AIDS has been scrutinized extensively for effects conferred by *HLA*, and involvement of *HLA* in HIV disease outcome has been confirmed by a large number of cohort studies. These data have been further underscored in recent years by a series of genome-wide association studies (GWAS) (“Genome-Wide Association Analysis”). Strong evidence points to *HLA* as the most significant single locus in determining outcome after HIV infection.

HLA polymorphism has been associated with over 100 diseases including autoimmune conditions, malignancies, as well as infectious diseases, virtually all of which are multifactorial. Among all infectious diseases studied to date, HIV shows the most clear-cut association with *HLA*. *HLA* polymorphisms may impact AIDS in many aspects including HIV infection/transmission, HIV viral load control, and the rate of progression to AIDS following HIV infection. This chapter will focus on the *HLA* associations that have been consistently detected in multiple cohort studies, including effects of *HLA* zygosity, frequency-dependent selection, and individual *HLA* alleles, along with newer findings including expressional variation of *HLA-C*.

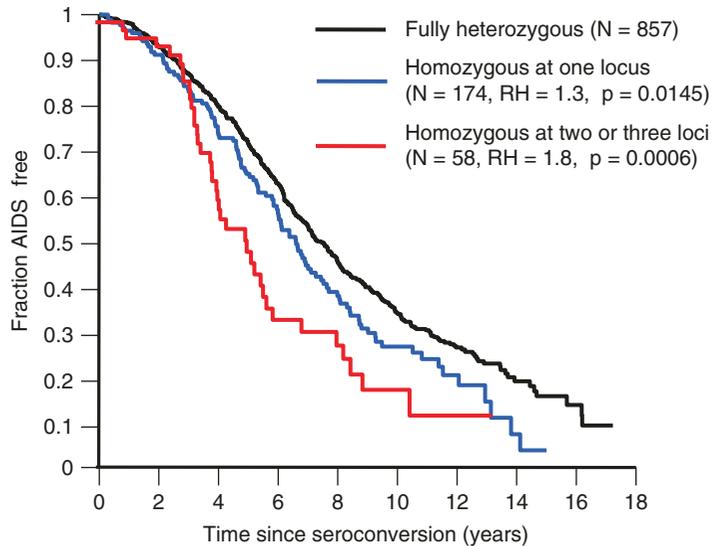

HLA Heterozygote Advantage and Frequency-Dependent Selection

The number of different HLA allotypes expressed on the cell surface is directly related to the size of the repertoire of foreign antigens that can be presented to T cells. An individual who is heterozygous at all three *HLA* class I loci expresses the maximum diversity (six alleles) and is able to present a greater variety of viral peptides than an individual who is partially or fully homozygous. Theoretically, it will take the virus a longer time to accumulate mutations to escape immune surveillance in *HLA* heterozygous individuals relative to homozygous individuals. Under this model, *HLA* homozygous individuals would be expected to progress more rapidly to AIDS than *HLA* heterozygous individuals after HIV infection. Indeed, survival analyses showed a significant association of *HLA* class I zygosity with rate of progression to AIDS outcomes (CD4 < 200, onset of AIDS-defining illness and AIDS-related death; Carrington et al. 1999). Individuals homozygous at any two or all three class I *HLA* loci progressed to AIDS significantly faster than individuals who were heterozygous at all three loci (Fig. 1). Individuals homozygous at only one locus showed an intermediate rate of progression relative to the other two groups. These results demonstrate that (a) all three class I loci, *HLA-A*, *HLA-B*, and *HLA-C*, contribute separately to the zygosity effect since homozygosity at any of the three loci showed more rapid progression to AIDS; (b) the homozygosity effect of any single *HLA* class I locus is enhanced when a second or third locus is also homozygous; and (c) the *HLA* zygosity effect on AIDS progression is not confined to particular populations, as it was detected in cohorts of different ethnic origins.

The effect of *HLA* zygosity on AIDS progression can be explained by recognition of a broader range of HIV-1 peptides by *HLA* heterozygous individuals resulting in a greater number of specific cytotoxic T-cell (CTL) responses against the virus. Other related mechanisms, however, should also be considered. One such mechanism is based on frequency-dependent selection (or rare allele advantage), which argues that the infectious

MHC Locus Variation,

Fig. 1 Kaplan-Meier survival analysis for class I *HLA* zygosity effect on progression to AIDS 1987 (the 1987 CDC definition of AIDS: AIDS-defining illness) in 1,089 seroconverters that include multiple ethnic groups, but mainly European and African Americans (Updated from Carrington et al. 1999)

pathogen is more likely to have adapted to common as compared to rare *HLA* alleles in a given population, such that the rare alleles confer greater protection against the pathogen. An advantage of rare *HLA* supertypes has been reported in HIV disease, where supertypes consisting of the more rare alleles associate with lower HIV viral loads (Trachtenberg et al. 2003). Frequency-dependent selection can be difficult to distinguish from heterozygote advantage, since nearly all homozygotes are composed of common alleles, and the rare alleles are found almost exclusively as heterozygotes. It is possible that both mechanisms are involved in protecting against HIV.

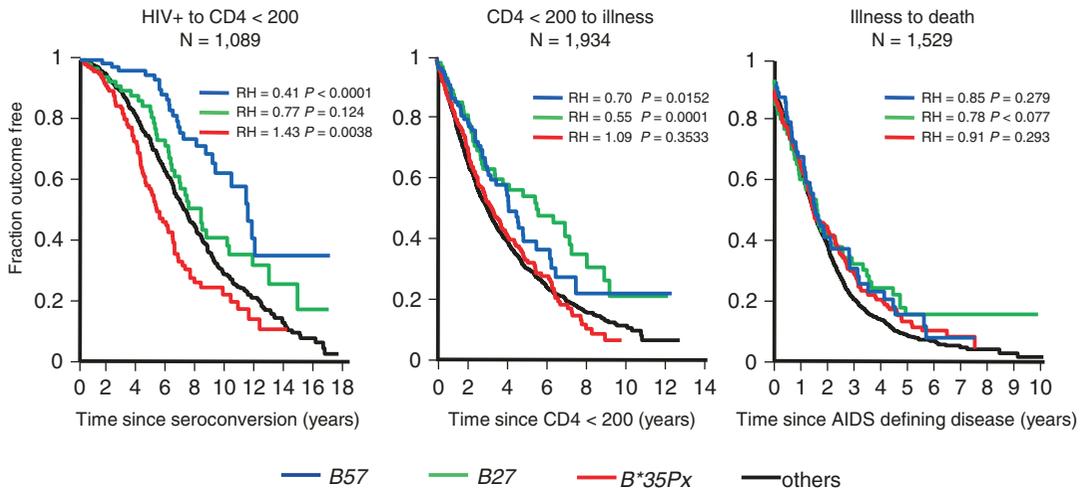

Effect of *HLA* Class I Alleles on HIV/AIDS

Distinct *HLA* allotypes may mediate differential responses to HIV infection and have varied capacities to contain HIV replication. Detection of individual allelic effects helps to identify critical HIV epitopes that are involved in protective immune responses. The most extreme *HLA* allelic effects on HIV/AIDS appear to involve the *HLA-B* locus to a greater extent than *HLA-A* or *HLA-C* (Kiepiela et al. 2004). Three *HLA-B* alleles, *B*57*, *B*27*, and *B*35* (particularly some subtypes of *B*35*), have been consistently associated with the HIV disease outcomes in multiple cohort studies.

*Protective Effect of B*57.* Large cohort studies have shown that *B*57* confers the strongest and most consistent protective effect in terms of viral load control and AIDS progression among all *HLA* variants (Bashirova et al. 2011). There are two major *B*57* subtypes: *B*57:01* in Europeans and *B*57:03* in Africans, which differ by only two amino acids. They share identical peptide-binding motifs and strongly associate with protection from HIV/AIDS as indicated by both the candidate gene approach and GWAS.

A small subset of HIV-infected individuals known as elite controllers (individuals who manage to contain HIV levels to less than 50 copies of the virus per ml of plasma without treatment) (“► **Viremic Non-Progressors**”) are highly enriched for *B*57*, where about 40% carry this protective allele as compared to only 9% in non-controllers, which is about the same frequency that is observed in the general population (Emu et al. 2008). *B*57* confers pronounced protection for time to CD4 < 200 as indicated by survival analysis (Gao et al. 2005; Fig. 2), but most people with the *B*57* allele do eventually develop progressive infection.

The *B*57* allele restricts four immunodominant HIV Gag epitopes, TW10 (TSTLQEQIAWp24₂₄₀₋₂₄₉), KF11 (KAFSPEVIPMEp24₃₀₋₄₀), ISW9 (ISPRTLNAWp24₁₄₇₋₁₅₅), and QW9 (QASQEVKNWp24₃₀₈₋₃₁₆). These

MHC Locus Variation, Fig. 2 Kaplan-Meier survival curves of *HLA-B*57* (blue), *B*27* (green), and *B*35Px* (red) alleles on different stages of AIDS progression from

seroconversion to CD4 < 200, from CD4 < 200 to AIDS-defining illness, and from illness to AIDS-related death

epitopes are relatively conserved, implicating structural constraints on viral mutation that limits ability of the virus to escape from the CTL response. One of the most frequently observed mutations in *B*57*-positive subjects, T242N in TW10, negatively affects viral fitness in vitro and is observed to revert back after transmission to a *B*57*-negative individual (Crawford et al. 2009).

As an allele bearing the Bw4 epitope, a known ligand for KIR3DL1 and potentially KIR3DS1, *B*57* is involved in regulating NK cell function. It has been demonstrated that patients carrying both *B*57* and highly expressed *KIR3DL1* allotypes exhibit a higher level of protection against AIDS progression as compared to patients without this compound genotype combination. These observations suggest that the *B*57* protection against AIDS progression is due at least in part to its interaction with KIR (“► [KIR Locus Variation](#)”) in addition to its role in the adaptive immune system (see “► [KIR Locus Variation](#)”).

Protective Effect of *B*27*. *B*27* allele carriers maintain lower viral loads over the course of infection (Pereyra et al. 2010) and develop AIDS more slowly as compared to non-carriers (Gao et al. 2005). *B*27* molecules restrict immunodominant CTL responses against a conserved Gag epitope, KK10 (KRWILGLNK

p24_{263–272}). Full viral escape typically arises late in infection and precedes a dramatic increase in viremia. This escape requires multiple mutations located within and outside the epitope (Schneidewind et al. 2007). Difficulty to achieve these mutations due to heavy fitness constraints and lack of particularly strong CTL pressure has been proposed to be the mechanism for protection (Gao et al. 2005; Schneidewind et al. 2007). Based on survival analysis, the protective effect is most evident after the CD4 T-cell counts (“► [CD4⁺ T Cell Depletion](#)”) drop below 200 (Fig. 2; Gao et al. 2005).

The predominant subtype of *B*27* in Europeans is *B*27:05*. Both *B*27:04* and *B*27:05* are common subtypes in Asians, whereas *B*27* is only sporadically detected in some other populations, such as Africans. There has been no clear evidence showing that the protective effect of *B*27* is confined to particular subtypes, but this would require very large sample sizes.

Susceptible Effect of *B*35*. *HLA-B*35* is the only *HLA* allelic group showing consistent associations with rapid progression to AIDS (Bashirova et al. 2011). The *B*35* effect on AIDS progression appears to be confined to a certain group of *B*35* subtypes collectively referred to as *B*35Px*, which exhibit distinct peptide-binding preferences. The set of *B*35Px*

molecules (B*35:02, B*35:03, B35:04, B*53:01) preferentially bind peptides with small hydrophobic residue at position 9 as opposed to B*35PY (B*35:01, B*35:08), which favors tyrosine at this position. *B*35Px* shows a consistent association with accelerated AIDS progression across races, whereas *B*35PY* is mostly neutral. The AIDS-associated *B*35:03* differs from the neutral *B*35:01* by only a single amino acid at position 116 on the floor of the peptide-binding groove, but this single replacement appears to have a significant impact on AIDS pathogenesis. Structural differences in the peptide-binding groove were suggested to effect the CTL response to HIV, making the *B*35Px* positive individuals more vulnerable during HIV infection. Similar to the timing of the *B*57* protection, the detrimental effect of *B*35* on progression is limited to time from seroconversion to CD4 < 200 (Fig. 2).

Recent data suggest that the differential *B*35* subtype effects might involve regulation of dendritic cells (DC) (Huang et al. 2009). DCs are major antigen-presenting cells that are crucial in staging CTL responses. DC activity is regulated by a series of inhibitory and activating receptors, one of which is the inhibitory leucocyte immunoglobulin-like receptor subfamily B member 2 (LILRB2). Binding of HLA ligand to LILRB2 expressed on the DC surface results in suppression of DC activity. Interestingly, B*35:03, an AIDS-susceptible B*35Px allotype, binds LILRB2 with greater affinity than does B*35:01, an AIDS-neutral B*35PY allotype, even when these molecules are folded with identical HIV peptides. The greater affinity of B*35:03 for LILRB2 is suggested to inhibit DCs function, which may explain the accelerated AIDS progression.

Other HLA Class I Associations. Additional class I *HLA* associations have been reported in multiple studies. These associations include the protective effect of several *HLA-Bw4* (a public epitope shared by many *HLA-B* and *HLA-A* subtypes, which serves as ligands for KIR) (“► [KIR Locus Variation](#)”) alleles, including *B*13*, *B*51:01*, *B*58:01*, and *B*81:01*, and the deleterious *B*58:02* and *B*45:01*. Some of these alleles have highly confined frequency

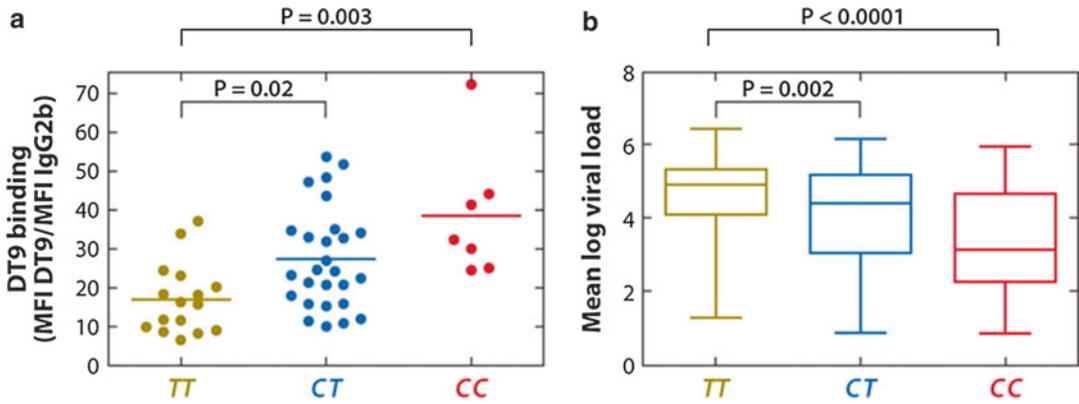

distributions across populations, such as the primarily African *B*81:01* and *B*58:02* alleles, which may explain their somewhat inconsistent associations in different cohort studies. Of particular interest, however, is the identification of *B*13*- and *B*51*-restricted HIV epitopes that result in HIV escape mutants with reduced viral fitness and delayed progression to AIDS (Kawashima et al. 2010; Prado et al. 2009). Since *B*13* and *B*51* are detected in most populations, the associated AIDS protection may have a general interest in terms of vaccine development.

Class II *HLA* and HIV Disease

Although some studies suggest that *HLA* class II allelic variation can influence HIV/AIDS outcomes, the data are not nearly as strong and consistent as that for class I alleles (Bashirova et al. 2011). Some associations with HIV acquisition and level viral load have been reported for the *HLA-DRB* and *HLA-DQB* loci, but the results are not terribly convincing due to the lack of reproducibility and/or small sample sizes. Promiscuity in binding of a given peptide across multiple distinct *HLA* class II allotypes may nullify allele-specific effects to some extent (Kaufmann et al. 2004), but more thorough examinations in larger cohorts with detailed clinical outcomes are necessary before a convincing conclusion can be drawn regarding the influence of *HLA* class II polymorphisms in AIDS pathogenesis.

HLA-C Expression and HIV Control

The limited polymorphism and lower cell surface expression of *HLA-C* relative to *HLA-A* and *HLA-B* have questioned its importance in defense against infectious disease, and no clear allelic effects at this locus have been identified in HIV disease outcomes. *HLA-C* serves as a “professional” ligand for KIR (“► [KIR Locus Variation](#)”), however, highlighting the functional significance of the locus, at least in terms of the innate immune response. The -35 variant

MHC Locus Variation, Fig. 3 The -35 genotype correlates with surface HLA-C expression on T cells (a) and mean log viral load (b). HLA-C expression was detected

using the DT9 monoclonal antibody and compared between pairs of genotypes. The viral load was analyzed in a cohort of 923 HIV-1-infected patients

identified in GWAS (see the section above) associates with HLA-C mRNA and cell surface expression of HLA-C (Bashirova et al. 2011; Fig. 3). The SNP was subsequently shown to be a marker for an insertion/deletion polymorphism within a microRNA (miR) binding site located in the *HLA-C* 3' untranslated region (UTR) (Kulpa and Collins 2011). An insertion variant at this locus allows the binding of hsa-miR-148 to its target site, resulting in relatively low cell surface expression of HLA-C alleles bearing this variant. Alleles with the deletion variant, on the other hand, escape posttranscriptional regulation due to disruption of the miR148a binding site, resulting in relatively higher surface expression. Individuals with the deletion polymorphism (high expression of HLA-C) were shown to progress more slowly to AIDS and control viremia (“► Viremic Non-Progressors”) significantly better than individuals with the insertion polymorphism (low HLA-C expressing alleles). These data implicate high HLA-C expression levels in more effective control of HIV-1, potentially through better antigen presentation to cytotoxic T lymphocytes or stronger NK cell responses to HIV-infected target cells (“► NK Cell Responses to HIV”). In support of this hypothesis, a recent study found that there was an increased frequency of *HLA-C*-associated mutations in HIV proviral DNA among individuals with the genotype that associates with high HLA-C expression (Blais

et al. 2012). These findings suggest that immune pressure on HIV is stronger in subjects with higher HLA-C expression. Linkage disequilibrium with *HLA-B* complicates the genetic analysis of variation within the *HLA-C* locus, however, and further data is necessary to define the role of HLA-C expression levels in HIV disease (Kulpa and Collins 2011).

Conclusions

HLA genes, in particular *HLA* class I, play an important role in determining the level of resistance to outcome after HIV infection. Both the candidate gene approach and GWAS point to *HLA* as the region harboring the most significant AIDS-restriction polymorphisms. Evaluation of the *HLA* influence on resistance to HIV infection has been difficult due to the lack of a precisely quantified measurement of HIV exposure, but analysis of heterosexual couples discordant for infection indicates no clear protective effect of *HLA* in HIV acquisition. Even the most prominent alleles that protect against multiple outcomes after HIV infection, *B*27* and *B*57*, do not associate with reduced risk of HIV infection. Postinfection, however, *HLA* may influence the infectivity of HIV transmitters through its effect on viral load levels. Further, more sharing of *HLA* alleles between HIV+ mothers and their infants does

appear to enhance the risk of infection in the infant.

While the *HLA* class I locus is the single most significant region of the genome in determining outcome after HIV infection, most individuals progress to AIDS in the absence of treatment regardless of their *HLA* type. *B*57* is common among the rare group of patients who control HIV to near undetectable levels off treatment, but most *B*57*-positive patients progress to AIDS as rapidly as those with other *HLA* types. These observations underscore the importance of other variables in determining control of HIV, including environmental and/or viral factors. It is entirely plausible that combinations of genetic variants that synergize in resistance to the virus may explain the discrepancies in viral control among carriers of a given *HLA* allele, such as *B*57*, and these epistatic interactions are not considered in GWAS. A deeper interrogation of genetic effects using a systems biology approach that takes into account the *HLA* loci may be warranted in HIV disease.

Microbial Translocation

Alexandra M. Ortiz and Jason M. Brenchley
Laboratory of Molecular Microbiology, NIAID,
National Institutes of Health, Bethesda, MD, USA

Definition

Human immunodeficiency virus (HIV) infection is associated with a multifaceted activation of the immune system, which predicts disease progression better than plasma viremia or the number of CD4 T cells in blood. One of the causes of this multifaceted immune activation is microbial translocation, which is associated with the progressive breakdown of the physical and immunological gastrointestinal (GI) barriers. One of the many detriments associated with persistent immune activation is the production of activated CD4 T cells, which serve as preferential targets for the virus in vivo. Ultimately, sufficient numbers of CD4 T cells are depleted, and HIV-infected individuals become susceptible to opportunistic infections, and the disease culminates in acquired immunodeficiency syndrome (AIDS). Ongoing research in both HIV-infected humans and simian immunodeficiency virus (SIV)-infected non-human primate models continues to reveal that a

failure to regulate GI tract immunity and GI-resident microbial communities underlies the persistent immune dysregulation observed in HIV-infected individuals.

Introduction

Human immunodeficiency virus (HIV) is the etiologic agent of acquired immunodeficiency syndrome (AIDS). Since the initial descriptions of AIDS in 1981, successive generations of antiretroviral (ARV) therapies have led to significant improvements in the quality and life span of infected individuals. Current-era ARV therapy is able to reduce virus replication to undetectable levels and generally to restore circulating CD4+ T-cell counts to near normal levels. However, even individuals treated with ARVs for prolonged periods of time still manifest increased mortality and morbidities compared to healthy, HIV-uninfected persons.

In both ARV-treated and untreated individuals, the strongest correlate of disease progression is chronic and multifaceted activation of the immune system. This includes persistent inflammation and stimulation of innate and adaptive leukocytes. As HIV preferentially replicates within activated CD4+ T cells, this persistently proinflammatory state promotes CD4+ T-cell depletion and contributes to immunodeficiency. Within the GI tract, CD4+ T-cell depletion and damage to the epithelial barrier permit gut-resident microflora and their immunostimulatory structural components to translocate from the GI lumen into the surrounding tissue space. Importantly, although opportunistic infections are a hallmark of AIDS progression, the translocation and dissemination of microbes into systemic circulation is evident throughout HIV infection and has been identified as a significant contributor to immune activation.

Another cause of microbial translocation in HIV-infected individuals appears to result from dysbiosis of the enteric microbiome that is not restored upon ARV initiation. As the commensal microbiome itself is essential for the development and maintenance of the intestinal immune system, persistent dysbiosis induced by HIV infection thus

impedes the recovery of intestinal CD4+ T cells. It is anticipated that continued research into the interplay between HIV, the enteric microbiome, and the human immune system will lead to improved HIV therapeutics.

HIV Infection as a Disease of the Gastrointestinal System

Approximately 10^{14} commensal bacteria colonize the lumen of the human GI tract and exist in a symbiotic relationship with the host (Kamada et al. 2013). Nutrients consumed by the host are utilized by the microflora for survival, and in turn, these microbes aid in nutrient digestion, compete with pathogenic species for nutrients and space, and promote the development of the intestinal immune system. Although commensal microbes are not pathogenic per se, these microflora can opportunistically cause systemic infection in a human host under conditions of genetic or acquired immunodeficiencies. In the absence of disease, several physical and immunological barriers limit the dissemination of both commensal and pathogenic bacteria from the luminal space into the surrounding tissues. These barriers include: (a) a sheet of intestinal epithelial cells that separates luminal contents from the underlying lamina propria of intestinal tissues, (b) a supra-epithelial bioactive layer of mucus that limits microbial colonization at the epithelial barrier, and (c) a cohort of innate and adaptive immune cells within the lamina propria that orchestrate antimicrobial immune responses. The integrity of these barriers is essential for preventing the dissemination or translocation of GI tract bacteria and bacterial products from the luminal space into the intestinal lamina propria.

HIV infection significantly compromises the structural and immunological integrity of the GI tract, resulting in progressive microbial translocation (Brenchley 2013; Marchetti et al. 2013). The GI tract is the largest lymphocyte-containing organ in the body containing an estimated 60% of the body's total lymphocytes. Although progression to AIDS is characterized by the loss of peripheral blood CD4+ T cells to less than

200 cells/ μl , it is well documented in acute HIV infection that the greatest loss of CD4⁺ T cells occurs with the GI tract, with an estimated depletion of 70% of intestinal CD4⁺ T cells. Intestinal CD4⁺ T cells represent the preferential targets for HIV infection by virtue of their activation phenotype, their expression of the CD4 receptor and CCR5 coreceptor, and their expression of the intestinal-homing integrin $\alpha 4\beta 7$, which has been shown to enhance the formation of the virologic synapse.

Despite representing the preferential HIV target population, reported infection frequencies of intestinal CD4⁺ T cells have varied widely and reflect the multiple mechanisms by which CD4⁺ T cells are depleted. Intestinal CD4⁺ T-cell depletion can be mediated by: (a) direct virally induced cell death of infected cells, (b) CD8⁺ T-cell-mediated recognition and cytolysis of HIV-infected cells, (c) activation-induced cell death (AICD), and (d) caspase-1-induced pyroptosis in abortively infected resting CD4⁺ T cells (Brenchley 2013; Doitsh et al. 2013; Marchetti et al. 2013).

Among CD4⁺ T cells within the GI tract, specialized CD4⁺ T cells with unique functionality, known as Th17 cells are preferentially depleted (Bixler and Mattapallil 2013). Th17 cells secrete IL-17 and IL-22, cytokines that can: (a) directly and indirectly promote the recruitment of innate immune cells to mucosal tissues, (b) induce the production of antimicrobial peptides such as S100 and β -defensin by the mucosal epithelial barrier, and (c) promote the proliferation of epithelial cells directly. Although Th17 cells are preferentially depleted, they are not preferentially infected, indicating that Th17 cell development and homeostasis are specifically compromised as a consequence of direct HIV infection. Th17 cell development is dependent upon priming by CD103⁺ dendritic cells (DCs) within the mesenteric lymph nodes and lymphoid follicles within the GI tract. Longitudinal studies in Asian macaque nonhuman primates (who can be progressively infected with SIV) have revealed that SIV infection is associated with a reduction in the total frequency of GI tract-resident CD103⁺ DCs, the net result of which is loss of lymphocytes which express

IL-17 and IL-22. The preferential loss of lymphocytes expressing IL-17 and IL-22 cells is associated with a reciprocal expansion of T cells with other functionalities, such as regulatory T cells or cells expressing proinflammatory cytokines such as TNF α and IFN γ .

The immunological dysfunction within the GI tract is associated with alterations to the actual structural integrity of the GI tract. This so-called HIV-associated enteropathy includes: enterocyte apoptosis, discontinuity of the epithelial barrier, decreased expression of epithelial repair genes, shortened villi, and fibrosis within the lamina propria, lymphoid follicles, and other lymphoid tissue (Brenchley 2013; Marchetti et al. 2013). Direct visualization the intestinal epithelium from biopsies of HIV-infected persons and SIV-infected macaques has revealed that disease progression is associated with the accumulation of breaches along the epithelial barrier. The accumulation of these breaches has been attributed to the widespread apoptosis of epithelial cells during the acute phase of SIV infection, regenerative exhaustion, and the absence of the Th17-directed epithelial repair program. The physical degradation of the mucosal epithelium allows microbes to directly translocate into the lamina propria and then systemically.

Microbial Translocation as a Consequence of HIV Infection

Microbial translocation was first demonstrated by the quantification of the gram-negative cell wall component lipopolysaccharide (LPS) from the plasma of HIV-infected individuals and SIV-infected Asian macaques (Brenchley et al. 2006). In these subjects, plasma LPS increased in tandem with disease progression and correlated directly with markers of innate and adaptive immune activation. Multiple groups have since corroborated and expanded upon these initial findings, demonstrating that a variety of microorganisms and microbial products can be isolated from systemic tissues and that microbial translocation begins at the end of the acute phase of infection. Importantly, although the initiation of ARV therapy is associated with a reduction plasma LPS levels,

plasma LPS remains significantly higher in infected, treated individuals than in uninfected individuals, suggesting that HIV replication precipitates but does not directly mediate microbial translocation and that ARV treatment alone is incapable of completely restoring the physiology of the GI tract.

Recent advances in next-generation sequencing platforms have made the identification of GI tract bacterial communities possible. These studies have revealed that HIV-associated microbial translocation is part of a larger phenomenon known as microbial dysbiosis – an imbalance in the makeup of the microbiome (Brenchley 2013; Marchetti et al. 2013; Vujkovic-Cvijin et al. 2013). This dysbiosis of the microbiome in HIV-infected individuals includes a relative expansion in immunostimulatory protobacterial orders such as Enterobacteriales and Bacteroidales. Dysbiosis also includes enrichment of bacterial genera known to be opportunistic pathogens including *Staphylococcus*, *Pseudomonas*, and *Campylobacter*. Effective ARV therapy does not necessarily promote the restoration of balanced microbial communities in HIV-infected individuals, suggesting that microbial dysbiosis may play a role in the residual inflammation observed in ARV-treated individuals. Microbial dysbiosis has been shown in other diseases associated with microbial translocation including Crohn's disease, ulcerative colitis, and pouchitis, and studies in nonhuman primates have revealed that although SIV infection is associated with an increased incidence of enteropathy, SIV infection itself is not associated with dysbiosis.

Microbial Translocation, Immune Activation, and AIDS Progression

In the absence of chronic or autoimmune disease, immune activation is resolved concurrent with the clearance of a recognized pathogen. With HIV, however, the GI tract is not able to completely heal and microbial translocation persists. Although viral replication contributes to immune activation in HIV-infected persons, immune activation is still evident following

years of ARV therapy, indicating that replication itself does not solely promote immune activation. Instead, microbial translocation and dysbiosis appear to contribute significantly to persistent immune activation.

The microflora and their associated microbial products are particularly immunogenic within the human host, and their accumulation during HIV infection correlates with immune activation and depressed CD4+ T-cell counts (Brenchley et al. 2006; Brenchley 2013; Marchetti et al. 2013). With regards to LPS in particular, several LPS-specific immune mediators are found to be elevated during acute HIV and SIV infection, such as LPS-binding protein (LBP) and soluble and membrane-bound CD14. LPS recognition by these immune mediators complements toll-like receptor 4 (TLR4) signaling to initiate a pro-inflammatory cascade characterized by high levels of IL-6, TNF α , and type I interferons. Although elevated microbial translocation is not limited to LPS or to gram-negative bacteria, the enrichment of disease-associated taxa themselves correlates with elevated levels of plasma markers of inflammation (such as IL-6 and IP-10), increased intestinal indoleamine (IDO), and elevated T-cell activation in chronic HIV infection (Vujkovic-Cvijin et al. 2013).

Indoleamine 2,3 deoxygenase is a tryptophan-metabolizing enzyme expressed by select subsets of activated myeloid cells. Tryptophan metabolism by IDO1 leads to production of catabolites including 3-hydroxyanthranilic acid (3-HAA), which has been shown to limit production of IL-17 by Th17 cells (Bixler and Mattapallil 2013; Brenchley 2013; Vujkovic-Cvijin et al. 2013). Moreover, IDO1 is the rate-limiting enzyme in the tryptophan/kynurenine catabolic pathway, and elevated kynurenine levels in HIV-infected individuals correlates with disease progression. In HIV-infected individuals, elevated IDO1 expression has been detected within myeloid dendritic cells, and interestingly, homologues to additional enzymes within the kynurenine pathway have been identified among disease-associated bacterial taxa within the GI tracts of HIV-infected individuals.

Chronic stimulation of the immune system by microbial products takes a toll on the immune

system. Indeed, monocytes isolated from chronically infected patients are refractory to prototypical LPS stimulation with decreased expression of TNF α and IL1 β (Brenchley et al. 2006). This refractoriness to LPS stimulation *in vitro* is, in turn, correlated with increased PD-1 expression by monocytes themselves and with the production of immunosuppressive IL-10. TLR stimulation of DCs isolated during chronic infection also exhibits a profound reduction in IL-12, IL-6, and TNF α production (Miller and Bhardwaj 2013). Altered TLR responses in dendritic cells have been associated with direct HIV-mediated downregulation of autophagy, which has been suggested to negatively affect antigen presentation. It has been speculated but not formally demonstrated that HIV-mediated autophagy interference or increased inhibitory receptor expression may similarly contribute to defective macrophage phagocytosis.

Microbial Translocation as a Mediator of HIV-Associated Comorbidities

HIV-infected individuals have a greater risk of non-AIDS-associated comorbidities and mortality as compared to uninfected population controls, even if the individual has been treated with ARVs (Brenchley 2013; Deeks et al. 2013; Marchetti et al. 2013). Cardiovascular diseases, neurocognitive dysfunctions, osteoporosis, liver disease, renal complications, and some cancers are more common in these individuals. It is clear that all of these comorbidities are associated with residual inflammation, especially elevated plasma levels of IL-6. There is evidence to suggest that microbial translocation may precipitate or exacerbate the residual inflammation. Indeed, a clinical association exists between microbial products, makers of inflammation, and cardiovascular risk. Consistent with this premise, in HIV-uninfected persons, bacterial endotoxin is a proinflammatory mediator of atherosclerosis. Similarly, plasma levels of soluble CD163, a scavenger receptor expressed by activated monocytes and macrophages, correlate with the presence of noncalcified coronary plaques in HIV-infected

individuals. Also related to cardiovascular disease is hypercoagulability, which is a common phenomenon in HIV-infected individuals. Biomarkers associated with excessive coagulation, particularly levels of D-dimer, are strongly associated with increased morbidity and mortality. Although levels of HIV replication correlate with D-dimer plasma levels in untreated, HIV-infected individuals, ARV-treated individuals still exhibit increased D-dimer levels as compared to control populations, suggesting that residual immune activation from ongoing microbial translocation may drive hypercoagulability. There is some evidence for this in nonhuman primate models of HIV infection, where high levels of virus replication in non-pathogenically SIV-infected monkeys are not associated with increased cardiovascular risks, whereas SIV infection in progressively infected monkeys is associated with increased D-dimer levels and multiorgan thrombus formation.

Antimicrobial Treatments in HIV Infection

A recent appreciation for the contributions of microbial translocation and dysbiosis to AIDS progression has promoted an interest in the development of prophylactic therapies aimed at restoring microbial stasis and antimicrobial immunity. These therapies fall into two broad categories: those aimed at directly repairing antimicrobial immune responses and those aimed at indirectly repairing intestinal immunity by restoring the commensal flora. Among the former, IL-21 cytokine therapy has been considered as a potential intervention for Th17 cell loss (Pallikkuth et al. 2013). IL-21 is essential for the development of Th17 cells and has additionally been demonstrated to promote CD8 $^+$ T-cell and NK cytotoxicity, to induce B-cell maturation and isotype switching, and to promote phagocytosis by macrophages. In acutely SIV-infected rhesus macaques, IL-21 administration has been demonstrated to restore intestinal CD4 $^+$ T-cell frequencies and to reduce plasma LPS into the chronic phase of SIV infection, as compared to untreated controls. Among the IL-21-treated animals, IL-21

therapy was associated with the maintenance of the Th17 population concomitant with the treatment period – the cessation of treatment in these animals was accompanied by the depletion of Th17 cells to the levels observed in control animals, likely due to ongoing virus replication. Although the effects of IL-21 therapy in HIV-infected patients have not been assessed, IL-21 has been demonstrated to be immunogenic and well tolerated in several therapeutic phase II clinical cancer trials.

Treatment with anti-PD1 has been considered as a potential therapeutic to reverse immune exhaustion in HIV-infected individuals and has also been demonstrated to be fairly well tolerated and active in phase II clinical cancer trials. In chronically SIV-infected rhesus macaques, treatment with anti-PD1 in the absence of ARV therapy has indicated that immune exhaustion is reversible (Dyavar Shetty et al. 2012). As compared to SIV-infected control animals, anti-PD1-treated animals displayed improved antiviral and antimicrobial lymphocyte function and decreased immune activation as measured by interferon-stimulated gene expression. Importantly, the improved health in these animals was not associated with a reduction in viral load but was associated with an increase in GI expression of tight-junction-associated genes, a decrease in plasma LPS, and a decrease in the incidence of opportunistic infections. Improved disease prognosis in anti-PD1-treated, chronically SIV-infected non-human primates reflects the paradox that although aberrant immune activation precedes immune exhaustion and correlates with disease progression, antiviral and antimicrobial immune responses are necessary for preventing overt septicemia and rapid disease progression.

Recently, there has been a significant interest in the effects of probiotics in modulating intestinal immunity for the purposes of treating GI-associated immunopathologies. Probiotics consist of single or multiple live bacterial species that have been shown to confer a protective benefit to their host upon consumption (Bron et al. 2012; Kamada et al. 2013). Probiotics benefit their host by competing with pathogenic bacterial species for nutrients and space, inducing the development

of a balanced intestinal immune system, and producing short-chain fatty acids as part of normal metabolic processes. Multiple trials have assessed the effects of probiotics on disease progression in HIV-infected individuals in the form of synbiotics – probiotics administered with “prebiotics” or oligosaccharide mixtures that are thought to promote the growth of probiotic organisms (Brenchley 2013; Marchetti et al. 2013). Although several publications have reported increased CD4 + T-cell counts in response to probiotic treatment, the specific additional benefits induced in these trials have varied widely, confounded by an inconsistent use of probiotic strains, varied administration conditions, and diverse cohort parameters. Of studies that have more rigorously assessed microbial dysbiosis and levels of immune activation in response to probiotic treatment, treatment of both ARV-treated and ARV-naïve HIV-infected individuals with synbiotics has resulted in improved CD4+ T-cell counts, decreased proinflammatory cytokine secretion and sCD14 levels, and improved dysbiosis as compared to placebo controls. Despite the beneficial systemic outcomes observed in these trials, the exact mechanisms by which probiotics promote improved health in HIV-infected individuals remain incompletely defined. In SIV-infected macaques, synbiotic treatment as a supplement to ARVs was recently demonstrated to improve intestinal APC frequency and function, to promote an increase in the functionality of Th17 cells, to decrease fibrosis in GI lymphoid follicles, and to increase GI tract CD4 T-cell reconstitution (Klatt et al. 2013). Although the effects of particular probiotic species and regimens on immune reconstitution during HIV infection warrant further study, the results reported indicate that symbiotic supplementation of ARV therapy may significantly improve the prognosis of HIV-infected individuals.

Conclusion

Progressive HIV infection is associated with the disruption of the physical and immunological GI barriers and the subsequent dissemination of GI

microflora (Brenchley et al. 2006; Brenchley 2013). The outgrowth and translocation of immunostimulatory microflora promote the persistent activation of both innate and adaptive leukocytes, contributing to the inflammatory sequelae characteristic of pathogenic HIV infection (Kamada et al. 2013; Marchetti et al. 2013). Although effective ARV therapy has been shown reduce immune activation, residual inflammation in treated individuals correlates with the continued translocation of microbial products and particularly, with the persistence of disease-associated microflora (Deeks et al. 2013). This lingering microbial dysbiosis inhibits the reestablishment of a competent intestinal immune system, thereby perpetuating inflammation and immunodeficiency (Brenchley et al. 2006; Vujkovic-Cvijin et al. 2013). Recent insights into the contributions of microbial translocation and dysbiosis to HIV disease progression warrant continued research into therapeutics aimed at restoring antimicrobial immunity and commensal stasis.

Definitions

- Microcredit:** Described as an approach that consists of providing credit in relatively small loan amounts through a group lending process and compulsory savings.
- Microfinance:** Involves the provision of credit along with other financial products (i.e., savings accounts), microinsurance (i.e., health, life, and disability), and/or business development education (i.e., literacy training, marketing, and accounting) offered either directly or indirectly.

Microfinance/Microenterprise Approaches to HIV Prevention

Structural factors affecting HIV risk are widely acknowledged; however, research evaluating structural HIV prevention interventions, such as microenterprise, is sparse. In this chapter, microenterprise is defined, a description of its history and potential for HIV prevention is provided, the effects of several microenterprise HIV prevention studies are described, and lastly, recommendations for future programs and studies are provided.

Microenterprise, Microfinance, and Micro-lending

Over the past decade, researchers have examined the role of microenterprise in reducing poverty as well as the risk and burden of HIV among various populations throughout the world. Although distinct, the terms microenterprise, microfinance, and micro-lending all refer to some level of access to resources, either financial and/or social, and are often used interchangeably. Microcredit is often described as providing credit in relatively small loan amounts through a group lending process and compulsory savings. Microfinance involves the provision of credit along with other financial products (i.e., savings accounts), microinsurance (i.e., health, life, and disability), and/or business development education (i.e., literacy training, marketing, and accounting) offered either directly or indirectly. Economists have suggested that participation in microfinance programs that increase the level of access to resources can improve economic well-being by building assets as well as increasing income, thereby decreasing economic vulnerability among the world's poorest people (Leatherman et al. 2012). This chapter will use the term "microenterprise" to encompass the range of these financial services that are targeted to low-income individuals, including credit, savings, insurance, money transfers, and trainings.

Microenterprise, Poverty, and HIV/AIDS

While prior research has established the positive effect of microenterprise schemes on economic outcomes, researchers have just recently started to examine their impact on more distal yet related outcomes, such as health (Sherman et al. 2010). Poverty is a common feature of HIV vulnerability throughout the world, and the link between poverty and HIV risk is tied intimately to the socio-economic context in which HIV occurs (Kim et al. 2007).

As HIV/AIDS enters its fourth decade, there has been a shift in HIV prevention from solely focusing on individual risk behaviors to the environments or structures in which HIV transmission occurs. Such interventions emphasize more on "upstream" factors, or social determinants of health (Williams et al. 2008), such as poverty, in ways that have the potential to produce more effective community responses to public health problems, such as HIV/AIDS (Kim et al. 2008).

By providing access to resources and/or money to those that are economically vulnerable and largely disempowered segments of society who are often times at greatest risk of HIV, microenterprise can play a particularly unique and important role within HIV/AIDS prevention. More specifically, because poverty has been linked with increased risk of HIV, HIV progression, and increased mortality, particularly among women (Kim et al. 2008; Mbirimtengerenji 2007; Piot et al. 2007), microenterprise has the potential to mitigate the effects of HIV prior to and after transmission.

Microenterprise and Women

Among the approximately one billion individuals living in poverty, women shoulder a disproportionate share of this burden: they earn 30–40% less than men for the same work, and most are employed in the informal sector, which places them at higher risk for income insecurity and poor working conditions (UNIFEM 2000). These factors may increase the vulnerability of women to HIV by extending their dependence on men and further limiting their ability to refuse sex, negotiate condom use, and get out of risky relationships (Rao 2002).

IMAGE Study

The few examples of microenterprise as an approach to HIV prevention have occurred in Southern Africa, India, and the USA. The Intervention for Microfinance and Gender Equity (IMAGE) study is the largest, most rigorous trial examining the effects of a microfinance and HIV education intervention for women in South Africa (Pronyk et al. 2008). The study was a randomized, prospective, community-level intervention in eight pairs of villages in rural South Africa with multiple structural-level outcomes. The intervention targeted women and was comprised of small group microfinance lending based on the Grameen Bank model and gender-focused training. Although the intervention was not associated with significant reductions in incident HIV, it was associated with significant reductions in physical and sexual partner violence among participants. The study also found significant improvements across a broad range of empowerment indicators.

Several smaller trials examining the effects of microenterprise as an HIV prevention tool have been conducted among female sex workers (FSWs), given the role of economic deprivation in some women's decision to enter sex work, and the occupational hazard of HIV for many FSWs. For example, a small randomized clinical trial among FSWs in Chennai, India, that trained FSWs to make canvas bags found that the intervention was associated with a significantly lower number of sex partners, significant increases in income, and a significantly lower number of paying clients per month at the 6-month follow-up (Sherman et al. 2010).

These two studies provide a snapshot of the types of interventions that have utilized a microenterprise approach to HIV prevention among women. Lessons learned from these and other microenterprise interventions should inform future work. First, the long-term survival of microenterprise activities by those that have limited skills should include an array of related business topics to enhance the success and sustainability of business endeavors. Many participants may not have any experience in engaging in finance programs; therefore, savings-led programs may provide a safer introduction to microfinance, since they foster

asset development and financial independence without the financial risks associated with debt. Microenterprise programs could benefit from the inclusion of training content that incorporates an explicit gender focus, raises awareness about gender roles and cultural beliefs, and provides an opportunity for women to discuss often stigmatized subjects such as sexuality, HIV/AIDS, and gender-based violence in a safe environment. Such content could potentially increase the success of a microenterprise program by simultaneously increasing empowerment among women. These topics are particularly important when vulnerable women participate in economic empowerment programs, given that such empowerment can often threaten their sexual partners. Including partners as a component in such interventions is important to minimize any deleterious repercussions on participants and to sustainably target the context that often generates HIV risk among these women. Lastly, the pilot in India demonstrated that women were interested in and successful at learning a new skill – in this instance, tailoring.

Microenterprise approaches have great potential in reducing HIV risk exposure among women. Because economic deprivation and dependency can push some women into high-risk means of livelihood, such as sex work or other behaviors that place them at higher risk of HIV exposure, microenterprise economic activities can empower women to make safe choices and increase their opportunities, which in turn can reduce their vulnerability to HIV.

Microenterprise and People Living with HIV and AIDS

People living with HIV and AIDS (PLWHA) are economically vulnerable for a myriad of reasons. For PLWHA, poverty poses a formidable obstacle to accessing antiretroviral treatment, due to both individual-level factors (such as prioritization for survival: food, childcare, or school fees) and structural-level factors (such as distance and transportation costs, long wait times, inadequate health infrastructure). For those that are able to initiate antiretroviral therapy (ART), financial losses resulting from HIV (debt, job loss, costs of medical care) present roadblocks to

socioeconomic recovery. In sum, PLWHA suffer increased levels of poverty, in part because of discrimination and in part because of the extra medical burden they face (Viravaidya et al. 2008).

Very little programmatic attention has been paid to the potential for microenterprise for HIV/AIDS stigma reduction efforts (Viravaidya et al. 2008). While a number of microfinance institutions operate in high HIV prevalence areas, most have been cautious to target HIV-positive/affected individuals. Concerns about utilizing microenterprise initiatives with PLWHA include greater rates of absenteeism, loan default, repayment delinquency higher drop-out rates, and premature death (Barnes 2005; Datta and Njuguna 2008).

CARE's Cote d'Ivoire Village Savings and Loan Pilot

In 2007, CARE, a humanitarian organization, launched pilot village savings and loan activities as a part of their HIV prevention and mitigation program in Cote d' Ivoire. Qualitative methods were used to explore the socioeconomic effects of the loan activities on HIV-/AIDS-related factors. Study participants reported using funds from income-generating associations (IGAs) to pay for ART, thereby increasing adherence and access to treatment. Improved health, in turn, then increased the likelihood that community members would loan them money, which then increased their capacity to carry out economic activities, and the use of revenue from IGAs to pay for medical expenses improved perceptions of PLWHA as they were viewed as contributors (Holmes et al. 2011).

A randomized controlled trial examined the impact of child savings accounts as an economic empowerment intervention among AIDS-orphaned youth in rural Uganda. The evaluation found that girls of families who possessed child savings accounts had more protective attitudes or attitudes that aligned with safer sex behaviors. The authors concluded that adolescent girls might be able to develop protective attitudes toward sexual risk taking through economic empowerment programs that address gendered social norms (Ssewamala et al. 2010).

These two studies exemplify ways in which PLWHA's economic vulnerability can be reduced

through involvement in microenterprise. First, income generation can directly translate into ART adherence, but in order to do so, microenterprise programs must be cognizant of the physical limitations that PLWHA may face, as these limitations affect the types of income-generating activities that are feasible for PLWHA. Before microenterprise programs are developed to target PLWHA, it would be pertinent to invest in research to understand which IGAs are most appropriate for PLWHA, based on their health status. Another important consideration is the type of activities that programs targeting PLWHA should offer. Because HIV-related expenses are typically recurring, it is important to choose activities that can yield profit all year long and are stable. Finally, microenterprise programs that include training sessions on risk behavior can shift attitudes and norms around behaviors that may place individuals at increased risk for HIV exposure, by increasing individual self-efficacy and risk perception.

Microenterprise is a tool that is well suited for PLWHA and those affected by HIV/AIDS. Savings-led community-managed microfinance, by providing PLWHA access to money, can mitigate the negative socioeconomic impacts of HIV/AIDS. Microenterprise can generally increase PLWHA financial security and well-being, and even when the benefits are small and are not able to restore business to pre-illness levels, microenterprise can provide a means to pay for food and medicine.

Conclusion

Microenterprise lends itself well to improving health outcomes, because when families have fallen into poverty or are economically vulnerable, health often emerges as a key reason. Specific to HIV/AIDS, reducing poverty is without doubt one of the major strategies for use against the HIV pandemic (Longuet et al. 2009).

While women and PLWHA are both important target populations with regard to HIV exposure, microenterprise can play a role in reducing risk among almost any population. This is due to the fact that microenterprise approaches are rooted in the promotion of access to resources that can

increase economic well-being, which provides individuals the means to have the opportunity to mitigate some of the negative factors that may place them at higher risk for adverse health outcomes.

In sum, microenterprise programs provide an innovative way to address the ongoing challenges of poverty that underlie a range of health issues. Opportunities are now emerging for microfinance institutions and organizations to increase their potential benefits by more directly addressing health-related concerns. There is mounting evidence that implies that combining economic and health interventions can create powerful synergies and broaden program effects. However, interventions and evaluations of such interventions are limited. There is a need to rigorously evaluate such interventions to determine what is the best combination of program components to maximize potential benefits in health and social outcomes. Finally, there is a need to plan for the extension and sustainability of such programs to create viable, self-financing microenterprise programs to encourage and ensure local ownership of such an approach.

Definition

Microsporidia are a group of intracellular protists related to Fungi that can cause chronic diarrhea in patients with AIDS, but, depending on the

particular species involved, can also infect many other organ systems with keratoconjunctivitis being a common nongastrointestinal manifestation.

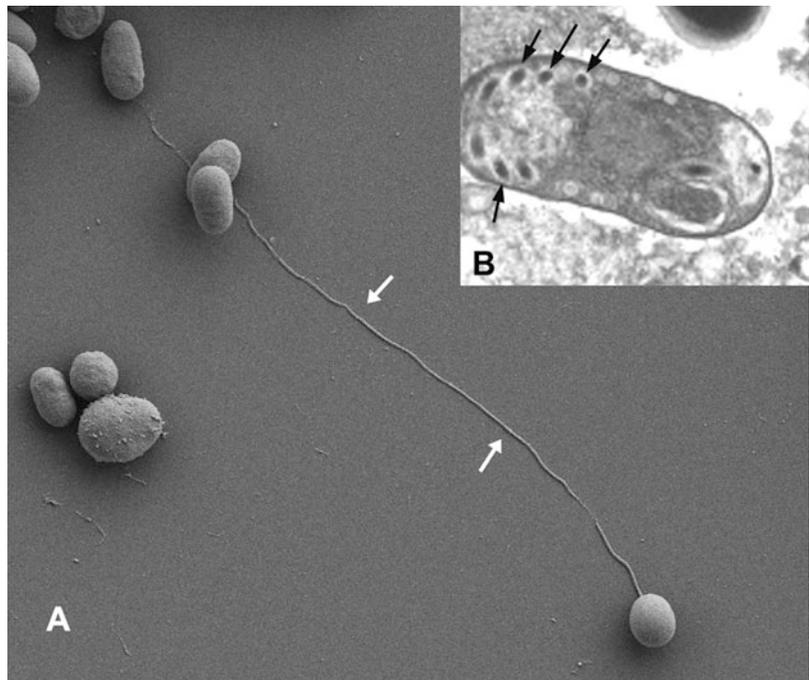

Introduction

The microsporidia are intracellular pathogens that infect both invertebrate and vertebrate hosts (Weiss and Becnel 2014). Microsporidia have a unique invasion organelle, the polar tube, that punctures host cells during invasion allowing transmission of this pathogen (Fig. 1). Given the wide host range of these organisms it is not surprising that they have been identified as human pathogens as they infect almost all animal phyla, including other protists. They were historically considered “primitive” protozoa; however, recent studies suggest that these organisms are related to the Fungi, either as a basal branch of the Fungi or as a sister group (Keeling 2009; Weiss and Becnel 2014), and are not primitive but have lost genes in their evolution as intracellular pathogens. The first description of these organisms was the identification of *Nosema bombycis* 150 years ago as the etiological agent of pébrine, an economically

important disease of silkworms, and the first description in mammalian tissues occurred in 1923. In their hosts, the majority of the microsporidia infect the digestive tract, but infections of almost all organ systems have been documented.

Microsporidia were first linked to infection in humans in 1959 with the description of a child with encephalitis, but until the HIV epidemic infections were only sporadically reported in humans (Franzen 1998). In 1985, intestinal microsporidiosis was reported to be associated with chronic diarrhea and wasting in patients with AIDS (Desportes et al. 1985) and the number of reported cases increased exponentially until the widespread use of combination antiretroviral therapy (cART) resulted in a decline in reported cases. The available literature supports that microsporidia display strength of association, coherence, and reproducibility with respect to being causative for a diarrheal syndrome in patients with AIDS (Coyle et al. 1996). Further proof of this association is provided by efficacy of albendazole, for *Encephalitozoon intestinalis*, and fumagillin, for *Enterocytozoon bieneusi*, in the treatment of diarrhea due to these pathogens. Besides gastrointestinal tract involvement,

Microsporidiosis,
Fig. 1 (a) Scanning electron micrograph (SEM) of a germinated *Anncaliia algerae* spore demonstrating the polar tube (arrow). (b). Transmission electron micrograph (TEM) of an *Encephalitozoon hellem* spore. Polar tube cross sections are indicated by arrows

infection with various species of microsporidia can also cause encephalitis, ocular infection, sinusitis, myositis, or disseminated infection (Weber and Bryan 1994).

In addition, to HIV/AIDS other causes of immune suppression, e.g., antibodies to TNF α , chemotherapy, immune modulating drugs and transplantation, have been demonstrated to be risk factors for microsporidiosis (Weiss and Becnel 2014). Microsporidiosis due to *E. bienersi* has been reported in patients with kidney, liver, or heart-lung transplants; Encephalitozoonidae infections in patients with kidney, pancreas, liver, or bone marrow transplantation; *T. acridophagus* in a patient with bone marrow transplantation; and *A. algerae* in a patient with lung transplantation. Microsporidiosis, however, is not limited to immune compromised hosts and infection can occur in immune competent individuals resulting in diarrhea (mostly due to *E. bienersi* and *E. intestinalis*) and other syndromes, such as keratoconjunctivitis (due to *Vittaforma corneae*, particularly in Southeast Asia).

Species and Life Cycle

The phylum contains over 1200 species distributed into at least 200 genera and the species shown in Table 1 have been demonstrated to be associated with disease in humans (Weiss and Becnel 2014; Weber and Bryan 1994).

Epidemiology

Studies conducted on patients with AIDS before 1998 and the widespread use of cART demonstrated that as many as 70% of patients with chronic diarrhea had microsporidia in their stool samples. There was no overall trend in these studies with regard to country of origin or other demographic characteristics. When combined, these studies identified 375 *E. bienersi* infections among 2400 patients with chronic diarrhea, for a prevalence of 15% in this population (Weiss and

Becnel 2014). In areas in which cART is not widely available the epidemiology of this disease has not changed and a similarly higher prevalence rate is present. Serosurveys in humans have demonstrated a high prevalence of antibodies to *E. cuniculi* and *E. hellem* ranging from 5% to 36% with the higher seroprevalence being seen in studies conducted in the tropics in patients with co-existent tropical infections, such as malaria or filariasis, or in HIV-infected populations. Positive serology has also been associated with travel to the tropics. In temperate countries, the average seroprevalence has been 5%. Although initially regarded as rare, these organisms are now understood to be common enteric pathogens that cause self-limited or asymptomatic infections in normal hosts. Cases of microsporidiosis have been identified from all continents except Antarctica.

Infection with microsporidia, in the majority of cases, occurs due to the oral ingestion of spores, and the site of initial infection is the gastrointestinal tract. Many of the species of microsporidia that infect humans are also found in animals, suggesting that human infection may be a zoonosis. For example, the Encephalitozoonidae are found in many mammals and birds, and the onset of human infection with these organisms has been associated with exposure to livestock, fowl, and pets. Other microsporidia are found in insects and surface water. *Nosema* and *Vittaforma* infections have been associated with traumatic inoculation of environmental spores into the cornea; exposure to hot springs was associated with ocular infections due to *V. corneae*. For both *Tubulinosema* and *Anncaliia* vector borne transmission has been suggested to occur. Spores of human pathogenic microsporidia have been found in municipal water supplies, tertiary sewage effluent, surface water, and ground water. Infectious spores are found in stool, urine, and respiratory secretions suggesting that person-to-person transmission occurs, as has been demonstrated in cohabiting homosexual men. Congenital transmission of *E. cuniculi* has been seen in many mammals including primates, but there are no reports in the literature of congenital infection in humans.

Diagnosis

Light microscopy is the standard technique for the identification of microsporidia using staining methods that produce differential contrast between the microsporidian spores and the debris

in clinical samples (Weber et al. 1992). Microsporidian spores are 1–5 µm in size, depending on the species, necessitating the use of a 60× or 100× objective for clear visualization. Chromotrope 2R (Fig. 2), calcofluor white (fluorescent brightener 28), or Uvitex 2B are

useful stains for stool or other body fluids. Generally, it is easier to identify microsporidian spores in body fluids other than in stool because of the absence of bacteria and debris, which can be confused with microsporidian spores. False positive samples, due to environmental microsporidia from insects or other sources, has not been a common problem in clinical samples. A number of molecular diagnostic tests have been developed for diagnosis of microsporidiosis using primers to small subunit rRNA genes which permit the identification of microsporidia at the species level without ultrastructural examination (Weiss and Vossbrinck 1998). These PCR techniques have been applied to biopsy specimens, urine, cultures, and stool specimens greatly facilitating diagnostic and epidemiologic studies. These tests are available in reference laboratories such as the Centers for Disease Control and Prevention. Monoclonal antibodies have been developed for *E. hellem*, *E. intestinalis*, and *E. bienewsi* but are not commercially available for diagnosis in human infections. Due to the presence of renal involvement with shedding of spores in the urine in those microsporidia that can cause disseminated infection, urine specimens should be obtained and examined whenever the diagnosis of microsporidiosis is considered. This has therapeutic implications because microsporidia that

disseminate (e.g., the Encephalitozoonidae.) are sensitive to albendazole, whereas those that do not disseminate (e.g., *E. bienewsi*) are resistant.

Endoscopy is useful for the diagnosis of microsporidiosis in cases of chronic diarrhea. Because microsporidian infections usually involve mucosa or epithelium, cytologic preparations are especially useful for diagnosis. In tissue samples, microsporidia can be seen with a modified tissue chromotrope 2R, tissue Gram stain (Brown-Hopp or Brown-Brenn), periodic acid-Schiff Giemsa, Steiner silver stain, or Luna stain. Microsporidia can also be seen on routine hematoxylin and eosin-stained sections. Spores can be demonstrated in fresh tissue by phase contrast microscopy as they are retractile and often birefringent. The definitive identification of the exact species of microsporidia causing an infection can be done using ultrastructural examination (e.g., electron microscopy) or molecular techniques (e.g., PCR). The isolation of microsporidia from clinical specimens is not a routine procedure and is available in only a few specialized research laboratories. Serological testing has been used in animals, but no tests are commercially available for human infections. In addition, serology has not been useful in patients with HIV infection in the diagnosis of microsporidiosis.

Clinical Manifestations

The various microsporidia infecting humans and described infections are summarized in Table 1. Although most reported cases of microsporidiosis involve diarrhea, the spectrum of diseases caused by these organisms has expanded to include keratoconjunctivitis, disseminated disease, hepatitis, myositis, sinusitis, kidney and urogenital infection, ascites, and cholangitis (Weiss and Becnel 2014; Weber and Bryan 1994; Weber et al. 1997).

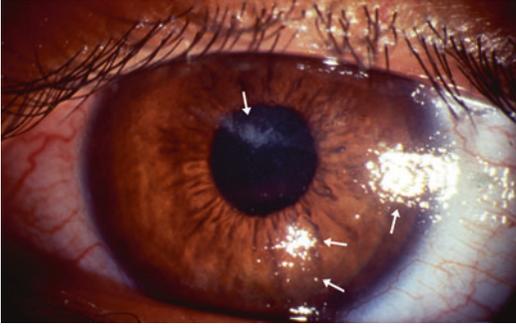

Gastrointestinal Tract Infection: At least 90% of cases of gastrointestinal microsporidiosis are due to *E. bienewsi* and the remaining cases are mostly due to *E. intestinalis*. In patients with AIDS infection it often manifests as chronic diarrhea, and stool examination may reveal multiple pathogens in these patients. In addition to

diarrhea, granulomatous hepatitis caused by Encephalitozoonidae has been reported in patients with AIDS and infection of the biliary system epithelium due to *E. bienersi* can lead to sclerosing cholangitis. Microsporidiosis due to *E. bienersi* is a cause of diarrhea in travelers, children in low income countries, and patients undergoing, kidney, lung, liver, or bone marrow transplantation. In immune competent patients, the diarrheal syndrome is self-limited, but in patients with immune suppression the diarrhea can be persistent and result in a wasting syndrome. Clinical manifestations include watery, nonbloody diarrhea, nausea, diffuse abdominal pain, and fever. In immune competent patients, the diarrhea syndrome is usually self-limited; however, in those with immune suppression the diarrhea can be persistent and result in a wasting syndrome. Infection with *E. bienersi* does not result in enteritis or ulceration; however, infection causes villous blunting and crypt hyperplasia. From three to ten bowel movements occur daily that consist of loose to watery stool without blood or fecal leukocytes with associated malabsorption exacerbated by eating. Within epithelial cells *E. bienersi* spores and proliferating forms are found on the apical surface, e.g., they are not present on the basal surface below the nucleus of these polarized cells or in the lamina propria. *E. bienersi* can also infect cholangioepithelium causing sclerosing cholangitis, cholangiopathy, or cholecystitis with associated abdominal pain, nausea, vomiting, fever, and elevation of alkaline phosphatase. Imaging studies can demonstrate dilated biliary ducts, irregularities of the bile duct wall, and gallbladder abnormalities such as thickening, distention, or the presence of sludge. In patients with AIDS, the prevalence of *E. bienersi* infection increases with declining CD4⁺ T cell counts and patients with CD4⁺ T cell counts less than 50 cells/ μ l are at high risk. In these patients, infection is associated with increased mortality rates. Systemic dissemination is not described for *E. bienersi* infection; however, there are reports of this organism in nasal mucosa (perhaps due to aspiration) with associated cough, dyspnea, wheezing, and interstitial infiltrates. Other members of the

Enterocytozoonidae, such as *Nucleoporea salmonis*, are found in lymphocytes and are capable of disseminated infection in their host species.

Three members of the family Encephalitozoonidae are associated with disease in humans – *E. cuniculi*, *E. hellem*, and *E. intestinalis* (originally called *Septata intestinalis*). All of these organisms can cause disseminated disease involving any organ system. They are associated with numerous clinical syndromes including gastroenteritis, keratitis, sinusitis, bronchiolitis, nephritis, cystitis, urethritis, prostatitis, hepatitis, fulminant hepatic failure, peritonitis, cerebritis, and skin nodules. *E. intestinalis* is the second most common microsporidian cause of diarrhea and in some geographic areas can be more common than *E. bienersi*. Unlike *E. bienersi*, spores and proliferative forms of *E. intestinalis* are found on both the apical and basal sides of infected intestinal epithelial cells as well as in cells in the lamina propria. Infection of the gastrointestinal tract can be locally destructive resulting in necrosis and perforation of areas of bowel that presents as an acute abdomen. A characteristic septated parasitophorous vacuole can be seen surrounding the developing spores. *E. cuniculi* has not been described as a cause of diarrhea but has been described as a cause of hepatitis, hepatic failure, and peritonitis. *E. hellem* has also not been reported in cases of diarrhea but can cause disseminated infection and hepatitis. *Tubulinosema acridophagus* infection with peritonitis and hepatitis has been reported in the setting of an allogeneic bone marrow transplant.

Ophthalmologic Infection: While *E. cuniculi*, *E. hellem*, or *E. intestinalis* can all cause keratoconjunctivitis with a punctate keratopathy (Fig. 3) and corneal ulcers, the most common cause is *E. hellem* infection, especially in patients with HIV infection. *Trachipleistophora anthropoptera* has also been reported to cause a similar keratoconjunctivitis. *T. hominis* and *A. algerae* have also been reported in cases of keratitis. Ocular infection can be the presenting manifestation of disseminated infection due to any of the Encephalitozoonidae. Clinical examination demonstrates coarse punctate epithelial keratopathy and conjunctival inflammation resulting in redness,

Microsporidiosis, Fig. 3 Keratoconjunctivitis due to *Encephalitozoon hellem*. Arrows point to punctate lesions in cornea

foreign body sensation, photophobia, excessive tearing, blurred vision, and changes in visual acuity. Slit-lamp examination usually demonstrates punctate epithelial opacities, granular epithelial cells with irregular fluorescein uptake, conjunctival injection, superficial corneal infiltrates, and a noninflamed anterior chamber. Corneal scraping or biopsy material demonstrates microsporidian spores in the corneal and conjunctival epithelium. Inflammatory cells are rarely present. Infection with Encephalitozoonidae responds to topical fumagillin (Table 2) and when there is associated disseminated infection systemic albendazole is indicated. While these ocular infections are more common in patients with immune suppression they can be seen in immune competent hosts. As is true for many pathogens, contact lens use is a risk factor for infection. There are now numerous reports, involving over 300 patients, from India and Singapore, of *Vittaforma corneae* infection presenting as a keratoconjunctivitis in immune competent hosts. This infection presents as a seasonal keratoconjunctivitis often associated with soil exposure due to playing sports. These *V. cornea* infections have been treated with various topical agents including 1% voriconazole, 0.02% polyhexamethylene biguanide, albendazole, ciprofloxacin, and fumagillin with variable success. Several species of microsporidia (*V. corneae*, *Microsporidium africanus*, *Microsporidium ceylonensis*, and *N. oculorum*) have also been reported to cause deep stromal infections especially in cases with

associated ocular trauma. Treatment of these deeper infections has been problematic but has included various topical agents until keratoplasty or corneal transplantation.

Central Nervous System Infections: Cerebral microsporidiosis has been reported to occur in both immune competent and immune compromised humans (Weber et al. 1997). In other mammals, granulomatous encephalitis is a common complication of *E. cuniculi* infection. In the setting of AIDS, cerebral microsporidiosis has presented as a mass lesion with associated seizures and focal neurological complications similar to the presentation of *Toxoplasma gondii* encephalitis. Histopathology has demonstrated spores in cerebral parenchyma, perivascular spaces, and macrophages. *Trachipleistophora anthropoptera* has also been reported to cause cerebral microsporidiosis and an associated disseminated infection. Histopathology demonstrated birefringent spores in the gray matter with associated tissue necrosis.

Other Infections: Infections of the skin due to *A. algerae* (patients with leukemia), *Encephalitozoon* sp. (nodular skin lesions), and *Tubulinosema acridophagus* (red macules and papules in a patient with an allogeneic bone marrow transplant) have been reported.

There are several case reports of myositis with inflammation due to *Pleistophora ronniaefiei*, *Pleistophora* sp., *Trachipleistophora hominis*, *Tubulinosema* sp., *Endoreticulatus* sp., *E. cuniculi*, *Anncaliia vesicularum*, and *A. algerae*. Clinically these patients have had myalgias, weakness, elevated serum CPK and aldolase levels, and abnormal electromyograms consistent with inflammatory myopathy. The *A. algerae* infection occurred in a patient with rheumatoid arthritis treated with steroids and monoclonal antibody to tumor necrosis factor- α (TNF- α). A case of endocarditis (large right atrial vegetation attached to a ventricle pacing lead) due to *E. cuniculi* has been reported. Infection of the mandible, most likely due *Encephalitozoon* sp., has also been described in a patient with advanced AIDS. Several of the patients with microsporidian myositis responded clinically to albendazole. The *A. vesicularum*

Microsporidiosis, Table 2 Treatment of Microsporidiosis

Organism	Drug	Dosage and duration ^a
All microsporidian infections	Combinations antiretroviral therapy (cART) with immune restoration (an increase of CD4 ⁺ count to >100 cells/ μ m) is associated with resolution of symptoms of enteric microsporidiosis. All patients should be offered cART as part of the initial management of microsporidian infection	
	Severe dehydration, malnutrition, and wasting should be managed by fluid support and nutritional supplement Antimotility agents can be used for diarrhea control if required	
<i>Enterocytozoon bieneusi</i>	No effective commercially available treatment. Fumagillin (oral) has been effective in a clinical trial. <i>Alternatives:</i>	20 mg tid (e.g., 60 mg/day)
	Albendazole ^a resulted in clinical improvement in up to 50% of patients in some studies but was not effective in other studies. Nitazoxanide, 1000 mg bid with food for 60 days, has been used, but is less effective in patients with low CD4 counts	
<i>Encephalitozoonidae</i> infection (e.g., systemic, sinusitis, encephalitis, hepatitis)		
<i>E. cuniculi</i>	Albendazole	400 mg bid ^b
<i>E. hellem</i>	Albendazole	400 mg bid
<i>E. intestinalis</i>	Albendazole	400 mg bid
<i>Encephalitozoonidae</i> keratoconjunctivitis	Fumagillin solution ^c (70 μ g/mL) Patients may also need albendazole ^a if systemic infection is present	2 drops every 2 h for 4 days then 2 drops 4 times a day ^d
<i>Trachipleistophora hominis</i>	Albendazole	400 mg bid
<i>Anncaliia</i> (formerly <i>Brachiola vesicularum</i>)	Albendazole	400 mg bid
	\pm Itraconazole	400 mg qd
Tubulinosema (<i>T. acridophagus</i> and <i>Tubulinosema</i> sp.)	There was no response to Albendazole (400 mg/d) in the published cases. Oral fumagillin 20 mg TID would be a reasonable choice	
<i>Endoreticulatus</i> sp.	Albendazole	400 mg bid

Adapted from Costa and Weiss (2000, pp. 1–16)

^aAlbendazole, 400 mg bid

^bThe duration of treatment for microsporidiosis has not been established. Relapse of infection has occurred on stopping treatment. Patients should be maintained on treatment for at least 4 weeks, and most patients should continue treatment until their CD4 count is higher than 200 cells/ μ L for at least 6 months following the initiation of cART

^cFumidil B (fumagillin bicyclohexylammonium; Mid-Continent Agrimarketing, Overland Park, KS, USA) is used at 3 mg/mL in saline (final concentration of fumagillin, 70 μ g/mL)

^dEye drops should be continued indefinitely; relapse is common on stopping treatment

infection that caused myositis in patient with AIDS responded clinically to a regimen of albendazole plus itraconazole.

Respiratory tract and sinus involvement has been reported in microsporidiosis. Encephalitozoonidae have caused rhinitis, sinusitis, bronchitis, and nasal polyposis often with associated

disseminated infection. In patients with *E. hellem* keratoconjunctivitis sputum examination demonstrated spores even without associated respiratory symptoms. *E. cuniculi*, *E. hellem*, and *E. intestinalis* have all been reported to cause bronchiolitis with or without pneumonia. Sinus biopsies in AIDS patients with chronic sinusitis

have demonstrated microsporidian spores in epithelium and supporting structures.

The Encephalitozoonidae cause granulomatous interstitial nephritis in mammals, including humans. Infection can be asymptomatic with shedding of spores. Infection is associated with tubular necrosis, with the lumen of the tubules containing amorphous granular material. Glomerular involvement is rarely seen. Interstitial nephritis due to microsporidiosis has been seen in patients with AIDS as well as in patients with renal transplantation. Infection can also result in necrotizing ureteritis or cystitis that can be seen on cystoscopy. Genital tract infection with *Encephalitozoon* sp. and with *V. corneae* has been associated with prostatitis with abscess formation. It is not known if these organisms can be sexually transmitted.

Treatment and Prevention

Treatment for microsporidiosis is reviewed in Table 2 (Weiss and Becnel 2014; Costa and Weiss 2000). In patients with impaired immune function restoration of immune function (e.g., cART in AIDS patients) has proven effective in the treatment of microsporidiosis by ameliorating disease, clearing the parasite and reversing intestinal damage. Therefore, restoration of immune function should always be part of the treatment plan for microsporidiosis. Fumagillin and albendazole are two therapeutic agents that are useful for the treatment of microsporidiosis. Albendazole is a β -tubulin-binding agent that is effective against all Encephalitozoonidae at a dose of 400 mg twice daily for 2–4 weeks. Unfortunately, the β -tubulin genes of both *Enterocytozoon bienewisi* and *Vittaforma corneae* have amino acid substitutions that provide resistance to albendazole and clinically it has shown little success against *E. bienewisi* (at most a 50% improvement in symptoms, but persistence of the parasite in stool). Albendazole is effective for treating microsporidiosis due to *Trachipleistophora* or *Anncaliia* with reports of improvement in myositis due to either pathogen. Despite efficacy, relapse of disease and recurrence of parasites have been

seen in cases of microsporidiosis in immune compromised hosts suggesting that, in the setting of persistent immune dysfunction, maintenance therapy may be needed.

Fumagillin, which inhibits methionine aminopeptidase type 2, is also effective in the treatment of microsporidiosis; however, this drug is not commercially available for the treatment of humans. Both fumagillin (Fumidil B) and a fumagillin derivative (TNP-470) have demonstrated efficacy in vitro and in vivo (in animals and insects) against many different microsporidia including *E. cuniculi*, *E. hellem*, *E. intestinalis*, *V. corneae*, *E. bienewisi*, *N. apis*, *N. kingi*, *Octosporea muscaedomesticae*, *P. anguillarum*, *Sphaerospora renicola*, *Loma salmonae*, and *Nucleospora salmonis*. A trial of this drug in AIDS patients with diarrhea due to *E. bienewisi* demonstrated that fumagillin at a dose of 60 mg/day for 2 weeks eliminated infection (Molina et al. 2002). This efficacy has been confirmed in subsequent case reports of both AIDS patients and transplant patients with *E. bienewisi* infection. Nitazoxanide was shown to have activity in an AIDS patient with diarrhea and *E. bienewisi* infection, but this has not been studied in a series of patients. Itraconazole and other azoles have demonstrated efficacy for microsporidia other than *E. bienewisi* and are recommended for some disseminated infections. Metronidazole, atovaquone, quinacrine, trimethoprim-sulfamethoxazole, azithromycin, paromomycin, and furazolidone have had no significant activity and are not recommended as therapeutic agents.

There are limited data on effective preventive strategies for microsporidiosis, and no prophylactic agents have been identified for these organisms. It is reasonable to screen close contacts of patients with index cases of microsporidiosis for the presence of these organisms. Microsporidian spores can survive and remain infective in the environment for prolonged periods. Although the epidemiology of the microsporidia that infect humans has not been fully elucidated, it is likely they are food- or water-borne pathogens, and the usual sanitary measures that prevent contamination of food

and water with animal urine and feces should decrease the chance for infection. Severely immune compromised patients may wish to consider using bottled or filtered water in some settings. The most effective prophylaxis for microsporidiosis is the restoration of immune function in immune compromised hosts and cART with immune restoration can produce remission during active microsporidiosis.

Conclusion

While only recently widely recognized as human pathogens, it is now clear that microsporidiosis is more common than previously appreciated and often zoonotic. New human pathogenic microsporidia are being recognized due to increased awareness of these organisms. In patients with HIV infection on antiretroviral therapy the incidence of this opportunistic infection has declined; however, it has not completely disappeared. These organisms can cause a wide range of clinical syndromes beyond the classic presentation of chronic diarrhea. Treatment can be problematic as there are no commercially available active drugs for the most commonly seen species *Enterocytozoon bieneusi*; however, immune reconstitution can result in cure of infection in the setting of AIDS and is an important therapeutic modality.

Molecular Biology of HIV-2

Andrew M. L. Lever
University of Cambridge, Cambridge, UK

Definition

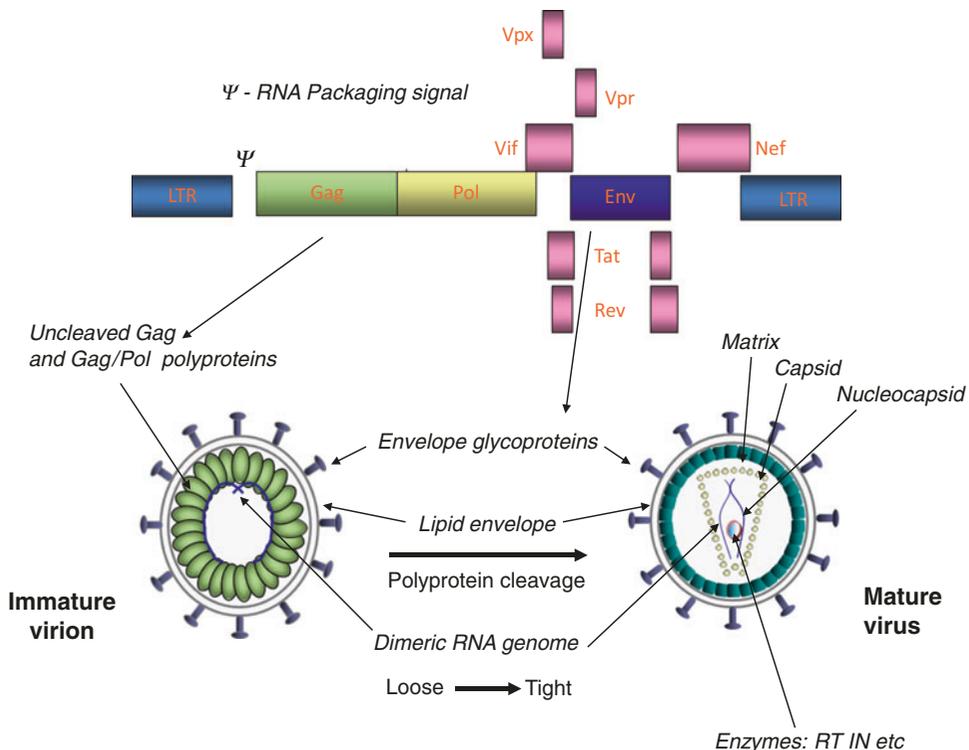

This entry describes the molecular biological aspects of HIV-2 and how they contrast with that of HIV-1.

Introduction

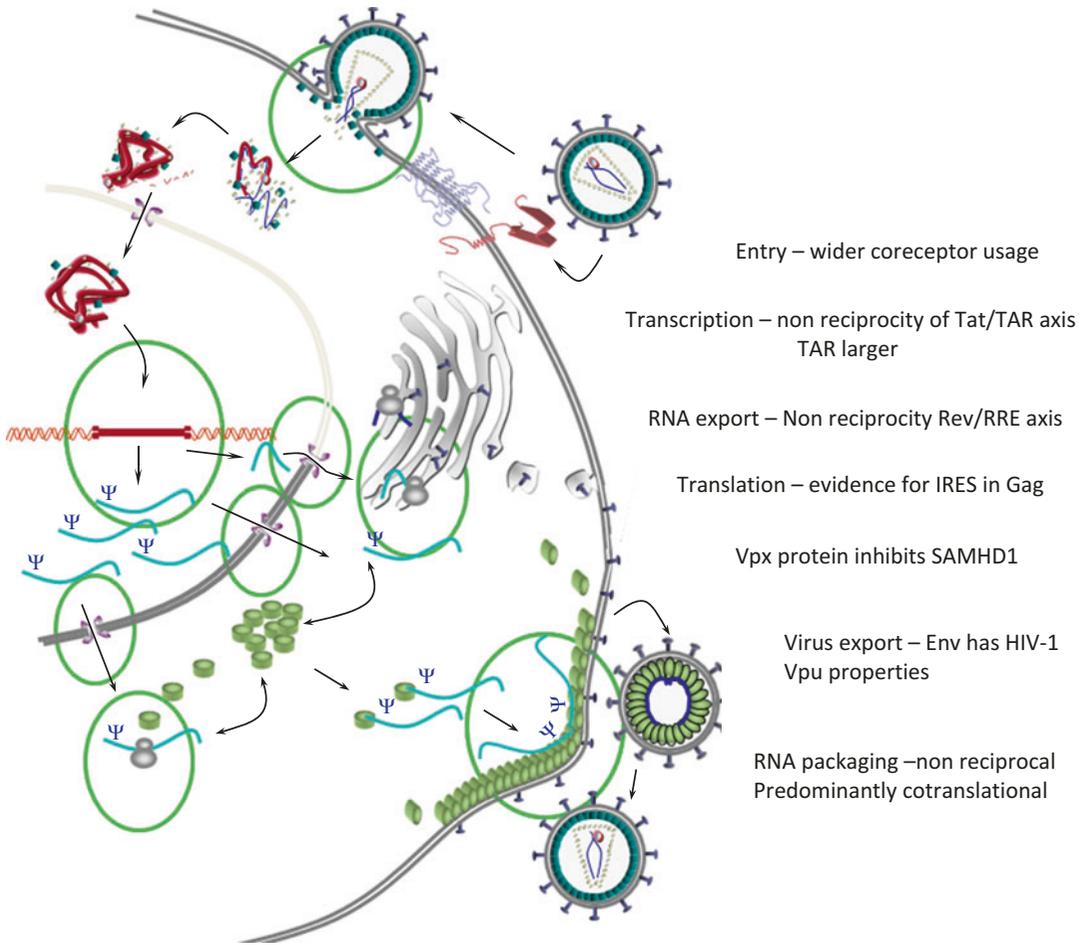

Since the first identification and cloning of the second human immunodeficiency virus HIV-2 (History of the AIDS epidemic, ► [Epidemiology of HIV-2 infection in Europe](#), ► [Recombinant forms of HIV-2](#), ► [The epidemiology of HIV-2 infection in West Africa](#), ► [The phylogeography of HIV-2 infection in West Africa](#)), it has been clear from an abundance of clinical studies that this is a much less pathogenic virus than HIV-1 (► [Dual HIV-1 and HIV-2 infection](#), ► [HIV-2 diagnosis and viral load measurements](#)) and that it has a number of genetic molecular and structural differences from HIV-1. In seeking to understand the more often (though not always) benign outcome of infection with HIV-2, many studies have focused on these differences in seeking an explanation for this and also for the potential insights which it might give to understanding the pathogenicity of HIV-1 and ways to combat those features which make the latter virus so much more

virulent. Both viruses are zoonotic and have had to adapt to the same new host, humans, within the last 100 years; the differences are thus perhaps greater than would be expected. The molecular biology of HIV-1 is covered elsewhere in the Encyclopedia; hence this entry does not aim to be a comprehensive description of HIV molecular biology. Rather it has been limited to areas in which important similarities or, more usually, differences between the two viruses have been identified.

The major open reading frames whose function has been investigated are shown in Fig. 1. While overall they are recognizably similar to those of HIV-1 (► [Virus Assembly](#)), there are obvious differences from the size of some ORFs and untranslated regions through to the contrasting absence or presence of specific accessory genes; HIV-1 uniquely has *vpu* and HIV-2 has *vpx*. Probably more important however are functional differences between homologous genes. These are summarized in Fig. 2 and discussed below.

Molecular Biology of HIV-2, Fig. 1 Major genes of HIV-2 and immature and mature virion structure

M

Molecular Biology of HIV-2, Fig. 2 Major differences in lifecycle between HIV-1 and HIV-2

Perhaps the most striking contrasts are seen in the processes involved in the viral life cycle, and these are described in detail at the end of the article.

All exogenous retroviruses characteristically contain three open reading frames, from 5' to 3' *gag*, *pol*, and *env* which encode the structural genes of the core, the viral enzymes, and the envelope glycoprotein, respectively. They assemble as shown in an immature particle and then the protease gene cleaves the core proteins to form the mature infectious particle (Fig. 1) (Virus structure). Inside the virus HIV-2, like all retroviruses, carries two copies of its genetic material in the form of RNA linked as a dimer at their 5' ends.

HIV-2 Gag

HIV-2 *gag* is similar in organization and genetic structure to that of HIV-1, but the Gag polyprotein gene product is larger at 57 kDa compared to 55 kDa for HIV-1. Gag comprises four major domains with functional elements: from the N-terminus – matrix (MA-p17), capsid (CA-p26), nucleocapsid (NC-p7), and the C-terminal p6 (Briggs and Krausslich 2011). Two spacer proteins exist flanking NC: at the N-terminus p2 and at the C-terminus p1. The sequential proteolytic processing of Gag begins with an initial cleavage between p2 and NC followed by p1/p6 separation and MA/CA

cleavage. Finally, NC and p1 separate and p2 is cleaved from CA. This cleavage sequence is tightly controlled, and there appears to be a very strong interdependence between the correct rate and sequence of cleavage and the presence of a dimeric RNA genome. Mutations in the HIV-2 genomic RNA dimerization signal lead to aberrant rates of the first two cleavages with an accumulation of the p41 MA/CA fusion protein. In vitro revertants, particularly a mutation, 70TI, in MA, can correct this processing defect and at the same time restore RNA dimerization (L'Hernault et al. 2012), suggesting that viral assembly is a complex interplay between the RNA and the protein. This matrix reversion restores replication competence to the mutant virus despite the persistence of the dimerization mutation.

HIV-2 Gag has been expressed successfully in vitro and is capable of assembling into virus-like particles. VLP assembly occurs when Gag is expressed as a baculovirus recombinant. HIV-1 can multimerize in *Saccharomyces* spheroplasts, a yeast-based assembly system, but HIV-2 fails to. This seems to be dependent on the membrane-binding surface of MA in the helix 2 region. In other cell-free systems, multimerization of Gag appears to be identical to that of HIV-1 and is likewise dependent on the cellular HP68 protein. HIV-1 and HIV-2 Gags can, in certain combinations, form virus-like particles by co-assembly and generate functional virus particles. HIV-2 viral assembly (► [Cofactors of HIV Assembly](#)) shows some dependence on incorporation of the correct RNA (see below). HIV-2 assembly and virus export are dependent on the ESCRT (endosomal sorting complexes required for transport) pathway (► [Budding](#), ► [HIV-1 Assembly Cofactors](#)), and Gag binds TSG101 (tumor susceptibility gene 101) (Weiss and Gottlinger 2011). HIV-2 Gag which is expressed from the unspliced viral mRNA may have an autoregulatory role in controlling viral RNA splicing through an interaction with PRP4, a serine-threonine kinase which inhibits phosphorylation of splicing factor SF2 (Bennett et al. 2004).

The Vpx and Vpr proteins of HIV-2 are incorporated into viral particles through interaction with the P6 region of Gag.

HIV-2 Protease

The aspartyl protease (PRO) of HIV-2 at the N-terminal of the *pol* gene product, like that of HIV-1, is a homodimer which when cleaved from the GagPol polyprotein is responsible for the processing to the completion of the Gag and the GagPol precursors during viral maturation and budding. The proteins are extremely similar in the two viruses. Given that their target sites for cleavage are slightly different, they, unsurprisingly, show differences in their rate of cleavage of different target peptide sequences (► [Anti-Retroviral Therapy and Drug Resistance in HIV-2 Infection](#)) (Tomasselli et al. 1990). However, functionally, they are similar enough such that in a construct expressing the HIV-1 homodimer as a single chain, the substitution of one of the subunits for an HIV-2 sequence leads to a functional chimeric protease. The variations in proteolytic specificity of the two enzymes have clinical relevance in that in general the licensed HIV-1 protease inhibitors have a lower potency against HIV-2 and in a number of cases a structural basis for this has been shown (Camacho 2012).

HIV-2 Reverse Transcriptase

This enzyme (Reverse Transcription) is responsible for converting the RNA genome in the virus into a DNA which is integrated into the cell the virus infects. HIV-1 and HIV-2 reverse transcriptase (RT) molecules are heterodimers of a differently processed single protein which, after proteolytic cleavage, forms a p66/p51 heterodimeric molecule (Herschhorn and Hizi 2010). Both enzymes use the natural tRNA (Lys3) as a primer and in vitro the HIV-2 RT can prime successfully on the HIV-1 RNA template. Unlike protease there are significant structural differences between the two viral enzymes. Heterodimer formation between subunits of the two enzymes does not occur efficiently; in particular p66 (HIV-2) and p51 (HIV-1) assembly is very inefficient although the reciprocal combination assembles more easily. Both lentiviral RTs show a similar low fidelity of polymerization, and in assays of DNA-dependent DNA polymerase

activity, HIV-1 and HIV-2 show a six- to ninefold greater successful extension of a mis-paired nucleotide than the RT from other retroviruses such as murine leukemia virus. This error-prone process is clearly a major contribution to viral variation in both HIVs. Structural and functional differences have been revealed by detailed crystallographic analysis. It is known that HIV-2 RT is singularly resistant to non-nucleoside reverse transcriptase inhibitors (NNRTIs) and the binding site of NNRTIs, the so-called NNRTI pocket, is structurally quite different in the two enzymes (► [Anti-Retroviral Therapy and Drug Resistance in HIV-2 Infection](#)). Perhaps more interesting is the suggestion that structural differences in the two enzymes influence their *mode* of developing resistance to individual drugs (Boyer et al. 2006). For example, HIV-2 tends to develop resistance to AZT by accumulating mutations that reduce incorporation of AZTTP, whereas HIV-1 tends to develop resistance by mutations which enhance excision of AZTTP. HIV-1 RT is intrinsically more efficient at ATP-mediated excision of AZTMP than HIV-2 RT, and the mutagenic pathway to resistance enhances this capability.

HIV-2 Integrase

This enzyme cuts and pastes the newly reverse-transcribed viral DNA into the cellular chromosome (► [Integration](#), ► [LEDGF/p75, Cofactors of Integration](#), ► [Transportin-SR2 \(TNPO3\), Nuclear import](#)). HIV-2 integrase (IN) is quite significantly different from that of HIV-1. The two genes show only 60% homology (Roquebert et al. 2008). Perhaps, surprisingly, susceptibility to therapeutic inhibitors is very similar in the two viruses. Minor differences appear to be seen in mutations which lead to resistance to these drugs, although the clinical impact of this is not yet apparent.

HIV-2 Env

This is structurally similar to all lentiviral envelopes comprising a heterodimer of a

transmembrane protein gp36 (TM) and a surface glycoprotein gp125 (SU) arranged as trimers (► [The HIV-2 envelope: structure, diversity and evolution](#)). Similarly to HIV-1, a variable domain of SU, the V3 loop, is critical for binding to the primary cell receptor CD4 (► [Attachment/Binding](#)). The hydrophobic terminus of the TM protein is involved in the process of virus/cell fusion during entry. The kinetics of HIV-2 interaction with the CD4 and CXCR4 receptor and coreceptor are different from those of HIV-1 envelope with the rate of engagement with CXCR4 following CD4 binding, leading to virus/cell fusion occurring around twice as fast (Gallo et al. 2006).

There are two important differences in the HIV-2 envelope compared to HIV-1 (Choe et al. 1998). One is in its coreceptor usage. Whereas HIV-1 largely uses CCR5 (Selection of CCR5 using viruses; transmission) or CXCR4 as its coreceptor (► [CXCR4, Co-receptors](#)), HIV-2 is far more promiscuous and can use CCR1, CCR2, CCR3, CCR4, CCR5, CXCR2, and CXCR4. Other cell surface chemokine receptors including BONZO and BOB have also been shown to support HIV-2 entry. The efficiency with which the virus can use these different receptors is very variable, and although the option is there for the virus to use a range of surface molecules to trigger virus/cell fusion, in vivo it is not clear how much of its diversity of capability is actually utilized.

The second surprising feature of the HIV-2 envelope is that, in addition to its receptor-binding capabilities, it has the functionality of the protein Vpu in HIV-1 (Le Tortorec et al. 2011), leading to enhanced virus export from the infected cell. The efficiency of enhancement of HIV-2 particle release by HIV-2 Env is comparable to that of HIV-1 Vpu. The HIV-2 envelope can clearly counteract the antiviral effects of the cellular protein BST2/tetherin as effectively as HIV-1 Vpu, and it does this by sequestration of the cellular protein in a perinuclear compartment. This arrangement of a Vpu-like function of envelope is shared with the envelope glycoprotein of feline immunodeficiency virus.

HIV-2 Tat

Tat (► [Tat expression and function](#)) is a small protein produced from a bicistronic spliced RNA and is a powerful transactivator of the HIV promoter in the viral long terminal repeat (LTR) sequence (Marcello et al. 2001). It functions by binding the nascent viral RNA transcript at the 5' end, annealing to an RNA helix loop structure, the Tat response element (TAR). Tat protein of HIV-2 is almost 50% longer than that of Tat-1 at 130 amino acids versus 86. It has similar cysteine- and arginine-rich domains. The nonreciprocity of transactivation is described below.

HIV-2 Rev

Rev (► [Rev expression and function](#)) is another small regulatory protein, again produced as the spliced product of two short ORFs (Kjems and Askjaer 2000). It is essential for nuclear export of incompletely spliced HIV RNAs from the nucleus; the mode of activity is through its binding to a *cis*-acting RNA sequence in the envelope gene region, the Rev response element (RRE), a complex RNA structure. This nucleoprotein complex uses the cellular Crm1/RanGTPase pathway (► [CRM1](#)) to export its RNA cargo to the cytoplasm. As is the case for Tat, there is a lack of reciprocity in activity between HIV-1 and HIV-2. There has been surprisingly little comparative biology done of the Rev/RRE regions of HIV-1 and HIV-2. One explanation for the lack of reciprocity may be the requirement for Rev to multimerize on the RRE, forming what has been termed as a “molecular rheostat”; the HIV-1 RRE does not facilitate multimerization of HIV-2 Rev (Garrett and Cullen 1992). Despite considerable expansion of the understanding of the roles of Rev in HIV-1 beyond that of nuclear export of RNA to influences on translation and genome encapsidation, similar studies have not been performed in HIV-2.

HIV-2 Nef

Since its original description as “negative factor,” the most 3' open reading frame of HIV, Nef has been shown to have multiple activities. In HIV-2, as in HIV-1, Nef can down-modulate cell surface expression of CD4 in infected cells involving direct interaction of Nef with the cytoplasmic tail of CD4. The site of binding of Nef-2 is distinct from but overlaps with that of HIV-1 and the process involves the mu chain of adaptor complexes which are components of clathrin-coated pits. HIV-2 Nef has also been shown to down-modulate MHC-II, but unlike SIV both HIV-1 and HIV-2 Nef proteins fail to down-modulate CXCR4. Perhaps the most fascinating is the demonstration that the T-cell receptor (TCR) is down-modulated by HIV-2 Nef and by related simian immunodeficiency virus (SIV) proteins but that this function has been lost in HIV-1. This has been suggested to explain the high level of T-cell activation (► [Chronic immune activation](#)) found in HIV-1-infected individuals which correlates with its higher pathogenicity (Kirchhoff 2010). The correlation between TCR down-modulation, decreased T-cell activation, and pathogenicity has been questioned since it was shown that, despite T-cell receptor down-modulation and decreased T-cell activation, there are still HIV-2-infected patients with relatively rapidly progressive disease, implying that other factors can influence the disease phenotype (► [HIV-2 infection: the role of immune activation in pathogenesis](#)).

HIV-2 Vpr

All primate lentiviruses encode a 96 amino acid 14 kDa Vpr protein which is packaged into the viral particle at about 40–50 copies per virion. It appears to be physically less stable than Vpx and the D-X-A-X-X-L-L sequence motif in the HIV-2 Gag p6 protein which is used by Vpr for packaging is different from that in HIV-1. In general, the established properties of Vpr are the same in HIV-1 and HIV-2. It is essential for replication in

macrophages. It can cause G2 cell cycle arrest. Vpr enhances nuclear import of the pre-integration complex and is a transactivator of the long terminal repeat. In HIV-1 Vpr has been implicated in a significant amount of pathogenicity with suggested contributions to neurotoxicity, nephrotoxicity, and immune dysfunction. Given the differential in pathogenicity of the two viruses, it is of interest that in one report it is noted that HIV-2 Vpr is less able to trigger apoptosis in human cells compared to the HIV-1 protein (Kirchhoff 2010).

HIV-2 Vpx

Possession of a Vpx protein in HIV-2 (and SIV) distinguishes it from HIV-1 (Fujita et al. 2010). It was noted early that Vpx facilitated and, in some cases, permitted viral infection of primary peripheral blood mononuclear cells but was dispensable in *in vitro* cultured cell lines. The virus packages 2,000–3,000 copies of Vpx into the particle bound to the p6 region of Gag. Early studies suggested that Vpx was important for nuclear import of the pre-integration complex and completion of reverse transcription and the protein appears to have a novel nuclear localization signal. Early cellular binding partners of Vpx were identified as being proteasome associated, and it was also shown that Vpx could work *in trans*, allowing HIV-1 to infect primary human mononuclear cells, including dendritic cells and macrophages. The cellular target of Vpx turns out to be SAMHD1 (sterile alpha motif and histidine/aspartic acid domain controlling protein-1). This is a dGTP-stimulated triphosphohydrolase which cleaves dNTPs into the deoxynucleoside and inorganic phosphate. Vpx targets this protein which would otherwise deplete the availability of dNTPs for viral cDNA synthesis. The mechanism appears to be by binding SAMHD1 to a ternary complex of DDB1/Cullin 4 and DCAF-1 which binds to the N-terminus of Vpx. This complex then targets SAMHD1 for degradation by the cellular proteasome.

HIV-2 Transcription

There are similarities between transcriptional control of HIV-1 and HIV-2 in that both viruses are switched on by the activation of the T cell in which they reside and both have the powerful Tat/TAR transactivation mechanism (Garcia-Martinez et al. 1995; Marcello et al. 2001) (► [Tat expression and function](#), ► [Acetylation](#), ► [Histone deacetylase \(HDAC\): YY1](#)). The mechanism of transactivation is similar in both with Tat recruiting a Tat-associated kinase (TAK) and cyclin T1, leading to the phosphorylation of the C-terminus of RNA polymerase II which dramatically increases its processivity. Transactivation of HIV transcription has long been known to involve Tat binding to TAR, leading to full-length transcription of the RNA genome. In the absence of Tat, multiple short-truncated transcripts are formed. The HIV-2 promoter appears to be more prone to produce large numbers of short transcripts than the HIV-1 promoter, possibly relating to the structure of its duplicated TAR element. Interestingly, the overall number of these short transcripts does not change on Tat activation in HIV-2; instead there is an overall increase in the total number of transcripts, many of which now extend for more than 500 nucleotides from transcription initiation site.

Several groups have identified the fact that there was non-reciprocity of transactivation in that HIV-1 Tat was able to activate both HIV-1 and HIV-2, but HIV-2 Tat could only transactivate its own promoter. Part of the functional difference appears to reside in the arginine-rich basic domain which when the HIV-2 sequence is substituted into the HIV-1 Tat equivalent leads to reduced transactivation of the HIV-1 LTR. Structural predictions of the Tat-binding region of both viruses demonstrated that the newly transcribed RNA formed tight stem-loop structures, but that in HIV-1 this was a single stem loop, whereas in HIV-2 a second stem loop directly 3' and linked to the first was seen. *In vitro* affinity assays show that Tat-1 can bind both TARs with similar affinity but Tat-2 binds TAR-2 with a much greater

affinity than it does TAR-1. Exon-2 (which is inessential for transactivation by Tat-1) is very important for Tat-2 activity and this, in part, is due to its ability to increase the affinity of the protein for the TAR-2 RNA (Garcia-Martinez et al. 1995). Deletion studies suggested that the first stem loop of TAR-2 was sufficient for transactivation but that the addition of the second stem loop enhanced the effect. The HIV-2 TAR element appears to have two important dinucleotide bulges responsible for HIV-2 Tat binding, and surprisingly, mutation of these inhibits HIV-2 Tat transactivation but not that of HIV-1 Tat. There is also evidence that a cellular factor interacts with the 3' arm of the proximal stem loop structure of TAR-2.

Upstream of the TAR region in the transcription factor binding sites of the promoter, HIV-2 has only a single NF- κ B-binding site as opposed to two found in HIV-1, and this correlates with a greater response to T-cell activation signals of HIV-1. Additional *cis*-acting regions are found in the HIV-2 enhancer, including two purine-rich sites, PuB1 and PuB2, and an additional region proximal to PuB2 (pets) also contributes to promoter activation. Mutation of any of these four sites reduces the response of HIV-2 to T-cell stimulation. An *ets*-related transcription factor E1f-1 has been shown to bind specifically to the PuB1 and PuB2. A 43 kDa nuclear factor has been shown to bind to the pets sites. This has been identified as the oncoprotein DEK. Activation through the pets site appears to be dependent on protein phosphatase-2A (PP2A).

HIV-2 Translation

Transcription of the proviral DNA produces an approximately 9 kb full-length transcript which is spliced into singly and multiply spliced variants. All of these, like conventional cellular messenger RNAs, have a 5' methyl cap and a poly(A) tail (Bolinger and Boris-Lawrie 2009). There is some evidence in HIV-1 of skewing of the preference for a particular form of capping, but this has not been investigated in HIV-2. There has been a degree of controversy in recent years over the primary method of translational control of

HIV transcripts. The high density of structured RNA regions in the 5' untranslated sequence might be expected to impair scanning from the 5' cap, and indeed, structures such as the TAR stem loop have been shown to be quite strong inhibitors of ribosomal scanning *in vitro*. Based on this, some groups have sought evidence of an internal ribosome entry site (IRES) in HIV-1 and HIV-2, and indeed, evidence of IRES activity has been detected in conventional dicistronic reporter construct assays. In HIV-1, the balance of evidence is in flux as to whether scanning or IRES-mediated translational initiation dominates; there is clear evidence from studies on UTR truncations that HIV-1 Gag can be translated quite effectively by ribosomal scanning, suggesting that the 5' structure is not in itself prohibitive of this mode of protein production. Nevertheless, the detection of IRES activity suggests that the virus may utilize both forms of translation, perhaps to optimize viral protein production during different parts of the cell cycle. In HIV-2 there has not been the same investigation of the practicalities of scanning and the majority of studies have focused on the existence of an IRES. This is an unusual form of IRES in that the structure appears to extend at least 50 nucleotides downstream of the Gag initiation codon into the coding region. There appear to be different isoforms of Gag protein produced with different start codons from within the Gag open reading frame, and there is evidence that the HIV-2 I.E. can recruit three initiation complexes onto the HIV-2 genomic RNA to initiate the production of these three Gag proteins. What the role of these three variants of Gag is has yet to be established. The apparent dominance of IRES-mediated translation in HIV-2 versus HIV-1 may relate to the more complex and extended TAR stem loop in HIV-2 which may be more inhibitory to scanning than the equivalent structure in HIV-1. Analogous to polio virus, the HIV-1 protease has been shown to cleave the poly(A)-binding protein (PABP). The protease being only released from its polyprotein precursor during viral assembly and budding would suggest that this was a rather late time point for this activity to influence translation. This is an area of active ongoing research which hopefully will become clearer with time.

HIV-2 Genomic RNA Packaging

The unspliced viral RNA is not only used as a template to translate the viral Gag and GagPol proteins; it is also the RNA which is encapsidated as a dimer into the viral particle (► [Virus Assembly](#)). The virus recognizes this RNA through the latter having a region at the 5' end which folds into a complex “knot”-like structure whose shape is sufficiently unique to distinguish it from the other RNAs in the cell in which this is bound by the virus Gag polyprotein (Lever 2007).

HIV-2 offers some similarities but interesting contrasts with HIV-1. An early clue was the observation that the major packaging signal region was upstream of the major splice donor, unlike in HIV-1 where it is downstream. The specificity of the packaging signal being confined to the unspliced RNA is, therefore, not present in HIV-2 and implies alternative mechanisms for genome selection. Interestingly, the distance from the RNA cap site to the packaging signal structure is similar in both viruses (and in all SIVs) and would be compatible with the recognition involving another molecular rheostat mechanism. Differences in packaging mechanism between the two viruses were further reinforced by a nonreciprocal relationship being identified, whereby HIV-1 could package HIV-2 RNA but not the reverse. Interestingly, the defect in reciprocity of HIV-2 extended to that of SIVmac Gag which was also able to package HIV-2 RNA, again nonreciprocally.

Like HIV-1 and distinct from simple viruses, such as murine leukemia viruses, capture of the genomic RNA was shown to be from the translating pool of full-length viral rather than from a separate pool of RNA destined specifically for packaging rather than translation to produce Gag. HIV-1 can package RNA from outside of this pool but HIV-2 is less promiscuous.

The RNA structures involved in genome dimerization and encapsidation bears some similarities to HIV-1 but again are distinct. In HIV-2 a palindromic sequence at the base of a stem loop in the RNA constitutes the major authentic *in vivo* dimerization and encapsidation signal. On the tip of the same stem loop, a second palindromic

sequence occurs which can influence RNA dimerization *in vitro* but is clearly dispensable for efficient packaging and dimerization in wild-type virus. In HIV-2 a clear association between packaging of a dimeric genome and particle assembly has been shown with abnormal morphology and an increase in viruses containing double capsids seen in particles bearing a mutation in the dimer linkage site. Recently a tight interdependence (L'Hernault et al. 2012) of correct Gag/GagPol protein processing and the presence of a functional RNA dimer site have been identified suggesting perhaps that dimeric RNA can enhance initial stages of Gag assembly and that after polyprotein cleavage, the nucleocapsid protein then enhances the transformation of the loose RNA dimer to the tight RNA dimer characteristic of that found in the mature particle.

Conclusion

This short entry has highlighted differences between the molecular biology of HIV-1 and HIV-2 and demonstrated how closely related viruses can evolve quite different mechanisms to achieve similar ends, that of successful infection of their host. The contrasts explain the value of comparative studies in helping to understand the biology of both pathogens.

Mother-to-Child Transmission of HIV-1: Role of Receptor Usage and Target Cells

Mariangela Cavarelli and Gabriella Scarlatti
Viral Evolution and Transmission Unit, Division of Immunology, Transplantation and Infectious Diseases, San Raffaele Scientific Institute, Milan, Italy

Definition

Mother-to-child transmission (MTCT) of HIV-1 occurs during pregnancy, delivery, and breastfeeding, although to different proportion. The latest reports still count approximately 330,000 new infections in babies although a significant decrease was observed since introduction of efficient preventive measures. Viral genotype and phenotype gave little evidence of a specific pattern associated with MTCT of HIV-1 and thus

are not useful absolute predictive markers of transmission. HIV-1 infection of children is initiated in most cases by an R5 virus, but viruses with other phenotypes can be isolated when the mother carries those. A sophisticated balance between inhibitory and facilitating factors as well as of competent target cells in the placenta, the breast milk, and at gastrointestinal level may redirect the transmission event.

Mother-to-Child Transmission of HIV-1: Epidemiological Notes

Mother-to-child transmission (MTCT) of HIV-1 can occur in utero, during delivery, and during breastfeeding. Indeed, transmission to the fetus or infant occurs through the placenta or by swallowing of large amounts of infected biological fluids as the amniotic fluid during gestation or blood and vaginal secretions during delivery and predominantly milk during breastfeeding. In the absence of any prevention strategy, the cumulative viral transmission accounts for 25–45% with 5–10% infections occurring in utero, 10–15% intrapartum, and 10–20% via breastfeeding. This latter one can increase with prolonged feeding practices.

In the last decade the introduction of antiretroviral therapy (ART), elective cesarean section, and exclusive bottle feeding as a prophylactic mean to prevent (► [Preventing HIV-1 MTCT](#)) MTCT of HIV-1 has contributed to an important reduction of newly infected babies in those areas of the world that can afford it. Although resource-limited countries have not yet reached full access to the whole array of these prophylactic measures, a significant trend in the reduction of new infections in babies has been achieved. According to the UNAIDS latest report, an estimated 330,000 children (► [Children, Epidemiology of HIV/AIDS](#)) became infected with HIV-1 in 2011 as compared to the more than 500,000 newly infected children occurring 10 years before. WHO (“History of the AIDS Epidemic”) and UNICEF have recently launched a global plan towards the elimination of new HIV infections among children by 2015 and keeping their

mothers alive, called “Eliminating Mother-to-Child Transmission.” The primary goal is to reduce by 90% the number of new infections in children and by 50% the number of HIV-related death in women during pregnancy, childbirth, and puerperium.

Maternal Viral Chemokine-Receptor Usage: Which Virus is Transmitted?

Maternal viral genotype and phenotype gave little evidence of a specific pattern associated with MTCT of HIV-1 and thus are not useful absolute predictive markers. Most maternal isolates are able to use CCR5 as co-receptor alone or in association with CXCR4 (“► [HIV and Sexual Violence](#)”) Co-receptors or other chemokine receptors, independently from transmission. A minority of pregnant women carries CXCR4-using viruses and even to a lower degree viruses able to use exclusively CXCR4, i.e., X4 viruses. Similarly, mothers harboring viruses with more flexible use of the CCR5 co-receptor (termed R5 broad viruses), such as those able to use chimeric CCR5-CXCR4 receptors, are not at higher risk of transmission than those carrying viruses able to infect via CCR5 exclusively, called R5 narrow (Cavarelli et al. 2008).

Unfortunately, due to the limited number of studies performed, it is difficult to define if chemokine receptors other than CCR5 and CXCR4, which are often used by HIV-1 of subtypes (HIV-1 subtype – overview and predominance) other than B, may be relevant for MTCT. Reports describing MTCT rates according to different viral subtypes were not always concordant. Pregnant women infected with subtype C virus appeared to transmit in utero more frequently than those with subtype A, D, or recombinant forms with an A or D envelope. In specific this was ascribed to a higher vaginal mucosal shedding of virus in those mothers with a subtype C virus infection.

If selection of specific viral phenotypes occurs during infection, there should be an association between viral phenotype and transmission. It is well established that HIV-1 infection of children is

initiated in most cases by an R5 virus. However, CXCR4-using viruses can be isolated from children, whose mothers carry a virus population with mixed R5 and X4 phenotype. Furthermore, a more in-depth analysis of the R5 virus variants showed that R5 broad viruses are not hampered during transmission and are indeed often isolated from newborns (Cavarelli et al. 2008). Of note is that isolation of R5 broad viruses with an enlarged chimeric receptor usage or of CXCR4-using viruses from neonates is predictive of an accelerated disease progression towards AIDS and death in the absence of a highly active antiretroviral therapy (HAART) (Cavarelli et al. 2010). This underlines that prevention of MTCT of HIV-1 should target both R5 and X4 viruses, as either viral phenotype can be detrimental to the baby and induce a fast disease progression.

Receptor Expression on HIV-1 Target Cells in MTCT

The availability of receptive cells able to replicate the virus may bias transmission towards a given virus phenotype. Indeed different lymphocyte subsets may become preferential target for R5 or X4 virus variants, accordingly. In vivo CCR5 is expressed mainly by the CD45RO⁺ subset of effector memory T cells, whereas CXCR4 is dense on the surface of naive ("Naive T cells") CD45RA⁺ T cells. Activated/memory T cells are those trafficking to peripheral lymphoid organs within the mucosal surfaces, where they form conjugates with dendritic cells (DCs) or macrophages, and thus represent the very early cellular targets for infection deputed to viral spreading. In vivo and in vitro studies confirmed that R5 virus isolates preferentially infect CCR5⁺-activated memory T cells, whereas X4 virus isolates infect CXCR4⁺ naive cells. Interestingly, the cord blood-derived CD4⁺ T cells are largely naive and do not express CCR5. In accordance with this observation, an in vitro study showed that CD4⁺ T cells derived from cord blood need to be activated to replicate HIV-1. These data support that in neonates, the naive CD4⁺ T cells are the predominant cell type, and thus, infection with

X4 viruses should be theoretically favored (Tuttle et al. 2004). However, a recent study showed an increased replicative capacity of R5 as compared to X4 viruses in a T-cell line derived from in vitro PHA-activated infant T cells as compared to that derived from adult cells (Mariani et al. 2012). This observation would suggest that infant cells are more susceptible to R5 strains than adult cells. Thus, a bias towards a specific viral phenotype goes beyond receptor expression on T cells. In addition, besides CD4⁺ T lymphocytes, HIV-1 can infect other cells of the immune systems, like macrophages ("► [Macrophages in HIV Immunopathogenesis](#)") and DCs. Cord blood-derived monocyte/macrophages have an increased susceptibility to HIV-1 infection in vitro with R5 but not X4 virus compared to adult cells.

Taken in consideration that the fetus and the infant independently from the transmission route ingest the virus, cells resident in the gut mucosa may play a crucial role in transmission. Indeed, CCR5 + CD4⁺ T cells with a memory phenotype are abundant at the level of the gut epithelium and in the gut lymphoid aggregates of the fetus and infant. Interestingly, in contrast to infant's CD4⁺ T cells derived from blood, these cells in the gut are highly susceptible to HIV-1 even without prior activation with cytokines, thus, supporting the possibility of a preferential transmission of R5 viruses through this route (Bunders et al. 2012).

DCs and Langerhans cells (LC), which are abundant at mucosal sites, have also been implicated in transmission, but little is known in infants. Indeed, Langerin expressed on LC and the C-type lectin DC-SIGN expressed on immature DCs have a high affinity for the HIV-1 gp120 surface protein and therefore can capture virus and transfer it to CD4⁺ T cells. In addition, immature DCs present in the periphery express high levels of CCR5. Analogously LCs have a preferential susceptibility to infection with CCR5-using viruses due to the lack of CXCR4 expression on their cell surface. Taken together these data suggest that there is a balance between different target cells, which at the end should favor transmission of R5 viruses.

In Utero Transmission: The Role of the Placenta

While in the simian immunodeficiency virus (SIV) (“► [SIVmac Infection of Macaques, Immunopathogenesis of](#)”) model it has been proposed that in utero infections occur when the infected amniotic fluid is ingested and the virus crosses the mucosal surfaces in the gastrointestinal tract of the fetus, for HIV-1 the data are not conclusive. Indeed, some early studies could detect HIV-1 proteins in the amniotic fluid of infected pregnant women, whereas other recent ones did not detect any virus in the amniotic fluid despite a concomitant high plasma viral load exceeding 10^5 copies/ml. Thus, it is likely that in utero transmission occurs primarily through the placenta although ingestion by the fetus and intake through the gastrointestinal route cannot be excluded.

In utero HIV-1 transmission seems to be relatively rare during the first trimester of pregnancy and usually occurs during the last trimester. This hints to the presence of effective natural control mechanisms particularly during the first months of gestation and suggests that the placenta itself possibly acts as a barrier for the virus. Contrasting data have been reported on the susceptibility of the trophoblasts to cell-free HIV-1 infection. These cells usually express CXCR4 and CCR5, but rarely the CD4 molecule and the mechanism of entry into trophoblasts have still to be elucidated. Furthermore, it is still under debate whether the varying expression levels of CCR5 on placental cells may augment the risk of MTCT of HIV-1 (Joubert et al. 2010). Instead, it was clearly shown that the interaction and fusion between trophoblastic cells and HIV-1-infected cells allow the virus to cross the trophoblastic barrier in an *in vitro* model.

Once trophoblastic cells carry HIV, molecules as DC-SIGN and ICAM-1 were implied to play a role in the viral passage to Hofbauer cells or T lymphocytes (Arias et al. 2003). Moreover, the identification of genetic variants of functional DC-SIGN, which were associated with an increased risk of in utero HIV-1 infection, further supports the implication of DC-SIGN in HIV-1

dissemination across the placenta (Boily-Larouche et al. 2012). Indeed, syncytiotrophoblasts and Hofbauer cells obtained from the placenta during the early and late stages of pregnancy were shown to carry HIV-1. Interestingly, these cells were not infected when the pregnant women received ART during gestation, clearly supporting the usefulness of such intervention strategy.

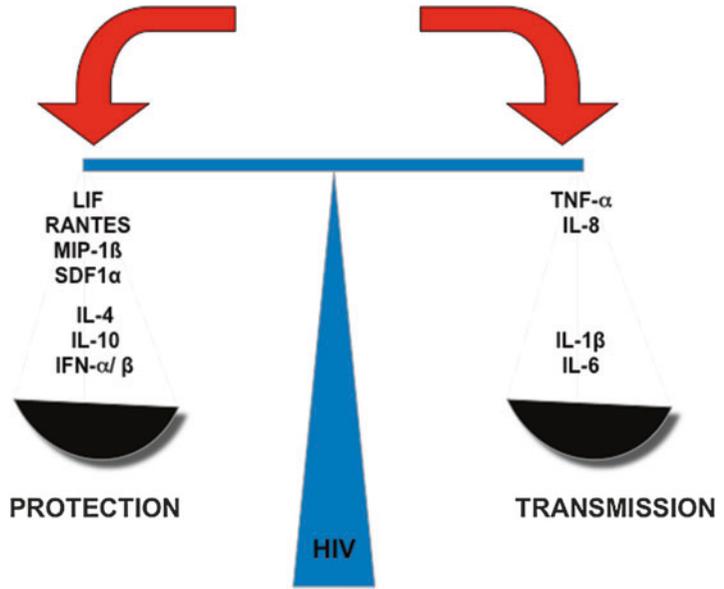

At the maternofetal interphase, the placenta is in close contact with the decidua, i.e., the maternal uterine mucosa, which contains plenty of target cells for HIV-1. In specific, decidual CD14⁺ cells are a preferential target for R5 viruses, whereas T lymphocytes for X4 viruses (Marlin et al. 2009). The same study showed that HIV-1 with R5 phenotype has a replication advantage in decidual cells over that with X4 phenotype (Marlin et al. 2009). Despite this, transmission through the placenta is a rare event, and the placenta may protect the fetus from infection through several mechanisms. The trophoblastic cells do not replicate HIV due to a restriction at postentry level. Furthermore a balance of cytokines and chemokines at placental level may direct the infection of trophoblastic cells. Recently Marlin et al. showed that soluble factors secreted by decidual cells inhibit HIV-1 infection (Marlin et al. 2011). The balance of pro- and anti-inflammatory factors (“IFN Signalling and Induction of Restriction Factors”) at the maternofetal interface, which is involved in stimulating leukocyte recruitment and angiogenesis and in regulating placental trophoblast invasion during pregnancy, may possibly play also an important role in controlling HIV-1 transmission (Fig. 1). Interestingly, a similar balance of inflammatory factors occurs also in other mucosae such as the gut mucosa, with the ultimate goal to regulate tolerance to the microflora and to prevent pathogen invasion.

Breast Milk: A Facilitator and Inhibitor of Transmission

During breastfeeding the neonate first and then the child ingest colostrum and milk at increasing volumes (Van de Perre et al. 2012). The breast milk of HIV-1-infected mothers contains large amounts of

**Mother-to-Child
Transmission of HIV-1:
Role of Receptor Usage
and Target Cells,**

Fig. 1 Role of the cytokine and pro-/anti-inflammatory factor balance of the placental environment in the control of HIV-1 infection. Pro-inflammatory cytokines, such as TNF- α , IL-6, IL-8, and IL-1 β , have been shown to enhance HIV-1 infection, whereas type 1 interferons (IFN- α and IFN- β), the leukemia inhibitory factor (LIF), and chemokines (Rantes, MIP-1 β) that bind to the HIV-1 entry co-receptors can inhibit HIV-1 infection

free virus and of HIV-infected lymphocytes and macrophages, which may initiate transmission during breastfeeding (Rousseau et al. 2004). It was clearly demonstrated that duration of exposure to virus via breastfeeding correlates with increased risk of transmission. Besides cell-free virus it has to be considered that also cell-associated virus transmission likely occurs. Whether cell-associated HIV may play a more relevant role in transmission via breastfeeding than does cell-free virus has to be clarified yet.

Breast milk CD4+ T cells have particular characteristics that distinguish them from circulating blood lymphocytes, as, for example, high frequency of cell activation and expression of memory and mucosal homing markers. These specific features may very well favor the establishment of active replication of HIV in these cells. Furthermore maternal milk contains HIV-1-infected macrophages. Interestingly, R5 HIV-infected macrophages but not X4 HIV-infected lymphocytes are able to transmigrate across the fetal oral epithelia to reach the submucosa, where they can easily be involved in cell-to-cell transfer of the virus (Tugizov et al. 2012).

Breast milk may have, however, also a protective role and reduce the risk of infection. Indeed, several antiviral factors have been identified, as,

for example, mucin 1 (MUC1), the blood group antigen LewisX, and bile salt-stimulated lipase (BSSL). All these act through a common mechanism, as they inhibit binding of cell-free HIV-1 to DC-SIGN and prevent transfer of infection to CD4+ T cells (Pollakis et al. 2011). The DC-SIGN binding properties of breast milk obtained from different lactating mothers, however, are not constant suggesting mother-dependent protection levels for HIV-1 transmission during breastfeeding (Stax et al. 2011).

A recent study reported a significant inhibition of cell-free HIV-1 with breast milk from HIV-positive and HIV-negative Tanzanian women (Lyimo et al. 2012). The effect was independent of the viral tropism and did not correlate with the presence or levels of individual cytokines, chemokines, or growth factors in the milk, including factors that serve as blocking ligands for the HIV-1 co-receptors, CCR5 and CXCR4. However, a correlation was found between HIV-inhibitory activity and the sialylated form of LewisX antigen (sialyl-LewisX) in the milk of HIV-positive women. Surprisingly, breast milk from the same subjects on the contrary enhanced infection via cell-associated HIV in vitro. Enhancement did not correlate with any of the abovementioned factors. These data indicate that

distinct factors in breast milk can modulate cell-free and cell-associated HIV-1 infection: the balance between these factors may bias the transmission event.

Enhancement of cell-cell interaction and HIV-1 infection by breast milk may result from several factors, which remain largely to be defined. Upregulation of cell surface molecules needed for efficient attachment and interaction of HIV-infected milk cells to target cells in the intestinal epithelium or submucosal tissue may play a major role. Breast milk contains high levels of soluble ICAM-1, which are involved in the formation of the virological synapse between HIV-1-infected cells and target cells; however, no correlation was found between the level of ICAM-1 in breast milk or of antibodies against ICAM-1 and cell-associated HIV-1 infection (Valea et al. 2011). Alternatively, activation of HIV-1 expression from latently infected cells may be promoted by the presence of stimulatory factors in breast milk. In vitro stimulated HIV-infected milk cells secrete higher levels of virus than the comparable population of cells from peripheral blood. Interestingly, activated milk CD4+ T cells from women receiving HAART produce HIV-1 in vitro (Valea et al. 2011), suggesting that these cells may constitute a reservoir that is relatively refractive to treatment. Moreover, localized and systemic inflammatory responses in the mother, which increase the levels of pro-inflammatory cytokines in the milk, may contribute to enhance HIV-1 release from infected cells and favor transmission.

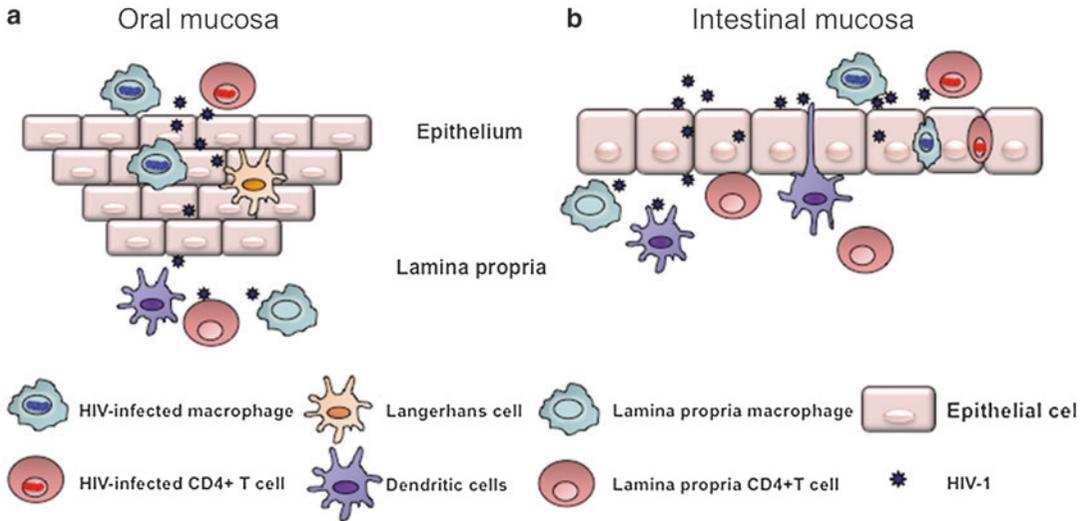

The Gastrointestinal Tract: A Primary Site of Infection

The interaction of HIV-1 with the mucosal epithelia of the oropharyngeal and gastrointestinal tract is the first step in the establishment of systemic HIV-1 infection during MTCT after ingestion of HIV-1 from maternal blood and cervical mucus during delivery or from breast milk. Tissue morphology and integrity, as well as distribution of relevant cell types within the mucosa can greatly

influence viral transmission, and the ability of HIV-1 to initiate systemic infection may vary considerably among the different mucosal types. The intestinal tract with its large extension of the epithelial surface provides an important site for viral uptake and consequent transfer to underlying and confining target cells. After crossing the mucosal barrier, the main target cells for HIV-1 replication are the CD4+ T (“▶ [Central Memory CD4 T cells](#)”) lymphocytes, which are rapidly depleted both in the periphery and in the mucosal tissues. However, many cell-type variants of both lymphocytic and monocytic lineage can be found in the mucosal tissues, which are potential targets for the incoming virus.

HIV spread across fetal/neonatal oropharyngeal epithelia is an important route of MTCT. While MTCT through the neonatal oral epithelium is considered to be common, in adults oral transmission occurs apparently less frequently. Virions can traverse both adult and fetal oral epithelial cells by transcytosis (Tugizov et al. 2011); however, infectivity of the virions is greatly diminished during the passage through the adult cells, but not through the fetal cells. This appears to be due to the high-level expression of anti-HIV innate proteins, the β -defensins, and the secretory leukocyte protein inhibitor (SLPI) by the adult oral epithelial cells. Cell-free HIV-1, which crossed the fetal oral epithelia, is able to further transfer infection to CD4+ T cells, DCs, and macrophages. Antibodies against galactosylceramide (GalCer) and heparan sulfate proteoglycan (HSPG) but not against CCR5 and CXCR4 reduce infection, suggesting that chemokine receptors do not play a primary role in transmission through the fetal/infant oral mucosa (Tugizov et al. 2011). Moreover macrophages but not CD4+ T cells can transmigrate across the oral mucosa (Fig. 2a).

The tonsil's mucosa contains M cells lying above regions where DCs are juxtaposed with CD4+ lymphocytes, whereas LCs cluster in the subepithelial papillae of the buccal mucosa. Accordingly in the primate MTCT model, infection was shown to occur through the surface mucosa of tonsils, where specialized M cells and DCs may transport HIV to the interior of the

Mother-to-Child Transmission of HIV-1: Role of Receptor Usage and Target Cells, Fig. 2 Oral and intestinal mucosal epithelia are key portals of entry for HIV MTCT. (a) Cell-free HIV transmigration across the stratified oral mucosal epithelium leads to passage of virions into the intraepithelial and subepithelial virus-susceptible cells. HIV-infected lymphocytes do not transmigrate across oral epithelia; however, HIV-infected macrophages penetrate into fetal epithelia and reach the lamina propria. (b) Cell-free HIV also transmigrates across

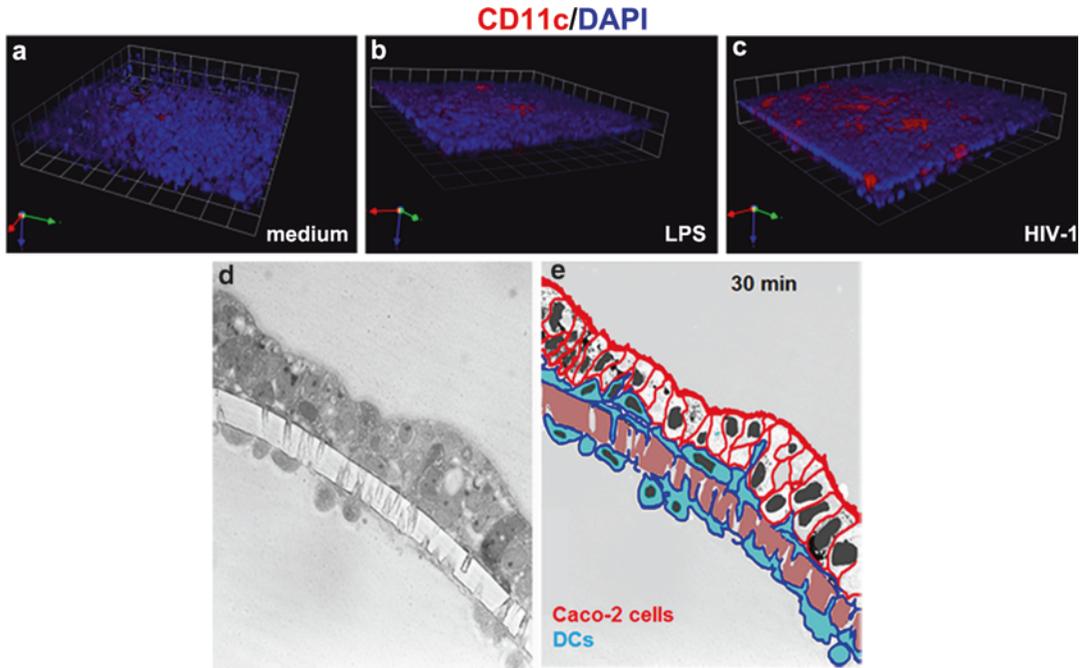

monostratified intestinal epithelia. Moreover subepithelial DCs extend dendrites across the epithelium to shuttle luminal virions. Both HIV-infected lymphocytes and macrophages transmigrate across fetal intestinal epithelia. Transcellular spread of cell-free and HIV-infected cells across oral and intestinal mucosal epithelia may lead to infection of intraepithelial and submucosal HIV-susceptible cells, including T lymphocytes, Langerhans/DCs, and macrophages

tissue. Tonsil lymphoid cells have an increased susceptibility to infection with HIV-1 compared to PBMC, which may in part be ascribed to the increased expression of early activation markers and the viral co-receptor CXCR4, relative to PBMC.

Transmission of HIV-1 through the gastrointestinal epithelial monolayer has been object of intensive studies. Different pathways have been suggested (Fig. 2b): cell-free and cell-associated viruses of R5 or X4 phenotype bind the GalCer receptor and cross the enterocytes via transcytosis. However, primary jejunal epithelial cells incubated with HIV-1 carry over only R5 viruses to receptive target cells, whereas M cells in Peyer's patches of the digestive epithelium, which deliver samples of foreign material directly to the close intraepithelial lymphoid cells, transport selectively X4 viral variants through a chemokine-receptor-mediated mechanism. In

addition, DCs in jejunum explant cultures are the predominant target cell of R5 HIV-1 early after infection and leave thereafter the tissue to transmit in trans the virus to lymphocytes (Shen et al. 2010). Bunders et al. recently showed that the fetus and the newborn gut mucosa and submucosa contain abundant levels of CD4 + CCR5+ T cells, which lay within the epithelial lining (Bunders et al. 2012). Being these cells in direct contact with the lumen may facilitate their infection with R5 viruses. In summary, some of the described mechanisms support a preferential transmission of CCR5-using viruses others instead provide evidence of the transmission of X4 viruses as well.

DCs or LCs of the intestinal and vaginal mucosa were repeatedly described to be the first target for HIV-1 and the vehicle for the virus to reach replication competent cells. More recently cell-free R5 but not X4 HIV-1 were described to attract colonic lamina propria-resident DCs to extend their cellular

Mother-to-Child Transmission of HIV-1: Role of Receptor Usage and Target Cells, Fig. 3 Migration of DCs across a monolayer of epithelial cells. Caco-2 cells were grown on Transwell filter to form a confluent monolayer, and then DCs were let to adhere to the bottom of the filter. Cell-free HIV-1 (a, d, e), LPS (b, positive control), or medium (c, negative control) were incubated on the apical side of the Caco-2 monolayer for 1.5 h. Filters were processed for confocal microscopy. (a–c) Three-dimensional rendering of representative fields obtained with Volocity 5.0 of the Caco-2/DCs coculture stained

with DAPI nuclear dye (all cells; blue) and mouse anti-human DC-SIGN-PE (DCs; red) are shown. DCs migrated between the epithelial monolayer in response to HIV-1 and LPS stimulation, but not in response to medium. (d, e) Semi-thin sections for transmission electron microscopy (d) and the corresponding explicative color mask (e, Caco-2 cells red, DCs blue, filter gray) show the morphology and the spatial organization of cells. DCs are disposed along the lower face of the filter, inside the membrane pores, and intercalated in between Caco-2 cells

processes through the intact epithelium (Fig. 3). Migrated DCs sample luminal virions and are able to transfer infection to CD4+ T cells (Cavarelli et al. 2013). The migratory process was dependent upon the interaction of the HIV envelope protein with CCR5, and therefore, providing CCR5-using viruses with an additional mechanism to gain access to the intestinal mucosa. It will be important to understand if these DCs will reside in the mucosa to be involved in antigen presentation and/or be able to reach the lymph nodes to spread further the infection. Unraveling this mechanism may help to identify the relevant cells involved during the early phases of infection and develop effective prevention strategies.

Conclusion

As of today the viral phenotype was not identified as a predictive marker of MTCT of HIV-1. The transmitted virus, when isolated from the newborn, is, however, predominantly of R5 phenotype. While the placenta is a player in the transmission during gestation, the gastrointestinal mucosa instead, with its large extension of the epithelial cell monolayer, is certainly involved in transmission during labor, delivery, and breastfeeding via ingestion of infected biological fluids. Different cellular pathways seem to be determinant, each of them showing a preferential transmission of one or the other viral phenotype.

Transmission through the mucosal surfaces is a portal of entry to reach the underlying cells, which are target for infection with HIV-1 and deputed to spread infection to other cells and tissues. Preventing the infection of the first target cell is the ultimate goal of all preventive interventions. Both vaccine and non-vaccine biomedical interventions could provide unique as well as complementary opportunities towards elimination of MTCT of HIV-1.

Definition

HIV can be transmitted from a mother to her child (mother-to-child transmission or MTCT) during pregnancy (in utero), labor/delivery (intrapartum), or via breastfeeding (postpartum). Mother-to-child transmission or vertical transmission of HIV occurs in 25–40% of pregnancies without intervention. With medical interventions including antiretroviral prophylaxis to both the mother and the infant, cesarean section and, breastfeeding avoidance, MTCT has been decreased to less than 2% in resource-rich settings, yet MTCT is still above 10% in resource-poor settings due to limited access to effective interventions.

Introduction

Vertical transmission, or mother-to-child transmission (MTCT) of HIV-1, may occur during pregnancy (in utero), during labor/delivery (intrapartum), or throughout the breastfeeding period (postpartum). Since the first report of vertical transmission of HIV in 1982, dramatic improvements in prevention of MTCT have been made. Despite these successes, an estimated 330,000 of the approximately 1.5 million children at risk of contracting the virus are infected annually (UNAIDS 2012).

Use of preexposure and postexposure prophylactic antiretroviral (ARV) treatment to interrupt MTCT has been implemented with great success in both resource-rich and resource-limited

settings. In resource-rich settings, universal antenatal testing, ARV use, caesarian section, and avoidance of breastfeeding have resulted in MTCT rates under 2%. Unfortunately, in low-to-middle income countries, poor access to antenatal testing, ARV treatment, and delivery services has limited the effectiveness of interventions (Luzuriaga 2007). In 2011, UNAIDS estimated that only 48% of HIV-positive pregnant women received the most effective ARV regimens to prevent MTCT and only 42% of infants received prophylaxis (UNAIDS 2012). Currently, implementation science is focused on reducing these significant gaps in intervention through a combination of best service delivery practices and health systems approaches. Provision of ARV agents is necessary but not sufficient to eliminate MTCT; health systems must be able to deliver services from the antenatal period through the end of breastfeeding in order to dramatically reduce MTCT (Chi and Bolton-Moore et al. 2013; Mofenson 2013). The ultimate goal of these efforts is to reduce MTCT globally to <5%.

Routes of Transmission

HIV-1 transmission from women to their infants may occur through the placenta, maternal genital secretions, or breast milk (Tobin and Aldrovandi 2013). Although the fetus and neonate are exposed to HIV at multiple time points, infection is rather inefficient. Without any intervention, 5–10% of pregnancies result in utero transmission, 10–20% of deliveries result in intrapartum infection, and 5–15% of breastfeeding infants become HIV infected (1995). Understanding how these immunologically vulnerable infants escape infection at any of these three stages could provide important insights into the mechanisms of natural protection.

Transmission and Infection

In all three routes of MTCT, infection of the infant occurs with HIV traversing an anatomical barrier and productively infecting the infant's CD4+ T cells. Viral amplification and dissemination to other tissues then occurs. It is still uncertain

whether HIV transmission occurs as a result of cell-free virions or infected cells. Both have been detected in blood, amniotic fluid, cervicovaginal secretions, and breast milk. Compared with levels in blood, mucosal fluids generally contain significantly lower amounts of virus (Shepard and Schock et al. 2000). MTCT risk is associated with both the levels of cell-free and cell-associated virus. As these two variables are highly correlated, it is difficult to disentangle which is more influential; however, studies have shown a stronger association between cell-free virus and HIV transmission (Lehman and Farquhar 2007; Fiscus and Aldrovandi 2012; Tobin and Aldrovandi 2013).

Within an HIV-infected individual, there are millions of HIV variants referred to as a quasi-species. However, during all forms of HIV transmission, usually only a single variant establishes productive infection in the new host. This is referred to as a “genetic bottleneck” (Shaw and Hunter 2012). The biologic basis of this genetic bottleneck is unknown but does not appear to be stochastic since transmitted forms appear to share certain viral characteristics. HIV entry necessitates viral interaction with cellular receptors, specifically the CD4 molecule, and a chemokine coreceptor, usually C-C chemokine receptor type 5 (CCR5) or C-X-C chemokine receptor type 4 (CXCR4). The overwhelming majority of transmitted variants use the chemokine receptor CCR5.

Whether the genetic bottleneck occurs within the transmitting compartment (e.g., maternal genital secretions or within breast milk) or later within the newly infected host is uncertain. Studies comparing viral variants in breast milk and plasma have found that despite a quantitative restriction of viral variants in breast milk, the variants in milk are genetically indistinguishable to those in maternal plasma. Thus, the transmission bottleneck does not occur in this transmitting compartment (Heath and Conway et al. 2010; Tobin and Aldrovandi 2013). Once the infant is infected, the variant that establishes infection replicates and dominates initially; however, over time, the HIV-1 population in the infant becomes more diverse through viral mutation as the virus replicates.

HIV can be divided into several subtypes or clades; particular subtypes are found in different locations globally and may impact the likelihood of MTCT. A few controversial and smaller studies have found that HIV clade C, the predominant clade in sub-Saharan Africa, is more likely to be transmitted and may be preferentially transmitted in utero compared to other subtypes (Lehman and Farquhar 2007; Selvaraj and Paintsil 2013).

Maternal Characteristics and Transmission Risk Factors

Regardless of the route of infection, maternal health and HIV-related characteristics influence the risk of transmission. The most predictive risk factors of MTCT are the levels of HIV in the mother and the maternal CD4+ T-cell count. HIV is generally measured in the blood as HIV RNA, often referred to as “viral load.” The level of maternal viremia is associated with disease progression and all forms of transmission. The higher the level of HIV RNA, the greater the risk; however, there are well-described cases where women with “undetectable” viral loads have transmitted HIV to their infants. HIV viremia, and thus risk of transmission, is highest at the time of primary HIV-1 infection and during advanced disease when the immune system cannot control viral replication. Women are at increased risk of HIV acquisition during pregnancy and subsequently at increased risk of transmitting the virus to both their infants and their sexual partners during their primary viremia (Gray and Li et al. 2005; Keating and Hamela et al. 2012; Mugo and Heffron et al. 2012).

The second important risk factor is maternal CD4+ T-cell count, which declines with advancing disease. CD4+ T cells are the major targets of HIV infection, and by both direct and indirect mechanisms, HIV infection results in progressive reduction of cells expressing CD4. As CD4+ T cells decrease, the likelihood of transmission increases. Healthy adults typically have CD4+ T-cell counts of 500–1,200 cells/ μ L, and when the CD4+ T-cell count is less than or equal to 200 cells/ μ L, a person is classified as having

AIDS. The majority of MTCT occurs in women who have a CD4+ T-cell count of less than 350 cells/ μ L.

Inflammation is a well-established risk factor for transmission of HIV. Local inflammation and systemic inflammation are associated with increased risk of MTCT. Inflammatory cytokines can activate CD4+ T cells, increasing the quantity of readily available targets for HIV infection; additionally, the inflammatory response may allow for easier passage of HIV across the mucosa. Women with conditions associated with inflammation, such as sexually transmitted infections (STIs), bacterial vaginosis, chorioamnionitis, mastitis, placental malaria, and other opportunistic infections (i.e., tuberculosis), are at increased risk of MTCT (Lehman and Farquhar 2007; Selvaraj and Paintsil 2013).

Both adaptive and innate maternal immune responses are associated with protection against MTCT (Lehman and Farquhar 2007). Levels of maternal HIV-neutralizing antibodies and CD8+ cytotoxic T-cell responses are associated with protection, while inflammatory cytokines and chemokines are associated with increased transmission. However, most of these studies are limited by small sample sizes. Data on the protective effects of certain genetic markers are more robust. Children who possess a 32-base pair deletion in the CCR5 receptor are much less likely to become infected, as the preferred coreceptor is non-functional. Children who share human leukocyte antigen (HLA) alleles with their mothers are at increased risk of HIV acquisition presumably due to a virus that has preselected fitness for the infant.

Mechanisms of Transmission

MTCT Transmission: In Utero

With in utero transmission, maternal HIV must traverse the placenta, productively infect an infant's T cells, and then begin viral replication to establish infection in the infant. Although HIV infection can occur throughout gestation, early in utero infection is associated with an increased risk of spontaneous abortion. Most in utero transmission occurs late in the third trimester. As only

5–10% of all pregnancies of HIV-infected women result in in utero infection, it is likely that a breakdown of the maternal-fetal barrier must occur in order for HIV to cross the placenta. Conditions where the maternal-fetal barrier is breached (i.e., prolonged rupture of membranes) or inflamed (i.e., chorioamnionitis) during pregnancy are associated with a marked increased risk in HIV infection/transmission (Bond et al. 2007). Furthermore, placental micro-transfusions (small exchanges of blood) increase the risk of transmission through the direct mixing of HIV-infected maternal blood with that of the infant (Selvaraj and Paintsil 2013). As mentioned above, HIV can only productively infect activated CD4+ T cells; yet most infant T cells are quiescent. This quiescent or tolerogenic state may help the infant escape infection.

MTCT Transmission: Intrapartum

During childbirth, the infant's mucosal membranes are exposed to maternal genital secretions and blood, which contain HIV. Over the course of labor and delivery, several factors have been identified that increase the risk of MTCT. High levels of HIV-1 in maternal blood or genital secretions, low maternal CD4+ T-cell counts, and inflammatory conditions (e.g., STIs) increase the risk of transmission to the infant. During parturition, prolonged rupture of membranes prior to delivery dramatically increases the risk of transmission, potentially due to ascending spread of HIV from the lower genital tract. Additionally, breaches in the infant's skin through the use of scalp electrodes or forceps during labor/delivery are associated with increased risk of transmission. Interestingly, the first twin is more likely than the second twin to be HIV infected during delivery presumably due to the first twin's longer exposure to HIV in the birth canal. Cesarean section reduces MTCT during labor and delivery if performed prior to the initiation of labor or, in other words, prior to the breakdown of the maternal-fetal barrier at the onset of labor.

MTCT Transmission: Postpartum

If the infant escapes HIV in utero and intrapartum infection, the child is still at risk of infection from

breast milk. Breastfeeding transmission of HIV may occur at any point during lactation. The amount of virus in breast milk, type of breastfeeding (mixed feeding or exclusive breastfeeding), duration of breastfeeding, as well as presence of breast and oral inflammation are important determinants of breast milk transmission.

The amount of HIV in breast milk is controlled by the mammary epithelial barrier, which is highly effective at reducing the passage of HIV from the blood to the breast milk. In the absence of inflammation, levels of HIV in milk are 100-fold less than those in the maternal circulation. Breast milk also contains antimicrobial and anti-inflammatory agents that decrease the incidence of infection (Tobin and Aldrovandi 2013). It appears that transmission is most likely when the mammary epithelium is permeable. Cellular tight junctions regulate the breast epithelial permeability; early in lactation these tight junctions are still forming and are thus more permeable. Additionally, the epithelium is more “leaky” in women who do not exclusively breastfeed and during the time of weaning. This increase in permeability is associated with increased levels of HIV in breast milk.

Risk of MTCT is modified based on woman’s breastfeeding pattern. Several large studies have demonstrated that exclusive breastfeeding [provision of only breast milk for the first 6 months postpartum] reduces the risk of transmission by almost half compared to mixed feeding [provision of breast milk and other foods or liquids]. This finding seems counterintuitive as an exclusively breastfed infant will be exposed to more breast milk and therefore more HIV compared to a child who is mixed fed. Why exclusive breastfeeding has such a profound effect on transmission risk is uncertain. Two non-mutually exclusive mechanisms have been proposed: (1) mixed feeding disturbs the gastrointestinal epithelium of the infant making establishment of infection easier, and (2) nonexclusive breastfeeding harms mammary epithelium causing increased permeability. With the first mechanism, new foods and potentially pathogens are introduced during mixed feeding that can lead to intestinal inflammation that is exacerbated by removal of the

anti-inflammatory agents found in breast milk. With the second mechanism, the mammary epithelial tight junctions may be disrupted due to less frequent emptying of the breast and subsequently levels of HIV in the breast milk may be increased.

Not only how a woman breastfeeds but how she stops breastfeeding appears to impact the risk of transmission to the neonate. As breastfeeding decreases over the course of weaning, in a mechanism similar to nonexclusive breastfeeding, potentially the mammary epithelium becomes more permeable. Abrupt weaning, or stopping breastfeeding quickly, is associated with increases in breast milk viral load. If comfort feeding or re-lactation takes place, the breast milk has a much higher level of HIV-1 RNA compared to preweaning breast milk (Kuhn and Kim et al. 2013). Additionally, timing of breastfeeding cessation is important since the infant is at risk of HIV infection as long as s/he breastfeeds. However, early weaning (prior to 6 months) has been associated with increased infant morbidity and mortality due to gastroenteritis (Read 2012). More research is needed to inform recommendations for women on best practices and timing for safe weaning in HIV-infected women.

As with in utero and intrapartum transmission, inflammation has been associated with higher risk of HIV transmission. Mastitis, or inflammation of the breast, and breast problems (i.e., cracked/bleeding nipples or abscess) can increase the risk of transmission, likely through a transient increase in HIV-1 RNA levels due to increased mammary epithelial permeability. Subclinical mastitis, defined by an elevated sodium-potassium ratio, has also been correlated with an increased risk of transmission (Lehman and Farquhar 2007; Tobin and Aldrovandi 2013). Unfortunately, subclinical mastitis is not easily detectable and makes clinical intervention and prevention difficult. Not only does inflammation in the mother increase risk of transmission, inflammation in the child may increase the risk. Introduction of new foods during the period of mixed feeding may cause inflammation in the mouth of the child, facilitating easier passage of HIV across the mucosal barrier. Breaches in infant oral mucosa during disease-related inflammation such as in the case of oral

Candida infection likely increase the risk of transmission (Wood and Chahroudi et al. 2013). Prevention of mastitis and other inflammatory illnesses in the mother and child can help reduce the risk of MTCT.

In resource-rich settings, avoidance of breastfeeding is recommended; however, this is not an option in many lower-resource settings. Making breastfeeding a safer option through anti-retroviral therapy, exclusive breastfeeding, and good breast health with prevention of mastitis can reduce the likelihood of transmission.

Conclusion

Over the past decades, millions of children have been exposed to HIV in utero, intrapartum, and postpartum. However, infection is not absolute; the majority of HIV-exposed infants will not become infected. Risk factors for HIV transmission include levels of maternal virus, maternal health, and HIV disease stage. Several maternal and infant immune and innate responses prevent transmission from occurring.

Models of antiretroviral care and treatment have dramatically decreased the risk of transmission globally; in parts of the developed world, transmission risk is less than 2% in the presence of ARV therapy. Interruption of MTCT with ARV has paved the way for preexposure and post-exposure prophylaxis in other contexts (i.e., sexual transmission). Prevalence of HIV has decreased globally; however, 50% of those living with HIV are women. In sub-Saharan Africa, women make up more than 59% of those living with HIV (Anon n.d.). Therefore, infants will continue to be at risk of contracting HIV through mother-to-child transmission.

Through provision of ARV and other prevention services, MTCT can be significantly reduced, as observed in resource-rich settings. Going forward the availability of and adherence to effective antiretroviral therapy in combination with safer breastfeeding practices could dramatically improve HIV-free child survival in resource-limited settings. Understanding the mechanisms of vertical transmission can provide important

insights into natural immunity and protection. These insights can be translated to a deeper understanding of HIV and improving prevention methods in the future.

Mucosal Immunity to HIV-1

Barbara L. Shacklett

Department of Medical Microbiology and Immunology, School of Medicine, University of California, Davis, Davis, CA, USA

Definition

Mucosal immunity refers to innate and adaptive immune responses that defend mucosal surfaces, which are the surfaces of the body that line passageways exposed to the external environment, such as the respiratory, gastrointestinal, and reproductive tracts. These defenses protect the body against potentially pathogenic microbes, including HIV-1. This review focuses on immune defenses in the female reproductive tract, the male reproductive tract, and the gastrointestinal tract, which are the major portals of entry for HIV-1.

Female Reproductive Tract

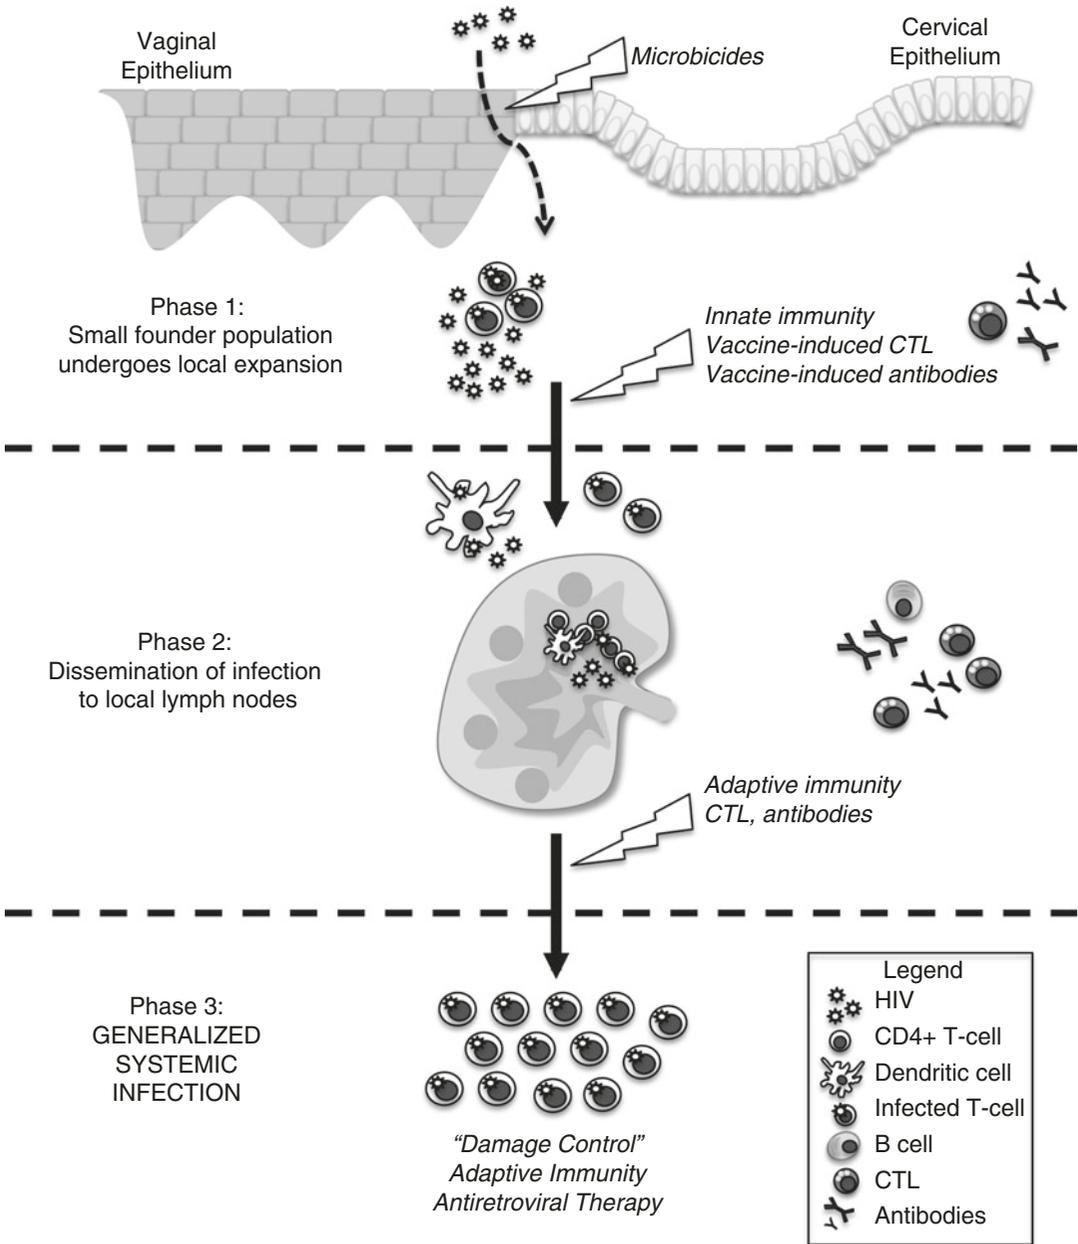

FRT and HIV-1 transmission (► [HIV-1 Sexual Transmission, Overview](#)). Women (► [Women, Epidemiology of HIV/AIDS](#)) account for approximately half of the 34 million individuals with HIV-1; nevertheless, transmission via the female reproductive tract (FRT) (► [Identifying Opportunities to Block HIV-1 Transmission in the Female Genital Tract](#)) is relatively inefficient, with an estimated relative probability of 1 transmission per 200–2,000 exposure events (Hladik and

McElrath 2008). Factors affecting transmission efficiency to the FRT are numerous and include HIV-1 viral load in the male partner's semen; the presence and thickness of vaginal mucus, which varies with the menstrual cycle; other changes in the mucosa occurring throughout the menstrual cycle; the presence of inflammation or lesions due to other sexually transmitted infections; and the composition of local microbial flora (Hladik and McElrath 2008; Xu et al. 2013).

The actual sites within the FRT where initial HIV-1 transmission and viral amplification occur remain controversial. The lower female reproductive tract, consisting of the vagina and ectocervix, is protected by a stratified squamous epithelium. In contrast, the upper tract, including the endocervix and uterine endometrium, is lined by a single layer of columnar epithelium that is easier to traverse than the multilayered epithelium of the lower tract (Fig. 1, top panel). The cervical transformation zone, or squamocolumnar junction, where the stratified squamous epithelium of the ectocervix and the columnar epithelium of the endocervix meet, is rich in CD4+ T cells, macrophages, and dendritic cells and therefore may be highly susceptible to HIV-1 transmission (Hladik and McElrath 2008).

Despite the increased thickness of lower reproductive tract epithelium relative to that of the upper tract, infection can and does occur via the lower tract: experimentally hysterectomized macaques can be infected after intravaginal inoculation; HIV-1 infection has been documented in women who lacked a uterus at birth; and a randomized clinical trial showed no reduction in HIV-1 acquisition in women using a diaphragm as compared to the control group (Hladik and McElrath 2008; Xu et al. 2013).

Cervical ectopy, a condition defined as extension of the simple columnar epithelium of the endocervix to cover a portion of the ectocervix, is associated with increased risk of acquiring HIV-1 and other STI including human papillomavirus and *C. trachomatis* (Wira and Fahey 2008; Rodriguez-Garcia et al. 2013). Cervical ectopy is most prevalent in adolescent girls and can also occur during pregnancy and oral contraceptive use.

M

Mucosal Immunity to HIV-1, Fig. 1 Idealized female genital mucosa showing potential points of intervention to prevent systemic infection. In the top panel, stratified squamous epithelium of the vagina is shown on the left, with the squamocolumnar junction or transition zone shown in the center and the simple columnar epithelium of the endocervix on the right. "Phase 1" in this figure refers to the earliest stage of mucosal infection, when virions have penetrated the epithelium and a small founder population is undergoing local expansion. During this time, microbicides, innate immune responses, and/or vaccine-induced adaptive responses can theoretically limit virus

propagation and expansion. If the virus is not eliminated at this stage, the infection is disseminated to local and regional lymph nodes, where it further expands and infects susceptible target cells. Antibody-secreting cells and CTL present in lymph nodes may restrict further replication. However, if immune responses in mucosal tissues and lymph nodes are insufficient, the infection rapidly becomes systemic. From that point forward, adaptive responses can provide "damage control" by limiting viral loads, but complete eradication of infection is unlikely (Figure redrawn and modified from Shacklett and Shattock (2004; Haase (2011))

The endocervical canal is lined with mucus (► [HIV-1 Transmission; Influence of Body Secretions](#)) (known as the “mucus plug”), which serves as an additional physical barrier to the entry of pathogens. The consistency of cervical mucus changes during the menstrual cycle, thinning during ovulation in order to enable fertilization. The extent to which fluids and/or cells containing HIV-1 can traverse the cervical mucus barrier, leading to direct infection of susceptible cells in the upper FRT, is unclear and may also vary with the menstrual cycle (Wira and Fahey 2008).

Initial target cells (► [HIV-1 Transmission, Cell-Types Associated with](#)). Mechanisms of transmission across the intact vaginal epithelium are difficult to study, but have been modeled in vivo using the simian immunodeficiency virus (SIV) model and ex vivo using explant cultures. These studies suggest that both cell-free and cell-associated virions can successfully establish infection through the female reproductive tract. The precise events that allow HIV-1 to traverse the genital epithelium remain controversial but may include transcytosis across intact epithelial cells; transport through gaps between epithelial cells, or through breaches in the epithelial layer; binding and uptake by Langerhans cells in the genital epithelium, followed by transfer of virion particles to T cells; and direct infection of intraepithelial CD4+ T cells (Hladik and McElrath 2008; Xu et al. 2013; Fig. 1). Viral penetration is believed to be rapid and has been detected in the rhesus macaque model by 30–60 min following experimental intravaginal exposure to SIV. Studies in this model system have identified resting vaginal CD4+ T cells expressing CCR5 (HIV-1 Transmission; Association with Host Genotypes) but negative for activation markers HLA-DR and Ki67, as early targets for infection (Haase 2011). The susceptibility of vaginal CD4+ T cells to infection is also illustrated by the rapid depletion of these cells following intravenous exposure to SIV (Xu et al. 2013).

Early viral dissemination. Extensive studies to determine the nucleic acid sequences of initial transmitted/founder viruses have revealed that the earliest transmitted strains utilize CD4 and CCR5 (HIV-1 transmission dynamics and HIV-1

transmission selection) as their primary receptor and coreceptor, respectively. Furthermore, infection is usually initiated by a single viral genotype, which then gives rise to a small cluster of infected cells near the portal of entry (Haase 2011). A local inflammatory response ensues, leading to attraction of additional susceptible target cells. Infected cells then spread via afferent lymphatics to draining lymph nodes, where further amplification and dissemination can occur (Haase 2011) (Fig. 1, middle panel).

In the rhesus macaque model of SIV exposure, an inflammatory cascade begins in the cervicovaginal mucosa by day 1 postinfection. At this point, there is increased expression of the chemokine MIP-3 α (CCL20), which drives an influx of CD123+ plasmacytoid dendritic cells (pDC) into the mucosa. The pDC then release type I interferons, which are important mediators of antiviral innate immunity. However, pDC also release beta chemokines MIP-1 α (CCL3) and MIP-1 β (CCL4); these chemokines attract additional CCR5+ CD4+ T cells that serve as targets for viral infection and amplification (Haase 2011; ► [HIV-1 Transmission; Cell-Types Associated with](#)). This model for early viral dissemination has been termed a “broadcasting” model because it begins with a single focus of infection, from which an inflammatory cascade leads to rapid amplification of the viral “signal.” The infection spreads from the initial site of infection to local lymph nodes and subsequently disseminates throughout the body (Fig. 1, middle and lower panels).

The role of immune activation (► [Immune Activation and HIV Transmission](#)). Since soluble molecules that promote inflammation contribute to rapid viral dissemination, it has been proposed that anti-inflammatory agents might be used to limit or prevent viral “broadcasting.” The hypothesis that immune quiescence can inhibit viral dissemination from mucosal foci of infection was tested by Li and Haase, who demonstrated that topical application of the anti-inflammatory compound glycerol monolaurate (GML) to cervicovaginal mucosa of rhesus macaques could prevent local cytokine/chemokine production and protect the macaques from mucosal SIV

infection (Haase 2011). This finding suggested that anti-inflammatory compounds could be developed for use as microbicides to prevent HIV-1 acquisition in high-risk humans.

Other factors contributing to transmission risk. Other sexually transmitted infections (STI), including *C. trachomatis*, chancroid (*H. ducreyi*), and herpes simplex viruses, can increase susceptibility to HIV-1 transmission by increasing local inflammation, recruiting infectable target cells, and through other mechanisms. Bacterial vaginosis may also facilitate HIV-1 transmission (Shacklett and Greenblatt 2011).

Semen and seminal plasma contain immunosuppressive agents that alter the immune microenvironment of the female reproductive tract in order to facilitate conception and implantation. These include high concentrations of TGF- β and prostaglandin E2, which can both inhibit innate immune responses and promote the differentiation of regulatory T cells (Sabatte et al. 2011). In vitro, seminal plasma also induces cervical epithelial cells to produce several proinflammatory cytokines and chemokines that could lead to infiltration by neutrophils and macrophages. Finally, amyloid fibrils derived from the semen protein prostatic acidic phosphatase have been shown to enhance HIV-1 infectivity in vitro. These fibrils, known as semen-derived enhancer of virus infection (SEVI), have been shown to promote non-specific attachment of virus particles to target cells under laboratory conditions (Sabatte et al. 2011). However, the effects of SEVI fibrils on HIV-1 transmission in vivo remain to be demonstrated.

Innate responses in the FRT (HIV & SIV, Innate Immune Responses to). The reproductive mucosa can deploy a wide range of innate immune defenses against viral infection (Iwasaki 2010). In addition to the previously cited physical barriers, these include soluble factors such as secretory leukocyte protease inhibitor (SLPI), lactoferrin, alpha and beta defensins, the antimicrobial peptide cathelicidin (LL-37), and various cytokines and chemokines. Several recent studies have implicated the serine protease inhibitor trappin-2/elafin as a potential biomarker of protection against HIV-1 acquisition (Rodriguez-Garcia et al. 2013).

Adaptive responses in the FRT (► HIV & SIV, CD4 T Cell Responses to; ► HIV & SIV, CD8 T Cell Responses to). Studies evaluating the kinetics of acute phase mucosal CD8+ T-cell (► HIV & SIV, CD8 T Cell Responses to) responses have reported that these responses emerge “too little and too late” near the site of infection to prevent viral dissemination to draining lymph nodes (Haase 2011). HIV-1-specific CD8+ (► HIV & SIV, CD8 T Cell Responses to) and CD4+ T-cell (► HIV & SIV, CD4 T Cell Responses to) responses remain detectable in the reproductive tract throughout the chronic phase of infection (Shacklett and Greenblatt 2011).

Detailed characterization of HIV-1-specific T-cell responses throughout the female reproductive tract is lacking, mainly due to the difficulties inherent in obtaining sufficient material for study. Nevertheless, HIV-1-specific CD4+ and CD8+ T cells have been detected in both the upper and lower RT of women with chronic HIV-1 infection, as well as in cervical tissue of highly exposed, persistently seronegative (HEPS) women (Rodriguez-Garcia et al. 2013).

Several studies have reported the detection of HIV-1-specific immunoglobulin A (IgA) in cervicovaginal secretions from HEPS women. This IgA has been reported to neutralize primary HIV-1 strains in vitro and to block viral transcytosis across an intact monolayer of cultured epithelial cells. However, this topic remains controversial, as other studies of HEPS cohorts have failed to detect such antibodies in secretions (Shacklett and Greenblatt 2011).

Hormonal influences on HIV-1 susceptibility. Vaginal epithelial thickness varies through the menstrual cycle: thickness of the vaginal epithelium peaks at ovulation in response to the surge in estradiol (Wira and Fahey 2008). In postmenopausal women, loss of estradiol leads to permanent thinning of the vaginal epithelium. Changes in the vaginal epithelial barrier may contribute to an increased risk of HIV-1 transmission among older women; however, this has not been proven.

Immune responses in the upper and lower FRT are affected differently by hormonal fluctuations during the menstrual cycle. In the lower tract,

cytotoxic T-cell (CTL) activity remains relatively constant throughout the cycle (Wira and Fahey 2008). However, levels of IgG and IgA in cervical secretions decline by 10–100-fold at mid-cycle, immediately after ovulation, and increase again near the end of the cycle. Soluble mediators of innate immunity, including lactoferrin, SLPI, and HBD2, also decline at mid-cycle and rebound late in the cycle just before menses. Taken together, these observations suggest a potential window of vulnerability in the lower reproductive tract at mid-cycle and during the secretory (luteal) phase due to suppressed immunoglobulin production and innate responses (Wira and Fahey 2008).

In the upper reproductive tract, CTL responses vary during the menstrual cycle. Under hormonal influence, lymphoid aggregates form in the uterine endometrium, consisting of a B-cell core surrounded by CD8⁺ T cells and macrophages. CTL activity within these aggregates is greatest during the proliferative phase, but the aggregates attain their maximal size, with reduced CTL activity, during the secretory phase. This finding suggests particular vulnerability of the upper tract to infection during the secretory phase due to suppressed cell-mediated immunity (Wira and Fahey 2008). These lymphoid aggregates are absent from postmenopausal women, whose uterine CTL activity is more robust than that of premenopausal women.

Hormonal contraception and HIV-1 acquisition. In rhesus macaques, progestin application increases susceptibility to vaginal SIV transmission, likely by promoting thinning of the vaginal epithelium. However, the effects of progestins on human vaginal epithelial thinning are reportedly less pronounced (Rodriguez-Garcia et al. 2013; Xu et al. 2013). Several studies have assessed whether use of progestin-based contraceptives affects HIV-1 susceptibility in women. Literature on this topic remains controversial, and interpretation of available data has been complicated by differences in study design. Some studies have raised concern about an association between use of depot medroxyprogesterone acetate (DMPA) and increased risk of HIV-1 transmission; however, this finding has not been universal (Polis and Curtis 2013). Further studies will be required to

firmly establish the relationship between hormonal contraception and the risk of acquiring HIV-1 and other STI.

Male Reproductive Tract

Sites of HIV-1 entry. In men, HIV-1 transmission via the genital tract can occur via the foreskin, where numerous T cells, macrophages, and dendritic cells are located. Early studies to investigate the specific sites of entry via the male reproductive tract focused on the inner foreskin, which was believed to have a thinner layer of keratin than the outer foreskin, rendering it more susceptible to infection. However, subsequent studies found no difference in thickness of the keratin layer between inner and outer foreskin (Dinh et al. 2010).

Two recent studies tested the infectability of penile explants acquired from individuals undergoing gender reassignment surgery. In the first, explants of foreskin, glans, meatus, and urethra were found susceptible to infection with HIV-1 BaL, an R5-tropic strain (Anderson et al. 2011). In the second, urethral macrophages were susceptible to infection with cell-associated HIV-1 (Ganor et al. 2013). Thus, these studies confirm the infectability of sites other than the foreskin within the male RT. However, the male reproductive tract remains understudied in HIV-1 transmission and pathogenesis, and further studies are needed to better elucidate the sites of initial infection, virus production, and immune responsiveness to infection (Anderson et al. 2011).

Immune defenses. Human foreskin and penile urethral tissue express mucin genes, as well as soluble mediators of innate immunity including SLPI, lactoferrin, lysozyme, and interferon-beta. The urethral mucosa contains numerous cytotoxic CD8⁺ T cells. HIV-1-specific CD8⁺ T cells have been detected in semen of men with chronic HIV-1 infection, but neither the presence nor the frequency of these cells correlated with reduced levels of HIV-1 RNA in semen (Sheth et al. 2005). The urethral mucosa also contains plasma cells secreting IgA, IgM, and to a lesser extent, IgG (Anderson et al. 2011). Compared with studies of

the female reproductive tract, relatively few studies have explored immune responses of the male reproductive tract, and there remain major gaps in our understanding of this important site of infection (Anderson et al. 2011).

Circumcision (► [Medical Male Circumcision, Infant Circumcision, Prevention of HIV](#)). Early epidemiological evidence from sub-Saharan Africa suggested that male circumcision might reduce the risk of HIV-1 acquisition. Subsequently, three randomized trials were conducted in sub-Saharan Africa (South Africa, Kenya, and Uganda, respectively), to test whether circumcision of adult heterosexual males reduced their risk for acquisition of HIV-1. In all three trials, circumcision reduced the participants' risk of HIV-1 acquisition by 50–60% (reviewed in (Anderson et al. 2011)).

The protective effect of foreskin removal is thought to be due in part to the presence of HIV-1 target cells in the foreskin epithelium and in part to trapping of virus and infected cells by the foreskin, facilitating acquisition through the foreskin and the other sites that it covers. Circumcision also reduces the prevalence of other STI that can enhance HIV-1 acquisition due to increased levels of genital inflammation. However, studies to evaluate whether male circumcision reduces transmission of HIV-1 to female sexual partners have not demonstrated a similar protective effect (Weiss et al. 2009), and observational studies to determine the effects of circumcision on transmission among men who have sex with men (MSM) have yielded mixed results.

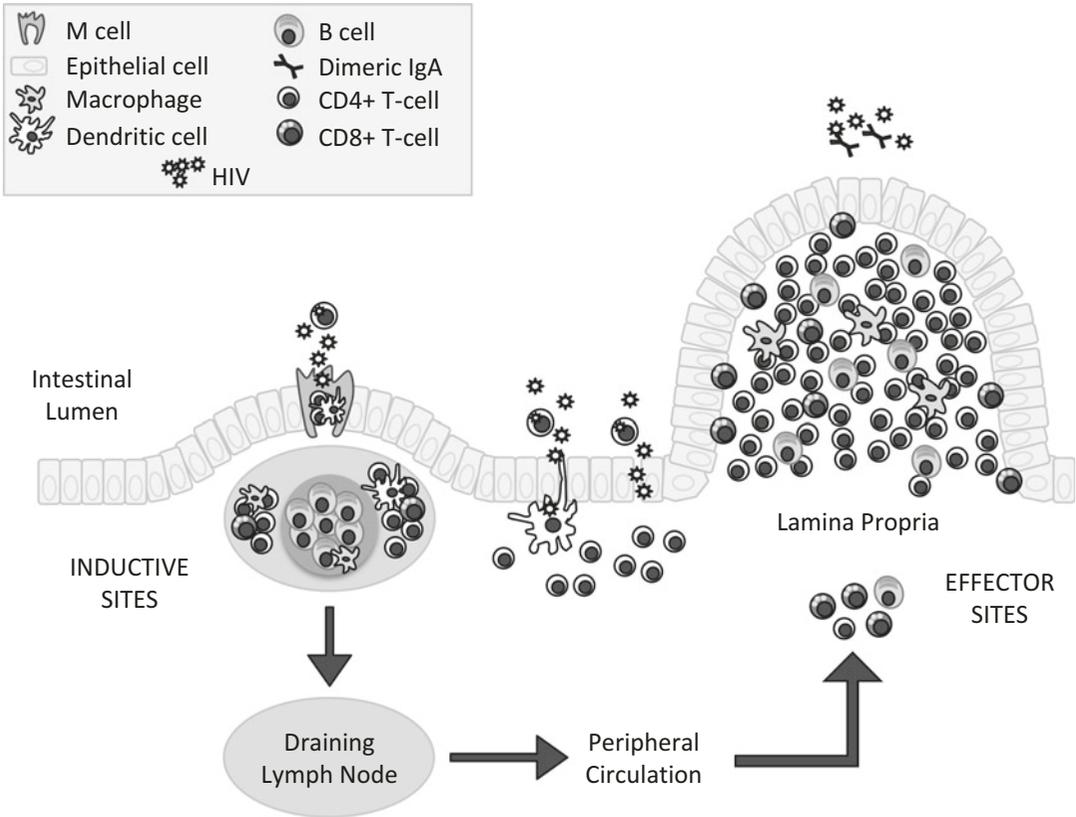

The Gastrointestinal Tract

Background. The gastrointestinal tract has been characterized as the largest lymphoid organ in the body, housing a majority of the body's lymphocytes as well as a large array of commensal organisms. Because of its role as an immunological barrier, in contact with dietary antigens and microbial flora, the GI tract maintains a tolerogenic environment; nevertheless, it must also be able to mobilize the defenses necessary for rapid response to mucosal pathogens. AIDS-associated

diarrhea and wasting syndromes were among the most common clinical features documented in the early years of the HIV/AIDS epidemic. Subsequent research revealed that the GI tract is a major site of viral replication, CD4+ T-cell depletion, and epithelial disruption irrespective of the route of initial HIV-1 infection. Furthermore, recent studies have provided evidence linking gut epithelial barrier dysfunction and microbial translocation to the generalized immune activation that has long been associated with HIV-1 disease.

Rectal transmission (► [Men who have sex with men \(MSM\)](#)). HIV-1 transmission frequently occurs during anal intercourse; however, as for other sites of HIV-1 transmission, the precise mechanisms leading to viral penetration of the GI mucosa remain unclear (Shacklett and Anton 2010; Fig. 2). During receptive anal intercourse, microabrasions and breaches can form in the simple columnar epithelium lining the rectal mucosa, allowing virus to access susceptible T cells in the underlying lamina propria. Intraepithelial dendritic cells may also bind virion particles and transfer them to nearby CD4+ T cells. Alternatively, virions may be taken up by intestinal epithelial cells and/or M cells via transcytosis and subsequently transmitted to CD4+ T cells. Several of these possible mechanisms are illustrated in Fig. 2. A recent study used SPECT/CT imaging of radiolabeled surrogates of cell-free and cell-associated HIV-1 to monitor movement of these surrogates in the distal GI tract during simulated intercourse. The radiolabeled molecules reached their peak concentrations at a distance of 10–20 cm from the anal verge, corresponding to the rectosigmoid junction (Louissaint et al. 2012).

Gut CD4+ T-cell depletion. Regardless of the initial pathway for viral penetration, the predominant target cell for productive HIV-1 infection in the GI tract is the CCR5+ CD4+ T cell. In the mid-1990s, several groups reported that CD4+ T cells in the gastrointestinal lamina propria underwent profound depletion during acute HIV/SIV infection. This depletion occurs rapidly, beginning 4–7 days postinfection, irrespective of the route of initial infection, as demonstrated by studies in rhesus macaques. The mechanisms driving CD4+ T-cell depletion include direct

Mucosal Immunity to HIV-1, Fig. 2 Idealized gastrointestinal mucosa. Inductive sites are organized structures, including Peyer's patches and lymphoid aggregates, where antigen presentation occurs. Effector sites are the epithelium and lamina propria. Intraepithelial lymphocytes are primarily CD8+ cytotoxic T cells, while the lamina propria is rich in activated memory CD4+ T cells expressing CCR5 that serve as targets for HIV. CD8+ T cells and antibody-secreting plasma cells (shown in legend as "B cells") are also found in the lamina propria. Lymphocytes primed in mucosal inductive sites move through efferent lymphatics

to the draining lymph nodes, eventually rejoining peripheral circulation at the thoracic duct. After circulating through peripheral blood, they selectively return to mucosal effector sites based on expression of specific chemokine receptors and integrins, as described in the text. HIV may infect the gastrointestinal mucosa by several mechanisms, including transcytosis across intact epithelial cells or M cells, by adhering to dendritic cells, or by passing through breaches in the epithelial layer (Figure redrawn and modified from Shacklett and Anton (2010))

viral infection and apoptosis of uninfected "bystander" cells (Shacklett and Anton 2010).

► **Th17 cells.** T helper cells secreting IL-17, known as Th17 cells, are a subset of CD4+ T cells that are important for mucosal defense against bacteria and fungi and also secrete cytokines that are critical for the maintenance of gut epithelial integrity (Cecchinato and Franchini 2010). However, Th17 cells can also contribute to inflammatory responses and have been implicated in the pathogenesis of human inflammatory bowel diseases (IBD). In humans, differentiation of Th17

cells requires expression of the transcription factor ROR γ t and exposure to polarizing cytokines including IL-23.

Th17 cells in the GI tract are rapidly depleted during acute HIV/SIV infection. This rapid loss may be due to preferential infection of Th17 cells; however, this point is controversial. Comparison of pathogenic and nonpathogenic models of SIV infection suggests that loss of these cells contributes to immune activation (Cecchinato and Franchini 2010). Nonpathogenic SIV infection of sooty mangabeys or African green monkeys is

characterized by retention of mucosal Th17 cells and absence of microbial translocation and immune activation. In contrast, pathogenic SIV infection of rhesus macaques leads to loss of intestinal Th17 cells, decreased intestinal barrier function, and reduced containment of bacterial infections such as *S. typhimurium* (Cecchinato and Franchini 2010). Partial restoration of intestinal Th17 cells has been reported in individuals on HAART (Cecchinato and Franchini 2010).

T_{reg} cells (► [Role of Regulatory T Cells during HIV Infection](#)). In contrast to the proinflammatory nature of Th17 cells, another subset of CD4⁺ T cells, termed regulatory T cells or T_{reg}, exerts anti-inflammatory functions and induces tolerance against “self” antigens. Like Th17 cells, T_{reg} are abundant in mucosal tissues. Their development is induced by expression of transcription factor Foxp3, retinoic acid, and cytokines including TGF- β . In the mouse, the pathway leading to T_{reg} development is considered a reciprocal pathway that can be polarized to induce either T_{reg} or Th17 development, depending upon the cytokine environment. In the context of HIV-1, T_{reg} may play a beneficial role by limiting harmful inflammation; however, evidence suggests that they also inappropriately suppress HIV-1-specific adaptive responses, thereby exacerbating the disease process. Accordingly, the balance between Th17 and T_{reg} may influence HIV-1 disease progression by modulating the equilibrium between inflammation and adaptive immunity in mucosal tissues.

Epithelial damage and microbial translocation (► [Microbial Translocation](#)). Systemic immune activation in HIV-1 infection has been recognized since the early days of the epidemic, but its etiology was unclear. This persistent activation is characterized by elevated plasma levels of proinflammatory mediators, high T-cell turnover, and elevated markers of T- and B-cell activation. Immune activation often persists despite successful reduction of viremia by antiretroviral therapy (ART) and is strongly predictive of morbidity. Indeed, individuals on ART remain at risk for many conditions, including cardiovascular disease, malignancy, and type II diabetes, which are associated with inflammation and immune activation.

Several studies have provided evidence that microbial translocation is a major contributor to the persistent immune activation observed in HIV-1 infection (Sandler and Douek 2012). First, numerous groups have reported elevated markers of microbial translocation in plasma of HIV-1-infected individuals as compared to healthy controls; these include bacterial lipopolysaccharide (LPS), soluble CD14 (sCD14), and bacterial 16S ribosomal DNA (rDNA). Second, in the SIV model (► [Non-Human Primate Models of HIV Transmission](#)), increased deposition of microbial products has been detected in tissues of rhesus macaques (which exhibit systemic immune activation and progress to disease following SIV infection), as compared to sooty mangabeys (which do not). Third, by several measures, gut epithelial barrier integrity is impaired in HIV-1 infection; these include loss of tight junction proteins, increased enterocyte apoptosis, increased plasma levels of intestinal fatty acid-binding protein (I-FABP), and increased villous atrophy. Taken together, these findings led to the hypothesis that impaired intestinal barrier function in HIV-1 infection contributes to increased translocation of commensal microbial products from the intestinal lumen into the circulation (Sandler and Douek 2012). These findings may lead to therapeutic interventions that can be used to complement HAART in HIV-1-infected individuals.

Cytotoxic T cells (CTL) in the GI tract (► [HIV & SIV, CD8 T Cell Responses](#) to). Several reports have addressed the nature of HIV-1-specific T-cell responses in the gastrointestinal tract during chronic infection, with most studies focusing on immune responses in sigmoid colon and/or rectal mucosa (Shacklett and Anton 2010). Generally, the breadth and specificity of CD8⁺ T-cell responses were demonstrated to be similar in gut mucosa and peripheral blood. In some studies, polyfunctional Gag-specific rectal CD8⁺ T-cell responses were positively associated with CD4⁺ T-cell count and inversely related to plasma viral load, suggesting a relationship between strong mucosal responses and immune control. In one such study, polyfunctional Gag-specific CD8⁺ T cells were significantly more abundant in rectal mucosa of “elite controllers,” rare

individuals able to contain HIV-1 viremia in the absence of antiretroviral therapy, than in “non-controllers,” individuals with viral load greater than 10,000 copies/mL of plasma. Similarly, gut CD4⁺ T-cell responses in elite controllers were unusually robust and polyfunctional. Not surprisingly, elite controllers showed relative preservation of gastrointestinal CD4⁺ T cells in contrast to typical progressors. MHC class I alleles HLA-B57 and B27 have been associated with HIV-1 control, and responses restricted by these alleles are also abundant in rectal mucosa of controllers. In individuals on HAART, gut HIV-1-specific CD4⁺ and CD8⁺ T-cell responses are generally weak to undetectable and tend to be monofunctional rather than polyfunctional (Shacklett and Anton 2010).

Gut B cells in HIV-1 infection (► [HIV & SIV, B Cell Responses](#) to). The effects of HIV-1 infection on antibody-producing cells in the gastrointestinal tract have not been extensively studied. As noted above, conflicting reports exist concerning the detection of HIV-1-specific IgA in mucosal secretions of HEPS individuals. However, in chronically infected individuals, HIV-1-specific IgA is typically absent or present at very low levels in mucosal secretions as well as in plasma, and this finding has been associated with reduced proportions of IgA-secreting plasma cells in the gastrointestinal lamina propria (Shacklett and Anton 2010). Several mechanisms have been proposed to account for this defect. These include impaired isotype switching in mucosal inductive sites, possibly related to HIV-1 Nef expression; impaired interactions with ► [T follicular helper cells](#); impaired IgA secretion by gut epithelial cells; or impaired homing of IgA-producing plasmablasts to the gastrointestinal lamina propria (Chaoul et al. 2012).

Mucosal B-cell impairment likely begins during the acute phase of HIV-1 infection. Acute infection induces polyclonal B-cell activation in both blood and gut, stimulating the production of antibodies specific for non-HIV-1 antigens as well as autoantigens. Acute HIV-1 infection also leads to a loss of germinal center architecture in Peyer’s patches, with an abundance of apoptotic T and B cells. Further studies are needed to address

the extent of mucosal B-cell impairment in HIV-1 disease and the mechanisms driving this impairment.

Gut immune reconstitution on HAART (► [Antiretroviral Medications, Adult Care and Treatment](#)). The GI tract is a major target for HIV-1 and SIV replication and CD4⁺ T-cell depletion. Although the extent of depletion can vary, studies in rhesus macaques have shown depletion of approximately 90% of gastrointestinal CD4⁺ T cells within the first weeks following infection [reviewed in (Shacklett and Anton 2010)]. Despite combination antiretroviral drug regimens that effectively reduce viral load to undetectable levels, reconstitution of CD4⁺ T cells in individuals on HAART is often incomplete. This may be due to a variety of factors, including patient compliance, drug pharmacokinetics and pharmacodynamics, persistent immune activation and disruption of lymphoid tissue architecture, and disruption of mucosal T-cell homing pathways.

A large number of cross-sectional and longitudinal studies have been performed to determine the extent and kinetics of mucosal CD4⁺ T-cell reconstitution in subjects on HAART (Costiniuk and Angel 2012). Early studies focused mainly on individuals with chronic and advanced infection, while more recent studies have tested whether more substantial T-cell recovery can be accomplished when HAART is initiated during acute or early infection. Outcomes have varied, with the extent of reconstitution varying from extremely low to virtually complete. For a detailed review of this topic, see Costiniuk and Angel (2012).

A consequence of increased immune activation in HIV-1 infection is the deposition of collagen fibrils in lymphoid nodes and the gastrointestinal tract (► [Collagen Deposition and Fibrosis](#)). Collagen deposition disrupts normal lymphoid tissue architecture and inhibits the cell-cell interactions that would normally drive the reconstitution process in patients on HAART. As compared to peripheral lymph nodes, CD4⁺ T-cell depletion in gut of individuals with chronic HIV-1 infection was found to correlate with the magnitude of collagen deposition. HAART did not completely restore gut CD4⁺ T cells, but treatment during early infection led to better restoration of CD4⁺

T cells with a central memory phenotype (Costiniuk and Angel 2012).

Mucosal homing may play an important role in gut CD4⁺ T-cell reconstitution during HAART. T cells primed in mucosal inductive sites, such as Peyer's patches and mesenteric lymph nodes, are programmed to express adhesion molecules and chemokine receptors that direct their eventual return to mucosal effector sites including the gut lamina propria. These molecules include integrin $\alpha\beta 7$, whose ligand is mucosal addressin cell adhesion molecule-1 (MAdCAM-1), and CCR9, a chemokine receptor whose ligand is thymus-expressed chemokine (TECK) or Ck β -15/CCL25. MAdCAM-1 is expressed on high endothelial venules in mucosal tissues, and CCL-25 is constitutively expressed in human small intestine but not in the colon. If expression of any of these molecules is perturbed, mucosal T-cell homing may be reduced (Costiniuk and Angel 2012).

Oral Mucosa and HIV-1 Transmission

Adults. Evidence from a variety of published studies suggests that the risk of HIV-1 transmission via oral-genital contact between adults is significantly lower than that associated with genital-genital or genital-anal sexual contact. Several factors likely contribute to the low risk of oral transmission. These include the structure of the buccal mucosa, which consists of a multilayered squamous epithelium containing relatively few CD4⁺ T cells, as well as the presence of numerous innate immune factors present in saliva that can inactivate the virus. HIV-1-specific antibodies are also detected in saliva. For a detailed review of this topic, see Campo et al. (2006).

Perinatal transmission (► [Mother to Child Transmission of HIV-1: Role of Receptor Usage and Target Cells](#)). Unfortunately, significant breast-feeding increases the risk of HIV-1 transmission from mother to child. Antiretroviral therapy administered to the mother around the time of delivery significantly decreases the likelihood of mother-to-child transmission, but does not provide protection from transmission via breast-feeding. The site of transmission in the infant is

believed to be the upper intestine, as infants have a neutral gastric pH. For a review of this topic, see John-Stewart et al. (2004).

HIV-1 Prevention and Mucosal Immunity

Vaccines to induce mucosal immunity (► [HIV-1 Transmission Blocking Vaccines; How Feasible Are They?](#)). Studies in the SIVmac model, cited above, suggest that induction of a high frequency of HIV-1-specific CD8⁺ T cells in mucosal tissues, translating to a high ratio of effector to target cells in vivo, could result in protection from mucosal exposure. Other studies have demonstrated that passive transfer of neutralizing antibodies, either via vaginal administration in a microbicide preparation or systemically via the bloodstream, can protect from intravaginal SIV challenge. However, with one exception, the human HIV-1 vaccine trials performed to date have failed to provide encouraging protection. Notably, in the Phase IIb STEP/Phambili trial (HVTN 502), a replication-defective adenovirus type 5 vector expressing HIV-1 Gag, Pol, and Nef genes failed to protect from infection or reduce viral loads in vaccinees that seroconverted. However, the recent RV144 trial, utilizing a prime-boost strategy involving a "prime" with canarypox vector expressing HIV-1 proteins followed by a boost with HIV-1 Env protein, provided 31% protection in a population of low-risk volunteers. The mechanisms of protection in this study are not fully understood, however, and mucosal immune responses were not measured. This trial nevertheless provided much-needed encouragement to the HIV prevention field (Bass 2013).

To date, two vaccine approaches have provided significant protection from pathogenic challenge in rhesus macaques: a live-attenuated virus derived from SIVmac with a deletion in Nef and a vaccine vector derived from rhesus cytomegalovirus (CMV) engineered to express SIV proteins (Picker et al. 2012). Both systems appear to induce widespread cell-mediated immune responses in tissues, including mucosal sites. Impressively, the CMV-based vaccine was shown to result in clearance of virus from 50% to 70% of challenged animals (Picker et al. 2012).

Microbicides (► **HIV-1 Transmission Blocking Microbicides**). To date, clinical microbicide trials have also met with mixed success. The CAPRISA 004 study, a Phase IIb trial performed in South Africa, found that vaginal application of a gel containing 1% tenofovir (an inhibitor of HIV-1 reverse transcriptase) was associated with a 39% reduction in HIV-1 acquisition risk overall and a 54% reduction in risk among highly adherent users when applied within 12 h before and 12 h after sex. In contrast, the VOICE study, which tested daily vaginal application of 1% tenofovir gel, was prematurely halted due to futility. Poor adherence in the VOICE study has been cited as a likely explanation for the outcome (Bass 2013). Many additional trials are underway, and new microbicide compounds, formulations, and delivery systems are under development for use in both women and men (Bass 2013).

Conclusions

As an infectious agent spread primarily through sexual contact, HIV-1 is a mucosal pathogen, and the study of HIV disease has provided clinicians and researchers with renewed awareness of the central importance of mucosal immunity in host defense. Although promising advances have been made toward an HIV “cure,” this goal remains elusive for the vast majority of HIV-1-infected individuals worldwide. Given this, intensive efforts are currently directed toward preventing transmission and providing treatment to those already infected. The next phase of “research for prevention” must continue to build knowledge in the field of mucosal immunology and apply the insights gained toward the development of more effective vaccines, microbicides, and antiretroviral drugs.

Definition

Mucosal pathogenesis is central to HIV infection and encompasses all the events triggered by HIV infection at the mucosal sites. The major virus targets are memory CD4⁺ T cells, which are

mainly presented at the mucosal sites. Thus, mucosal sites are the main sites of virus replication and CD4⁺ T cell depletion, with the majority of memory CD4⁺ T cells being whipped out from the mucosal sites in just 3 weeks from infection. This major immunological insult is further fueled by increased mucosal inflammation which results in breaches of the mucosal barrier, the translocation of intestinal microbes and microbial products from the intestinal lumen to the gut submucosa and then into the general circulation leading to chronic mucosal and systemic inflammation and immune activation that further fuel viral replication, mucosal damage, microbe release and ultimately result in HIV disease progression. As such, virus-host interactions should be targeted mostly at the mucosal sites in order to counteract the deleterious consequences of HIV infection.

Overview

Simian immunodeficiency virus (SIV) effects on the gastrointestinal tract are at the core of AIDS pathogenesis (Veazey et al. 2001; Dandekar 2007). The virus infects and kills activated memory and effector CD4⁺ T cells expressing the viral co-receptor CCR5, which are the major CD4⁺ T cell subset in the lamina propria of the gut and at the mucosal sites in general (Veazey et al. 2001). CD4⁺ T cell depletion in the gastrointestinal tract is therefore a hallmark of SIV infection. Similar to HIV-1 infection, in SIV-infected non-human primates, CD4⁺ T cell depletion occurs early, is substantial, and, if persisting through the chronic stage, is predictive for the clinical outcome of SIV infection. Mucosal CD4⁺ T cell depletion is also associated with chronic local immune activation and inflammation that trigger mucosal lesions and enteropathy. These processes damage the mucosal barrier and lead to leakage of the gut microflora into the general circulation, termed “microbial translocation.” This microbial translocation is a major cause of systemic immune activation and inflammation, which are key drivers of non-AIDS comorbidities, accelerated aging, and SIV disease progression. As such, gut dysfunction is a cornerstone feature of

HIV/SIV infection in driving disease progression (Brenchley et al. 2006).

Use of nonhuman primate models was critical for establishing this new paradigm in which the impact of HIV infection on the mucosa is a core determinant of HIV infection outcome (Dandekar 2007). The reports on the massive rapid depletion of the CD4⁺ T cells at the mucosal sites in nonhuman primates preceded the first observations in humans by a decade. Detailed comparative studies facilitated by invasive sampling at key time points of infection in multiple animal models with different outcomes of SIV infection (Fig. 1) permitted this major paradigm shift in AIDS pathogenesis. Furthermore, current studies in nonhuman primate models are instrumental for developing new therapeutic strategies aimed at limiting mucosal pathology, controlling microbial translocation and immune activation, and improving the overall prognosis of HIV infection.

Mucosal CD4⁺ T Cell Depletion During SIV Infection: Characteristics and Significance

Initial studies of the pathogenic SIV infection in macaques showed that massive depletion of mucosal CD4⁺ T cells occurred immediately after the peak of viral replication, with the majority of the mucosal CD4⁺ T cells being killed at mucosal sites in less than 3 weeks from the time of infection (Fig. 1a). These observations generated tremendous enthusiasm in the field and focused the research on understanding the events occurring during the first 3 weeks of infection.

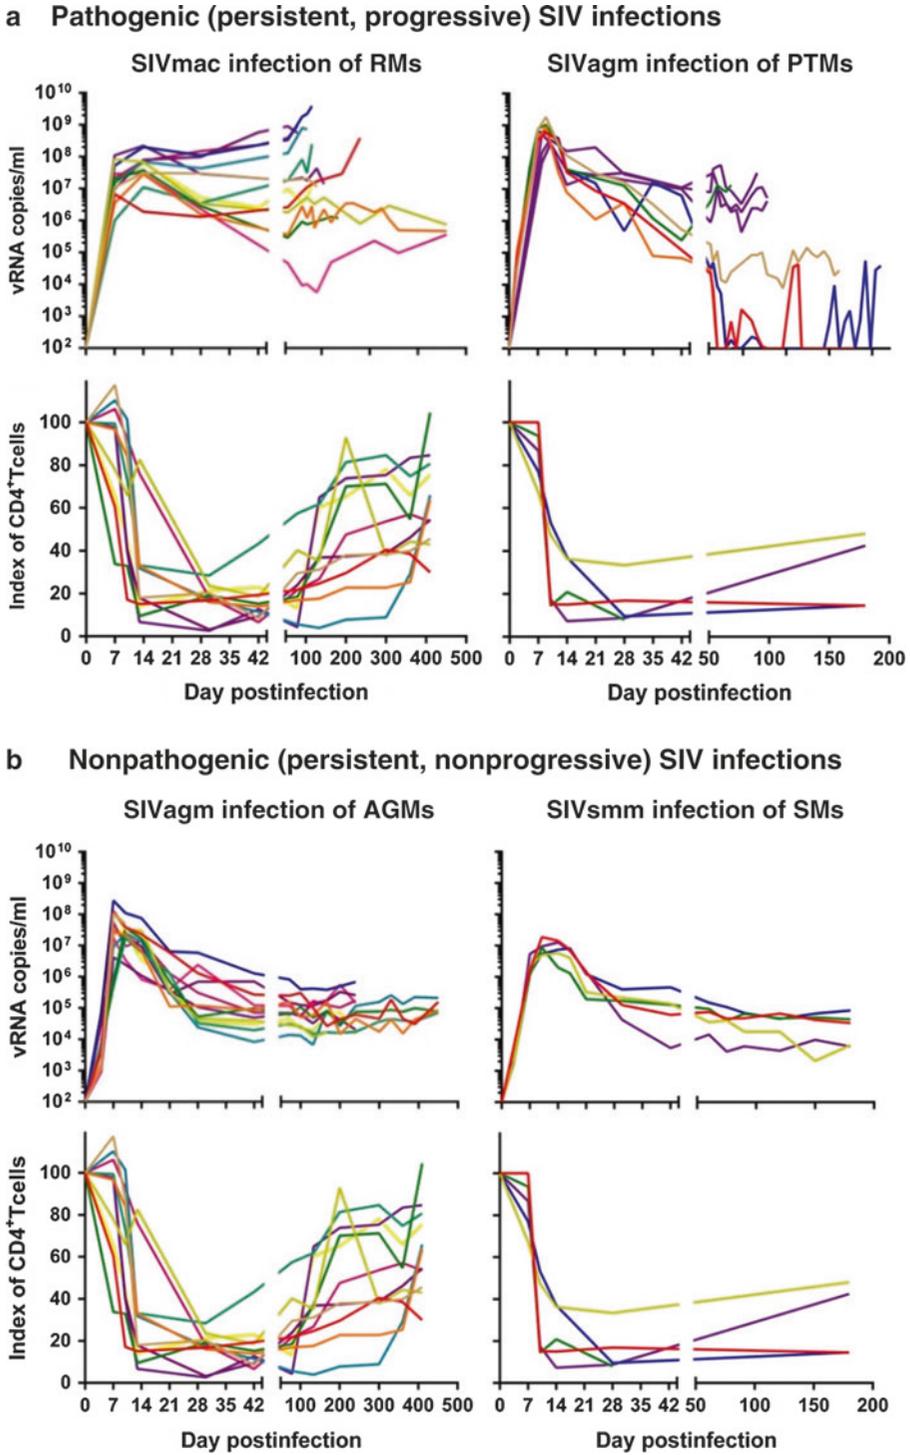

A more detailed understanding of mucosal HIV pathogenesis (Pandrea and Apetrei 2010; Grossman et al. 2006) was achieved with the inclusion in the overall picture of SIV pathogenesis of other nonhuman primate models with different outcomes of SIV infection. Comparative studies in various nonhuman primate hosts infected with an array of SIV strains, such as progressive SIV infections of rhesus macaques and pig-tailed macaques (Fig. 1a), persistent nonprogressive infections of the African nonhuman primates that are natural hosts of SIV (such as

African green monkeys and sooty mangabeys) (Fig. 1b), and spontaneously controlled SIV infections (such as the SIV_{agm} infection of rhesus macaques) (Fig. 1c), showed that massive CD4⁺ T cell depletion occurs in every pathogenic scenario, and therefore, acute mucosal CD4⁺ T cell depletion is not predictive for the virulence of SIV infection (Fig. 1). Instead, mucosal CD4 depletion that persists in chronic infection is predictive of disease progression and development of simian AIDS.

The initial mucosal CD4⁺ T cell depletions associated with SIV infection are (i) rapid (occurring within the first 3 weeks of infection); (ii) profound (impacting over 95% of the total population of mucosal CD4⁺ T cells and virtually the totality of SIV target cells, i.e., memory cells expressing the CCR5 co-receptor); (iii) exceeding the proportion of SIV-infected cells (thus suggesting that the mechanism of depletion is not only through direct effect of the virus, i.e., pyroptosis, but probably through additional mechanisms, such as bystander apoptosis); and (iv) persisting throughout the initial stages of chronic infection, irrespective of the virological and clinical outcome. As such, while the circulating CD4⁺ T cells are rapidly restored to near preinfection levels with the transition to chronic infection, the restoration of the CD4⁺ T cells at the mucosal sites is virtually nonexistent during the first months of chronic infection (Pandrea and Apetrei 2010; Okoye and Picker 2013).

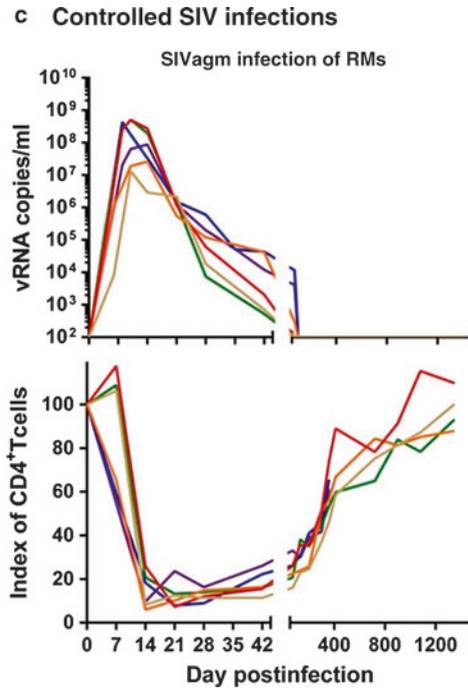

This disproportionate impact of the virus on the CD4⁺ T cells from the lamina propria of the gastrointestinal tract compared to those in circulation or in the lymph nodes supports the concept that the gastrointestinal tract is the primary site of virus replication and CD4⁺ T cell infection. Indeed, high levels of viral replication were documented in the gastrointestinal tract of acutely SIV-infected RMs, suggesting that a significant proportion of the mucosal CD4⁺ T cells are directly depleted by the virus.

Comparative studies between different animal models of pathogenic, nonpathogenic, and controlled infection also permitted identification of additional characteristics of CD4⁺ T cell depletion

M

Mucosal Pathogenesis in SIV Infection, Fig. 1 (continued)

Mucosal Pathogenesis in SIV Infection, Fig. 1 Comparative dynamics of viral loads and mucosal CD4⁺ T cell depletion in (a) pathogenic, (b) nonpathogenic, and (c) controlled infections. Plasma viral loads (measured in viral RNA copies/ml) are depicted in parallel to the CD4⁺ T cell counts in the duodenal biopsies (expressed as an index of CD4⁺ T cells, i.e., changes from the preinfection levels). (a) Pathogenic models are represented here by the highly pathogenic SIVmac infection of rhesus macaques (RMs) and the SIVagm infection of pig-tailed macaques (PTMs), which has variable pathogenicity upon direct cross species

transmission but uniformly high pathogenicity upon serial passage (serially passed infections being depicted in violet). (b) Nonpathogenic models are represented by natural infections in African nonhuman primates, illustrated here by SIVagm infection in African green monkeys (AGMs) and SIVsmm infection of sooty mangabeys (SMs). (c) Controlled infections are represented here by macaque infection with cross species-transmitted SIVagm (that naturally infects AGMs). The X axis illustrates the duration of infection, while the Y axis illustrates the levels of viral loads or the levels of CD4⁺ T cell depletion at the mucosal sites

that are actually predictive for the outcome of SIV infection: (i) Depletion is correlated with the levels of acute viral replication, being minimal in animals in which the peak of viral load is below 10^6 viral RNA copies/ml of plasma. (ii) Restoration of mucosal CD4⁺ T cells is incomplete and tardive in progressive disease models. During the early stages of chronic pathogenic SIV infections, there is a relatively modest recovery of up to 10–25% of the preinfection levels, similar to HIV-1-infected patients (Fig. 1a). (iii) The degree of chronic restoration and preservation directly correlates with the levels of viral set point and the outcome of infection in pathogenic hosts (Fig. 1a, PTMs), with the best predictor of a better

clinical outcome being the restoration of memory CD4⁺ T cells (Grossman et al. 2006). In rapid progressor macaques, in which there is virtually no viral control, there is no recovery of CD4⁺ T cells at the mucosal sites (Fig. 1a).

Differently from pathogenic infections, in natural hosts there is a partial restoration of mucosal CD4⁺ T cells to up to 50–70% of the baseline levels during the chronic SIV infection (Fig. 1b) (Sodora et al. 2009). This restoration occurs independently of viral loads, in the context of the complete control of chronic inflammation and immune activation which is pathognomonic to nonpathogenic infections. This partial recovery of mucosal CD4⁺ T cells is not immediate, being

observed only after a few months of chronic infection (Fig. 1b).

Finally, spontaneously controlled SIV infections (that are equivalent to human elite controllers) associate a robust restoration of mucosal CD4⁺ T cells, with the caveat that complete restoration can only be observed years after viral replication, and residual immune activation and inflammation are completely controlled, a period which is necessary to enable healing of the mucosal lesions inflicted during the replicative stage of SIV infection (Fig. 1c).

In conclusion, mucosal depletion of CD4⁺ T cells occurs rapidly, is massive, and is a common feature of pathogenic, nonpathogenic, and controlled SIV infection. Therefore, acute mucosal CD4⁺ T cell depletion is likely not predictive for the outcome of SIV infection. Conversely, CD4⁺ T cell restoration during chronic infection is highly indicative of favorable clinical outcome. Restoration is slow and incomplete and depends on both the levels of viral replication and the amount of immune activation and inflammation. A partial CD4⁺ T cell restoration is possible even if viremia is not completely controlled, allowing survival and lack of disease progression in non-human primates that control immune activation and inflammation to preinfection levels. However, CD4⁺ T cell recovery may be complete only in the animals that control both viral replication and immune activation, but restoration of CD4⁺ T cells at the mucosal sites is a very long process.

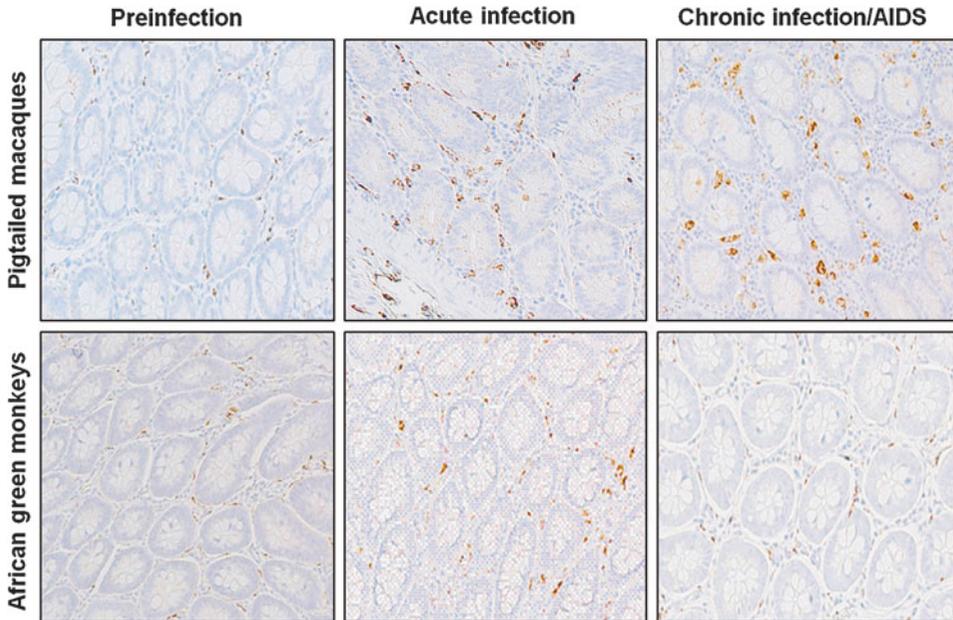

Immune Alterations in the Mucosal Tract During SIV Infection of Nonhuman Primates

The very active interactions between the virus and its target cells at mucosal sites trigger key pathogenic features of chronic SIV/HIV infection leading to disease progression.

Mucosal CD4⁺ T cell depletion involves all T cell subpopulations, yet there are subsets that appear to be particularly impacted by SIV infection (Okoye and Picker 2013). First, CD4⁺ T cells that express the CCR5 chemokine receptor are preferentially depleted. This is not surprising, as

CCR5 is the major co-receptor for both HIV and SIV. With the majority of the CD4⁺ T cells at the mucosal sites expressing CCR5 and CCR5-expressing CD4⁺ T cells having a memory phenotype, this explains the major impact of HIV/SIV on the mucosal memory CD4⁺ T cells. Memory cells being the preferential targets of HIV infection, depletion is more prominent at the effector sites, such as the lamina propria, while CD4⁺ T cells from the inductive sites (i.e., the Peyer patches) are less impacted by HIV infection (Veazey et al. 2001).

With regard to CD4⁺ T cell functionality, CD4 cells capable of producing IL-17 (Th17 cells), which are the cell subsets responsible for maintaining mucosal integrity, also appear to be preferential targets for infection (Hartigan-O'Connor et al. 2011; Paiardini et al. 2008). Therefore, most of the pathological features associated with CD4⁺ T cell depletion in the gut are related to the preferential loss of Th17 cells, which have a critical contribution to the immune dysfunction observed during pathogenic SIV infection: (i) Loss of Th17 cells results in a reduced production of IL-17 and IL-22, two cytokines that induce granulocyte colony-stimulating factors, which promote the recruitment of myeloid cells and neutrophils at the mucosal effector sites. (ii) Th17 cells are involved in the maintenance of mucosal integrity through induction of claudins, defensins, and mucins, which are components of the mucosal junctions and have antimicrobial activities, and as such, loss of Th17 has a direct impact on mucosal integrity. (iii) IL-22 produced by Th17 cells is involved in the division of epithelial cells. (iv) Low levels of Th17 cells are associated with increased expression by antigen-presenting cells of indoleamine-2,3-dioxygenase (IDO), an enzyme that is involved in the metabolization of tryptophan, and IDO metabolites directly inhibit Th17 cell differentiation (Brenchley and Douek 2008a). Increased levels of IDO are associated with decreased frequencies of CD103 antigen-presenting cells, which can induce Th17 cells. Altogether these features, which are specifically associated with pathogenic SIV infection and absent during the SIV infection of natural NHP hosts (in which Th17 cells are preserved), point to

Mucosal Pathogenesis in SIV Infection, Fig. 2 Changes in the mucosal macrophages in SIV_{sub}-infected African green monkeys versus pig-tailed macaques. Immunohistochemical staining of the CD68 cells from the mucosal sites demonstrate that macrophages accumulate in the lamina propria during the

acute stage of both progressive and nonprogressive SIV infections of macaques and African green monkeys, respectively. However, during the late stages of infection, the innate cells remain increased at mucosal sites only in the progressive infections of the macaques

a vicious circle that prevents maintenance of the Th17 population leading to the occurrence and enhancement of mucosal damage during the pathogenic SIV infection.

The impact of HIV/SIV infection on the innate immune cell populations at the mucosal sites is currently a subject of intense research. Progressive SIV infections are characterized by a reduction of both plasmacytoid dendritic cells (pDCs) and myeloid dendritic cells (mDCs) in both the peripheral blood and spleen and their homing to the gut. At the mucosal sites, both pDCs and mDCs were shown to release large amounts of proinflammatory cytokines, which are not produced by these cells in a normal mucosal environment. Due to their excessive immune activation, mDCs experience high rates of mortality. The same high rate of apoptosis and an altered functional profile are observed for the NKp44⁺ natural killer (NK) cells residing in the gut, an important innate effector population. As such, while the recruitment of innate immune cells to the gut

mucosa could facilitate virus control, the overproduction of cytokines and the high rate of mortality of these cells (which also triggers release of more inflammatory cytokines by surrounding cells) further enhance mucosal immune activation and inflammation. Interestingly, the recruitment of mDCs and macrophages to the mucosal sites also occurs during the nonprogressive SIV infections of the natural hosts or controller rhesus macaques (Fig. 2). This process is, however, only transient, is not associated with excessive production of inflammatory cytokines, and does not result in the death of these cells, strongly suggesting that the fate of the immune cell subsets and their functions in the gut is driven by the local environment. As such, the current view is that, being programmed to fight against the infections, the innate cells migrate to the gut in progressive, as well as in nonprogressive and controlled SIV infections. Yet, the innate cells become hyperactivated only in the pathogenic infections, due to their mucosal environment, which is altered by

both the virus and the translocated microbial products, and thus further fuel the inflammation, deepen the damage of the mucosal barrier, and contribute to the negative outcome of HIV/SIV infection.

Structural Alterations of the Gastrointestinal Tract Associated with SIV Infection

The SIV-associated immunological alterations at the mucosal sites result in structural and functional pathologies of the gastrointestinal tract. Virus replication, inflammation, and immune activation together with bystander apoptosis of the epithelial cells throughout the GI tract result in enterocyte loss and alterations of mucosal integrity (Brenchley and Douek 2008b).

There are multiple mechanisms of the enterocyte loss observed during HIV/SIV infections:

- (i) The virus itself can decrease glucose uptake by enterocytes through a Tat-mediated microtubule disruption;
- (ii) increased apoptosis of enterocytes through bystander effects, similar to other colitis (i.e., celiac disease).
- (iii) Increased production of proinflammatory cytokines, such as tumor necrosis factor (TNF) at the mucosal sites, is associated with increased apoptosis of the epithelial cells and perturbations of the tight epithelial barrier.

TNF-mediated enterocyte destruction was also reported to occur in subjects with inflammatory bowel disease. The increased inflammation and immune activation characteristic to chronic SIV infection are associated with enterocyte loss.

Enterocyte loss and subsequent intestinal alterations are associated with (i) low levels of serum citrulline (most of which is being produced by enterocytes); (ii) decreased ratio of the villous height/crypt depth (demonstrating atrophy); (iii) increased stem cell proliferation in the crypt (associated with malabsorption); (iv) increased

levels of intestinal fatty acid-binding protein (I-FABP), indicating enterocyte damage; and (v) abnormal enterocyte differentiation due to an impaired sodium glucose cotransport and to increased concentrations of intraepithelial calcium (Hartigan-O'Connor et al. 2011; Sandler and Douek 2012).

The massive destruction of the epithelial cells and decreased expression of the epithelial tight junction repair genes further result in focal breaches of the gastrointestinal epithelium. Alterations of the epithelial tight junctions are evidenced by discontinuous staining of the tight junction proteins in chronic SIV-infected rhesus macaques. These alterations in the tight junctions occur as early as 14 days post-infection, are the primary mechanism of the increased permeability of the epithelial barrier, and are clinically expressed as colitis, diarrhea, and malabsorption.

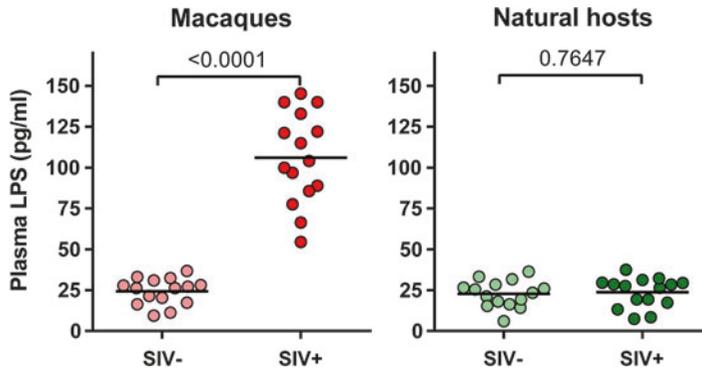

Villous atrophy and crypt hyperplasia were also reported in SIV-infected macaques and are associated with decreased levels of plasmacytes producing immunoglobulin A (IgA) leading to bacterial overgrowth.

These pathologies are specifically associated with pathogenic SIV infections in macaques and absent during SIV infections in African non-human primate hosts.

Microbial Translocation and Its Key Role in the Pathogenesis of AIDS

One of the most important consequences of the gut damage caused by loss of enterocytes and disruption of the tight junctions between the cells is the loss of barrier function of the gut and translocation of microorganisms from the intestinal lumen to the general circulation. This phenomenon is not specific to SIV/HIV infection, occurring in multiple clinical conditions in which mucosal epithelium is altered and gut permeability is increased (Brenchley and Douek 2012).

Microbial translocation is a key determinant of systemic chronic immune activation and inflammation, which are the most important drivers of SIV disease progression. The intestinal flora is large (approximately 10^{14} bacteria) and diverse,

Mucosal Pathogenesis in SIV Infection, Fig. 3 Comparative levels of microbial translocation in pathogenic and nonpathogenic SIV infections. (a) In rhesus macaques, the levels of microbial translocation significantly increase upon SIV infection as a result of the mucosal damage and are associated with persistent high

levels of systemic immune activation and inflammation. (b) In African green monkeys, the levels of microbial translocation are virtually unchanged upon SIV infection as a result of the maintenance of a healthy mucosal barrier. In these species, chronic immune activation and inflammation are controlled

and translocated microbial products include peptidoglycan, lipoteichoic acid, lipopolysaccharide (LPS), flagellin, ribosomal DNA (rDNA), and unmethylated CpG-containing DNA. These translocated microorganisms/products are bioactive, and they can induce potent proinflammatory responses through activation of a plethora of receptors [i.e., nucleotide-binding oligomerization domain 1 (NOD1) and NOD2, toll-like receptor 2 (TLR2), TLR4, TLR5, TLR6, and TLR9], which are expressed by multiple cell types, including innate immune cells (Sandler and Douek 2012). Therefore, microbial translocation can induce chronic activation of both adaptive and innate arms of the immune system and initiate a signaling cascade, leading to increased production of proinflammatory cytokines IL-1 β , IL-6, TNF, and interferons (Sandler and Douek 2012).

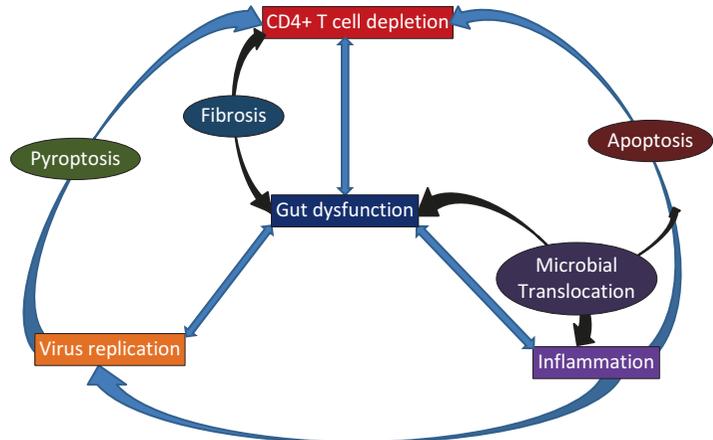

Microbial translocation is specifically associated with pathogenic SIV infection being nearly absent in African nonhuman primates that are natural hosts of SIV (Pandrea and Apetrei 2010) (Fig. 3), and studies in nonhuman primates have established a direct link between microbial translocation and chronic immune activation (Fig. 4). Chronically SIV-infected AGMs that do not progress to AIDS maintain a healthy mucosal barrier and lack evidence of microbial translocation, chronic immune activation, and systemic inflammation. However, intravenous administration of

LPS, either in single dose or in prolonged administration over a 3-week duration, resulted in increased levels of immune activation, inflammation, and coagulation markers. Similarly, alcohol or dextran sulfate administration to AGMs increased gut permeability, induced microbial translocation, and resulted in increased levels of immune activation and viral replication. Conversely, direct blockade of microbial translocation with sevelamer, a chelator of LPS in the gut, resulted in a significant reduction of systemic immune activation, inflammation, and coagulation markers. Altogether, these studies bring direct proof for the role of microbial translocation as a key determinant of immune activation and associated pathologies, such as non-AIDS comorbidities, in SIV infection (Fig. 4) (Deeks et al. 2013; Pandrea et al. 2015).

Due to the key role of microbial translocation in the pathogenesis of HIV/SIV infection, studies have also focused on characterization of the impact of infection on the gut microbiome. These studies failed to identify any significant alteration in the gastrointestinal bacteriome during the progressive SIV infection of macaques. These results are in disagreement with studies in humans reporting that dysbiosis, i.e., an altered balance in the composition of commensal microflora in the gut, is frequently observed in HIV-infected patients and is linked to immune

Mucosal Pathogenesis in SIV Infection,

Fig. 4 The vicious circle of gut dysfunction and its role in the pathogenesis of AIDS

activation. The significance of these differences between HIV-infected humans and SIV-infected macaques is not yet completely understood. Note, however, that the animal model allows for well-controlled sampling, at key time points of infection collected longitudinally, and in a context of a similar lifestyle and diet, with less impact from behavioral factors. These factors may significantly influence the way HIV and SIV infections alter the intestinal bacteriome and its role in driving the outcome of infection.

Gut viruses may also play a role in SIV-associated mucosal pathogenesis. A significant increase in the size of the fecal virome was reported to occur in the progressive SIV infection macaques, while no such change was detected in the non-progressive SIV infection of AGMs. Furthermore, potentially pathogenic viruses, such as adenoviruses, are specifically co-localized with the areas of structural damage of the gastrointestinal tract in progressively SIV-infected macaques.

Therapeutic Approaches Aimed at Limiting the Impact of Gut Dysfunction on the Outcome of HIV Infection

Administration of antiretroviral therapy (ART) dramatically improved the outcome of HIV infection and is one of the most effective medical achievements of modern medicine. In nonhuman primates, administration of ART has also been documented to improve the outcome of SIV

infection. However, the overall impact of ART on the chronic mucosal damage in HIV-infected humans is relatively limited, and resolving residual immune activation and inflammation in patients on ART is a major priority of current research. It is generally acknowledged that other therapies, in addition to ART, are needed to control mucosal damage and its consequences on the pathogenesis of AIDS.

There are multiple therapeutic options to limit the impact of gut pathology on the outcome of SIV/HIV infection (Pandrea and Landay 2012). Most of these approaches target microbial translocation. In addition to treatment with sevelamer, administration of prebiotics and probiotics to SIV-infected macaques increased frequency and functionality of antigen-presenting cells in the gut, enhanced reconstitution and functionality of CD4⁺ T cells, and reduced fibrosis of lymphoid follicles in the colon, suggesting that supplementing the intestinal flora may contribute to intestinal healing. Treatment of SIV-infected rhesus macaques with IL-21 resulted in preservation of intestinal Th17 cells and reduced microbial translocation. Administration of a combination of the antibiotic rifaximin and the anti-inflammatory agent sulfasalazine to acutely infected macaques resulted in a transient reduction in the plasma levels of sCD14, proinflammatory cytokines, and T cell activation and slightly ameliorated the CD4⁺ T cell decline. Further, monoclonal antibodies directed against the proinflammatory cytokines induced by NF- κ B activation may attenuate

immune activation. As an example, administration of an anti-TNF monoclonal antibody ameliorated some of the consequences of inflammation in SIV-infected macaques. Yet, as shown by recent studies of interferon and anti-interferon administration, blocking or boosting the cytokine responses is difficult and may lead to deleterious results. While none of the therapeutic interventions aimed at targeting the causes of chronic immune activation in chronically SIV-infected macaques completely reversed the pathological features triggered by SIV infection, the composite results of these studies show that targeting mucosal pathology has a real potential to improve the outcome of HIV infection and warrants additional studies.

Conclusion

Mucosal immune dysfunction is a key feature of the pathogenesis of SIV/HIV infection, being at the core of the vicious circle triggered by viral replication and followed by depletion of memory CD4⁺ T cells, mucosal inflammation, endothelial breaches, microbial translocation to general circulation and consequent chronic systemic inflammation and immune activation. In the current paradigm of HIV pathogenesis, each element of this vicious circle boosts the others, ultimately resulting in HIV disease progression. Strategies aimed at controlling progression of HIV infection should include interventions aimed at maintaining mucosal integrity and disrupting the vicious circle of AIDS pathogenesis.

Definition

Multicentric Castleman disease is a systemic disorder of lymph nodes characterized by inflammatory symptoms including fever, night sweats, cachexia, malaise, and lymphadenopathy together with laboratory abnormalities including anemia and hypoalbuminemia. Together these symptoms may be life threatening. The diagnosis is based on specific pathological findings in affected lymph nodes. In individuals infected with HIV, multicentric Castleman disease is almost exclusively caused by infection with a cancer-causing herpesvirus, Kaposi sarcoma-associated herpesvirus (KSHV, also known as human herpesvirus 8). This may be considered a separate entity from the non-KSHV-related or idiopathic form of multicentric Castleman disease and from unicentric forms of Castleman disease. While these disorders have pathological and clinical similarities, the KSHV-related form is distinguished by its pathological characteristics and unique viral etiology.

Introduction

One of the earliest signs of the AIDS epidemic in the early 1980s was the recognition of an

increased occurrence of certain unusual tumors in the particular risk groups who also developed opportunistic infections. Tumors of lymphoid tissue were prominent among these, as was an unusual skin tumor called Kaposi sarcoma (KS). Along with common lymphoid cancers (lymphomas), by the 1990s, it was recognized that a hitherto uncommon lymphoid tumor called multicentric Castleman disease (MCD) was occurring at increased rates in people with HIV/AIDS. Following the discovery that a novel human herpesvirus, Kaposi sarcoma-associated herpesvirus (KSHV, also known as human herpesvirus 8), was the causative agent of KS (Chang et al. 1994), it was soon appreciated that both a rare lymphoma and primary effusion lymphoma (PEL) and almost all cases of multicentric Castleman disease in people with HIV/AIDS were also caused by KSHV (Soulier et al. 1995).

Rather than being a true clonal malignancy or cancer, MCD is best considered a hyperproliferative state affecting mainly the lymph nodes and spleen. Its clinical features are those of uncontrolled systemic inflammation and lymphoid proliferation, especially fever, night sweats, cachexia, malaise, and lymphadenopathy. These occur together with laboratory abnormalities including anemia and hypoalbuminemia that are themselves at least in part consequences of systemic inflammation. In some cases, true clonal lymphomas may arise within lymph nodes affected by KSHV-MCD or in association with it (Oksenhendler et al. 1996). Until recently, outcomes for patients affected by this disorder were dismal. The time to survival from diagnosis of KSHV-MCD was usually only 1–2 years, as patients succumbed to the severe inflammatory symptoms or to secondary lymphomas. However, with the transformation of care of the underlying HIV/AIDS and an appreciation of the viral etiology and pathogenic mechanisms of KSHV-MCD, new therapeutic modalities are being developed that appear to be both improving short-term outcomes and reducing the long-term sequelae of KSHV-MCD, including secondary lymphomas.

Clinical and Pathological Features of Multicentric Castleman Disease and Related Diseases: Historical Perspective and Current Understanding

Benjamin Castleman's name has been applied to a group of related but distinct disorders since his seminal description in 1954 of what is now known as unicentric Castleman disease, hyaline vascular variant (Waterston and Bower 2004). This initial description was of patients with a single (unicentric) slowly enlarging mass in the anterior chest (mediastinum), which on pathological examination demonstrated an unusual pattern of atrophy (technically involution) of the central portion of the lymph node follicles. This portion, called the germinal center, was instead replaced by protein material ("hyalinized") and an increase in local blood vessels. The cause of this disorder was, and remains, unknown. Patients rarely had systemic symptoms and responded to local approaches, specifically surgical resection or irradiation of the affected node.

Soon after this initial description, a group of patients with similar unicentric lymph node masses but distinct histopathological features was recognized. In these cases, the germinal center was less prominently abnormal. Rather, the affected nodes were characterized by sheets of mature lymphocytes (plasma cells) replacing the normal architecture of the node follicle and interfollicular spaces. Vascularity was again increased, and in some cases the germinal center was involuted or reduced in cell number. In some cases, these findings occurred in solitary sites away from the mediastinum. These patients were in most cases asymptomatic, but a proportion did exhibit systemic inflammatory symptoms (including fever, cachexia, sweats, and malaise) or hematologic cytopenias (anemia or thrombocytopenia). This disorder was named the plasma cell variant of Castleman disease.

Following this, it was further recognized that in a proportion of patients with Castleman disease – predominantly but not exclusively those with systemic inflammatory symptoms or cytopenias – more than one lymph node or group of nodes was affected by the same pathological process. Most,

but not all, multicentric cases had the histopathological features of the plasma cell variant. Thus the description of multicentric Castleman disease introduced an essentially clinical distinction, the presence of unicentric versus multicentric disease, to what had formerly been a histopathological classification and in doing so combined the two different pathological types (hyaline and plasma cell) under this new umbrella.

The etiology of these intriguing disorders remained elusive. In some cases, the nodal changes appeared to be secondary to an additional pathological process. Commonly this included lymphomas or certain slow-growing infections (including mycobacterial infection) occurring elsewhere, presumably giving rise to Castleman disease as a consequence of lymphoid growth factors being present in abnormal excess. In the 1970s and 1980s, a group of small molecules, now called cytokines, were discovered and found to act on lymphocytes to modulate their growth and inflammatory responses. It soon became evident that one such cytokine, interleukin 6 (IL-6), was responsible for many of the pathological and clinical findings of multicentric Castleman disease, as well as contributing to the clinical features of those with symptomatic unicentric disease (Yoshizaki et al. 1989). Notwithstanding the discovery of IL-6, the underlying cause of the IL-6 excess remains unexplained in most cases. Nonetheless, the development of inhibitors of IL-6 (antibodies to the molecule itself, or to prevent the molecule acting at its specific receptor) has led to the use of these agents as a therapeutic modality in patients with symptomatic idiopathic Castleman disease.

A further critical step in unraveling the etiology of many cases of MCD came with the discovery of KSHV. Because of its unusual epidemiology, including its tendency to occur in only some of the behavioral risk groups affected by HIV/AIDS, KS had long been suspected to be caused by an infectious agent. However, the agent remained a mystery until Chang and Moore identified novel herpes viral sequences in KS tissue (Chang et al. 1994). This virus was subsequently found in the affected lymph nodes in most cases of MCD in patients with HIV/AIDS and also in a minority of cases of MCD occurring

in persons without HIV. Further evidence for the role of KSHV in the etiology of these cases of MCD emerged with the recognition that symptomatic flares in these patients were associated with high levels of KSHV in the peripheral blood and pathological evidence of KSHV infection in the involved lymph nodes. Furthermore, these viral levels improved with treatment or disease remission (Oksenhendler et al. 2000).

Clinically, these KSHV-associated cases of MCD resembled their non-KSHV-associated counterpart. The disease course is characterized by intermittent flares of inflammatory symptoms as described above, together with widespread and often marked lymphadenopathy and prominent splenomegaly. Nonspecific gastrointestinal and respiratory symptoms are common, as are neurological symptoms including cognitive dysfunction and personality changes. Flares are often severe and can be fatal. Common laboratory abnormalities include anemia, thrombocytopenia, low serum albumin levels, low serum sodium, and elevated blood inflammatory markers such as C-reactive protein (CRP). The clinical course waxes and wanes, but until recently has generally been fatal within 2 years of diagnosis, with patients succumbing to the severe inflammatory syndrome and concurrent infections or progressing to lymphoma. The differential diagnosis of fever and adenopathy in the HIV-infected individuals is broad. As a result, KSHV-MCD may be difficult to diagnose and is often missed. Clinicians should be alert to the possibility of KSHV-MCD in patients with unexplained inflammatory symptoms and laboratory abnormalities resembling those described, and consider biopsy with adequate material (a substantial core or ideally excision of affected nodes) to establish the diagnosis.

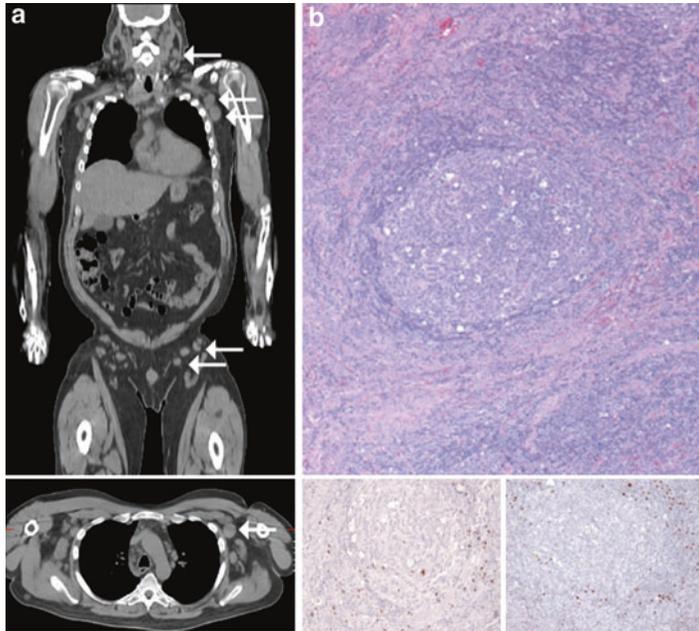

The pathology of KSHV-MCD bears substantial resemblance to idiopathic MCD. In affected nodes, the mantle zone and interfollicular zone are largely replaced by a plasma cell infiltrate forming characteristic concentric sheets (so-called onion skinning, named for the resemblance to the layered skins of the onion). These are polyclonal, but are usually restricted in secreting the lambda light chain and immunoglobulin M (IgM). There

are also increased numbers of blood vessels between follicles. However, unlike idiopathic MCD, a minority of cells in the affected node can be shown to be infected by KSHV using immunohistochemical stains for viral proteins. These occur predominantly toward the periphery of the follicle (Fig. 1). Furthermore, a proportion of these KSHV-infected cells are seen to express certain KSHV lytic proteins, suggesting the virus in its lytic (replicative) phase.

It can therefore be seen that the historical progression of the recognition of these disorders has led to the current nomenclature. This unfortunately commonly gives rise to confusion, combining as it does local and systemic diseases whose etiology, pathological and clinical characteristics, optimal therapy, and prognosis are each distinct. A summary of these different types is given in Table 1. It could be argued that, with the recognition of KSHV as the cause of a distinct group of cases of MCD, KSHV-associated MCD is best considered a separate disorder from the idiopathic variants (be it unicentric or multicentric), albeit sharing certain histopathological features. As the overwhelming percentage of cases of MCD in patients with HIV/AIDS are KSHV associated, the remainder of the chapter focuses on KSHV-MCD.

Pathogenesis of Multicentric Castleman Disease in HIV-Infected Patients: Role of Kaposi Sarcoma-Associated Herpesvirus and Immune Deficiency

The discovery of KSHV and its role as the cause of KS and MCD was pivotal in developing an understanding of these disorders and of the crucial role that HIV infection plays in promoting the pathogenesis of KSHV-MCD. KSHV is a herpesvirus, most closely related to Epstein-Barr virus (the cause of infectious mononucleosis). All herpesviruses including KSHV have in common a complex life cycle with two distinct phases. The first of these phases is *latency*, in which a minimal set of viral genes is expressed, many of which are directed at the twin goals of promoting survival of the host cell (and so the virus itself) by modulating

Multicentric Castleman Disease, Fig. 1 Radiological and pathological findings in KSHV-associated MCD. Radiographic findings in a patient with KSHV-associated multicentric Castleman disease and HIV (panel **a** upper and lower rows) demonstrate key features of the disease through structural and functional imaging. In the upper row, whole torso coronal images obtained by computed tomography show widespread lymphadenopathy (*white arrows*) involving the cervical, axillary, and inguinal regions together with mild hepatomegaly. This patient was previously splenectomized so the spleen is not seen, but it is commonly markedly enlarged. In the lower row, sagittal images at the level of the axilla show the axillary nodal abnormalities in detail. Pathological sections (panel **b**) stained with hematoxylin and eosin show characteristic

changes including the plasma cell infiltrate in distinct sheets and an increase in vascularity. The lower panels show KSHV-infected cells by immunohistochemistry: lower left demonstrates all KSHV-infected cells (using an antibody to a viral latent protein, LANA), and lower right shows those KSHV-infected cells in lytic phase and producing vIL-6 (using an antibody to vIL-6). Original magnification of all pathology sections was 20 \times (The authors gratefully acknowledge Dr. Stefania Pittaluga, Laboratory of Pathology, National Cancer Institute, for assistance with histopathological images, and Dr. Corina Millo, Positron Emission Tomography Department, Clinical Center, National Institutes of Health, for assistance with radiographic images)

cellular survival pathways and of impeding the normal host immune response to the virally infected cell. The second, or *lytic*, phase is characterized by viral replication and expression of the full complement of proteins encoded by the virus's own genome. The host cell's machinery is commandeered in the service of viral replication, being turned over to produce progeny virus particles that in turn infect other cells or are transmitted to other hosts. Importantly, all current antiviral therapies affect only replicating virus. No strategy has been effective in disrupting latent herpesvirus infection, and infection once established is lifelong.

Like other herpesviruses, KSHV modulates host pathways to facilitate its survival and replication. It does this in part by producing its own variations of certain critical host proteins, using genes acquired from the host by "molecular piracy" during the course of the virus's evolution. Notable among these is a viral version (homologue) of the aforementioned human cytokine IL-6, called viral interleukin 6 (vIL-6). In addition, KSHV directly affects the production of human IL-6 by several other mechanisms. The relationship of KSHV and its human host in normal circumstances is a delicate balance reflecting millennia of coevolution. Prior to the HIV epidemic, most individuals

Multicentric Castleman Disease, Table 1 Clinical and pathological characteristics of various forms of Castleman disease

	Unicentric		Multicentric	
	Hyaline vascular variant	Plasma cell variant ^a	Idiopathic	KSHV associated
Pathological characteristics	Involved node shows germinal center involution: lymphocytes are depleted and replaced (hyalinized). Between follicles, fibrosis and increased blood vessels are seen. Plasma cells are not a feature	Germinal centers usually uninvolved or paucicellular, while the adjacent mantle zone is replaced by plasma cell infiltrate in concentric sheets. These extend between follicles with increased blood vessels	Affected nodes almost always resemble those of unicentric plasma cell variant, but are multiple. In rare cases multiple nodes showing hyaline vascular change are seen instead	Mantle zone and interfollicular zone replaced by plasma cell infiltrate in concentric sheets. Increased vessels between follicles. A minority of cells are KSHV infected, some in “lytic” phase
Location	Single lymph node or local chain, commonly mediastinal, may be very enlarged	Single lymph node or local chain, commonly abdominal	Multiple nodes throughout body. Spleen may be enlarged	Multiple nodes throughout body, particularly above diaphragm. Spleen commonly enlarged
Clinical setting	Highly variable in age presentation, but commonly early adulthood. Occurs in both genders	Highly variable in age presentation, but commonly in early adulthood. Occurs in both genders	Highly variable in age presentation. Occurs in both genders	Most common in HIV infection, including well-controlled disease
Etiology	Unknown, may be reactive	Unknown, may be reactive. A proportion of cases appear to be reactive to intercurrent lymphoma	Unknown, may be reactive. A proportion of cases appear to be reactive to intercurrent lymphoma. Most manifestations relate to increase in interleukin 6 levels	KSHV/HHV8 infection, usually in the setting of immune dysregulation (HIV infection) Manifestations relate to increase in viral and human interleukin 6 and other cytokines
Clinical symptoms	Symptoms uncommon	Fevers, cachexia, night sweats, malaise occur in some cases	Fevers, cachexia, night sweats, malaise occur in almost all cases	Fevers, cachexia, night sweats, malaise. Nonspecific respiratory and gastrointestinal symptoms may also be seen
Laboratory features	May not have any abnormalities	Hematologic cytopenias (most commonly anemia, thrombocytopenia) and low albumin levels in a minority of cases	Hematologic cytopenias (most commonly anemia, thrombocytopenia) and low albumin levels with elevated C-reactive protein	Hematologic cytopenias (most commonly anemia) and low albumin levels with elevated C-reactive protein
Treatment	Local therapy, most commonly surgical resection; radiation has been used in cases not amenable to surgery	Less well defined than for hyaline vascular variant, but usually similar: Local therapy, most commonly surgical resection; radiation has been used in cases not amenable to surgery. Treatment of any precipitant	Systemic therapy, commonly directed at IL-6 inhibition. Chemotherapy may also be used Treatment of any precipitant	Systemic therapy, commonly directed at B-lymphocyte depletion by the monoclonal antibody, rituximab alone or in combination with chemotherapy KSHV-directed therapies effective in some cases
Outcomes	Generally excellent	Generally excellent	Variable but improving with IL-6-directed therapies	Formerly very poor but improving with current regimens. May progress to large cell lymphoma

^aPlasmacytic and plasmablastic variants are distinguished by some pathologists

infected with KSHV showed no clinical symptoms of infection and those that did occur (almost exclusively KS) were mainly in older individuals, presumably as a result of a diminution of the host immune response with advancing age. The introduction into the human species of HIV fundamentally disrupted this relationship, as HIV infects and destroys CD4⁺ T lymphocytes and so impairs the critical role of the host immune system in detecting and controlling KSHV-infected cells and replication. Thus, there is substantially less control of KSHV, leading to increased viral replication and the development of KSHV-associated tumors. Even when treated with antiretroviral therapies and achieving a normal CD4⁺ T cell count, HIV-infected patients continue to exhibit defects in their immune response that permit the development of KSHV-associated tumors, especially KSHV-MCD. Tumor development may be further enhanced by the presence of HIV-associated inflammation and perhaps by direct interactions between HIV and KSHV at the cellular level.

In KSHV-MCD, it appears that the crucial elements leading to the development of the tumor are dysregulation of viral replication and proliferation of KSHV-infected B lymphocytes, with consequent marked elevations of human and viral cytokines. In particular, levels of both viral and human IL-6 are elevated during KSHV-MCD flares, as are KSHV viral loads (at least in part as a result of replication) and several other host cytokines including IL-10 (Aoki et al. 2001). In addition, as noted above, affected lymph nodes show virus in its lytic (replicative) state in a substantial proportion of virally infected cells. Notably, it has been shown that detectable KSHV replication in peripheral blood commonly precedes the development of symptoms in patients later found to have KSHV-MCD.

Interestingly, KSHV-MCD develops most commonly in patients with relatively well-controlled HIV (CD4⁺ T-lymphocyte count above 200 cells/mm³). There is also some evidence that its incidence has increased in recent years, following the widespread adoption in the developed world of highly active antiretroviral therapy for HIV (Powles et al. 2009). Taken together, these observations suggest that the

development of the full clinicopathological syndrome of KSHV-MCD requires a level of preservation of the host immune infrastructure and mechanisms that is absent in patients with the more profound immunodeficiency of uncontrolled AIDS. It is also possible that its development requires longer survival with HIV than was seen early in the epidemic.

It should also be noted that similar inflammatory symptoms to those seen in KSHV-MCD have recently been described in KSHV-infected patients *without* pathological evidence of KSHV-MCD (Uldrick et al. 2010). These patients presented with a constellation of fevers, cachexia, and laboratory abnormalities including cytopenias, hypoalbuminemia, and elevated CRP. However, lymphadenopathy and splenomegaly were not prominent, and the pathognomonic nodal changes of KSHV-MCD were not demonstrable, in some cases even with repeated lymph node biopsies. Patients showed evidence of KSHV replication and disturbances of human and viral IL-6 similar to those seen in KSHV-MCD flares. Many of these patients had other KSHV-associated diseases (KS or PEL), suggesting that these tumors might contribute to or be the major source of the inflammatory abnormalities. This putative syndrome has provisionally been named the KSHV inflammatory cytokine syndrome (KICS) and a working case definition has been proposed (Polizzotto et al. 2012). Its pathophysiology, clinical outcomes, and relationship to KSHV-MCD are now being defined prospectively.

Treatment of KSHV-Associated Multicentric Castleman Disease in HIV-Infected Patients

Partly as a result of its recent recognition as a disease entity, rarity, and consequent difficulty in establishing high-quality clinical studies, there is no standard therapy for KSHV-MCD. This difficulty is further compounded by the complexity of clinical studies in patients who have both HIV and an associated tumor or malignancy, where both life-threatening diseases must be successfully managed. Therefore the majority of articles

describing the therapy of KSHV-MCD have consisted of either retrospective case reports or series or small prospective studies without control arms. Nonetheless, the evolving understanding of the unique aspects of the viral etiology of KSHV-MCD has suggested several novel approaches to therapy, and there is now emerging evidence that these therapies are having a positive impact on patients with KSHV-MCD, improving their symptom control and, importantly, long-term survival when compared to historical controls.

Early treatment strategies for KSHV-MCD reflected its unusual position at the interface of infectious diseases and clonal lymphoid malignancies. The first therapies studied generally approached the disease from one of these perspectives. One approach adapted a commonly used antiviral agent with known activity against herpesviruses, ganciclovir (Casper et al. 2004). As noted above, this agent is activated by phosphorylation by KSHV and then acts on the replicating virus, becoming incorporated by the viral DNA replication enzyme (DNA polymerase) into the DNA chain and arresting further replication by preventing the addition of additional nucleotides to the chain. It can thus reduce the cell-to-cell spread of KSHV. In parallel, other investigators used single chemotherapy agents or combination chemotherapy regimens adapted from successful lymphoma strategies, particularly CHOP (doxorubicin, vincristine, cyclophosphamide, and prednisolone). In both approaches, patients were usually started on antiretroviral therapy to control the associated HIV infection. Each of these approaches showed modest activity in KSHV-MCD but overall outcomes remained suboptimal.

More recently, the development of a humanized monoclonal antibody directed at the CD20 antigen on B lymphocytes has opened a new approach to KSHV-MCD therapy. As noted above, many of the cytokine-producing cells in lymph nodes affected by KSHV-MCD express CD20. CD20-positive lymphocytes are also a major reservoir of KSHV infection in the infected host, potentially providing an ongoing source of replicating virus to perpetuate the disease state. Several groups have now reported good results

with rituximab therapy of KSHV-MCD (alone or following chemotherapy) in patients with KSHV-MCD, including patients who had previously failed other approaches, as measured by the resolution of symptoms, viral replication, and cytokine abnormalities (Bower et al. 2007). On the basis of these initial results and more recently reported long-term outcomes, rituximab has become probably the most commonly used initial therapy for symptomatic KSHV-MCD. Rituximab therapy of KSHV-MCD is associated with the development or progression of KS in a substantial minority of cases, and some approaches therefore use it in combination with chemotherapy agents that have some activity against KS spindle cells, including the liposome-encapsulated formulation of doxorubicin. It may also be that some patients, perhaps those with the most KSHV-MCD, would benefit from a therapeutic approach that combines rituximab with cytotoxic chemotherapy agents directed at B cells. The question of when, how, and for whom to add chemotherapy to a rituximab therapy “backbone” will be a critical issue in KSHV-MCD investigation in the coming years.

An additional novel approach is targeted at KSHV, exploiting the virus’s own enzymatic machinery to deliver a toxin specifically to KSHV-infected cells in which lytic replication is occurring (as it is in KSHV-infected plasmablasts in nodes affected by KSHV-MCD). This approach, called “virus activated cytotoxic therapy,” uses the combination of two agents, high-dose zidovudine (or AZT) and valganciclovir. Each of these is commonly used as a conventional antiviral drug, acting as described above as a chain terminator (zidovudine in the HIV reverse transcriptase and valganciclovir in the herpes DNA polymerase). However, in this approach they function differently. Rather than interrupting DNA replication, each is activated through phosphorylation by two KSHV-encoded enzymes to moieties that are toxic to the infected cells. These enzymes are expressed by KSHV only in its lytic phase, and therefore this approach provides a method to selectively target and kill only those cells which are central to the pathogenesis of KSHV-MCD. This approach has been shown to

be moderately effective in patients with symptomatic KSHV-MCD, again as measured by the resolution of symptoms, viral replication, and cytokine abnormalities (Uldrick et al. 2011). This combination may also have a role in combination with other approaches or in “maintenance” or “consolidation” therapy for patients who have completed therapy with other agents.

Further targets for the therapy of KSHV-MCD are suggested by the critical role of human and viral IL-6 in its pathogenesis and symptomatology. Inhibitors of human IL-6 may not affect KSHV vIL-6, which has little antigenic similarity with hIL-6 and may also signal differently. However, while there has been little economic incentive to develop inhibitors of vIL-6 specifically, as noted above two monoclonal antibodies inhibiting IL-6 activity have been developed (one directed at the molecule itself, the other at its receptor). One, tocilizumab, has been approved by the US Food and Drug Administration and is now in clinical use in several rheumatologic diseases. While rituximab was recently approved for idiopathic castleman’s disease. Alone or in combination with other drugs, these may in the future provide add to the armamentarium against KSHV-MCD.

Prevention of KSHV-Associated Multicentric Castleman Disease and Related Lymphomas in HIV-Infected Patients

The role of the oncogenic virus KSHV in the pathogenesis of KSHV-MCD and other tumors raises the possibility that preventive strategies directed at the virus, over and above the management of immune deficiency through control of the HIV infection, may be of benefit in preventing the development of these tumors. There are currently no vaccines against KSHV, and as our understanding of its transmission remains incomplete, even behavioral risk modification strategies are limited. However, there is at least proof in principle that KSHV-related disorders can be prevented with antiviral agents: ganciclovir, when used for cytomegalovirus retinitis, was incidentally found to

reduce the risk of KS. This observation, together with the fact noted above that asymptomatic KSHV replication commonly precedes the onset of symptomatic KSHV-MCD, suggests that carefully targeted preventive antiviral strategies may be of use in the future. A better understanding of the precipitants of KSHV lytic replication is likely to be a crucial step in this direction.

On a related front, significant progress has been shown in preventing the most feared complication of KSHV-MCD through effective therapy. As noted above, as many as 20% of patients with KSHV-MCD previously progressed to large cell lymphoma. In the majority of lymphomas arising in this setting, the malignant cells show evidence of KSHV infection with plasmacytic features and immunoglobulin expression that distinguish them as the cells of primary effusion lymphoma, the other lymphoma established to be caused by KSHV. Rarely, large cell lymphomas not associated with KSHV are also seen. The lymphomas in the setting of KSHV-MCD carried a poor prognosis and were one of the most common causes of death. Recent studies of patients treated with rituximab, with or without chemotherapy, have shown evidence of reductions in lymphoma incidence as well as good control of the symptoms of KSHV-MCD (Gérard 2012). It remains unclear if this is a specific outcome of CD20⁺ B-lymphocyte depletion by rituximab (since the most common lymphomas arising in KSHV-MCD are B-cell lymphomas) or a general consequence of the reduction of the local and systemic inflammatory milieu with treatment. Further studies to extend this seminal observation will be crucial.

KSHV-Associated Multicentric Castleman Disease in Resource-Limited Countries

As has been discussed elsewhere, the co-occurrence particularly in parts of sub-Saharan Africa of high endemic rates of oncogenic virus infection (including KSHV) and an epidemic of HIV infection (until recently uncontrolled) has led to very high rates of virally associated malignancies. For example, in sub-Saharan Africa KS is

among the most common cancers. Intriguingly though, until recently cases of KSHV-MCD have only rarely been reported from this region. This is particularly notable as KSHV-MCD is reported in immigrants from these regions in the United States and Europe.

There are a number of possible explanations for this apparent discrepancy. Until the widespread rollout of antiretroviral therapy in Africa through the Joint United Nations Programme on HIV/AIDS (UNAIDS) and the US President's Emergency Plan for AIDS Relief (PEPFAR), most HIV in this region was untreated. It may therefore be that many patients succumbed to other sequelae of profound immunodeficiency before the development of KSHV-MCD. Furthermore, as noted above KSHV-MCD commonly occurs in patients with at least relatively well-controlled HIV, and it may be that at least some level of immune competence is required for the full clinicopathological syndrome to manifest. Perhaps the most important contribution to the paucity of reported KSHV-MCD in this region is that the relatively undeveloped and under-resourced state of clinical and pathological services in this region has hampered the recognition of this complex diagnosis. KSHV-MCD clinically may be mistaken for uncontrolled mycobacterial infection, lymphoma, or other chronic infective and inflammatory processes. Given the magnitude of the burden of tuberculosis in Africa, empiric anti-mycobacterial therapy of suspected lymphadenopathic tuberculosis is relatively common throughout this region. Even in cases where lymph node sampling is performed, limited tissue sampling and in some instances inadequate resources to complete a comprehensive pathological assessment likely contribute to missed diagnoses. The very high untreated mortality of KSHV-MCD and the emergence of relatively low-cost therapies that are potentially deliverable in resource-limited settings (such as ganciclovir with or without high-dose zidovudine) suggest that improved surveillance for and recognition of KSHV-MCD has the potential to deliver important health benefits for people with HIV/AIDS in resource-limited settings (Gopal et al. 2012).

Conclusion

The advent of the AIDS epidemic has brought new prominence to this hitherto uncommon lymphoproliferative disorder and further led indirectly to the discovery of a new oncogenic virus, KSHV, and the recognition that MCD caused by KSHV is a distinct entity with unique pathophysiology and therefore additional specific therapeutic targets. Building on this knowledge, new therapies have greatly improved outcomes for patients with HIV and KSHV-MCD, including important improvements in long-term survival and reduction in the risk of lymphomas. There is the prospect of continued improvements as new agents become available. The challenges of preventing this disease in those most susceptible, and of bringing these improvements in outcomes to the resource-limited settings most affected by HIV/AIDS, continue to occupy researchers and clinicians.

Multilevel Interventions/Structural Approaches to HIV Prevention

Crystal Fuller Lewis¹ and Natalie D. Crawford²

¹Division of Social Solutions and Services Research, Nathan Kline Institute for Psychiatric Research, New York State Office of Mental Health, NY, USA

²Behavioral Sciences and Health Education, Rollins School of Public Health, Emory University, Atlanta, GA, USA

Definition

Multilevel interventions/structural approaches to HIV prevention include structural prevention strategies that, by definition, target the economic,

social, contextual, policy, or organizational levels or factors that have increased risk of or protected against HIV. Multilevel interventions or approaches include strategies that target both individual and structural levels.

Introduction

Structural interventions, including those that either directly target or explicitly incorporate structural factors, are gaining support in both research and practice. HIV-related structural factors are defined as barriers to, or facilitators of, individual HIV prevention behavior that function on an economic, social, contextual, policy, or organizational level (Sumartojo 2000). Further expanding on the structural environment, the United States (US) Centers for Disease Control and Prevention (CDC) suggests a framework of structural factors including economic resources, policy, societal attitudes, and organizational structures and functions associated with governments, service organizations, businesses, workforce organizations, faith communities, justice systems, media organizations, educational systems, and healthcare systems (Sumartojo 2000). The importance of structural factors when considering HIV risk and transmission is based on the premise that behavior is shaped by more distal features of the environment, and failure to carefully consider these features will result in only partial realization of positive health behavior change. In this entry, key examples of prominent US interventions that operate solely at the structural level and/or exist at an individual level but heavily and/or directly impacted by structural factors will be discussed. Relevant HIV-related policy, as well as socio-contextual factors of relevant communities, including high-risk groups, and the neighborhoods within which they live will be emphasized. Finally, multilevel interventions will also be discussed, including intervention approaches that target individual-level factors and at least one macro-level feature. For the purposes of this entry, the macro-level features of multilevel interventions discussed in this entry will be of a structural nature.

Policy Impact on HIV Prevention

Policy can directly impact individual behavior, including health behaviors that increase risk or protect against acquisition of HIV. In the USA, public health policies that have influenced HIV prevention include condom distribution, sterile syringe access, routine HIV testing services, and HIV partner notification. Either led by the federal, state, or local government, policies enacted to help prevent the spread of HIV have shaped the HIV epidemic by creating social norms that have influenced individual risk and protective behaviors.

Condom Distribution

The absence of an HIV vaccine coupled with persistent sexual risk behavior provides more than adequate support for the promotion of condom use as the leading HIV prevention message. Since the start of the HIV epidemic, with little exception over the past three decades of this disease, federal, state, and local health agencies have actively promoted and financially supported condom use through large-scale condom distribution programs for those at risk for HIV (Abstinence, Be Faithful, Condoms (ABC), Prevention of HIV). Promoting condom use through individual-, group-, and community-level interventions has demonstrated positive intervention effects. Interventions that have specifically incorporated features beyond individual-level factors have had a greater impact on condom use (Charania et al. 2011), while HIV intervention strategies exclusively targeting individual behaviors have often failed to demonstrate impact (Wohlfeiler and Ellen 2008). Condom use strategies that consider structural concepts of availability, accessibility, and acceptability are what researchers and public health practitioners consider as an example of a structural intervention approach to promoting condom use. For example, in addition to conveying the importance of using condoms, a structural approach may also provide free condoms in places where high-risk groups frequent (e.g., drug treatment facilities, STI clinics, brothels, etc.) that is financially supported by local government (e.g., city or state health

departments). These activities clearly address challenges to access and availability; however, such structural approaches are unlikely to influence acceptability. Attempts to change social norms by making condom use more normative have been the most common approach for condom acceptability, which has been done through the use of public service announcements, large-scale media, and social network marketing campaigns (Alstead et al. 1999). A recent meta-analysis of 21 US and international studies provides strong evidence of not only the critical importance of structural approaches to increasing condom use and distribution but also the importance of multilevel approaches that target both individual and structural factors which has provided evidence of even greater impact (Charania et al. 2011).

Syringe Access Programs

In the USA, injection drug use has been a driving force of the HIV epidemic since the mid-1980s. At the start of the epidemic, close to half of all new infections were among injection drug users (IDUs) in northeastern cities. The geographic distribution of HIV has closely followed the heroin and cocaine epidemics across the USA, with northeastern cities representing the heaviest drug markets (Department of Health and Human Development 2000) (Substance Use). Two potential structural approaches to preventing HIV among IDUs would be to decrease availability of illicit drugs (e.g., heroin and cocaine) and decreasing demand (e.g., drug treatment). Neither has been successful as exemplified by the failure of the “War on Drugs” campaign (Fields 2009) and the limited, individually targeted treatment modalities which are tainted with high rates of relapse which is particularly problematic among African Americans, who carry the highest risk and burden of HIV and AIDS in the USA. Thus, for those who are unable to stop injecting, the use of sterile hypodermic needle and syringes (“syringes” hereafter) for each injection has been recommended by public health professionals and researchers, since the use of non-sterile syringes was largely responsible for HIV transmission among IDUs at the height of the

epidemic. However, given the illegality of injection drug use, simply providing public health messages emphasizing the importance of using a sterile syringe for each and every injection was ineffective given the extremely limited access and availability of sterile syringes for the purposes of injecting illegal drugs. In response, the USA established its first syringe exchange program (SEP) in Tacoma, Washington, in 1988, which allowed for the legal exchange of used syringes for sterile syringes. Other SEPs were subsequently established in Portland, San Francisco and New York City. However, because of political and economic constraints, success varied. New York City, for example, had one of the highest rates of HIV in the country, but struggled to establish an exchange large enough to meet the needs of the IDUs population. Since 1988 and in the absence of federal government funding, local and private funding supported many SEPs across the country in urban centers of high heroin and cocaine markets. By 1995, access to SEP services had been positively associated with several outcomes including reduced drug use, decreased incidence and prevalence of HIV and other blood-borne infections, improved access to HIV prevention programs, decreased rates of criminal activity, decreased needle sharing and other high-risk injection drug use behaviors, and improved entry and retention in drug treatment programs. These outcomes have been directly linked to subsequent structural changes in service delivery by coupling SEPs with (1) health education; (2) alcohol swabs to prevent abscesses and other bacterial infections; (3) condoms to further prevent the transmission of HIV and other sexually transmitted infections (STIs); (4) on-site medical services including counseling and screening for tuberculosis, hepatitis B, hepatitis C, HIV, and other infections; and (5) referrals to substance abuse treatment and other medical and social services. These additional services continue to be important, as many IDUs have difficulty accessing public health and medical services for fear of being mistreated in the healthcare system because of their drug use (Miller et al. 2001).

While SEPs (Needle Exchange) have been instrumental in reducing HIV transmission

among IDUs (Injection Drug Users), laws and regulations preventing legal possession of syringes for the purposes of injecting illegal drugs has prevented SEPs from reaching their full potential as an HIV prevention strategy. Furthermore, police harassment at SEP sites has been directly associated with decreased use of SEPs (Bluthenthal et al. 1997). Even where SEPs are legal, the criminalization of syringe possession creates a conflict between public health recommendations and law enforcement practices.

A growing number of states permit IDUs to access syringes through pharmacies without requiring a prescription. Structurally, pharmacies provide direct access to syringes, are already established in high-risk communities, have longer and more convenient hours of operation than SEPs, can potentially provide greater anonymity for syringe customers, and may attract those uncomfortable with SEPs or who require syringes outside the hours of SEP operation. Twelve states (Connecticut, Hawaii, Maine, Minnesota, New Hampshire, New Mexico, New York, Oregon, Rhode Island, Washington, Wisconsin, and California) have implemented legislation to permit pharmacy sales of syringes without a prescription (Pouget et al. 2005), plus New Jersey where an SEP pilot program (New Jersey Department of Health 2012) has been recently instituted.

Evaluations of pharmacy syringe access from the New York State's Expanded Syringe Access Program (NYS-ESAP) have provided evidence of impact on decreased syringe sharing (Pouget et al. 2005), ability to reach non-SEP participants (Fuller et al. 2002), lack of increase in needlestick injuries, lack of increase in criminal activity or drug abuse (Vlahov et al. 2003), and increased positive attitudes toward drug users and pharmacy syringe sales specifically for the purposes of preventing HIV among pharmacists (Crawford et al. 2013). Similar to SEPs, tensions between public health recommendations and law enforcement overshadow nonprescription syringe sales in pharmacies due to the criminalization of syringe possession.

Routine HIV Testing

Providing free HIV testing in venues outside of hospital settings and in a confidential and/or

anonymous manner greatly increases both access and availability and, to a lesser extent, acceptability in situations of anonymous testing. Along with the “use condoms” HIV prevention message, “get an HIV test” has risen as an equally critical prevention message particularly since early detection is critical to treatment and prevention. Until recently, HIV testing has only been routinely recommended for those at high risk for HIV (e.g., men who have same sex partners, IDUs, and the sexual partners of these subgroups). But, in 2006, the Centers for Disease Control and Prevention (CDC) recommended routine HIV testing for all Americans 13–64 years of age. The CDC definition of routine testing is that all patients in all types of healthcare facilities be told that HIV testing is a routine part of care and they will be tested unless they decline. Aside from “how” and “where” HIV testing is offered, implementation of routine HIV testing tackles several social, contextual, and structural factors. First, routinely testing everyone essentially removes the responsibility of deciding to get tested from the individual who must perceive themselves to be at risk as a first step in HIV testing decision process (Mimiaga et al. 2007). Second, offering HIV testing to everyone and presenting it as routine without prior discussion of risk behaviors may have potential to ease HIV testing-associated stigma. Third, there is evidence that patients are more likely to agree to HIV testing when it is suggested by a physician (Mimiaga et al. 2007). And fourth, routine testing does not require written informed consent or pretest counseling in an effort to decrease the time involved in providing HIV testing which, in turn, may increase the likelihood of physicians implementing this new recommendation; physicians may not feel comfortable discussing risk behaviors, and eliminating pretest counseling reduces such instances (Freedberg and Samet 1999). As expected, many public health practitioners have not supported removal of written informed consent and pretest counseling, arguing that consent and counseling are essential for educating individuals about risks and also better prepare individuals psychosocially in the event of a HIV-positive result. Furthermore, the CDC recommendation for routine testing is unable to

reconcile individual state laws and regulations requiring informed consent and information related to the pretest counseling session.

While routine HIV testing may overcome many individual and structural barriers to HIV testing, the impact of this structural approach is unknown, likely due to conflicting state policies. Many states have attempted to apply this recommendation in some form or fashion. For example, one hospital emergency department (ED) offered HIV testing to all ED patients and offered HIV informational literature, posted HIV testing posters, and obtained consent (Informed Consent) using a special script with the express goal of reducing the need for questions when interacting with clinical providers (Wolf et al. 2007). In another instance, an adolescent clinic provided physicians with a pocket guide in addition to patient brochures, HIV testing posters, and reduced pretest counseling time to support and increase routine testing in this clinic (Branson et al. 2006). While such modified approaches have not been formally evaluated, attention to reducing time necessary to spend with patients and clinician preparation and education might be structural features to address when attempting to implement a successful routine HIV testing program. For example, the ease and efficiency with which physicians discuss risks related to diabetes, heart disease, or other chronic disease illnesses requiring routine screening should occur similarly with HIV which can further normalize HIV for both patients and providers.

Partner Notification

Since the beginning of the epidemic, partner notification has been recommended as an intervention strategy to help prevent HIV transmission and connect newly identified HIV-positive individuals to care. Also known as contact tracing, partner notification is the process of informing individuals of their potential exposure to an infectious disease (in this case, HIV) and offering HIV testing, counseling, and treatment. The CDC has released recommendations for how to provide partner notification services, also known as “partner counseling and referral services” (PCRS), which can also be applied to the private sector

and nonprofit service organizations where new HIV diagnoses occur (Partner Notification). From a structural perspective, the manner in which partner notification occurs and the level of funding for these services (which is largely dependent upon laws and legislation surrounding the level of obligation to notify partners) is directly related to the success of the program's goals.

Acknowledging the varying state-mandated laws surrounding partner notification, CDC recommends three strategies for notifying partners of HIV-positive individuals: (1) provider referral, (2) patient or client referral, and (3) contract referral. In the case of provider referral, the clinical provider or the health department official obtains partner contact information, locates the partner, informs the partner of potential exposure without disclosing the identity of the HIV patient or client, and provides the partner with a referral to counseling, testing, and support services. In this case, the burden of responsibility is on the provider or health department official. A second strategy involves the burden of responsibility residing with the HIV-positive client or patient known as patient or client referral. Here, the patient is entirely responsible for contacting their partners and referring them to testing. In contract referral, the HIV-positive individual is granted several days to notify their partners, and if these identified partners have not come into the health department for counseling and testing at the end of the 3-day period, the health department initiates contact. A variation to this approach is dual referral, wherein partner notification is a collaborative effort – the HIV-positive client or patient and the provider work together to locate partners and inform partners together. Individual states either require the permission of the HIV-positive individual to contact their partners or not, which is known as “the duty to warn.” The duty to warn is based on the premise that while the confidentiality for HIV-positive individuals is required for autonomy, the protection of third parties who are at heightened risk for serious, potentially lethal harm must be given priority. It is important to note that while all states attempt to maintain confidentiality when notifying third-party individuals, it is not entirely possible to do so in all

situations. For example, some third parties may have had only one partner and would therefore be able to deduce the identity of the HIV-positive individual. Known as the *Tarasoff* doctrine (Partner Notification), duty to warn began to gain support, while the public health and medical communities remained at odds beginning in the early 1990s for a myriad of reasons related to confidentiality and fear that such a policy could cause more harm than good (Bayer and Toomey 1992). For example, could this policy undermine trust between providers and patients, limiting the capacity of providers to encourage their patients to test for HIV, reduce risk and transmission, or volunteer partner information? Regardless of state-specific “duty to warn” policies, the Federal Ryan White CARE Reauthorization Act requires that all health departments receiving Ryan White funds show a “good faith” effort to notify partners of HIV-positive individuals and the overwhelming majority of US states receive these funds.

The structure of partner notification services will likely impact their success. While some clinicians may wish to take on the responsibility of informing partners, one study indicated greater success among health department specialists compared with clinicians, likely due to insufficient time and training among clinicians to effectively locate and properly inform partners (Giesecke et al. 1991). Additionally, health department officials may be more effective than HIV-positive individuals when notifying partners (Landis et al. 1992). A 2009 report using data from Chicago and Los Angeles found that 75% of participants who identified one or more locatable partners used client referral to notify partners. However, many HIV-positive study participants reported not discussing partner notification with their HIV testing counselors (48.8%) and/or medical care providers (33.7%) and were not offered health department partner notification services by their HIV counselors (60.8%) or medical providers (52.8%) (Mackellar et al. 2009). A San Francisco study suggested that once an HIV-positive individual was referred to partner notification services, a vast majority were interviewed (80%) and most partners of the

HIV-positive individuals were located and interviewed (12% not located and 8% refused to talk with health department official) (Ahrens et al. 2007). Regardless of the level of use, partner notification exists in every jurisdiction with varying levels of resources to locate, inform, and test partners. Issues of confidentiality, lack of trust, lack of location information for some short-term partners, and discomfort in disclosing (Mackellar et al. 2009) may limit use of partner notification services. Thus, structurally targeting social normative attitudes toward HIV is critical for greater impact of partner notification services.

Community and Neighborhood Structural Features that Impact HIV Prevention

Governmental policies must function within previously established community and neighborhood structures which can result in differential impact of HIV-related policies and/or policy-related interventions by community. Here, “neighborhood” is defined in terms of geographic location with formal (e.g., zip code or census tract) or informal physical boundaries, as opposed to “community,” which is defined as a specified group delineated by social boundaries (e.g., race/ethnicity, culture, sexual identity, religion, etc.) and may or may not be confined by physical geographic boundaries.

A clear example of the interplay between public health policy and neighborhood and/or community is the implementation of New York State’s Expanded Syringe Access Program, ESAP, in 2001 (Fuller et al. 2007). As discussed earlier, this policy intervention was established to increase syringe access and availability through nonprescription syringe sales in pharmacies to help reduce the use of previously used syringes among IDUs. Overall, ESAP was successful and ultimately became permanent NYS law in 2009 (Fuller et al. 2007); however, early evaluations revealed uneven program uptake, with lower rates of utilization in communities most heavily burdened with HIV, namely, black and Latino

IDUs, and in specific low-income neighborhoods (Fuller et al. 2004). An evaluation in 2003 indicated perceived race discrimination as a significant correlate of self-reported “nonuse” of pharmacies as a syringe source, above and beyond individual characteristics, including knowledge of the new program (Fuller et al. 2004). In response, a large-scale multilevel intervention targeting minority neighborhoods was implemented to increase ESAP participation by targeting individual IDUs with education about HIV prevention services such as ESAP; targeting pharmacy staff with education about ESAP, drug use, and importance of HIV prevention for the IDU community; and targeting community residents with information about the importance of ESAP in reducing community HIV risk and harm reduction approaches to help reduce drug use- and HIV-associated stigma – all of which fulfilled the overarching goal of creating a more receptive social environment for this public health policy. The intervention resulted in significantly higher support toward HIV prevention for IDUs and pharmacy syringe access among community residents and pharmacy staff and a significant increase in IDU self-reported use of pharmacies as a syringe source, particularly among black IDUs (Fuller et al. 2007). This example highlights the importance of implementing policy in tandem with other institutional or community norms and/or practices to not only alleviate existing disparities, as in this case with HIV/AIDS, but also to help prevent new social disparities from arising as a result of a new policy or practice. This is also an example of how and why comprehensive, multi-level approaches that target individual, and structural-level factors, rather than “risk factor-targeted” interventions, are needed to address physical (e.g., syringe access venues) and social (e.g., drug use- and HIV-associated stigma) barriers to HIV prevention services.

There are a host of neighborhood- and community-level points of intervention that can be drawn from the multilevel intervention example described above. Below, a brief discussion follows that includes these features and other salient neighborhood- and community-level targets for HIV prevention in the USA.

Stigma

The effect of social policies and community-level HIV prevention efforts are often dampened among those at the highest risk of HIV such as substance users, men who have sex with men (MSM), and homeless or unstably housed individuals. A growing body of literature suggests this may result from stigmatization and discrimination which may isolate high-risk individuals from critical HIV prevention and treatment resources and may limit the availability of safe/low-risk social relationships, thereby creating “hot spots” of isolated HIV infection (Crawford et al. 2012). Bridges between stigmatized and non-stigmatized individuals often exist in many disadvantaged communities linking those at high risk with those at low risk, making targeted interventions difficult. Recent literature has shown that labeling-induced stigma awareness, stereotype agreement, and anticipated stigma predict lower frequency of reported HIV testing, willingness to test for HIV, and greater HIV test refusal. In such instances, structural interventions that tackle community norms and work to create and reconnect community resources to stigmatized populations by reducing stigma are necessary.

Racial Residential Segregation

The most apparent and recognized explanation for persistent racial and ethnic disparities in HIV on a neighborhood level is racial, ethnic, and social class segregation, which systematically limits critical resources not only for HIV prevention but also several other indicators of health and well-being (White and Borrell 2011). While the evidence of the impact of segregation on health suggests an important effect, many studies fail to examine measures of segregation consistently and use both formal (i.e., dissimilarity index) and proxy (i.e., neighborhood proportion minority) measures of segregation on various scales (e.g., metropolitan statistical areas, census tracts) that limit the interpretability and comparability of the literature in this field (White and Borrell 2011). Despite this, the mechanism through which residential segregation (by race and social class) influences HIV transmission has most often been through access to critical HIV testing

promotion and substance use treatment resources (Discrimination). In fact, studies have shown a relationship between racial residential segregation measured by the dissimilarity index with lower HIV testing behaviors (Ford et al. 2009), access to clean syringes (Cooper et al. 2009), and drug treatment programs (Jacobson et al. 2007) in minority and disadvantaged neighborhoods, where there is clear public health need denoted by high rates of drug-related hospitalizations and high burden of HIV disease.

Gentrification, the process of neighborhood renewal and increasing neighborhood values as a result of the influx of high-income residents and the displacement of low-income residents (Freeman 2009), has been shown to disenfranchise racial and ethnic minorities who are often residents of gentrifying neighborhoods (Freeman 2009). The role of gentrification on previously established networks of HIV prevention and treatment services has not been examined. However, studies have shown that neighborhood change processes, including gentrification and neighborhood revitalization, directly influence increases in HIV incidence and substance use (Rhodes et al. 2005). Therefore, it is plausible that through neighborhood gentrification, prevention and treatment services are broken, barriers to critical resources needed to prevent HIV arise, and social relationships and connections are disrupted, creating several points of opportunity for increases in HIV risk and transmission. Research that focuses on neighborhood gentrification and the mechanisms through which it may affect HIV, and other related health outcomes, is needed to better understand and prevent systematic disadvantage of communities at high risk of and heavily burdened with HIV.

Policing and Incarceration

A critical area of HIV research today investigates the impact of racialized policing and incarceration which, in turn, facilitates a revolving door between jail, prison, and the community on HIV risk in the USA. The criminalization of drug use in the USA results in a fear of being arrested which can prevent drug users from accessing HIV prevention resources (e.g., HIV testing, syringe

exchange, pharmacy-based syringe sources) and toward higher-risk environments (e.g., shooting galleries). Furthermore, criminalization of drug use reduces the availability and promotion of drug abuse treatment therapies, which could reduce HIV transmission while incarcerated or upon release, within the criminal justice system. In many jurisdictions, drug users are often sentenced with incarceration time instead of directed to evidence-based addiction programs, which may disrupt HIV treatment and increase transmissibility of HIV via higher viral loads and ART resistance (Fields 2009).

Investigating the criminal justice system becomes particularly important when addressing racial/ethnic HIV disparities, given the burgeoning incarcerated population over the past several decades, which is overwhelmingly racial/ethnic minorities (Rhodes et al. 2005; Fields 2009; Drucker 2011). The mass incarceration of black and Latino men and women in the USA is fueled by arrests and sentencing for misdemeanor drug offenses with short prison sentences (Drucker 2011). Systematic imprisonment and release of individuals from these communities creates a bridge between high-risk institutionalized and lower-risk noninstitutionalized populations, which lends to a continuum of debilitating social and health consequences, one being facilitation of HIV transmission (Rhodes et al. 2005). While individual-level interventions to reduce HIV transmission within prisons and among the formerly incarcerated populations are important, structural interventions addressing penal policies that disproportionately target minorities for drug offenses are needed.

Conclusion

Structural and multilevel interventions show great promise for optimizing individual behavior change. Targeting structural level factors and/or incorporating structural features in HIV intervention approaches can have significant and far-reaching impacts. Further, multilevel intervention strategies that address both individual-level and structural-level factors have also resulted in

high public health impact. To create an optimal socio-environmental context within which positive health behaviors are more likely to occur, attention to policy, social norms, and relevant systems is essential when designing and implementing effective HIV intervention strategies.

MX2 and HIV-1 Restriction

Caroline Goujon
Centre d'études d'agents pathogènes et
biotechnologies pour la santé, CNRS
FRE3689 – UM, Montpellier, France

Definition

The human myxovirus resistance 2 protein (MX2, also named MxB) belongs to the dynamin superfamily of high molecular weight guanosine

triphosphatases (GTPases). MX2 is homologous to human MX1 (or MxA) and mouse Mx1 and Mx2 proteins. The Mx genes are inducible by type 1 and type 3 interferons (IFNs). Human MX1 has been long recognized as a potent antiviral factor, capable of preventing replication by numerous RNA viruses, including influenza A and measles viruses, and DNA viruses, such as hepatitis B virus. Human MX2 was recently shown to possess a strong antiviral activity against HIV-1 and other primate lentiviruses. MX2 participates in the type 1 interferon-induced block to HIV-1 infection and acts after reverse transcription, at the level of viral DNA nuclear import and/or integration into the host cell genome.

Introduction

Detection of viruses and other microbes by cellular sensors in infected cells induces the production of type 1 and type 3 interferons (IFNs). These antiviral IFNs in turn induce an “antiviral state” in target cells through the regulation of hundreds of genes, termed interferon-stimulated genes (ISGs). Some of these ISGs, such as *protein kinase R (PKR)*, *2'-5' oligoadenylate synthetase (OAS)*, and *MX1*, are well known to possess antiviral activity. It has been known for decades that the IFN-induced antiviral state efficiently protects some cell types against HIV-1 infection in vitro (Ho et al. 1985). Interestingly, exogenous administration of type 1 IFN is capable of producing a profound, although reversible, decrease in HIV-1 viral load in the majority of infected patients and of allowing control of viral load during antiretroviral treatment interruption in half the patients (Asmuth et al. 2010; Azzoni et al. 2013). Analysis of the kinetics of viral load decline during IFN administration in vivo suggests that IFN acts by blocking the de novo infection of susceptible cells (Neumann et al. 2007). In a model of rhesus macaques infected with SIV, type 1 IFN appears essential in the initial control of viral replication (Sandler et al. 2014).

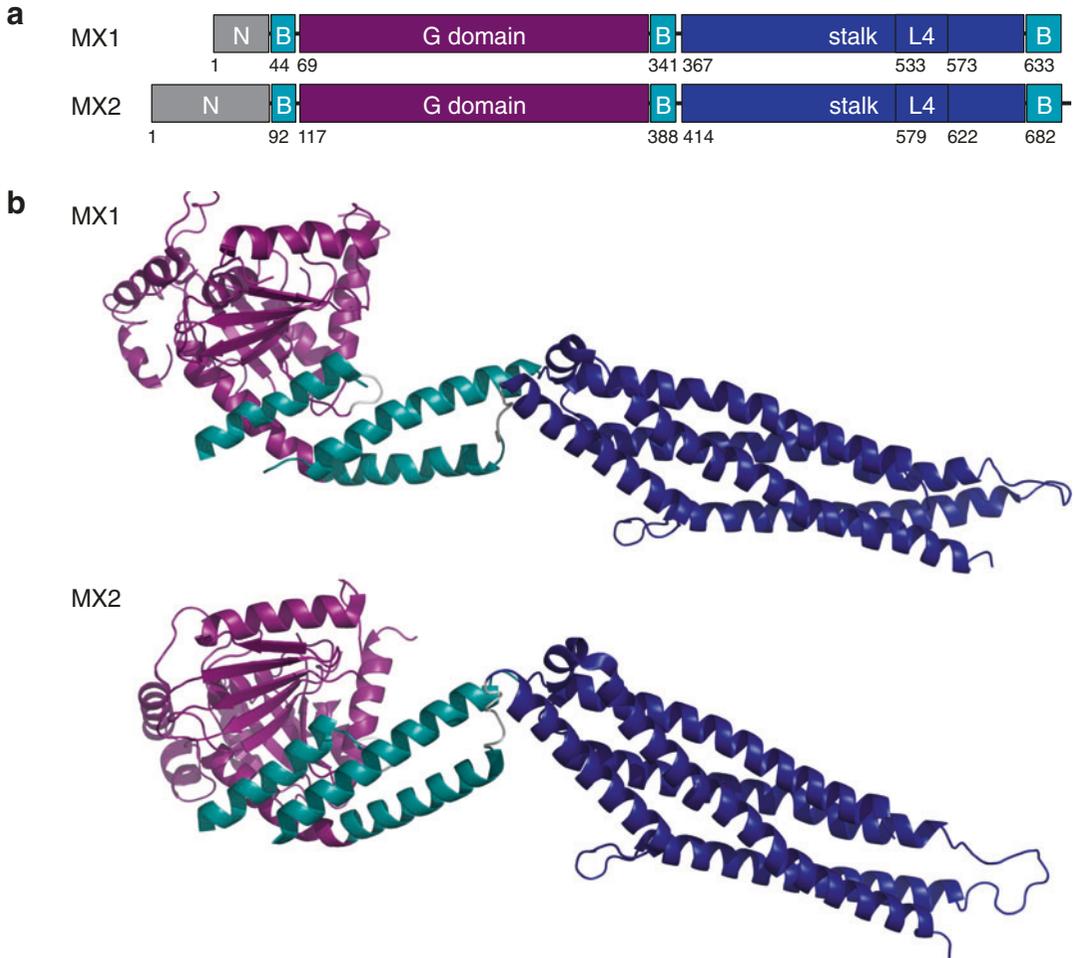

In vitro, the IFN-induced infection block to HIV-1 infection correlates with a strong defect in viral DNA accumulation, and an even stronger

effect is observed on the amount of integrated viral DNA (Goujon and Malim 2010; Cheney and McKnight 2010). Whereas the cellular factors responsible for the block to viral DNA accumulation are yet to be identified, the MX2 GTPase was recently identified as a potent postentry inhibitor of HIV-1, suppressing nuclear import and proviral formation (Goujon et al. 2013; Kane et al. 2013; Liu et al. 2013).

The Mx GTPases

Historically, the Mx genes were discovered in mice: *Mx1* was first identified in a specific mouse strain (A2G) unusually resistant to influenza A virus infection (Lindenmann 1962; Horisberger et al. 1983). Mx genes are highly IFN-inducible, cell-autonomous restriction factors, capable of blocking replication of various viruses. Most mammals possess two Mx genes, which arose by gene duplication and present different antiviral specificities often correlated with their subcellular localization. For instance, nuclear mouse Mx1 prevents influenza A virus and Thogoto virus replication, whereas cytoplasmic mouse Mx2 inhibits vesicular stomatitis virus. Humans also possess two homologous MX genes: *MX1* (the product of which is also called MxA) and *MX2* (MxB). Human MX1 and MX2 share 63% identity at the amino acid level. Despite the nomenclature, human MX1 is actually closer to mouse Mx2 (77% identity) than to mouse Mx1 (67%), and human MX2 and mouse Mx2 share only 62% identity.

Human MX1 is cytoplasmic and has broad antiviral activity against many RNA viruses, such as orthomyxoviruses (e.g., influenza A virus, Thogoto virus), paramyxoviruses (e.g., measles virus), bunyaviruses (e.g., LaCrosse encephalitis virus), and rhabdoviruses (e.g., vesicular stomatitis virus), as well as DNA viruses (e.g., Hepatitis B virus, HBV, and asfar viruses) (reviewed in (Haller et al. 2015)). The antiviral activity of human MX2 was initially tested against the main viral targets of MX1, such as influenza A virus. As MX2 had no effect on the targets of MX1, it was thought for a long time that MX2

MX2 and HIV-1 Restriction, Fig. 1 Structure of human MX1 and MX2 proteins. (a) Domain organization of human MX1 and MX2. The amino-terminal domain (N) of the proteins is represented in *gray*, the GTPase domain (G domain) in *purple*, the bundle-signaling element (B) in *light blue*, and the stalk domain (with the

position of L4 indicated) in *dark blue*. (b) Crystal structures of human MX1 and MX2 without their amino-terminal domains (Adapted from Gao et al. (2011) and Fribourgh et al. (2014) (PDB 4WHJ and 3SZR, respectively)

lacked the antiviral activity possessed by its homologous human or murine proteins.

Human MX1 and MX2 proteins share a similar domain organization and structure, as shown by their recently solved structures that are almost completely superimposable (Gao et al. 2011; Fribourgh et al. 2014; Haller et al. 2015; Fig. 1). These proteins are composed of an amino-terminal domain of different lengths (43 and 91 amino acids for MX1 and MX2, respectively) of which the structure has not been solved, a

globular head containing the GTPase domain (that binds and hydrolyzes GTP), connected to a stalk domain (important for multimerization and viral target recognition in the case of MX1 (Gao et al. 2011; Mitchell et al. 2012), see below) via a tripartite bundle-signaling element (BSE), which transfers conformational changes between the GTPase domain and the stalk, upon GTP binding and hydrolysis.

Two isoforms of human MX2 are co-expressed in human cells following IFN

treatment, due to alternative translation initiation: a long isoform of 78 KDa corresponding to the full-length protein of 715 amino acids and a shorter one of 76 KDa, lacking the first 25 amino acids (Melen et al. 1996; Melen and Julkunen 1997). The latter is dominant (representing about 80% of the total MX2 protein in the cell) and is cytoplasmic. The long isoform is mainly localized at the nuclear envelope, as well as in cytoplasmic granules or bodies of unknown composition (Melen et al. 1996; Kane et al. 2013; Goujon et al. 2014; Matreyek et al. 2014). A sequence enriched in arginine and lysine present in the first 25 amino acids of MX2 was initially thought to act as a nuclear localization signal (NLS) (Melen et al. 1996; Melen and Julkunen 1997; King et al. 2004). However, a more recent study has shown that the 91 amino acids of MX2 function as a nuclear envelope-targeting domain and not an NLS per se as they are able to relocate the turbo-red fluorescent protein at the nuclear envelope (and not inside the nucleus) when appended to its amino-terminus (Goujon et al. 2014). The binding partners of this amino-terminal domain of MX2 and the mechanism-conferring nuclear envelope localization are currently unknown.

Based on the subcellular localization of MX2 at the nuclear envelope and its apparent constitutive expression in some cell types, a potential physiological role for MX2 has been explored (King et al. 2004). It was proposed then that MX2 may regulate the nuclear import and/or cell cycle progression, as the expression of GTPase mutants (potentially acting as dominant negatives) or MX2 depletion disturbed these processes (King et al. 2004).

Three recent studies have shown that similarly to its human and murine homologous counterparts, MX2 is actually an antiviral effector of the IFN response. MX2 is able to act against HIV-1 and other primate lentiviruses. Indeed, the silencing of MX2 in the context of the IFN-induced antiviral state significantly rescues HIV-1 infection, and conversely, the overexpression of MX2 induces a potent block to HIV-1 infection (Goujon et al. 2013; Kane et al. 2013; Liu et al. 2013).

MX2 Blocks the Viral Life Cycle After Viral DNA Accumulation

When overexpressed, MX2 prevents HIV-1 DNA integration into the host cell genome as well as the formation of 2-LTR circles, an episomal form of viral DNA generated only in the nucleus and often used as a surrogate for viral DNA nuclear entry (Goujon et al. 2013; Kane et al. 2013; Matreyek et al. 2014). This suggests that MX2 may act at the level of viral DNA nuclear entry. Interestingly, MX2 is mainly localized at the nuclear envelope (Melen et al. 1996; King et al. 2004; Kane et al. 2013; Goujon et al. 2014) and may have a role in regulating nucleocytoplasmic trafficking, as aforementioned (King et al. 2004).

Capsid Determines the Susceptibility to MX2

The overexpression of human MX2 is sufficient to confer resistance to the infection with most lab-adapted and primary strains of HIV-1 (Goujon et al. 2013). Whereas some SIVs are sensitive to the antiviral activity of MX2, HIV-2 and SIV_{MAC} are partially resistant (Goujon et al. 2013, 2014; Matreyek et al. 2014), and non-primate retroviruses, such as the feline immunodeficiency virus (FIV), the equine infectious anemia virus (EIAV), and the murine leukemia virus (MLV), are insensitive to MX2 (Goujon et al. 2013; Busnadiago et al. 2014; Matreyek et al. 2014). Interestingly, some transmitted/founder HIV-1 strains have recently been shown to be resistant to MX2 (Liu et al. 2015). This might partially explain why transmitted/founder viruses are less sensitive to the IFN-induced antiviral state (Fenton-May et al. 2013; Parrish et al. 2013).

Initial studies have shown that HIV-1 Capsid determines the sensitivity to MX2, with some amino-terminal mutants of Capsid being able to escape antiviral activity, such as the P90A and G89V mutants (Goujon et al. 2013; Kane et al. 2013; Liu et al. 2013). These Capsid mutants are unable to bind to Cyclophilin A (CypA), a

known cofactor of HIV-1 (Zhou et al. 2012). Extended mutagenesis analyses have confirmed the importance of the CypA-binding loop of Capsid for MX2 restriction (Busnadiego et al. 2014; Matreyek et al. 2014; Liu et al. 2015). Moreover, CypA has been suggested to play a role in the restriction as MX2 may interact with CypA (as shown in a co-immunoprecipitation experiment) and cyclosporin A (CSA), a drug inhibiting CypA binding to Capsid, may rescue HIV-1 from MX2 restriction (Liu et al. 2013). However, the ability of CSA to alleviate MX2 restriction has been questioned (Busnadiego et al. 2014). Therefore, the effect of CSA and the importance of CypA in MX2 restriction will require further investigation. Other determinants of MX2 sensitivity have been mapped in the carboxy-terminal domain of Capsid, with mutants P207S, G208R, and T210K being less sensitive or completely resistant to MX2 activity (Busnadiego et al. 2014), confirming the importance of Capsid in the MX2-mediated restriction.

MX2 Is Able to Physically Interact with Capsid

MX1 is well known to recognize and interact with some components of viral nucleoprotein complexes such as Thogoto virus Nucleoprotein (Haller et al. 2015), and HIV-1 Capsid determines the sensitivity to MX2. Taken together, this strongly suggested that MX2 may be able to physically interact with HIV-1 Capsid. A clear physical interaction of MX2 with assembled HIV-1 Capsid has indeed been reported, using systems of recombinant Capsid or Capsid-Nucleocapsid nanotubes, which are known to mimic the tridimensional structures of HIV-1 cores (Fribourgh et al. 2014; Fricke et al. 2014). However, the relevance of this interaction is currently unclear as MX2 interacts as efficiently with wild-type Capsid as with Capsid mutants that are able to escape from the restriction, such as the aforementioned P90A mutant (Fribourgh et al. 2014; Fricke et al. 2014).

The Amino-Terminal Domain of MX2 Specifies the Anti-HIV-1 Activity

A 40-amino acid loop present in the stalk domain, the L4 loop, has been shown to be essential for viral target recognition by MX1 (Mitchell et al. 2012; Patzina et al. 2014). Indeed, sequence analyses of MX1 orthologs in primates reveal strong signatures of positive selection in L4 during primate evolution, and a particular amino acid in L4 largely determines antiviral specificity against orthomyxoviruses (Mitchell et al. 2012). Moreover, L4 can be swapped between orthologous proteins and confer the antiviral specificity of the parental protein, showing that it can act as an autonomous module (Mitchell et al. 2012; Patzina et al. 2014). Additional sites of positive selection have been identified in the flexible amino-terminal part of MX1, suggesting alternative interfaces that might be used to recognize other viruses (Mitchell et al. 2012).

Contrary to what is observed for MX1 and orthomyxoviruses, an approach using engineered chimeric MX1/MX2 proteins has shown that L4 was not important for HIV-1 recognition by MX2 (Goujon et al. 2014). Instead, the 91-amino acid-long amino-terminal domain of MX2 confers antiviral specificity in the case of HIV-1 restriction. Indeed, only the long isoform of MX2, containing the full-length amino-terminal domain, is active against HIV-1 (Kane et al. 2013; Goujon et al. 2014). In addition, the amino-terminal domain contains positively selected sites within primates and seems to dictate antiviral specificity between primate MX2s (Busnadiego et al. 2014). Strikingly, a human MX1 chimeric protein containing the first 91 amino acids of MX2 becomes fully active against HIV-1 (Goujon et al. 2014). And this MX1 chimeric protein containing the amino-terminal domain of MX2 is able to bind to HIV-1 Capsid, whereas MX1 is not (Fricke et al. 2014). Moreover, the transfer of anti-HIV-1 activity to completely unrelated proteins with the transfer of MX2 amino-terminal domain (Goujon et al. 2015) (see below) further demonstrates its essential role in HIV-1 restriction.

An alanine-scanning mutagenesis approach has shown that the amino-terminal domain of MX2 contains a crucial triple arginine motif at positions 11–13 (Goujon et al. 2015). Surprisingly, mutating this domain completely abrogates antiviral activity without changing subcellular localization to the nuclear envelope and cytoplasmic granules. Canine MX2 is not active against HIV-1, and the transfer of either the first 27 amino acids of human MX2 to this homologous protein (Busnadiego et al. 2014) or only the missing third arginine in the triple arginine motif (Goujon et al. 2015) completely rescues anti-HIV-1 activity, highlighting the importance of this motif. Determining the cellular binding partners of this specific motif will certainly shed light onto the mechanism of action of MX2.

MX2 Dimerization, but Not GTPase Activity, Seems Essential for Antiviral Activity

Antiviral activity of human MX1 and mouse Mx1 proteins generally requires GTP binding and hydrolysis, an intact BSE and oligomerization via the stalk (Pitossi et al. 1993; Ponten et al. 1997; Gao et al. 2010, 2011). However, there are exceptions, and, for instance, restriction of HBV infection by MX1 does not rely on GTPase activity (Yu et al. 2008). Similarly, MX2 GTPase mutants partially or fully retain anti-HIV-1 activity (Goujon et al. 2013, 2014; Kane et al. 2013; Matreyek et al. 2014). This possibly underlies a different mechanism of action for MX1 and MX2, which may also depend on the viral target.

High-order homo-multimerization is essential for the activity of MX1 against influenza A virus (Ponten et al. 1997; Kochs et al. 2002; Gao et al. 2010, 2011), and the current model for viral restriction proposes that MX1 may form oligomeric rings around viral nucleoprotein complexes upon GTP hydrolysis. But recent analyses have shown that contrary to MX1, dimerization of MX2, but not oligomerization beyond dimers,

appears to be necessary for viral suppression (Fribourgh et al. 2014; Buffone et al. 2015), once again evoking different mechanisms of action for the 2 homologous proteins.

Interestingly, fusion of the 91 amino-terminal amino acids of MX2 confers potent anti-HIV-1 activity to Fv1, an unrelated protein and known restriction factor of some strains of MLV, which naturally forms oligomers (Bishop et al. 2006; Goujon et al. 2015). In addition, partial and significant anti-HIV-1 activity could be conferred with fusion of this domain to a dimeric leucine zipper but not to a monomeric mutant (Goujon et al. 2015), emphasizing the importance of dimerization for MX2 activity.

Conclusion

MX2 appears as a potent inhibitor of HIV-1 infection, acting on the particularly vulnerable post-entry steps of the viral life cycle. MX2 does not have a described viral antagonist (as yet); therefore, this protein cannot be strictly referred as a restriction factor in the current definition used in the retrovirology field. It has nonetheless become clear from a number of recent studies that MX2 can be added to the list of HIV-1 resistance factors, which are able to efficiently limit HIV-1 replication. MX2 is clearly one of the major effectors of the IFN-induced antiviral state against HIV-1 in vitro (Goujon et al. 2013; Liu et al. 2013). The importance of MX2 in HIV-1 control in vivo remains to be analyzed, but it is tempting to speculate MX2 certainly plays a role in the positive effect of type 1 IFN observed in HIV-1-infected patients (Asmuth et al. 2010; Azzoni et al. 2013) and on SIV in infected rhesus macaques (Sandler et al. 2014). In agreement with this, two recent studies have shown a correlation between MX2 expression levels and resistance to HIV-1 infection in highly exposed seronegative individuals, possibly highlighting a protective role of MX2 (Sironi et al. 2014; Stein et al. 2015).

Further work is now needed to fully understand the mechanism of action of MX2. For instance, it

will certainly be helpful to understand why some Capsid mutants are able to escape from MX2 antiviral activity, whereas the latter is able to interact with them. Understanding the mechanism of MX2 restriction will certainly bring light to some of the postentry events of HIV-1 replication, which remains poorly understood.

Natural History and Clinical Features of HIV-2 Infection

Kevin Peterson

Department of Clinical Sciences, Institute of Tropical Medicine, Antwerp, Belgium
Department of Epidemiology and Social Medicine, Faculty of Medical Sciences, University of Antwerp, Antwerp, Belgium

Definition

A summary of the key literature on the virological, immunological, and clinical progression of HIV-2-infected individuals, with emphasis on the contrast between HIV-2 and HIV-1.

Natural History and Viral Load

The single most distinguishing feature of HIV-2 compared to HIV-1 is its much lower viral load set point. There are no data on the viral loads achieved during the acute phase of HIV-2 infection and less data than for HIV-1 on the viral loads maintained during chronic infection, limiting the precision of viral load estimates at a population level. The viral loads of individuals with untreated chronic HIV-2 infection show considerable variability. While a minority of those infected with HIV-2 have viral burdens typical of progressive HIV-1 infections, in approximately 80% of

HIV-2-infected individuals, viral loads remain very low or, in up to perhaps a third of cases, undetectable (Grant et al. 1997; van der Loeff et al. 2010). This is in contrast to HIV-1, where only 1% of those infected have a similar level of control without treatment (Saksena et al. 2007).

The lower viral set point typically seen with HIV-2 has profound implications for its progression and transmission. It makes HIV-2 much less readily transmissible than HIV-1 (Gottlieb et al. 2006). Disease progression is also related to viral load and is typically slower with HIV-2, with greater diversity in outcomes (Ariyoshi et al. 2000). As a result, most individuals with HIV-2 experience a much longer delay before developing severe symptoms related to their immune compromise. HIV-2-infected patients thus tend to present with higher CD4⁺ T-cell counts and later in life.

Mortality rates are lower with HIV-2 than HIV-1. Compared to HIV-uninfected controls, mortality rate ratios of approximately 2–3 have been reported for individuals infected with HIV-2. The mortality rate ratios for HIV-1 infection, by contrast, are approximately 10–15 (Jaffar et al. 2004). For those infected with HIV-2 having undetectable viral loads, mortality is probably equivalent to HIV-negative controls; this was most convincingly demonstrated in an 18-year follow-up of a community cohort in Guinea-Bissau with serial viral load measurements (van der Loeff et al. 2010).

While HIV-2 shares the same modes of transmission as HIV-1, its prevalence in endemic areas is dropping even as that of HIV-1 rises. This appears to be the result of competitive exclusion of HIV-2 by HIV-1 as a consequence of the lower viral loads in the former (de Silva et al. 2013).

Mechanism of Viral Suppression

The lower viral set point in HIV-2 is a combination of multiple virus- and host immune-related factors. HIV-2 successfully infects CD4+ T-cells, integrating into host cell genomes as well as HIV-1 does. Thereafter, HIV-2 generates less mRNA and fewer viral particles (MacNeil et al. 2007). It induces less immune activation in the host and less apoptosis of infected cells. HIV-2 also appears more susceptible to host immune responses. Most individuals infected with HIV-2 generate greater CD4+, CD8+, NK cell, and antibody responses, and exert greater control over their virus, than people infected with HIV-1 (Leligowicz and Rowland-Jones 2008). Variation in HIV-2 viral control is more a function of differences in host immune response than differences in the viral genome (de Silva et al. 2013), however differences between viruses appear to be important determinants of immune control. The key finding linking the structure of the virus and the effectiveness of the immune control in HIV-2 may be the prevalence of proline-rich P-26 capsid proteins in the virus, which make viral particles less stable intracellularly, facilitating both their breakdown by TRIM5 α and the presentation of their antigens to other elements of the immune response (reviewed in de Silva et al. (2008)).

CD4+ T-Cell Decline

Immunologic decline in HIV infection is represented by falling CD4+ T-cell counts. CD4+ T-cell decline is a function of viral load in both HIV-1 and HIV-2. In modal HIV-2-infected individuals with low viral loads, this decline is more gradual than that typically seen in HIV-1 infections, and those with undetectable viral loads may experience essentially no progression at all (van der Loeff et al. 2010). By contrast, among the minority of HIV-2-infected individuals with viral loads equivalent to those seen with progressive

HIV-1 infections, the rate of CD4+ T-cell count decline is roughly the same (Gottlieb et al. 2002).

Dual Infection with HIV-1

Dual infection with both HIV-1 and HIV-2 occurs routinely in settings where both viruses are common. Rate estimates of dual infection vary by setting and testing method, subjects which lie outside the scope of this entry. Immunologic and clinical deterioration in dual infection are driven by viremia. As is the case in mono-infection, HIV-2 viral loads in dually infected individuals are generally lower than their HIV-1 viral loads; they may be very low or undetectable while HIV-1 viral loads are high in the same individuals. The clinical course of dually infected individuals is therefore typically determined by their HIV-1 infection (Jaffar et al. 2004). The existence of a meaningful interaction between the two infections has long been debated. Recent research suggests that prior infection with HIV-2 may modulate early responses to HIV-1 infection, with a possible effect on viral set point and progression, though this remains contested (de Silva et al. 2012; Esbjornsson et al. 2012).

Clinical Features

The spectrum of clinical disease in both HIV-1 and HIV-2 is dominated by the degree of immune impairment, generally measured by CD4+ T-cell counts and/or CD4 percents. Opportunistic diseases in HIV infection, primarily infectious, are frequently associated with specific CD4+ T-cell counts below which their incidence increases substantially. Furthermore, local epidemiology, particularly of infectious diseases, plays a crucial role in determining the clinical presentation of HIV-infected people.

Opportunistic Infections

In general, the opportunistic infections associated with HIV-2 are the same as those associated with HIV-1, after controlling for the effect of CD4+ T-cell count (Grant et al. 1997; Martinez-Steele et al. 2007). The relative paucity of data on the clinical presentation of HIV-2 however limits the

certainty with which differences in clinical associations between the two forms of HIV can be asserted or excluded.

Several retrospective studies have suggested specific differences between the opportunistic infections associated with HIV-1 and HIV-2. In the most conclusive of the studies, Kaposi's sarcoma was found to be 12 times more common in individuals infected with HIV-1 than in those infected with HIV-2 (Ariyoshi et al. 1998). In this study population, asymptomatic human herpes virus 8 coinfection was equally common among those with HIV-1 and HIV-2 infections, and sex and degree of immune suppression were both controlled for. It has been proposed that this difference may be the result of HIV-1 Tat proteins being more potent tumor inducers than HIV-2 Tat proteins (Weiss and Boshoff 2000).

In a study of 790 hospitalizations, presentation with either bacterial or chronic diarrhea was more common among those infected with HIV-2, while oral candidiasis, meningitis, and chronic fevers were more common in HIV-1-infected patients (Ndour et al. 2000). The authors of this study are nonetheless reluctant to assert this represents a true clinical difference between HIV-1 and HIV-2, as only 17% of the subjects had CD4+ T-cell counts done and these were not controlled for in the analysis. Furthermore, no statistical correction was made for multiple comparisons, and 21% of the subjects were repeat admissions.

In a landmark autopsy series from the Ivory Coast, CMV, HIV encephalitis, and cholangitis were more frequently found among the 40 people who had died with HIV-2 and undergone autopsy compared to the 154 who had died with HIV-1. For those people undergoing autopsy for whom a CD4+ T-cell count was available, the median of HIV-2-infected subjects was $50 \times 10^6/l$, compared to $101 \times 10^6/l$ for those with HIV-1 infection. Taking into account the natural history of the diagnoses at autopsy, the authors conclude that the differences between HIV-2 and HIV-1 in their series can be explained by the lower CD4+ T-cell counts combined with a slower disease progression in the terminal phase of the illness among their HIV-2 subjects, rather than being a

consequence of the virus type itself (Lucas et al. 1993).

Results from a cross-sectional study published in 2003 suggested a greater risk of high-grade squamous intraepithelial cervical cancer lesions with HIV-2 infection compared to HIV-1 infection. This association was however not confirmed in a longitudinal prospective study, controlling for the duration of infection, carried out by many of the same investigators at the same study site (Hawes et al. 2006).

Response to Antiretroviral Therapy

A substantial body of literature has developed around antiretroviral therapy for HIV-2. Diminished sensitivity to a number of agents, as well as different resistance pathways, complicates HIV-2 therapy. This is particularly problematic for second-line and salvage therapy. For treatment-naïve individuals, standard combination therapy with boosted lopinavir has the best clinical data supporting it, though selected other boosted protease inhibitors (saquinavir, darunavir, and possibly indinavir) may also be used (Peterson et al. 2011b; Camacho 2012). With appropriate antiretroviral therapy, immunologic recovery appears comparable in HIV-2 and HIV-1 infections, although recovery may initially be slower in HIV-2 (Drylewicz et al. 2010; Peterson et al. 2011a).

Conclusion

HIV-2 infection is mechanistically very similar to HIV-1 infection. It shares the same modes of transmission and generally infects the same cells. HIV-2 is a less fit virus in humans than HIV-1, and the immune system is better able to exert some control over it. Only a minority of HIV-2-infected individuals generate high levels of viremia. As a consequence of this diminished viremia, most people infected with HIV-2 will experience a much slower rate of immunologic decline, present with HIV-related symptoms later and at an older age, and have a lower mortality rate than those infected with HIV-1. For a given CD4+ T-cell count, the clinical manifestations of HIV-2 are

indistinguishable from those of HIV-1, although the data in HIV-2 are much more limited. The only opportunistic condition for which strong evidence of a difference between HIV-1 and HIV-2 exists is Kaposi's sarcoma. This appears to be much less common in HIV-2-infected individuals after controlling for CD4+ T-cell count.

Causal inferences about differences in clinical presentation between HIV-2 and HIV-1 are limited by a paucity of data and epidemiological confounders. As HIV-2 is endemic to West Africa, regional disease epidemiology is a potential confounder, both in studies conducted in West Africa and in studies conducted elsewhere with emigrants and travelers from West Africa. And, as demonstrated by the two high-quality studies on cervical cancer mentioned above, prospective studies are needed to minimize the effects of subject age and length of HIV infection on differences in clinical presentation between HIV-2 and HIV-1.

Clinical management of individuals infected with HIV-2 differs from HIV-1. While issues with HIV-2 testing, treatment, and monitoring are covered in depth elsewhere, the natural history of HIV-2 bears on its clinical management in several ways. The threshold for HIV testing needs to remain low in HIV-2 endemic areas or where there is a plausible risk of HIV-2 infection, even among those with no HIV-related symptoms and no recent history of potential HIV-2 exposure, as infections may only manifest themselves many years after initial infection. The variable course of HIV-2 infection argues for effective monitoring, in particular the use of viral loads to determine prognosis. Slower declines in CD4+ T-cell counts and the more limited antiretroviral armamentarium could be taken as arguments for deferred antiretroviral treatment of HIV-2. On the other hand, deferring therapy prolongs the risk of transmission, and recovery of CD4+ T-cell counts on therapy is blunted at lower CD4+ T-cell counts, suggesting earlier initiation may be needed in order to achieve a satisfactory level of immune reconstitution.

Although its prevalence appears to be dropping and it is less rapidly progressive than HIV-1, HIV-2 continues to be transmitted and its variable course includes aggressive disease indistinguishable from

HIV-1. Testing, monitoring, and treatment of HIV-2 infection also have specific challenges, discussed in detail elsewhere. For these reasons, public health authorities and treating physicians cannot afford to be sanguine about HIV-2.

Natural Killer Cells and Their Role in Preventing HIV-1 Transmission

Wim Jennes and Luc Kestens

Department of Biomedical Sciences, Institute of Tropical Medicine, ANR, Belgium

Definition

Despite the enormous efficacy of HIV-1 transmission resulting in a worldwide epidemic, the virus is extremely vulnerable in the brief period between initial HIV-1 exposure and establishment of systemic infection with most HIV-1 infections being prematurely abrogated by the innate immune defenses of the human host. Evidence is accumulating that natural killer (NK) cells play an important role in mediating this innate resistance to HIV-1 infection. NK cells are innate lymphocytes in the first line of defense against viruses capable of rapidly killing virus-infected cells without prior sensitization. NK cells also modulate the ensuing adaptive immune responses by releasing cytokines and promoting dendritic cell maturation. Genetic studies of highly HIV-exposed but seronegative (HESN) subjects consistently showed that these individuals are enriched for NK cell receptor repertoires with an NK cell-activating profile. While functional studies of NK cells are starting to unravel the mechanisms behind these genetic associations, ex vivo analyses frequently identified signatures of

activated NK cells in HESN individuals. Recent investigations of the mucosal genital immune environment, however, show that protection against HIV-1 infection depends on a delicate balance of protective and detrimental consequences of innate immune activation and of NK cells in particular. Further research will have to unravel the specific components of this balance before seeking to apply the HIV-1 preventive potential of NK cells in immune-based medical interventions.

Introduction

HIV-1 has been remarkably successful since it was first transmitted from a SIV-infected chimpanzee to a human host in West-Central Africa around the beginning of the twentieth century. By the 1960s, the virus had steadily made its way to the local urban centers from where it started seeding the worldwide HIV-1 epidemic. To date, HIV-1 has infected approximately 60 million people of whom 30 million have died, making it the most devastating infectious disease of the recent times. The successful spreading of HIV-1 around the world is remarkable given its actually rather low transmission efficiency per unit of exposure. Sexual exposure to HIV-1, which accounts for the large majority of HIV-1 infections, has a transmission probability between 1/100 and 1/1,000. Although several factors are known to increase the risk of “► [HIV-1 sexual transmission](#)” like a high viral load of the index partner, concurrent sexually transmitted infections, anal vs. vaginal and receptive vs. insertive intercourse, and lack of male circumcision, the prevailing view is that the defense mechanisms of the human genital tract are very effective most of the time in preventing HIV-1 infection (Haase 2011). This is supported by single-genome-amplification studies showing that the majority of acute HIV-1 infections start with only a single HIV-1 virus clone that was capable of breaking through the genital defense barriers.

Detailed investigations of the first events following HIV-1 exposure are difficult to perform in humans, but SIV infection experiments of

nonhuman primate species like rhesus macaques have been highly informative in that regard (Haase 2011; Keele and Estes 2011) (also see “► [Nonhuman Primate Models of HIV Transmission](#)”). Both cell-free virus particles and virus-infected cells present in genital secretions contribute to HIV-1 transmission. Infected cells could be notably efficient mediators of transmission because they can continue releasing virus while penetrating deeply into the recipient's tissues. In case the virus succeeds in crossing the mucosal barriers of the genital tract, its next challenge is to get access to suitable submucosal target cells that support viral replication and dissemination in the recipient host (see “► [Cellular Cofactors for HIV-1 Transcription](#)”). Mucosal Langerhans cells, dendritic cells, and macrophages take up viral particles, which are either processed endogenously for the stimulation of the innate and adaptive immune responses or passed on to infect other target cells, but they cannot be productively infected themselves. Reproductive tract histological studies of acutely infected rhesus macaques show that the first productively infected target cells are CD4+ T cells residing in the submucosal layers, a finding that is consistent with the obligate CD4+ T cell/CCR5-tropic nature of isolated transmitted/founder viruses. Sufficient numbers of HIV-1-permissive CD4+ T cells have to be present in the submucosa to sustain a beginning infection, which can either result from prior mucosal immune inflammation for instance due to another sexually transmitted infection or from newly arriving activated CD4+ T cells in response to the developing innate immune response (see “► [Immune Activation and HIV Transmission](#)”). The virus first replicates in mucosal CD4+ T cells for about a week, establishing small founder populations of infected cells which progressively expand in size and number. After that, the virus spreads to the local lymph nodes where it suddenly has access to large numbers of permissive CD4+ T cell targets which go on to traffic through the blood circulation and into the tissues thereby causing an irreversible systemic infection.

Accumulating evidence suggests that adaptive immune responses like B cell responses, CD4+

T cell responses, or CD8+ T cell responses cannot prevent infection because they require priming and proliferation and only develop well after HIV-1 has established itself as an irreversible systemic infection (Picker et al. 2012). Even anamnestic HIV-1-specific T cell responses which develop more rapidly after a prior exposure to the virus require days to expand and come too late to prevent infection. Although the adaptive immune responses eventually reduce the HIV-1 viral load levels in the blood and contribute to viral control in at least some individuals (see “► Long-Term Nonprogressors and Elite Controllers”), they are incapable of clearing the virus from the body because of viral immune escape. In fact, error-prone HIV-1 replication rapidly results in the establishment of a swarm of viral variants soon after systemic infection from which new escape mutants are perpetually selected. In addition, HIV-1 has evolved numerous mechanisms that actively deregulate the antiviral immune responses (see “► Overview: Immunopathogenesis”). Together with a progressive decline in CD4+ T cells, this contributes to the exhaustion of the adaptive immune responses eventually leading to immunodeficiency and death (see “► HIV-Associated Immune Exhaustion”).

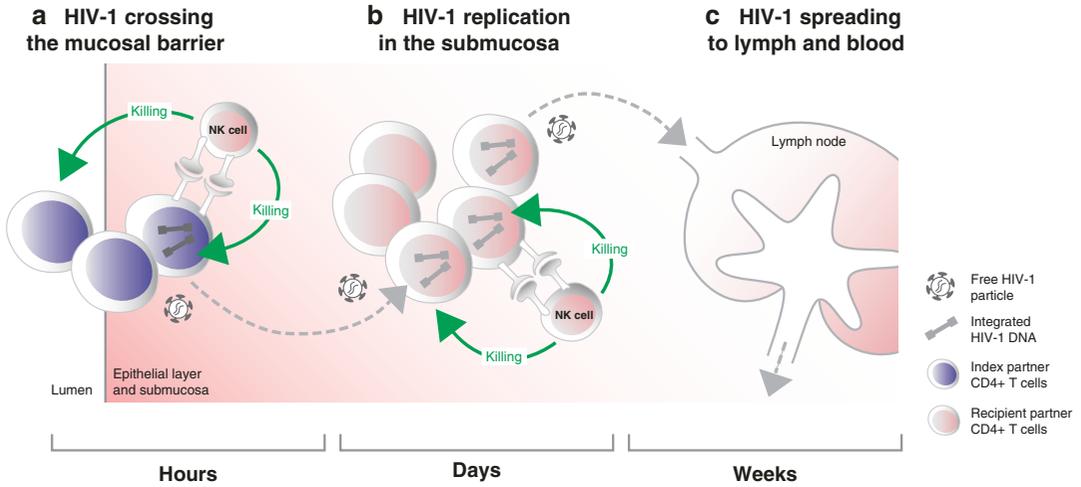

The innate immune response to HIV-1 likely plays a much more important role in determining the outcome of HIV-1 exposure because of its capacity to respond immediately without requiring priming or proliferation (Tomescu et al. 2011; Ploquin et al. 2012). Mucosal genital secretions contain several low-molecular-weight innate proteins with potent antiviral activity, e.g., defensins, elafin/trappin-2, and several protease inhibitors (see “► Mucosal Immunity to HIV-1”). Mucosal plasmacytoid dendritic cells that recognize incoming HIV-1 particles via Toll-like receptor-7 (TLR-7) and TLR-9 rapidly respond by secreting innate cytokines like IFN-alpha, IL-15, and IL-18. IFN-alpha induces the expression of several innate cellular factors like APOBEC3G, TRIM-5alpha, and tetherin that restrict HIV-1 replication in potential target cells. The innate cytokines also result in the activation of a specific innate cytotoxic cell subset, the natural killer (NK) cells. NK cells can directly kill virus-infected cells, and they secrete cytokines like IFN-gamma and TNF-alpha

that in turn induce the maturation of mucosal dendritic cells, thereby regulating their functions towards adaptive immunity. At the same time, however, IFN-alpha starts a cascade of local immune inflammation resulting in a mucosal influx of immune mediators including activated CD4+ T cells which can subsequently become the target cells for HIV-1 propagation (see “► Immune Activation and HIV Transmission” and “► Inflammatory Cytokines”). This duality can best be illustrated by comparing pathogenic SIV infections in rhesus macaques with ► nonpathogenic SIV infections in African green monkeys. Although acute SIV infection results in a strong upregulation of IFN-alpha-stimulated genes in both species, the expression levels rapidly return to basal levels only in African green monkeys thereby preventing pathogenic ► chronic immune activation. Thus, the right balance of protective and detrimental effects of the innate immune response appears crucial towards preventing HIV-1 infection and disease pathogenesis.

Two early steps of the HIV-1 transmission process are likely extremely vulnerable to the innate immune defenses and to NK cells in particular (Fig. 1). These viral Achilles' heels include the initial transfer of free virus or virus-infected cells across the mucosal epithelial barrier and the subsequent viral replication in submucosal founder populations of infected cells before spreading to the local lymph nodes. During these steps, the number of virus-infected cells is still sufficiently low to be efficiently targeted by the innate immune responses. Knowing that the physical barriers of the human genital tract are already very effective in preventing HIV-1 infection, a potent innate immune defense could certainly tip the balance in favor of the host to significantly reduce incidence (Keele and Estes 2011). In this chapter we focus on NK cells and the existing evidence regarding their role in preventing HIV-1 transmission.

Receptor/Ligand Regulation of NK Cells

NK cells play an important role in the innate immune response against virus infections, either

Natural Killer Cells and Their Role in Preventing HIV-1 Transmission, Fig. 1 Opportunities for NK cells to prevent HIV-1 transmission early after exposure. Two early steps of the HIV-1 transmission process are likely extremely vulnerable to NK cells. These include the initial transfer of free virus or virus-infected cells over the mucosal epithelial barrier (a) and the subsequent viral replication in submucosal founder populations of infected cells (b).

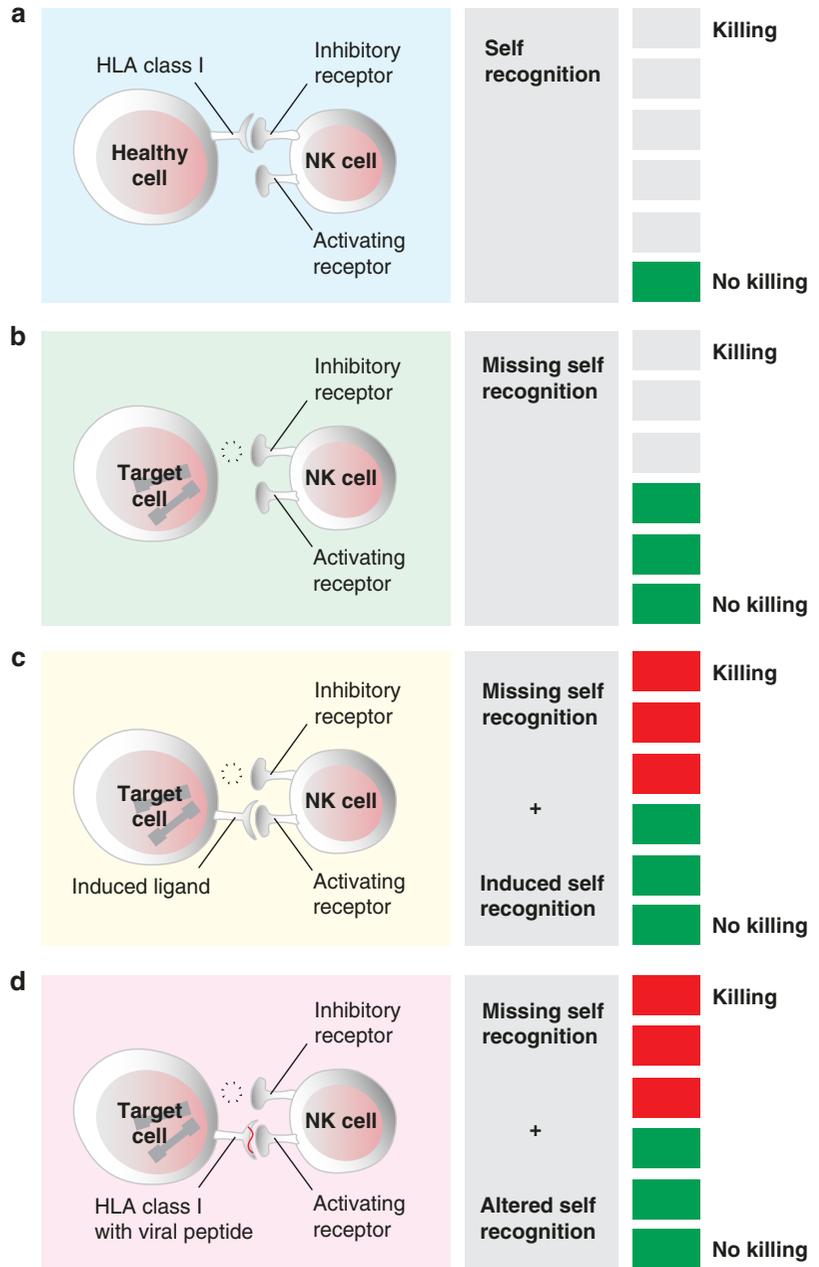

During these steps, the number of virus-infected cells is still sufficiently low to be efficiently targeted by NK cell responses. This is no longer true when the virus reaches the local lymph node (c), where it has access to large numbers of permissive CD4+ T cell targets which go on to traffic through the blood circulation and into the tissues thereby causing an irreversible systemic infection

by directly killing infected cells or by modulating the other arms of the innate and adaptive immune response. NK cells are regulated by complex sets of activating and inhibitory cell surface receptors that interact with ligands on potential target cells and the integration of all signals determines whether the target cell will be killed or not (Lanier 2005) (Fig. 2). NK cell receptors belong to different receptor families with different genetic and structural characteristics. The best studied NK cell receptors are the killer immunoglobulin-like receptors (KIR) which belong to the immunoglobulin superfamily and consist of 15 different inhibitory and activating genes (see “► [KIR Locus Variation](#)”). The number and kind of KIR genes vary between individuals, individual KIR genes themselves are polymorphic, and KIR genes are randomly expressed on the surface of a given NK cell, resulting in enormous variation in KIR expression both at the individual and population level. Several inhibitory KIR recognize classical HLA class I molecules (see “► [MHC Locus Variation](#)”) generally expressed on healthy cells. This interaction

results in NK cell sparing of healthy tissue but in loss of NK cell inhibition towards cells that have downregulated HLA class I expression, e.g., on virus-infected cells, a process termed “missing self-recognition” (Fig. 2). The ligands of the activating KIR are less well characterized but are often stress molecules expressed on aberrant or virus-infected target cells thereby inducing NK cell activation in a process termed “induced self-recognition” (Fig. 2). Activating KIR were also shown to recognize HLA class I molecules presenting viral peptides, termed “altered self-recognition” (Fig. 2). A second important set of NK cell receptors belong to the C-type lectin-like family and include heterodimers of CD94 with either an inhibitory receptor, NKG2A, or an activating receptor, NKG2C or NKG2E. Unlike the KIR, NKG2 genes are present in most individuals and display limited polymorphism. NKG2 receptors recognize nonclassical class I HLA-E molecules which bind peptides derived from classical HLA class I molecules, allowing them to monitor classical HLA class I expression on potential target cells in parallel with the inhibitory KIR.

Natural Killer Cells and Their Role in Preventing HIV-1 Transmission, Fig. 2

Receptor/ligand regulation of NK cell killing. NK cells are regulated by activating and inhibitory receptors that interact with ligands on potential target cells and the integration of all signals determines whether the target cell will be killed or not. Interaction of inhibitory receptors with HLA class I molecules on healthy target cells delivers strong inhibitory signals to the NK cell (a). This inhibition is lost when NK cells encounter cells that have lost HLA class I expression, e.g., as a result of viral infection. However, such “missing self-recognition” is not sufficient to trigger NK cell killing (b). NK cells require additional activating signals to induce target cell killing. These signals can come from activating receptors interacting with induced self, e.g., virus-induced stress molecules (c), or altered self, e.g., HLA class I molecules presenting viral peptides (d)

Genetic Evidence for NK Cell Protection Against HIV-1 Transmission

Because of their extreme population variability and crucial roles in innate and adaptive immunity, KIR and HLA class I genes are believed to be important determinants of disease outcome at the individual level. This is supported by several

epidemiologic studies showing associations between KIR/HLA genotype and susceptibility to infection, autoimmune and inflammatory conditions, and cancer (Kulkarni et al. 2008). A series of studies of a large North American cohort of HIV-1 infected patients showed that certain gene combinations of activating KIR3DS1, high-expressing inhibitory KIR3DL1 (KIR3DL1^{hi})

N

and HLA-Bw4, the HLA class I ligand for KIR3DL1, contribute to improved control of HIV-1 disease (Bashirova et al. 2011). Although it has remained unclear how exactly these gene combinations translate into protective NK cell responses, the KIR3DS1/HLA-Bw4 combination was suggested to induce stronger NK cell killing of HIV-1 infected target cells presenting HIV-1 peptides in the context of HLA-Bw4 (“altered self-recognition”), while the KIR3DL1^{hi}/HLA-Bw4 combination was suggested to better “educate” NK cells for the killing of HIV-1-infected target cells with downregulated HLA-Bw4 (“missing self-recognition”) (further discussed in “► [NKT Cells: Bridging Innate and Adaptive Immunity](#)”). Studies of the role of KIR3DS1, KIR3DL1, and HLA-Bw4 genes in resistance to HIV-1 acquisition made comparable observations (Bashirova et al. 2011; Tomescu et al. 2011). HIV-exposed seronegative (HESN) intravenous drug users and HESN partners in HIV-1 discordant couples from European or Euro-American populations showed increased frequencies of KIR3DL1^{hi}/HLA-Bw4, similar to what was observed in HIV-1 controller patients, as well as of homozygous KIR3DS1, either in the presence or absence of HLA-Bw4. A series of studies analyzing all known activating and inhibitory KIR genes in two African populations of HESN subjects, female sex workers from Côte d’Ivoire and HIV-negative partners in HIV-1 discordant couples from Senegal, could not confirm a direct role for KIR3DS1, probably because of the low frequency of this gene in African populations (Tomescu et al. 2011; Jennes et al. 2006, 2013). These studies, however, found other group B haplotype genes than KIR3DS1 to be enriched in HESN subjects, i.e., KIR2DS2, KIR2DS3, KIR2DL2, and KIR2DL5, at the expense of typical group A haplotype genes like KIR2DL3. Because of extensive linkage disequilibrium in the KIR locus, KIR genes are inherited in two broad haplotypes termed A and B (see “► [KIR Locus Variation](#)”). Group A haplotypes contain fewer and mostly inhibitory KIR genes, while group B haplotypes contain more activating KIR genes, implying that HESN subjects have a more NK cell-activating genetic profile. In

addition, both African HESN populations showed increased frequencies of inhibitory KIR genes in the absence of their cognate HLA ligands, i.e., KIR2DL2 or KIR2DL3 in the absence of HLA-C1 and KIR3DL1 in the absence of HLA-Bw4, combinations that could decrease the threshold for NK cell activation (Jennes et al. 2006, 2013). Polymorphisms in HLA-G and HLA-E, nonclassical HLA class I ligands for KIR2DL4 and NKG2 receptors, respectively, have also been implicated in NK cell-mediated resistance to HIV-1 infection in ways that are similar to those described above. HIV-seronegative African women showed increased frequencies of an HLA-G*0105N null variant, resulting in abrogated KIR2DL4 inhibition and a lowering of the NK cell activation threshold, and of a HLA-E^G variant with higher affinity for viral peptides facilitating “altered self-recognition” (Tomescu et al. 2011). In summary, the available genetic studies so far collectively suggest that resistance to HIV-1 infection is associated with carriage of an NK cell-activating genetic profile. Different NK cell receptor/ligand systems and mechanisms are implicated, possibly reflecting the different ethnic origins and routes of HIV-1 exposure of the studied HESN cohorts. Independent confirmatory studies of the observed genetic associations as well as functional studies investigating their precise mechanisms are required to move this field forward.

Functional Evidence for NK Cell Protection Against HIV-1 Transmission

The first functional data which suggested that NK cells play a role in resistance to HIV-1 infection came from a study of Vietnamese HESN intravenous drug users showing increased levels of NK cell activation, cytokine production, and cytotoxicity when stimulated with NK-sensitive cancer cell lines (Tomescu et al. 2011). Several studies since then have contributed to our further understanding of the functional mechanisms of NK cell-mediated protection against HIV-1 infection. NK cells of HESN subjects consistently displayed increased levels of cellular activation and

degranulation, after *in vitro* stimulation but also when directly tested *ex vivo*, possibly reflecting ongoing innate immune reactivity in response to frequent episodes of HIV-1 exposure. In one study, HESN subjects specifically showed increased mRNA expression ratios of activating KIR3DS1 relative to inhibitory KIR3DL1, and of activating NKG2C relative to inhibitory NKG2A, in line with the activating NK cell receptor genotypes discussed above. *In vitro* studies have started to unravel the functional consequences of the different NK cell-activating genetic profiles that are observed in HESN subjects (Bashirova et al. 2011). Notably, the protective KIR3DS1/HLA-Bw4 genotype was shown to effectively result in increased NK cell killing of HIV-1 infected CD4⁺ T cells, and the protective KIR3DL1^{hi}/HLA-Bw4 genotype was shown to display increased NK functionality towards NK-sensitive cancer cell lines. Another study found that NK cells of HESN subjects make stronger responses towards exogenously HIV-1 infected autologous CD4⁺ T cells, but here KIR/HLA genotype was not taken into account. Thus, in order to unravel the precise functional mechanisms of KIR/HLA genotype in resistance to HIV-1 infection in HESN subjects, comprehensive studies of NK cell-mediated killing of HIV-1 infected CD4⁺ T cells in the context of KIR/HLA genotype are required.

NK cell activation and cytotoxicity depend in part on virus recognition by mucosal plasmacytoid dendritic cells which secrete innate cytokines like IFN- α that stimulate the antiviral innate immune responses. Evidence is accumulating that plasmacytoid dendritic cell functionality and the NK cell-dendritic cell cross talk are important additional correlates of resistance to HIV-1 infection (Ploquin et al. 2012). Plasmacytoid dendritic cells in HESN subjects showed increased levels of maturation and activation and they secreted more cytokines upon specific TLR triggering. In turn, NK cells more efficiently killed the immature dendritic cells, improving the capacity of the dendritic cell compartment to regulate the adaptive immune responses. Interestingly, the increased dendritic cell responses upon TLR triggering in HESN

subjects coincided with lower baseline levels of inflammatory cytokines and CD4⁺ T cell activation in the genital mucosa, illustrating the importance of a precisely tuned and narrowly targeted innate immune response in resistance to HIV-1 infection (Yao et al. 2013). These findings are in agreement with the strong but rapidly controlled IFN- α responses seen during nonpathogenic SIV infection of African green monkeys, like discussed above. Along the same lines, pre-treatment of macaques with IFN- α increased NK cell frequencies and protected against intrarectal SIV transmission, but accelerated SIV disease progression once infected (Sandler et al. 2014). Further investigations at the level of the genital mucosa are warranted to identify all components of a successful antiviral innate immune response.

Most of the evidence supporting a role for NK cells in mediating protection against HIV-1 infection is derived from observational studies of at-risk populations while precisely designed clinical trials confirming their function are lacking. A recent HIV-1 vaccine trial in Thailand, termed RV144, demonstrated for the first time that a vaccine can provide protection against HIV-1 infection (see “► [HIV-1 Transmission Blocking Microbicides](#)”). Although the protection was rather modest, a 31% reduction in new HIV infections among trial participants, the results provided an unprecedented opportunity to investigate the immune mechanisms of vaccine protection. A detailed investigation of immune mechanisms revealed an important role for NK cells and antibody-dependent cellular cytotoxicity (ADCC) in vaccine protection (Haynes et al. 2012). During ADCC, Fc γ receptors (Fc γ RIII also known as CD16) on NK cells bind to the constant domains (Fc) of HIV-specific IgG antibodies that coat the surface of infected cells, thereby triggering a cytotoxic NK cell response. These findings have invigorated HIV-1 vaccine research now focusing on antibody vaccines that are capable of inducing strong ADCC responses. However, the contribution of ADCC to protection against HIV-1 infection in HESN populations is unclear, as HIV-specific IgG antibodies are not expected to be present in these populations.

Alloreactive NK Cells in HIV-1 Transmission

Although NK cells are best known for their potential to lyse virus-infected and tumor cells, they were first discovered because of their cytotoxic activity against allogeneic target cells in the context of transplantation. Recently, the important role of NK cells in killing allogeneic target cells came to the fore again in studies of haploidentical hematopoietic stem cell transplantation as a treatment for acute myeloid leukemia (Moretta et al. 2011). It was found that ► [stem cell transplantation](#) from a haploidentical donor, i.e., matched for only half of the leukemia patient's HLA, often resulted in the emergence of an alloreactive NK cell subset with strong cytotoxic activity against residual leukemia cells, thereby greatly reducing the risk of leukemia relapse. Alloreactivity of NK cells was found to specifically depend on "missing self" KIR/HLA combinations consisting of inhibitory KIR in the donor that recognize a self HLA in the donor but that is missing in the recipient. The requirement for a KIR-specific self HLA in the donor reflects the need for proper NK cell education towards recognition of aberrant or missing HLA on potential target cells. A recent study investigated whether comparable allogeneic KIR/HLA combinations and NK cell alloreactivity play a role in HIV-1 transmission and lack thereof among African couples who are either HIV-1 concordant (phylogenetically confirmed HIV-1 transmission from one partner to the other) or HIV-1 discordant (one partner HIV-1 positive, the other HIV-negative) (Jennes et al. 2013). Such an effect would be plausible, given that incoming HIV-1 infected cells are effective mediators of HIV-1 transmission as well as strong inducers of innate immune activation. HIV-1 discordant couples indeed showed an increased frequency of a specific "missing self" KIR/HLA combination, while HIV-1 concordant couples showed an increased frequency of a specific "matched" KIR/HLA combination. Functional experiments confirmed the involvement of "missing self" as opposed to "matched" KIR/HLA combinations in provoking alloreactive NK cell killing of HIV-1 patient-derived CD4+

T cells. These findings could have important implications for our understanding of NK cell protection against HIV-1 transmission and urgently require confirmation in other cohorts of HIV-1 discordant couples, in the setting of mother-to-child transmission, and by SIV transmission experiments using simian models. These data may also help to understand recent attempts to cure HIV infection in a number of patients by allogeneic stem cell transplantation (Cannon et al. 2014). One patient, referred to as the "Berlin patient", received a CCR5-delta32 homozygous allogeneic stem cell transplant and is HIV free now 6 years after stopping antiretroviral therapy. Two other patients, referred to as the "Boston patients", received CCR5-wild type allogeneic stem cell transplants resulting in temporary viral remissions lasting 3 and 8 months off therapy, respectively. Although the exact mechanisms contributing to HIV control are unknown, the possibility that alloreactive NK cells as part of the graft versus host reaction have contributed to HIV remission certainly warrants further investigation.

Conclusions

Despite the enormous efficacy of HIV-1 transmission resulting in a worldwide epidemic, the virus is highly vulnerable during sexual acquisition and the first few days thereafter with most HIV-1 infections actually being prematurely abrogated by the innate immune defenses. Evidence is accumulating that NK cells play an important role in mediating this innate resistance to HIV-1 infection. Genetic studies of HESN subjects consistently show that these individuals are enriched for NK cell receptor repertoires with an NK cell-activating profile and functional studies are starting to unravel the precise mechanistic implications of these associations. Promising new findings are pointing towards antibody-dependent cell-mediated cytotoxicity and NK cell alloreactivity as additional mechanisms of NK cell protection against HIV-1. Based on these findings and on investigations of the mucosal genital immune environment of HESN subjects and nonhuman primate species, it is becoming

increasingly clear that resistance to HIV-1 infection depends on a delicate balance of protective and detrimental consequences of the innate immune defenses and of NK cell responses in particular. Further research will need to understand the specific components of this balance before seeking to apply the HIV-1 preventive potential of NK cells in immune-based medical interventions.

Natural Killer Cells Function and Innate Immunity in HIV-2 Infection

Samuel Victor Nuvor

School of Medical Sciences, University of Cape Coast, Cape Coast, Ghana, West Africa

Definition

This entry describes what is known about the function and activity of the innate immune cell populations natural killer (NK) cells and natural killer T cells (NKT) in HIV-2 infection.

Introduction

In contrast to the extensive efforts made to learn more about HIV-1 in the fields of epidemiology, geographical distribution, and viral pathogenesis, very little work has been carried out to understand the interactions between the HIV-2 and the host immune system. Although both cellular and humoral immune responses to HIV-1 have been shown to play a part during acute infection, these activities are impaired during chronic infection, leading to disease progression and eventually death (Zhang et al. 2003).

Studies of HIV-2-infected individuals have shown that the majority experiences a slower and more prolonged disease course than seen in HIV-1 infection: therefore, a better understanding of the interactions between HIV-2 and the host immune response may be useful in providing insights for therapeutic and vaccine strategies. One way viruses are attacked early in infection is through the action of natural killer (NK) cells, which are one of the key components of the innate immune response to infections (Biron and Brossay 2001). These cells are naturally activated in response to infection without the requirement for prior sensitization and may play an important role in the outcome of viral infections. NK cells provide the first line of defense in the early stage of many infections, including HIV, and continue

to render a critical service in nonspecific host defense mechanisms. However, little is known about NK cell function in HIV-2 infection.

Natural Killer Cells

Natural killer (NK) cells are large granular lymphocytes forming about 15% of the total lymphocyte population. There are two main subpopulations of NK cells. These are CD56^{bright}, which produce cytokines and form about 10% of the NK cell population (Cooper et al. 2001), and CD56^{dim}, which exhibit cytotoxicity and form about 90% of the NK cell population. They respond to bacterial, parasite, and viral infection, as well as to tumor cells, without the need for prior antigen sensitization. Early studies showed evidence that the nonadaptive immune response mediated by NK cells played a role in bacterial, parasite, tumor, and viral immunity (Fehniger et al. 1998). NK cells exert their activities by the use of both inhibiting and activating receptors expressed on their surface. In addition to direct stimulation through activating receptors, NK cells are indirectly activated during the initial stages of viral infection by cytokines secreted by various cells of the immune system (Biron and Brossay 2001). Infection stimulates the direct production of innate cytokines such as interferon (IFN)- α , IFN- β , interleukin-2, interleukin-12, and interleukin-15. In response to these cytokines, NK cells release cytolytic granules that directly lyse infected cells. They also rapidly produce IFN- γ , tumor necrosis factor alpha (TNF- α), granulocyte-monocyte colony-stimulating factor (GM-CSF), and chemokines such as macrophage inflammatory protein-1 α (MIP-1 α), MIP-1 β , and RANTES to prevent further infection of new cells and also suppress viral replication in already infected cells (Scott-Algara and Paul 2002). As a result, the cytokines and chemokines produced during viral infection in vivo may serve not only to induce an antiviral state in nearby cells but also to enhance NK cell activity within circulating leukocytes. In addition, the activated NK cells play a role in modulating hematopoietic cell growth, reviewed in Cooper et al. (2001), and their functions further enhance the adaptive immune response.

Natural Killer Cell Development

Natural killer cells develop within the microenvironment of the bone marrow (BM) with CD34+ hematopoietic stem cells expressing growth factors (c-KIT and FLT31), cytokine receptors (IL2R β and IL-15R α), as well as other lymphoid development transcriptional factors (Yu et al. 1998).

Numerous studies have identified IL-15 as the most important soluble factor for the development of human and murine NK cells (Cooper et al. 2001). Interleukin-15 induces differentiation of human hematopoietic progenitor cells (HPCs) into NK cells in the absence of other cytokines *in vitro*. Interleukin-2 was also identified to play a role with IL-15 in inducing the differentiation of bipotential cells into NK cells, whereas IL-7 and stem cell factor (SCF) support further maturation and differentiation of NK cells. The recently described cytokine, IL-21, in combination with IL-15, was also reported to induce the development of CD56+16+ NK cells from BM HPCs (Parrish-Novak et al. 2000). The induction of IL-15 results in the development of NK cells that are CD56^{bright} cells (Cooper et al. 2001). These produce immunoregulatory cytokines or chemokines upon stimulation. The development of CD56^{dim} cells might have a distinct precursor that has not yet been identified.

Location and Subsets of Natural Killer Cells

As well as forming about 15% of circulating lymphocytes, NK cells have a similar frequency in the spleen. Natural killer cells have also been identified in the lungs, gastrointestinal tract, and liver, together with populations of NKT cells at these sites (Norris et al. 1999). They are however not commonly found in unstimulated lymph nodes and do not circulate through the lymphatic system.

The cell surface density of the CD56 receptor allows classification of NK cells into two functionally distinct NK cell subsets. About 10% of NK cells are CD56^{bright} CD16+ (Cooper et al. 2001) and the majority (90%) are CD56^{dim}CD16+, exhibiting high cytotoxic activity.

The CD56^{bright} NK cells secrete high levels of cytokines that are useful in preventing viral

infection after stimulation with monokines (Cooper et al. 2001). They show low-density expression of CD16 and are of low natural cytotoxicity as well as low antibody-dependent cellular cytotoxicity (ADCC) (Cooper et al. 2001). They also exhibit potent lymphokine-activated killer (LAK) activity. The expression of inhibitory receptors also varies in this subset of NK cells. The inhibitory CD94/NKG2A C-type lectin NK receptors (NKR) are highly expressed but they have low expression of killer immunoglobulin-like receptors (KIR). The cytokine and chemokine receptors expressed include high-affinity interleukin-2 receptors (IL-2R $\alpha\beta\gamma$), c-kit, and CC-chemokine receptor 7 (CCR7) (Andre et al. 2000). The adhesion molecule L-selectin, in combination with CCR7, is involved in trafficking to secondary lymph nodes and is predominantly found on CD56^{bright} NK cells.

In contrast CD56^{dim} NK cells have a more granular morphological structure than CD56^{bright} NK cells and produce lower levels of NK-derived cytokines (Cooper et al. 2001). They are potent mediators of ADCC, LAK activity, and natural cytotoxicity. The CD56^{dim} NK cell subsets have low levels of expression of cytokine receptors (e.g., IL-2R $\beta\gamma$) and chemokine receptors (e.g., CXCR1 and CX3CR1) (Campbell et al. 2001). They however lack L-selectin but highly express PEN5-P-selectin glycoprotein ligand-1 (PSGK-1) adhesion molecules.

Natural Cytotoxicity Receptors

There are other distinct receptors that have been identified on the surface of NK cells. They allow NK cells to recognize their target cells in a manner that is quite different from that of T cells and B cells, which depend on the presence of foreign antigen. These include the natural cytotoxicity receptors (NCRs): NKp30, NKp44, and NKp46. NKp 30 and NKp46 are uniquely expressed on resting NK cells, and their blockage impairs lysis of target cells by NK cells (De Maria et al. 2001). Their ligands, however, have not yet been identified, although it has recently been suggested NKp30 and NKp46 interact with dendritic cells and hemagglutinin, respectively (Ferlazzo et al. 2002). NKp44 is expressed when NK cells are

activated and facilitates killing of target cells during NK cell activation.

Other receptors called killer cell immunoglobulin-like short-tail (KIR-S) activating receptors in humans also contribute to the cytolytic activity of NK cells. Most activating NK cell receptors are transmembrane molecules with short cytoplasmic domains that lack intrinsic signaling features. They are associated with adaptor signaling proteins through charged amino acid residues of their transmembrane domains. The activating receptors KIR2DS, Ly49D/H, NKp44, and CD94/NKG2C associate with KARAP/DAP12 signal-transducing adaptor proteins (LaBonte et al. 2006), whereas CD16, NKp30, and NKp46 couple to the Fc ϵ R1 γ and CD3 ζ transmembrane adaptor proteins. The activating receptors recognize both MHC Class I and non-MHC Class I ligands. There are also a number of other coreceptors, which are implicated in the activation of NK cells. These include 2B4 (CD244) NKp80 and NTB-A (Bianconi et al. 2001) and CD48, CD58, and CD84 and SLAM/CD150 belonging to the CD2 subfamily of Ig-SF. They work in combination with NCRs in mediating NK cytotoxicity.

Natural Killer Inhibitory Receptors

Natural killer cells use a set of activating and inhibitory receptors to identify cells that lack MHC Class I expression. The balance between the engagements of these receptors by the target cells may result in cytolysis. Thus, NK cells do not lyse healthy MHC Class I positive cells because the presence of MHC Class I molecules usually engages inhibitory receptors on NK cells. The upregulation or downregulation of MHC Class I molecules, as may occur in tumors or infected cells, plays a major role in the ability of NK cells to lyse infected or target cells or become inhibited from cytolysis, depending on which type of these molecules is engaged by NK cells.

There are three different groups of inhibitory receptors identified for classical MHC Class I molecules on target cells. The first family of the inhibitory receptors is the killer cell immunoglobulin-like receptors (KIRs) with different numbers of immunoglobulin-like domains

(Borrego et al. 2002). They include CD158a (KIR2DL1), CD158b (KIR2DL2), CD158e (KIR3DL1), and CD158k, which recognize different alleles of HLA-A, HLA-B, and HLA-C molecules. The second is the leucocytes Ig-like receptor (ILT2/LIR1/CD85j) family found in human cells. The third family of inhibitory receptors is the lectin-like heterodimers, represented by CD94/NKG2, which are found in both rodents and human.

Natural Killer Cell Activity in Viral Infection

Natural killer cells are important in controlling intracellular pathogens. In viral infection, NK cells provide an important early defense against pathogens, while T cells, which are responsible for adaptive immunity, are undergoing a process of activation. The importance of NK cell functions in the defense against pathogens was appreciated from observations such as in an adolescent case of a selective NK cell defect which led to recurrent herpes virus infection in the patient (Biron and Brossay 2001). Loss of NK cell function also resulted in severe infection by cytomegalovirus (MCMV) in mice (Biron and Brossay 2001). Thus, NK cells play a major role in controlling microbial infections at a very early stage in infection before the adaptive immune response mediated by T lymphocytes sets in.

One way in which NK cells control infection is by direct lysis of infected cells. This involves the release of cytolytic granules, perforin, and granzyme A in close contact with the infected cells. However, it has been shown in CMV infection that NK cells could function even in the absence of perforin to mediate cytotoxicity (Seaman 2000), acting through the secretion of soluble factors which enhance the immune response of the host. These factors include cytokines such as IFN- γ , TNF- α , IL-10, IL-13, and GM-CSF. The production of such effector cytokines by NK cells is initially induced by early innate cytokine secretion in response to infection, such as IL-12, IL-15, and IL-21 (Cooper et al. 2001), and plays a major role in the early development of antiviral immune responses by recruiting other cells of the immune system to the sites of infection. These early innate-induced

cytokines not only activate NK cells but also stimulate their development and differentiation.

Natural killer cells also produce substantial amounts of IFN- γ in response to pathogenic/viral infections (He et al. 2004). This cytokine promotes a Th1 response, which in turn promotes adaptive cellular immunity as well as the effective production of antibodies that fix complement, all of which are important in host defense against intracellular infections. Moreover, NK cells are also known to support the production of cytokines that promote Th2 responses, which include the production of IgE and IgG4 and the activation of eosinophils. The capacity of NK cells to secrete IL-5 has been shown to be important in the eosinophilic response to allergen in the peritoneal cavity. Allergen-induced eosinophilic airways inflammation in the mice is also under the influence of IL-5 produced by NK cells (Kiessling et al. 1977). Thus the promotion of Th2 responses by NK cells contributes to host defense against extracellular parasites. NK cells also attack viral-infected cells by the use of fas ligands and tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) receptors as well as soluble TRAIL (Hayakawa et al. 2004).

The extent of NK cell activation is known to vary in different infections. Infection of mice with murine CMV promotes the production of IL-12, IFN- $\alpha\beta$, and IL-18 by dendritic cells (DC) that enhances IFN- γ secretion by NK cells to defend the host (Andrews et al. 2003), with IFN- $\alpha\beta$ mainly required for cytotoxicity. In contrast, infection with lymphocytic choriomeningitis virus (LCMV) activates NK cells through the release of IFN- $\alpha\beta$ mainly from DC and other monocytes which promote natural cytotoxicity. Infection with this virus actually suppresses the production of IL-12 by DC and subsequently the secretion of IFN- γ by NK cells respectively (Biron and Brossay 2001), making the role of adaptive cytokine production less important in the control of LCMV.

Type I interferons are the primary cytokines that provide the first line of immune defense against viral infections and are known to enhance the activity of NK cells during infection. They are encoded by 13 α -genes that are responsible for the

secretion of 12 IFN- α subtypes and one β -gene for the IFN- β cytokine (Smith et al. 2005). Infection of mice with murine cytomegalovirus (MCMV) induces innate cytokine IFN- $\alpha\beta$ secretion within 2 days of infection that stimulates NK cell function by promoting cytolytic activity as well as IFN- γ secretion. IFN- γ secretion in turn enhances T-cell polarization in the lymph node leading to an expansion of CD4⁺ T cells during infection. This demonstrates the cascade effect of the innate immune response in the early control of viral infection.

NK Cell Function in HIV-1 Infection

HIV-1 infection is associated with significant changes in the distribution of NK subsets in the circulation, together with the appearance of a dysfunctional subset of NK cells that are CD3-CD56-CD16⁺ and are rarely found in healthy individuals (Alter and Altfeld 2009). It is thought that accumulation of this aberrant subset accounts for the decline in NK function observed with HIV-1 disease progression. Generally, HIV-1-infected individuals with long-term nonprogression exhibit normal values of NK cells as well as normal NK functional activity (Scott-Algara and Paul 2002). A restoration of NK cell numbers has also been noted in individuals on highly active antiretroviral therapy (HAART) (Parato et al. 2002), which may support the hypothesis that continued HIV-1 replication plays a role in impaired NK cell function with disease progression. It has been suggested that infection of NK cells by the virus may favor the persistence of the virus in the host (Valentin et al. 2002). Viral proteins may also contribute to the inhibition of NK cell activities. Whereas the *env*, *nef*, and *vpu* proteins induce a strong reduction in the lytic activity of NK cells (Kottlilil et al. 2006), the *tat* protein blocked L-type calcium channels, thus interfering with NK cell activation. High viremia has been associated with the upregulation of inhibitory and downregulation of activating receptor expressions on the surface of NK cells (Kottlilil et al. 2006). Nevertheless, the mechanisms underlying the low activity and the deregulation of receptor expression of NK cells may be complex, as cytolytic activity has also been observed to correlate with low plasma viral load in some cases (Ahmad et al. 2001).

Enhanced cytolytic activity by NK cells with increased levels of perforin and granzyme A expression has been demonstrated in HIV-1-infected patients following IFN- α administration (Portales et al. 2003). The administration of IL-12 has also been used in early HIV-1 infection to increase the number of NK cells and their activity in patients. A reduced level of IL-15 may contribute to the impaired function of NK cells during chronic infection. However, in vitro costimulation of infected cells with IL-12 and IL-15 resulted in suppression of viral replication by NK cells that produce CC chemokines (Ferlazzo and Munz 2004). Interleukin-18 is produced by macrophages and has an antiviral effect, which is mainly mediated by inducing IFN- γ secretion from NK cells (Pien et al. 2000).

HIV-2 Infection

There are close similarities between the genetic structure of HIV-1 and HIV-2, the main difference being that HIV-2 expresses a *vpx* gene which in HIV-1 is *vpu* (Guyader et al. 1987). HIV-2 is closely related to SIV_{sm} which infects sooty mangabeys in West Africa, overlapping with the distribution of the HIV-2 epidemic. Currently, eight HIV-2 groups, A–H, have been reported, thought to have arisen from eight different cross-species transmissions from sooty mangabeys to humans (Chen et al. 1997), analogous to the HIV-1 groups. Unlike HIV-1 with various epidemic subtypes and circulating recombinant forms (CRFs), HIV-2 is characterized by an epidemic of only two groups (A and B) and six non-epidemic groups (C–H) (van der Loeff et al. 2006).

The Epidemiology of HIV-2 Infection

HIV-2 was first isolated from three AIDS patients from West Africa (Guinea Bissau, Senegal, and Cape Verde) in 1986 (Brun-Vezinet et al. 1987) and has subsequently been found predominantly in heterosexual populations in West Africa. Outside West Africa, HIV-2 infection also occurs in Angola and Mozambique (De Cock and Brun-Vezinet 1989). Sporadic cases of HIV-2 infection have also been identified in Europe, mainly

Portugal, in the Americas, and in India, but also in other places such as Brazil and South Korea.

In recent years, several surveillance studies have revealed a declining trend in HIV-2 prevalence in the region of origin. In West Africa from 1985 to 1996, HIV-2 infection in blood donors has decreased in nine out of ten nations (Bouckennooghe and Shandera 1999). There was also decline in HIV-2 infection rates in a survey carried out from 1988 to 2003 in 23,363 patients aged 15 years or older in the Gambia from 7.0% to 4.0% (van der Loeff et al. 2006). Between 1988 and 1992, Ivory Coast witnessed a drop in HIV-2 infection rates from 2.6% to 1.5% during a survey of 19,701 women of reproductive age (Eholie and Anglaret 2006). Similar declines have been reported in men in Guinea Bissau, with a decrease in HIV-2 prevalence from 9.1% to 4.7% in a period of 9 years from 1987, accompanied by a decline among pregnant women from 8.3% to 3.3% in 14 years from 1987 (van der Loeff et al. 2006).

Transmission of HIV-2 Infection

Although HIV-2 can be transmitted by the same routes as HIV-1, transmission usually occur through heterosexual contact. HIV-2 can also be vertically transmitted from mother to child as well as through blood transfusions, but transmissions through homosexual contact and in intravenous drug users (IVDU) are not common (van der Loeff et al. 2006). Human immunodeficiency virus type 2-infected patients show lower rates of transmission and lower plasma viral burdens than HIV-1 in infected subjects in asymptomatic stage of the disease. The mortality rate is also significantly lower than HIV-1 in subjects with CD4 counts >500 cells/ μ l but similar at lower CD4 counts (van der Loeff et al. 2006). The plasma viral load is much lower in HIV-2, but the proviral load is similar to patients with HIV-1 at the same stage of disease. This may be due to the increased sensitivity of HIV-2 to the recently described host restriction factor TRIM-5 α (Ylinen et al. 2005), which restricts the activity of retroviruses after cell entry.

HIV-2 Pathogenesis and Progression to Disease

HIV-2 infects cells of the immune system and the central nervous system, resulting in disease that occurs in very similar stages to those found in HIV-1 infection. However, HIV-2-infected individuals have a much slower disease progression and longer survival, with some individuals never progressing to AIDS (Mota-Miranda et al. 2001). The asymptomatic phase lasts for much longer periods in the majority of HIV-2-infected individuals, sometimes more than 27 years. Longitudinal studies in Caio, Guinea Bissau, have indicated that the majority of HIV-2-infected people do not progress to AIDS (van der Loeff et al. 2006).

Toward the last stage of the disease, defined as AIDS, HIV-2-infected individuals show the same clinical manifestations as seen in HIV-1 infection, with a few exceptions. Researchers in Ivory Coast found that extrapulmonary tuberculosis (TB) was less frequent in HIV-2 infection, whereas multi-organ cytomegalovirus (CMV) infections, HIV encephalitis, and cholangitis were more frequent in HIV-2 compared with HIV-1 infection (Abouya et al. 1995). In an 11-year study in Senegal, researchers found that oral candidiasis and chronic fever were more frequent in HIV-1 infection and that bacterial and cryptococcal meningitis was found only in 59 HIV-2-infected patients (Ndour et al. 2000). On the other hand, chronic diarrhea, especially those caused by bacterial infections, were observed more frequently HIV-2 AIDS patients (Ndour et al. 2000). Studies in the Gambia showed that Kaposi's sarcoma (KS) is less frequent in HIV-2 than in HIV-1 infection, but that wasting syndrome was more frequent in HIV-2 (Martinez-Steele et al. 2007).

Natural Killer Cell Function in HIV-2 Infection

Previous studies of adaptive responses in HIV-2 infection have highlighted the strong broadly neutralizing antibody responses in HIV-2-infected subjects (Rodriguez et al. 2007) and the preservation of HIV-2-specific CD4⁺ T-cell function in subjects with a normal CD4⁺ T-cell count

(Duvall et al. 2006), both of which contrast with findings in HIV-1 infection.

Only one study comparing NK cell numbers and function between HIV-1 and HIV-2 infection has been reported. In a cross-sectional study of 30 HIV-1- and 30 HIV-2-infected patients at different stages of disease recruited from clinics in the Gambia, there were similar frequencies of NK cells in both asymptomatic HIV-1- and HIV-2-infected individuals. However, in subjects with a CD4 count in the normal range, NK cell cytolytic activity was significantly higher in HIV-2-infected individuals, in whom it was comparable to that seen in seronegative controls (Nuvor et al. 2006). These differences between HIV-1 and HIV-2 infection were lost in the groups with disease progression as evidenced by lower CD4 counts: this suggests that preserved NK function may play a part in viral control in the long asymptomatic period of HIV-2 infection.

Further studies in these subjects demonstrated higher levels of expression of activating NKp44 and NKp46 receptors on NK cells from HIV-2-compared with HIV-1-infected individuals, while the expression of NKp30 was similar between the groups (V. Nuvor, personal communication). The levels of expression of the inhibitory receptor CD158a were similar between HIV-1- and HIV-2-infected subjects, but there was significantly higher expression of inhibitory receptors p70 and CD158b in HIV-1+ compared to HIV-2+ subjects. The expression levels of the NKG2D receptor and coreceptors, 2B4 and NTBA, were similar in both infections. The upregulation of activating receptors on the NK cells in HIV-2-infected subjects and the absence of the increased expression of some inhibitory receptors seen in HIV-1-infected subjects may explain our previous observations of enhanced NK-mediated cytotoxicity in HIV-2 asymptomatic infection compared to HIV-1-infected donors at the same stage of disease (Nuvor et al. 2006).

NKT Cells in HIV-2 Infection

Another lymphocyte subset, natural killer T (NKT) cells, which express invariant $\alpha\beta$ T-cell

receptors, may also play a role in HIV infection. These cells express NK cell receptors as well as the CD3 marker characteristic of T cells. Natural killer T cells form part of the early response to infection but can also enhance adaptive immunity by activating cytotoxic T lymphocytes through the secretion of Th1/2 cytokines such as IFN- γ , TNF- α , IL-4, IL-10, and IL-13 upon activation (Kotsianidis et al. 2006). These cytokines play a critical role in regulating the immune response: secretion of IL-4 in particular inhibits Th1 responses by inducing a Th2 response, whereas the production of IFN- γ enhances Th1 responses, resulting in an effective adaptive immune response. However, NKT cells are susceptible to HIV-1 infection and are significantly reduced in the peripheral blood of HIV-1-infected individuals with high levels of viremia (Mureithi et al. 2011). CD4⁺ NKT cells appear to be even more susceptible to infection than conventional CD4⁺ T cells. Thus, they are rapidly depleted during disease progression when the viral load is high, whereas CD4⁻ NKT cells are much less affected by HIV-1 infection.

It was noted that a population of NKT cells that express CD4 but are impaired in IFN- γ production was expanded in asymptomatic HIV-1- compared to HIV-2-infected individuals (Nuvor et al. 2012). These cells may serve as target cells for virus infection and replication in HIV-1-infected individuals leading to their subsequent depletion during chronic infection.

HLA-KIR Genotypes in Resistance and Susceptibility to HIV-2 Infection and Disease Progression

The function of individual NK cells is tightly regulated by the combination of inhibitory and activating receptors expressed on their surfaces, which interact with specific MHC Class I molecules and other unidentified ligands. Among these receptors are the killer cell immunoglobulin-like receptor (KIR) groups, which are categorized according to the number of immunoglobulin-like domains they encode (Borrego et al. 2002; Moretta et al. 2001). The binding of these receptors usually transmits inhibitory signals to NK cells, preventing their activity. However, when

there is downregulation of MHC or altered MHC Class I expression, as observed during HIV-1 infection (Hultstrom et al. 2004), the inhibitory receptors are not engaged by their MHC ligands, allowing the activation of NK cells and subsequent lysis of their target cells. Certain KIR gene products have been strongly implicated in the control of HIV-1 (Carrington et al. 2008), for example, KIR3DS1 in combination with ligands HLA-B Bw4-80 has been shown to confer protection against rapid progression to AIDS in HIV-1 infection (Martin et al. 2002). A recent report from Yindom et al. analyzed the relationship between KIR and HLA alleles with susceptibility and resistance to HIV-2 infection in a community cohort in Caio, Guinea Bissau (Yindom et al. 2010). This cohort was of Manjako ethnicity and was found to have more activating KIRs than seen in other W. African populations, particularly KIR3DS1. Although, in this cohort, there were no significant associations between KIR genotypes and HIV-2 disease progression, certain compound genotypes of KIR and HLA (KIR2DS2 and KIR2DL2 with at least one HLA C allele of the C1 group) were with resistance to HIV-2 infection, raising the possibility of a contribution of NK cell activity to preventing HIV-2 infection.

Conclusion

Taken together, the published data suggest that the early innate immune function of NK cells may contribute to both resistance to HIV-2 infection and long-term viral control. Adaptive cellular responses are much better preserved in asymptomatic HIV-2-infected compared to HIV-1-infected subjects, and it may be that the interactions between NK, NKT, and T cells make an important contribution to this phenomenon.

Although the NK cell function appears to be preserved in asymptomatic HIV-2-infected individuals, further studies to explore the contribution of NK cells to immune control and determine the underlying mechanisms. These efforts will complement the current search for effective vaccines and immunotherapy for HIV-1 infection.

Nef/Env/Vpu/Tetherin

Daniel Sauter

Institute of Molecular Virology, Ulm University
Medical Center, Ulm, Germany

Definition

The interferon-inducible protein tetherin (also called BST2, CD317, or HM1.24) is a key component of the innate immunity against retroviral infections. Tetherin was named after its unique ability to restrict the release of enveloped viruses by physically tethering them to the plasma membrane of infected cells. Notably, tetherin also acts as a pattern recognition receptor inducing NF- κ B-dependent expression of antiviral genes upon sensing of budding virions.

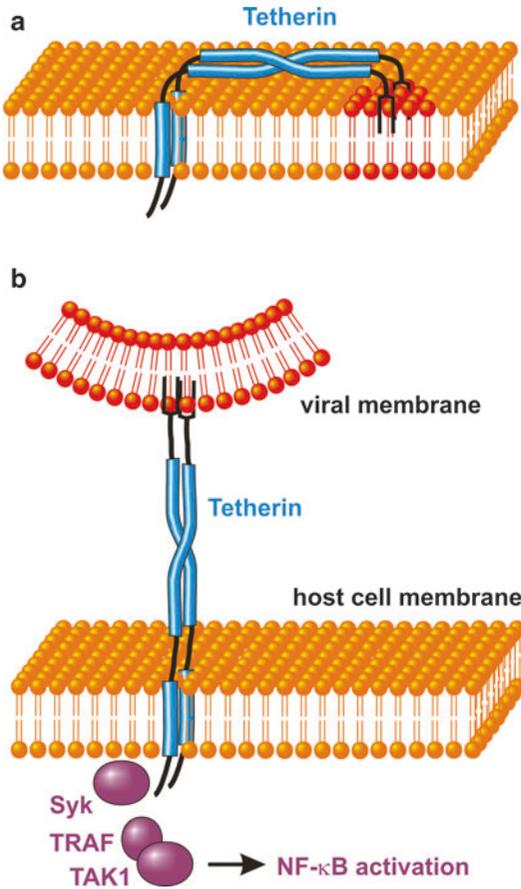

At least three primate lentiviral proteins (Vpu, Nef, and Env) have evolved the ability to counteract tetherin and enable the virus to evade this restriction. Due to a constant evolutionary arms race between virus and host, antagonization of tetherin by viral proteins is frequently species-specific. Human tetherin, for example, is resistant against counteraction by many simian immunodeficiency viruses (SIV) and represents a significant hurdle for successful zoonotic transmissions of SIV to humans. Thus, the evolution of a potent antagonist of the human tetherin ortholog may have been a prerequisite for the efficient spread of HIV in the human population.

Discovery of Tetherin

Although tetherin was already described as an interferon (IFN)-inducible gene in the 1990s, it was initially thought to be involved in the maturation of B cells since it is constitutively expressed at high levels on the surface of bone marrow stromal cell lines (“BST2”) and (plasma) B cells. Various types of cancer cells also express high levels of tetherin, and it has been hypothesized that this may constitute an evasion mechanism to inhibit the immune response against tumor cells. In agreement with this hypothesis, tetherin was shown to inhibit the secretion of type I IFN and other cytokines by interacting with immunoglobulin-like transcript 7 (ILT7) on plasmacytoid dendritic cells (pDC). A recent study, however, challenged this finding and suggested that the interaction of tetherin with ILT7 serves as a homeostatic regulation loop on immature pDCs rather than a negative feedback signal for IFN secretion (Tavano et al. 2013). The observation that the K5 protein of the Kaposi sarcoma-associated herpesvirus (KSHV) induces the ubiquitination and subsequent degradation of tetherin gave a first hint that tetherin may also be involved in the antiviral immune response. Although it had long been known that the HIV-1 accessory protein U (Vpu) counteracts an interferon-inducible restriction to enable the efficient release of progeny virions, it took until 2008 to identify tetherin as the restriction factor that blocks the release of budding HIV particles and is antagonized by HIV-1 Vpu (Neil et al. 2008; Van Damme et al. 2008).

Inhibition of HIV Release

The ability of tetherin to restrict the release of budding virions is based on its unusual topology: Tetherin has a length of about 180 amino acids and is a type II transmembrane protein with an N-terminal alpha-helical transmembrane domain that is followed by a flexible coiled-coil ectodomain and a C-terminal glycosylphosphatidylinositol (GPI) anchor (Fig. 1a) (Kupzig et al. 2003). This combination of an N-terminal

Nef/Env/Vpu/Tetherin, Fig. 1 Topology and antiviral activity of tetherin. (a) Tetherin consists of a short N-terminal intracellular tail that is followed by an α -helical transmembrane domain, an extracellular coiled-coil domain, and a C-terminal GPI anchor that is localized in lipid rafts. Three disulfide bonds mediate the formation of parallel homodimers. (b) In the presence of tetherin, newly formed virions are trapped at the surface of an infected cell since they incorporate the GPI anchor into their membrane, whereas the transmembrane domain of tetherin remains attached to the plasma membrane of the cell. The intracellular tail of tetherin is phosphorylated upon binding of budding virions and induces an NF- κ B-dependent antiviral immune response via the recruitment of Syk, TRAFs, and TAK1

transmembrane domain with a C-terminal GPI anchor is almost unique among vertebrate proteins and probably only shared with an isoform of the prion protein. Mature tetherin is glycosylated at two asparagine residues in its ectodomain and recycles between the plasma membrane, endosomes, and the trans-Golgi

network (TGN). Clathrin-mediated endocytosis depends on recruitment of AP2 to a noncanonical tyrosine motif in its intracellular N-terminal tail. Three conserved cysteine residues in the extracellular domain mediate the formation of parallel homodimers and stabilize the ectodomain of tetherin. Ultimately, antiparallel four-helix bundles may form between two homodimers. The C-terminal GPI anchor targets tetherin to cholesterol-rich microdomains (lipid rafts) which have been suggested to represent the main budding sites of HIV. As a result, budding virions predominantly incorporate the GPI anchor of tetherin into their membrane, whereas the N-terminal transmembrane domain that is located outside the lipid raft remains attached to the plasma membrane of the cell (Fig. 1b). Thus, tetherin serves as a physical bridge preventing the release of newly formed progeny virus from infected cells. This process requires a structural flexibility of the ectodomain, which is achieved by alternating stretches of stabilizing and destabilizing residues. Structural analyses revealed a distance of around 170 Å between the viral and the cellular membrane. Tethered virions are endocytosed and ultimately probably degraded in intracellular compartments.

The functional characterization of a chimeric protein with a tetherin-like topology revealed that the combination of an N-terminal transmembrane domain, a flexible ectodomain, and a C-terminal GPI anchor rather than a specific primary sequence is required for restriction of viral release (Perez-Caballero et al. 2009). In agreement with an unspecific targeting of the viral membrane, tetherin does not only inhibit the egress of lentiviruses but also that of many other enveloped viruses including filo-, arena-, herpes-, paramyxo-, or rhabdoviruses (Neil 2013; Swiecki et al. 2013; Sauter 2014).

Sensing of HIV Infection

In 2003, tetherin was identified in a screening for proteins inducing the activation of NF- κ B (Matsuda et al. 2003). Meanwhile, it has been shown that this activation of NF- κ B signaling is

linked to the ability of tetherin to act as an innate sensor. Tetherin is a classical pattern recognition receptor (PRR) and contains a hemi-immunoreceptor tyrosine-based activation motif (hemITAM) that is phosphorylated upon binding of budding virions. Tyrosine phosphorylation depends on the connection of tetherin to the cortical actin network and induces the subsequent recruitment of the tyrosine kinase Syk (Galão et al. 2014). This in turn promotes the assembly of TRAF2 and/or TRAF6, which mediates the activation of the kinase TAK1 and activates the canonical NF- κ B signaling cascade to induce the expression of antiviral genes (Fig. 1b).

Tetherin orthologs have been identified in many mammalian and some reptile species. Whereas the ability to restrict virion release is highly conserved among different species, only human and to a lesser extent chimpanzee tetherin are able to sense viral infections in human cells. Thus, innate sensing seems to be an evolutionarily novel function that tetherin has acquired rather recently.

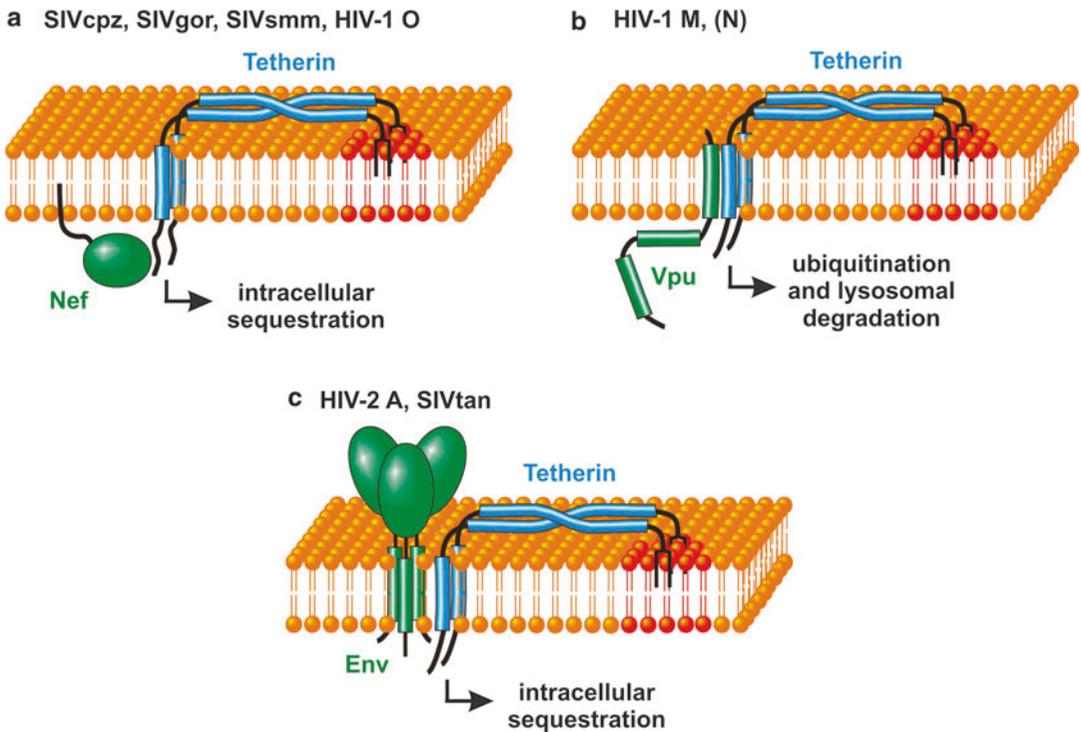

In summary, the antiviral activity of tetherin is not limited to its ability to trap budding virions at the surface of infected cells but also involves the induction of an antiviral immune response (Hotter et al. 2013).

Retroviral Countermeasures

Since tetherin does not target a specific viral protein but rather nonspecifically interferes with the budding process by targeting the viral envelope, viruses cannot simply acquire evasion mutations that render them resistant against tetherin. Instead, many enveloped viruses have evolved direct *trans*-acting antagonists that remove tetherin from the sites of budding and/or target it for degradation. Among the tetherin antagonists identified until today are three primate lentiviral proteins: Nef, Vpu, and Env. Most simian immunodeficiency viruses (SIV) including SIVcpz and SIVgor – the direct chimpanzee and gorilla precursors of HIV-1 – use their accessory protein Nef to counteract tetherin in their respective host species (Zhang et al. 2009; Sauter et al. 2009). The

myristoyl-anchored SIV Nef protein targets the N-terminal cytoplasmic tail of monkey or ape tetherin to enhance its AP2- and clathrin-mediated endocytosis (Fig. 2a). Notably, total cellular levels of tetherin are not altered in the presence of Nef since it does not target the restriction factor for degradation but rather sequesters it in intracellular compartments. Residues within and adjacent to a conserved di leucine motif (EXXXLL) in the C-terminal loop of Nef are crucial for tetherin counteraction. These amino acids may either directly interact with the cytoplasmic domain of tetherin or affect the affinity for specific adaptor proteins that are involved in cellular trafficking pathways. Interestingly, human tetherin is resistant against SIV Nef due to a deletion of five amino acids in its cytoplasmic tail that evolved after the divergence of chimpanzees and humans. As a consequence, tetherin constitutes a significant barrier for successful zoonotic transmissions of SIV to humans (Sauter et al. 2010).

HIV-1 groups M, N, O, and P are the results of four independent cross-species transmissions of SIVcpz or SIVgor and have evolved different means to overcome this hurdle. HIV-1 group M, which is largely responsible for the global AIDS pandemic, has switched from Nef to Vpu to antagonize tetherin in humans (Fig. 2b). The ~16 kDa protein Vpu interacts with tetherin in the trans-Golgi network via its transmembrane domain and inhibits the anterograde transport of the restriction factor. Although this sequestration of tetherin in the TGN may already enhance virion release to a certain extent, full anti-tetherin activity depends on a conserved diserine motif (DSGXXS) in the cytoplasmic part of Vpu that binds the adaptor protein β -TrCP to recruit an E3 ubiquitin ligase complex. As a result, tetherin is ubiquitinated and ultimately degraded in endolysosomal compartments. Vpu proteins of HIV-1 group N strains have also evolved the ability to directly interact with human tetherin. Many HIV-1 group N Vpus however lack the β -TrCP-binding motif and/or additional functional domains. Therefore, most of them are only poor tetherin antagonists and have lost their second function: the ability to decrease the surface levels of CD4 (Sauter et al. 2009). The poor anti-tetherin activity

Nef/Env/Vpu/Tetherin, Fig. 2 Viral counteraction of tetherin. (a) Nef proteins of HIV-1 group O and many simian immunodeficiency viruses target the N-terminal tail of tetherin and sequester it in intracellular compartments by inhibiting its anterograde transport or accelerating its endocytosis from the plasma membrane, respectively. (b) Vpu proteins of HIV-1 group M inhibit the anterograde transport of tetherin and recruit an E3 ubiquitin ligase complex to induce its ubiquitination and subsequent endolysosomal

degradation. HIV-1 group N Vpus have only weak anti-tetherin activity since most of them fail to recruit the ubiquitin ligase complex. Vpu and tetherin interact via their transmembrane domains. (c) HIV-2 Env enhances clathrin-mediated endocytosis of tetherin and relocates it to intracellular compartments. The extracellular gp120 subunit of Env probably interacts with the ectodomain of tetherin

and loss of Vpu-mediated CD4 down-modulation may be one plausible explanation why HIV-1 group N strains did not spread significantly in the human population. Only about 17 patients infected with HIV-1 group N have been identified until today. HIV-1 group O has spread epidemically in Africa and infected around 100,000 individuals, although it has not evolved a Vpu-mediated counteraction of tetherin. Instead, HIV-1 O Nef acquired the ability to target a motif adjacent to the protective deletion in the intracellular tail of human tetherin to enable efficient egress of progeny virions (Kluge et al. 2014). Similar to SIV Nef, HIV-1 O Nef does not induce the degradation of tetherin but sequesters it in intracellular compartments. This sequestration depends on amino acid residues in the

C-terminal loop of Nef and involves the inhibition of the anterograde transport of newly synthesized tetherin (Fig. 2a). With only two cases described, HIV-1 group P is the rarest of all four known groups of HIV-1. In agreement with a poor adaptation to the new human host, no anti-tetherin antagonist has been described in this group so far.

The direct precursor of HIV-2, the second human immunodeficiency virus, is SIVsmm naturally infecting sooty mangabeys. At least nine independent cross-species transmissions of SIVsmm to humans occurred and gave rise to HIV-2 groups A-I. Similar to SIVcpz and SIVgor, SIVsmm Nef efficiently antagonizes tetherin in its natural host (Fig. 2a) but fails to counteract the human ortholog due to the protective five-amino-acid deletion in its cytoplasmic tail. HIV-2 does

not encode a *vpu* gene and mastered the tetherin hurdle by switching from Nef- to Env-mediated antagonism (Le Tortorec and Neil 2009). The HIV-2 envelope protein probably interacts with the extracellular domain of human tetherin and accelerates its clathrin-mediated endocytosis (Fig. 2c). The latter effect depends on an endocytosis signal in the cytoplasmic gp41 subunit of Env and results in an intracellular sequestration of tetherin. Interestingly, the envelope protein of a distantly related virus from tantalus monkeys (SIVtan) employs a similar mechanism to antagonize tetherin (Fig. 2c). However, it remains to be determined whether this is a real and general ability of SIVtan Env proteins since the only isolate that was analyzed so far had been passaged in a human T cell line before cloning. In contrast to HIV-1 group M Vpu, HIV-2 and SIVtan Env do not induce the degradation of tetherin but only interfere with its subcellular trafficking. The nine groups of HIV-2 differ substantially in their prevalence in the human population: Whereas groups A and B spread to a certain extent in Western Africa, groups C to I have only been isolated in single patients and may represent dead-end zoonoses. It should be noted that only envelope proteins of HIV-2 group A have been characterized for their anti-tetherin activity. Thus, it remains unclear if and how HIV-2 groups B-I counteract human tetherin.

Interestingly, two different isoforms of human tetherin exist that differ in their sensitivity against Vpu- and Nef-mediated counteraction (Cocka and Bates 2012). The shorter isoform lacks twelve amino acids at its N-terminus since translation is initiated from an alternative start codon. This N-terminal truncation involves the loss of the dual tyrosine motif that is essential for activation of NF- κ B signaling, binding to the cortical actin network and endocytosis. Although the short isoform does not act as an innate sensor, it may still confer a selective advantage against viral proteins that target residues in the intracellular N-terminal tail of tetherin. HIV-1 O Nef, for example, sequesters only the long isoform of human tetherin in intracellular compartments but fails to antagonize the short isoform due to the lack of its target sequence. Similarly, the short isoform is largely

resistant against HIV-1 group M Vpu since full anti-tetherin activity of Vpu depends on the presence of the endocytosis signal and N-terminal ubiquitination sites.

In addition to the evolution of direct antagonists, primate lentiviruses may also employ alternative strategies to evade restriction imposed by tetherin. One such strategy is to inhibit the expression of tetherin on a transcriptional level. Vpu proteins of most primate lentiviruses, for example, have been shown to inhibit the activation of the transcription factor NF- κ B that regulates the expression of interferons and interferon-stimulated genes (ISGs). As a result, Vpu prevents the induction of tetherin and several additional antiviral genes in SIV- or HIV-infected cells. Notably, this effect of Vpu on NF- κ B is independent of its anti-tetherin activity and involves the stabilization of I κ B (Sauter et al. 2015).

It has also been suggested that tetherin restriction may be saturated by large amounts of budding virions and (at least partially) be overcome by direct cell-to-cell spread, which constitutes a major route of transmission in an HIV-infected individual. All in all, primate lentiviruses have evolved various independent sophisticated means to counteract or evade the host restriction factor tetherin (Neil 2013; Swiecki et al. 2013; Sauter 2014).

Role in Pathogenesis and Spread

Several mouse models confirmed a significant role of tetherin in restricting retroviral infections *in vivo* and revealed that lack of tetherin is associated with increased viral loads and faster disease progression. For example, Moloney murine leukemia virus infections were more pathogenic in tetherin knockout mice than in their wild-type littermates. Similarly, Friend murine leukemia virus replication was inhibited by increased tetherin surface expression levels in another mouse model. In agreement with this, Vpu boosted the initial phase of HIV-1 M replication in humanized mouse models, although it seemed less important for viral dissemination during later stages of infection. The role of tetherin in the

pathogenesis of AIDS is underscored by an association study that identified a 19-base-pair insertion/deletion polymorphism in the promoter of human tetherin that is associated with disease progression, potentially due to differences in total tetherin expression levels (Laplana et al. 2013). Although HIV-1 groups M, N, O, and P differ in their ability to antagonize human tetherin, all four groups are pathogenic, and infected patients may ultimately progress to AIDS. Noteworthy, however, the pathogenic potential of these viruses has never been compared systematically, and it remains unclear whether the rates of disease progression are comparable. The investigation of longitudinal samples from HIV-1 M-infected individuals revealed that Vpu-mediated anti-tetherin activity is highly conserved throughout the course of infection, arguing for a constant selection pressure exerted by tetherin.

Notably, tetherin may not only limit viral dissemination and pathogenesis within an infected individual but also reduce transmission of the virus and inhibit its spread in the human population. The fact that only HIV-1 groups M and O spread significantly after zoonotic transmission from apes to humans suggests that the evolution of a potent tetherin antagonist may have been a prerequisite for the efficient spread of primate lentiviruses in the human population. In contrast, HIV-1 groups P and N, which do not or only poorly antagonize tetherin, respectively, have remained rare and largely restricted to Cameroon. Thus, the host restriction factor tetherin has clearly shaped the evolution of HIV, and the current AIDS pandemic may be a sinister example for the striking ability of primate lentiviruses to quickly adapt to new hosts.

Conclusion

Tetherin unifies all characteristics of a classical antiretroviral restriction factor. As a first line of defense against viral pathogens, it is constantly expressed on many cells including activated

CD4⁺ T cells and macrophages, the main target cells of HIV. Furthermore, tetherin is interferon-inducible, and its expression is upregulated upon viral infection. Similar to other host restriction factors such as TRIM5 α , SAMHD1, or APOBEC3G, tetherin also inhibits a specific step of the viral replication cycle, and many retroviruses have evolved means to antagonize or evade this restriction. Due to the strong and constant selection pressure exerted by viral antagonists, tetherin shows signatures of site-specific positive selection, another feature of prototypic host restriction factors. As a consequence of the rapid coevolution between viruses and their respective hosts, tetherin antagonism is often species-specific. A significant example with probably far-reaching implications for the evolution of HIV is the deletion of five amino acids in the N-terminal cytoplasmic tail of human tetherin that rendered it resistant against Nef-mediated counteraction by many simian immunodeficiency viruses. Similar species-specific effects have also been described for Vpr-/Vpx-mediated counteraction of SAMHD1 and the interaction of TRIM5 α with lentiviral capsid proteins. Thus, tetherin and other host restriction factors do frequently not only inhibit the spread of viral pathogens within a population but may also represent significant hurdles for successful (zoonotic) cross-species transmissions.

In addition to these classical features of antiretroviral restriction factors, tetherin also exhibits a unique characteristic: Unlike TRIM5 α and APOBEC3G, which are largely retrovirus-specific, tetherin only unspecifically targets the viral budding process and has broad activity against diverse enveloped viruses. In this regard, tetherin resembles pattern recognition receptors of the innate immune system because it senses a conserved pattern (i.e., budding of progeny virions) of only distantly related pathogens and induces the activation of NF- κ B to trigger an antiviral immune response. Since tetherin senses the very last step of the viral replication cycle, this alert signal certainly comes too late for the infected cell. Nevertheless, tetherin-mediated release of

interferons and other antiviral cytokines triggers the induction of ISGs and the establishment of an antiviral state in neighboring cells that are at risk for infection.

In summary, the coevolution of primate lentiviruses and the tetherin orthologs of their respective host species is a vivid example of the Red Queen hypothesis proposing that organisms must constantly evolve and adapt to not become extinct in an ever-changing environment. Tetherin combines all features of a classical restriction factor with those of a pattern recognition receptor. Its potent and broad antiviral activity has driven the evolution of at least three different antagonists in primate lentiviruses, and the degree of adaptation to human tetherin may be an important determinant of the spread and potentially pathogenesis of HIV in humans.

Network Interventions

Melissa A. Davey-Rothwell and Carl A. Latkin
Department of Health, Behavior and Society,
Johns Hopkins Bloomberg School of Public
Health, Baltimore, MD, USA

Definition

Social networks refer to the web of social ties or relationships that exist among individuals. Some common examples of social network members include family, friends, sex partners, drug partners, neighbors, etc. Social network members influence each other's behaviors because individuals often compare themselves to others (Latkin and Knowlton 2005).

This entry describes network-level interventions which are designed to change the knowledge, skills, norms, and behaviors of a social network rather than a specific person. These interventions capitalize on naturally occurring relationships among individuals.

HIV and Social Networks

The behaviors that increase the risk for HIV, such as having unprotected intercourse and sharing needles, are social behaviors. This means that each behavior involved is often done in the presence of one or more people. HIV is transmitted through risk networks including sex partners or drug partners (Neaigus et al. 1994).

Social network members' characteristics and behaviors have been linked to a variety of HIV risk behaviors such as frequency of drug use, sharing injection equipment, multiple partners, condom use, and exchanging sex for money or drugs (Davey-Rothwell et al. 2010; Latkin et al. 1995; Neblett et al. 2011). For example, individuals are more likely to engage in unprotected sex or share needles if they have social network members who also do these risky behaviors. In addition, social network characteristics are associated with health-promoting behaviors such as HIV

medication adherence and HIV testing (Downing et al. 2001; Simoni et al. 2007). If a family member or friend encourages or supports a person living with HIV/AIDS (PLHA) to take HIV medications, that PLHA will be more likely to take medications due to the social support provided in their social network.

Because HIV risk may be shared among social network members, interventionists have capitalized on social network dynamics as a vehicle to disseminate HIV risk reduction. By engaging a relatively small number of individuals in a social network, social network interventions are a viable method to reach hidden populations that may not access prevention services or participate in interventions.

In network-level interventions, social network members may provide support to each other, establish and enforce norms about appropriate behaviors, and share information and skills.

Social Networks and Diffusion

Social networks are a vehicle through which HIV prevention information, resources, social norms, skills, and behaviors can be diffused from a few people to a larger number of individuals. Network structures may also influence the ability for intervention diffusion and sustainability. Behavior change may diffuse more quickly in dense (i.e., close) networks. Isolated networks (i.e., small networks, with few connections to other individuals) may be more likely to sustain behavior change, yet there is likely to be less diffusion of behavior change from these networks to other networks (Latkin and Knowlton 2005). More than one distinct behavior may be diffused in HIV prevention interventions. Given the diversities of network structures and social positions or statuses, providing individuals and communities with a variety of risk-reduction options is more likely to succeed compared to promoting only one risk-reduction option.

Social Support and Social Networks

Social network members provide resources to each other in the form of social support. Social

support may include tangible support, such as lending money, or intangible support such as offering advice. Common types of social support include emotional support (i.e., sharing advice), informational support (i.e., sharing information and resources), financial support (i.e., lending money), and material support (i.e., sharing goods). Social support may be perceived or enacted. *Perceived support* is an individual's perception that she could obtain support from social network members if needed. For example, perceived support could be measured by the question "Do I have someone in my social network that could lend me money (financial support)?" while *enacted support* is support that has actually been provided, such as "Who has given me a loan in the past?" In social network interventions, individuals learn skills to influence network members as well as provide emotional, informational, and even material support for behavior change.

Social Norms and Social Networks

Social norms serve as guides for which behaviors are common in a social network. Social networks establish and proliferate norms about which behaviors network members should practice as well as behaviors that network members disapprove of. Norms have consistently been found to predict HIV risk behaviors. Specifically, if a person believes that members of their social network, such as sex partners or friends, share needles, that person is more inclined to share needles, too.

Social norms are created by observing others and comparing behaviors to others as well as verbal and nonverbal communication. Through observance of others' behaviors and comparing actions, norms about which behaviors are appropriate for a given social environment may emerge. Research has shown that people are more likely to be influenced by others that they perceive as similar to them (Festinger 1954). Thus, a person who uses drugs may be more likely to utilize a needle-exchange program if they believe that other social network members use them too or if a network member encourages them to use the program.

Social network interventions are designed to promote HIV risk-reduction behaviors as socially acceptable and socially approved behaviors. For example, as participants learn risk-reduction techniques such as how to clean injection equipment, they begin to model their behaviors among their drug partners. By observing this risk-reduction behavior among network members, drug users may be persuaded to change their own risky behaviors. As more and more people practice risk reduction, cleaning injection equipment becomes a normative behavior. Some behaviors, however, are not readily observable among network members. For sex behaviors such as condom use, network members may change acceptable communication norms by discussing safer sex. Consequently, these discussions may lead to changes in perceived norms that endorse safer sex and changes in risk behaviors.

Examples of Network-Level Interventions

Two models of HIV prevention network interventions that have been shown to lead to behavior change and have been widely implemented in both the USA and international settings are presented in the next section. Both of these interventions have been disseminated by the Centers for Disease Control and Prevention to community-based organizations and public health departments across the USA (www.effectiveinterventions.org).

Network-Oriented Peer Education Interventions

One type of network intervention model is peer education. Network-oriented peer education programs train a small group of individuals to educate members of their social networks. Through peer education, individuals serve as a vehicle to share information and exert social influence through persuasion and modeling to members of their social network. Any individual in a social network may be trained as a peer educator. Peer education has been implemented in both the USA and international settings within a variety of populations such as college students, commercial sex workers,

people living with HIV/AIDS, and people who use drugs.

During a peer education intervention, peer educators acquire knowledge, skills, and resources such as condoms and information about local HIV testing or addiction services. Skills are built through hands-on activities such as role-playing and problem-solving exercises. In addition to learning about risk reduction, participants are also taught communication and outreach skills. Peer educators use communication and outreach skills to engage their peers and disseminate the intervention material. Thus, peer education interventions have the potential to reach a wider range of individuals than just those who participate in the intervention. In addition to diffusing information, peer educators also model risk-reduction behaviors (Davey-Rothwell et al. 2011).

As network members observe peer educators and increase discussion about safer behaviors, network members may perceive risk reduction as normative and begin to change their behaviors. Likewise, as peer educators share information and resources with people in their network, they may also begin to change their own behavior. Thus, peer education interventions have been shown to lead to behavior change among peer educators and the recipients of peer outreach (Tobin et al. 2011).

The Self-Health in Eliminating Life-Threatening Diseases (SHIELD) intervention was developed in Baltimore, MD, through a research study funded by the National Institutes of Health (Latkin et al. 2003). In the SHIELD intervention, people who used drugs were trained to be peer educators. The peer educators attended several group sessions led by two facilitators. Through intervention activities, participants learned HIV risk-reduction information and options; practiced safer sex, safer drug use, and peer outreach skills; and reached risk-reduction materials. After attending each session, participants were asked to share risk-reduction information and materials with members of their social network through outreach and modeling of safer behaviors. A 6-month evaluation showed that peer educators reduced their needle sharing and drug injection frequency and increased condom use with casual partners as

compared to the comparison condition. Additional analyses from this study showed that this approach changed the norms of network members, which could lead to changes in behavior. This model has been tailored and implemented in a variety of other locations including Philadelphia, Pennsylvania; Vietnam; St. Petersburg, Russia; Chiang Mai, Thailand; and Chennai, India.

Popular Opinion Model

Another network-level intervention implemented in HIV prevention is the popular opinion model. While peer educator interventions are guided by the premise that any member of a social network can affect another member's behavior, the popular opinion model emphasizes the importance of identifying key (i.e., popular) social network members to promote risk reduction. Key network members often have high centrality (i.e., high number of ties with other members of the network) or information social roles within their social network. Through formative work, researchers identify individuals in a social network who interact with a large number of people and are considered influential or popular and may be able to have an influence on other people's behavior. These individuals participate in training and then are asked to share information and model behavior with people they know such as close friends and acquaintances.

The popular opinion model was first introduced in the early 1990s as part of an HIV prevention intervention for men who have sex with men (Kelly et al. 1991). In this intervention, bartenders were asked to identify popular individuals, who were then trained to endorse and promote risk reduction among their bar-attending friends. These key network members, called "opinion leaders," were trained in HIV risk reduction and communication skills, such as practicing HIV-related conversations that they could then repeat with their peers. This intervention model has been widely applied in the USA and in international settings. Initial studies of the "popular opinion leader" model showed decreases in unprotected anal sex, decreased sex partners, and increased condom use (NIMH Collaborative HIV/STD Prevention Trial Group 2010).

Conclusion

Network-level interventions can have a broad impact and therefore play an important role in HIV prevention. Social network interventions are cost-effective because they serve participants in the interventions as well as the hidden populations who are not directly trained by the program staff. Through the diffusion of information, social support, and norms, network-level interventions have great potential for sustainability and change in a given population.

NeuroAIDS in Resource-Poor Settings, Assessment, and Treatment of

Leigh van den Heuvel¹, Soraya Seedat¹ and Christine Fennema-Notestine²

¹Faculty of Medicine and Health Sciences, Department of Psychiatry, University of Stellenbosch, Cape Town, Western Cape, South Africa

²Departments of Psychiatry and Radiology, University of California, San Diego, La Jolla, CA, USA

Introduction

In 2013, an estimated 35 million people (0.8%) were infected with human immunodeficiency virus (HIV) globally, although the burden of the epidemic is disparately distributed, with over two-thirds of the world's HIV-infected individuals residing in sub-Saharan Africa where the adult prevalence is as high as 4.7% (UNAIDS 2014). Thus, the majority of individuals affected by HIV who require treatment reside in resource-poor settings. With increased dissemination of, and access to, combined antiretroviral therapy (cART), the profile of HIV infection is changing to that of a chronic disease, with the cause of death more likely to be from an HIV-associated non-AIDS condition. This has implications for clinicians

and other health-care providers in terms of the goals of care and the approach to management.

In low-resource settings, many individuals with HIV will develop some form of peripheral or central nervous system (PNS or CNS) disease. Neurological disorders most often associated with HIV can include opportunistic infections (e.g., tuberculosis, cryptococcal meningitis, toxoplasmosis, and cytomegalovirus encephalitis), CNS neoplasias (e.g., Kaposi's sarcoma, primary CNS lymphoma), progressive multifocal leukoencephalopathy (PML), and CNS manifestations that are the adverse effects of cART (Singer et al. 2010). Seizures, myelopathies, aseptic meningitis, neuropathies, and myopathies occur less commonly. Similar to developed regions, however, HIV-associated neurocognitive disorders (HAND) are the most prevalent neuroAIDS disorder in low- and middle-income countries (LMICs) (Chibanda et al. 2014), including Africa, the region with the highest HIV burden (Alkali et al. 2013). Since most of the CNS disorders develop in the advanced or acquired immunodeficiency syndrome (AIDS) stage, when CD4 (cluster of differentiation 4) cell counts fall below 200 cells/mm³, their prevalence has decreased with increased access to cART; however, opportunistic infections still pose a major health problem in developing countries where patients often present late with advanced immunosuppression (Wright 2014). In Africa, stigma remains a major problem and can delay HIV testing and seeking help, and even then, the diagnosis of opportunistic infections is often delayed due to a lack of neuroimaging and laboratory facilities, and appropriate treatment for cryptococcal meningitis is often not available or is unaffordable (Alkali et al. 2013). Furthermore, neuro-IRIS (immune reconstitution inflammatory syndrome) is also a common condition in resource-poor settings where cART is delayed and often initiated at advanced stages of HIV (e.g., CD4 cell counts below 50 cells/mm³) (Alkali et al. 2013), resulting in clinical deterioration that occurs shortly after cART initiation due to a dysregulated inflammatory response to underlying infections (commonly CNS tuberculosis, toxoplasmosis, and cryptococcal meningitis). Thus in low-resource settings, the

aforementioned conditions remain major causes of morbidity and/or mortality due to the many challenges that can hamper their timely identification and management.

HAND, one of the major causes of dementia worldwide, remains the most prevalent neuroAIDS disorder in all settings and a primary challenge for clinicians, and will thus be the focus of this review. Although the burden of disease is higher in resource-poor settings, much of the research on HAND has been conducted in developed regions. In low-resource settings, already burdened by delayed initiation of cART and fewer treatment options, there is often a dearth of expertly trained personnel, while existing personnel are overburdened by high patient throughput, limiting early diagnosis.

Classification

The neurocognitive impairments associated with HIV were previously known by various terms, such as "AIDS dementia complex," "HIV dementia," "HIV encephalopathy," and "minor cognitive motor disorder," with more recent consensus criteria now commonly employed (Antinori et al. 2007). HAND is subclassified into asymptomatic neurocognitive impairment (ANI), mild neurocognitive disorder (MND), and HIV-associated dementia (HAD). Both ANI and MND involve a minor decline in cognition, but MND is diagnosed when there is mild impairment in more difficult activities of daily living (ADL), such as work, financial planning, and driving. In contrast, in HAD there is evidence of a significant decline in cognition, as well as considerable impairments in more routine ADL, such as daily errands, housekeeping, and self-care. Due to decreased availability of formal neuropsychological testing in resource-poor settings, it is likely that ANI goes largely undetected.

Pathophysiology

HIV invades the CNS shortly after initial infection as leucocytes infected with HIV cross the blood-

brain barrier (BBB). The virus then continues to replicate and infect cells in the CNS, such as microglia, macrophages, and astrocytes. HIV infection in the CNS leads to the release of neurotoxic viral proteins and host inflammatory molecules, leading to neuronal cell damage, breakdown of the BBB, and decreased immune function. Higher viral loads in the CNS are associated with increased neurological sequelae (Singer et al. 2010). The main areas demonstrating degenerative changes are the basal ganglia and the frontal white matter tracts. Although limited pathology studies have been conducted in resource-poor settings, these studies support similar pathological changes (Robertson et al. 2010).

Epidemiology

HAND is prevalent across settings internationally; however, varying approaches to neurocognitive assessment make comparison difficult. The wide range in prevalence may be attributable to differences in measurement, ART treatment status, HIV 1 subtypes, comorbidities, or demographic features (e.g., age, education, gender distribution). The prevalence of HAND has remained fairly unchanged even since improved treatment, with about half of individuals stable on cART demonstrating some form of HAND, although the presentation is generally more mild (Clifford and Ances 2013). A systematic review and meta-analysis assessing HAND in sub-Saharan Africa, the region with the highest prevalence of HIV, reported similarly high prevalence of HAND as in developed settings (Habib et al. 2013). The authors estimate that eight million HIV-infected individuals in sub-Saharan Africa are likely to be affected by HAND. While HAND is probably the most common cause of cognitive dysfunction in young adults in LMICs (Sacktor et al. 2007), the burden is likely to be underappreciated in resource-poor settings where HAND may be overshadowed by other serious medical conditions and under recognized by health-care workers. The

persistence of HAND in the current era may be attributed to continued CNS HIV infection and inflammation, despite peripheral viral suppression with cART, as well as late initiation of cART and potential ART neurotoxicity (Clifford and Ances 2013).

Risk factors for HAND include factors related to the virus, treatment, host-related factors, as well as comorbid disorders. Cognitive reserve (premorbid cognitive capacity) is fostered by enriched environments, improved education, and employment, and high reserve can delay or reduce the impact of cognitive disorders. Reserve, however, can be impeded by CNS insults, trauma, and stress, and lower cognitive reserve is a risk factor for the development of dementia, including HAND. In resource-constrained environments, individuals often have barriers to attaining higher cognitive reserve, such as lower levels of poorer quality education and higher unemployment rates, alongside increased medical comorbidity and trauma exposure, leaving these individuals at higher risk for HAND (Tedaldi et al. 2015; Vance et al. 2014). Due to variable quality of education in resource-poor settings, reading ability or literacy may be a better indicator of underlying cognitive functioning (Tedaldi et al. 2015). In these settings, HAND generally appears to be unrelated to HIV 1 subtype (clade), although some studies in African countries have demonstrated differential risk for HAND according to HIV subtype (Robertson et al. 2010). A number of mental and substance use disorders, in particular depression and alcohol use disorders, are frequently comorbid with HAND in LMICs (Chibanda et al. 2014). Similar to developed countries, in sub-Saharan Africa, psychiatric comorbidity is associated with an increased risk of HAND, while the use of cART reduces risk. In a meta-analysis of studies in sub-Saharan Africa, HAND was not associated with age, gender, CD4 cell count, or years of education, risk factors commonly observed in developed settings (Habib et al. 2013). However some studies in Africa have demonstrated associations between anemia, low CD4 cell count, and advanced clinical stage and HAND (Robertson et al. 2010).

Clinical Features

HAND usually develops over a period of months, and symptom severity can fluctuate over time. The pattern of cognitive impairment is typically that of a subcortical dementia, with early impairments in working memory and executive functioning. These impairments correlate with brain regions primarily affected by HIV, such as the striatum and subcortical white matter tracts. Individuals with HAND generally display impairments in three domains: cognition, behavior, and motor functioning (Alfahad and Nath 2013). Studies from Africa similarly demonstrate impairments in executive functioning, verbal fluency, processing speed, memory, and motor speed (Robertson et al. 2010). The majority of individuals with HAND have ANI, and even though impairments are found on testing, these individuals display no symptoms or difficulties with daily functioning. Individuals with MND typically have milder neurocognitive symptoms, with deterioration and slowed performance in complex tasks such as problem solving, comprehension, and mild memory difficulties. Patients with HAD typically have pronounced slowing in thinking and movement, with prominent apathy and mood changes (Alfahad and Nath 2013). Mania and psychosis can develop in patients with HAD with advanced immunosuppression (CD4 count falls below 200 cells/mm³). In individuals stable on cART, HAD can emerge at higher CD4 counts. Cortical impairments characteristic of other dementias, such as episodic memory, language, and visuospatial decline, are seen more frequently in those who develop dementia on cART, which can increase diagnostic complexity (Clifford and Ances 2013).

Screening

Screening may identify individuals who need further evaluation and more formalized testing, particularly if functional impairment is also reported. Ideal screening tests for HAND should be brief, easy to administer, and able to reliably identify individuals with HAND, with annual screening.

Screening shortly after HIV diagnosis and prior to cART initiation can provide a baseline estimate with which to compare future testing. Routine screening for HAND, however, is still not the norm in LMICs (Chibanda et al. 2014), and many effective screening tools in existence have not been culturally and linguistically validated in most LMICs. Of several common pen and paper bedside tests, the International HIV Dementia Scale (IHDS) (Sacktor et al. 2005) is predominantly used in LMICs as it is brief, relies less on language proficiency, and can be administered by health-care workers with varying levels of expertise. The IHDS involves three subtests, a non-dominant finger tapping test, a non-dominant hand position sequence, and a four word recall test (4 points for each test, a total score of 10 or less out of 12 indicates possible HAND). In resource-poor settings, however, patients who screen negative on the IHDS often display impairments of executive functioning on formal testing. Furthermore, the IHDS is best suited for detecting possible HAD than milder forms of HAND, limiting its utility. Adding tests of executive functioning to a screener such as the IHDS may improve sensitivity (Habib et al. 2013). Screens that use a combination of three to five neuropsychological tests (tests of verbal learning, attention/working memory, and processing speed) appear to perform better than paper and pen screens such as the IHDS (Kamminga et al. 2013). However these tests require administration and interpretation by a qualified psychologist which diminishes the practicality of their use. A Swiss study identified three screening questions that can effectively identify symptomatic HAND in individuals stable on cART and can easily be applied in low-resource contexts (Simioni et al. 2010). The three questions focus on difficulties in concentrating, remembering, and reasoning and planning abilities and should preferably be combined with a brief bedside test, such as the IHDS.

As depression and alcohol abuse are the most prevalent mental and substance use disorders in LMICs and are commonly comorbid with HAND, integrated screening approaches that combine screening for cognition, depression, and alcohol

use may work best (Chibanda et al. 2014). ANI and MND can predict the future development of HAD but are often only identified following a full neuropsychological assessment (Alfahad and Nath 2013). Early detection of these milder forms of HAND can help identify individuals at risk allowing for regular monitoring and earlier access to treatment. Future efforts at developing improved screening approaches should ideally take place in resource-poor settings to ensure broader applicability.

Diagnosis

HAND is diagnosed when there is evidence of cognitive deterioration and impairment in functioning, and alternative causes have been excluded or addressed (Antinori et al. 2007), although increased comorbidity of other medical and mental disorders may complicate diagnosis (Chibanda et al. 2014). There are no pathognomonic laboratory or imaging investigations for HAND, and milder symptoms of HAND can easily be ascribed to other disorders. Individuals who have HAND may benefit from earlier ART initiation and require additional planning and support to ensure adequate adherence.

Official diagnosis of HAND requires formal neuropsychological testing, which often is not available in resource-poor settings in part owing to the lack of expertise and personnel shortages (Alkali et al. 2013). Neurocognitive testing is mainly utilized in research, and its use in clinical settings is fraught with difficulties. Determination of cognitive impairment requires the use of population-specific reference norms which are lacking in most low-resource settings (Clifford and Ances 2013). Translated versions of the tests also require validation prior to their use. Increased efforts need to be directed at developing local norms for low-resource settings with a high burden of HIV. Even so, neuropsychological testing may fail to differentiate underlying cognitive limitations from that caused by HAND (Chibanda et al. 2014). Guidelines suggest that if neuropsychological testing is not available, clinicians should depend on clinical assessments, such as

bedside testing, and their professional judgment to diagnose HAND (Antinori et al. 2007).

Self-report can be used to assess functioning, but patients often have limited insight and are not aware of their deficits. Collateral information can be sourced from family and friends but relies on their perceptiveness and acceptance of the situation. More objective measures can also be used, such as pill counts and reports from employers. Formal scales designed to assess ADL in other dementias can be employed but generally do not appear to accurately detect the impairments found in HAND (Clifford and Ances 2013). Functional assessments also need to be culturally appropriate, for instance, in certain parts of Africa, individuals often do not drive and may engage in less complex daily activities (Robertson et al. 2010).

Additional imaging and laboratory investigations are directed toward excluding alternative causes and identifying comorbid disorders that need to be managed. Imaging modalities, such as brain computerized tomography (CT) and magnetic resonance imaging (MRI), may reveal atrophy and white matter changes in some cases of advanced HAD (Singer et al. 2010). Sophisticated imaging techniques can demonstrate changes earlier in the course of HAND but are largely inaccessible in LMICs. Cerebrospinal fluid (CSF) examination is also generally employed to eliminate alternative causes in HAND and may show a raised HIV viral load and slightly raised protein levels, immunoglobulin G (IgG), and lymphocytes (Singer et al. 2010). However, these imaging and laboratory findings are relatively nonspecific for HAND and must be interpreted alongside clinical findings. The search for potential biomarkers may assist in more reliably identifying HAND.

Differential Diagnosis

A diagnosis of HAND requires that alternative causes of cognitive impairment be excluded. Comorbid medical, psychiatric, and substance use disorders must be adequately treated before a diagnosis of HAND can be confirmed.

Delirium entails an acute confusional state that develops rapidly and has a fluctuating course.

Prior to diagnosing HAND, delirium must be excluded, as it indicates a serious underlying medical cause requiring urgent identification and treatment. With advanced immunosuppression, CNS opportunistic infections, such as PML, toxoplasmosis, and cryptococcal meningitis, can present with features similar to that of HAD. While these can usually be distinguished from HAD by diagnostic testing, such as imaging and CSF analyses, in resource-poor settings with limited access to diagnostic testing, these treatable conditions can often be missed (Wright 2014). The dementia developing in individuals stable on cART often involves a wider variety of deficits than those typically encountered in HAD. Other causes of dementia, such as Alzheimer's dementia and vascular dementia, may thus be difficult to distinguish from HAD (Clifford and Ances 2013). Vitamin deficiencies and endocrine disorders are potentially reversible causes of cognitive impairment and should be evaluated for in all individuals presenting with cognitive deficits.

Common mental disorders, particularly depression, occur at increased rates in HIV in developed and in LMICs and must also be differentiated from HAND (Chibanda et al. 2014). The apathy that commonly occurs in HAND can be misdiagnosed as depression; therefore symptoms such as sadness and tearfulness are required to discern major depressive disorder (MDD). Individuals with MDD often report cognitive problems and can have marked functional impairment. These symptoms tend to improve, however, once depression is properly treated. The psychosis and mania developing in the context of HAND can be differentiated from primary psychiatric disorders, such as schizophrenia and bipolar disorder, based on the course and clinical features. Personal or family history of serious mental illness is typically lacking in HAND, and atypical features are observed. The psychosis may have a predominance of visual, and other nonauditory hallucinations and delusions of being cured of HIV frequently arise. AIDS mania is typified by irritability rather than euphoria, psychomotor slowing instead of hyperactivity and prominent aggression. They also tend to have a greater number of symptoms, have a protracted course, respond

inadequately to psychotropic treatments, and have a poorer prognosis. Substance use is frequently comorbid in HIV and can present with a clinical picture suggestive of HAND. In LMICs alcohol use disorders are also more common in HIV-infected individuals than in the general population (Chibanda et al. 2014). Use of certain substances, such as methamphetamine and cocaine, is associated with increased CNS damage and faster HIV disease progression. Substance use disorders must be addressed antecedent to diagnosing HAND and to improve outcomes in HIV. The possibility of symptoms being due to neuropsychiatric side effects of ART should also be explored, such as efavirenz which can cause dizziness, impairments in concentration, and, less commonly, more severe adverse effects such as psychosis and depression (Kenedi and Goforth 2011).

Course and Prognosis

Although the situation is improving globally, individuals in resource-poor settings have decreased access to medical care, including cART, and to sufficient screening and diagnostic approaches for cognitive impairment. Obstacles to care can include limited time available to attend clinics, a lack of transport, and an inability to afford appropriate medical care. Lower health literacy also contributes to increased HIV morbidity, as individuals may not be aware of preventative measures and treatment options available and may only seek help when stigmata of advanced HIV are present (Vance et al. 2014). HAD (HIV encephalopathy) is a WHO clinical stage 4 (AIDS-defining) disease, and without treatment, the disorder generally leads to death within a year (Singer et al. 2010). Untreated individuals with HAND initiated on cART tend to improve; however some exhibit progressive cognitive deterioration despite adequate viral suppression on cART. The course of HAND in individuals on cART tends to be more unpredictable (Clifford and Ances 2013). Some individuals with milder HAND subtypes progress to HAD, while many remain stable on cART. Nonetheless milder forms

of HAND predict progression compared to HIV-positive individuals with no HAND. Prognosis is worsened by the presence of increased risk factors and sustained immunosuppression even with cART. HAND is associated with various detrimental consequences for the individual (Alfahad and Nath 2013). Impairments related to HAND can diminish an individual's ability to work and thus negatively influence their socioeconomic status. Individuals with HAND have increased psychiatric comorbidity, relationship difficulties, and a reduced quality of life. Cognitive impairments and apathy contribute to adherence difficulties, such as forgetting to take medication and missing appointments. Very few studies have evaluated the impact of HAND on adherence in resource-poor settings; however, depression and alcohol use disorders have been associated with reduced cART adherence in LMICs (Mayston et al. 2012). HAND also increases a person's vulnerability to sexual abuse, decreases their likelihood of using HIV preventive measures, and lowers survival rate (Alfahad and Nath 2013). The relationship between HAND and outcomes is less well explored in resource-poor settings (Chibanda et al. 2014).

Management

The first step in the management of HAND is early detection of individuals at risk through screening. Individuals with suspected HAND should then be referred to existing services for testing and diagnosis according to availability. If HAND is diagnosed in ART-naïve individuals, it is advisable to initiate cART. Risk factors and comorbid psychiatric and physical conditions need to be identified and treated to improve outcomes.

The only treatment that has demonstrated some benefit in HAND is cART, moderating the morbidity and mortality associated with HIV in both high-income and LMICs (Chibanda et al. 2014). Response may be variable and unpredictable as some individuals remain stable, some improve, and others continue to deteriorate. Not all ARVs penetrate the CNS equally, and studies examining

whether cART combinations with better penetration improve outcomes have delivered inconsistent results (Clifford and Ances 2013). The optimal cART regimen for HAND remains to be established. Maximally suppressive ART regimens should be used to accomplish peripheral viral suppression and prevent resistance. Tolerability, cost, and ease of dosing need to be considered when determining which cART regimen to use. Medication burden is reduced by fixed-dose combination (FDC) formulations containing all the ARVs in a regimen in a single pill. Efavirenz is regularly avoided due to its neuropsychiatric adverse effects; however, WHO guidelines advise using regimens with lower toxicity and increased convenience, and their recommended first-line regimen is a FDC containing efavirenz (WHO 2013).

Patients with HAND and their caregivers need to be educated about the diagnosis and the steps that need to be taken to improve outcomes. Psychosocial problems, such as bereavement, stress, and trauma, common comorbidities in LMICs, can contribute to a poorer prognosis in HIV and thus also need to be identified and addressed (Seedat 2012). Increased social support slows HIV disease progression and improves adherence. Caregivers such as family and friends should ideally be engaged and involved in treatment planning and providing support. Patients with HAND may require assistance in remembering their appointments as well as taking their medication and ought to be directed to treatment support groups, or practical tools such as diaries, alarms, or pillboxes can be utilized. In more advanced HAND, it may be advisable for caregivers to manage the patient's medication directly. Dementia is best managed by multidisciplinary teams including social workers, occupational therapists, and specialized nursing care. Close collaboration and good communication are required between all individuals involved in the person's care. The safety of the patient and the community should be assessed throughout, and if increased supervision is necessitated, the patient can be referred to a residential care facility. Psychoeducation regarding mental illness and HIV is required to improve insight.

Psychiatric disorders are major causes of poor adherence in developed and resource-poor settings and lead to HIV disease progression (Chibanda et al. 2014). Individuals with HAND should be screened for symptoms of mental illness. If mental illness is suspected to be secondary to or aggravated by HIV, cART must be initiated in addition to appropriate psychotropic medications. Individuals with HIV are generally more sensitive to medication side effects, and thus it is advisable to initiate psychotropic medication at a low dose and gradually increase up to a therapeutic level. As far as possible, treatment regimens should be simplified, with the minimum required medications prescribed and less-frequent dosing used when possible, prescribers should be cognizant of potential drug interactions between psychotropic drugs and ARVs. Interventions for mental illness in resource-poor settings need to be cost-effective, culturally acceptable, and integrated into HIV services (Mayston et al. 2012). As there is a critical shortage of specialists in resource-poor settings, interventions may need to be provided in innovative ways such as training community health workers to provide interventions.

Conclusions and Future Directions

The pathways leading to the development of HAND are complex, and an increased understanding of social and economic contextual factors is required. Of the 35 million individuals infected with HIV, around 37% are on antiretroviral treatment (ART), with regional variability in access to treatment (UNAIDS 2014). In the North American and European regions, one in two individuals are on ART, whereas in the Middle East and North Africa region, only one in ten individuals are on ART. Increasing HIV testing, earlier diagnosis and access to cART, and cART adherence support all contribute to decreasing the frequency and severity of HAND. However despite increased dissemination of cART, HAND remains a significant problem, yielding unfavorable outcomes. There is an ongoing search for treatments that can improve consequences in

HAND. Trials investigating neuroprotective and anti-inflammatory drugs have largely been unsuccessful (Alfahad and Nath 2013). Research into the use of nanotechnology to increase ART delivery to the CNS is expanding and holds promise for improved treatments in the future.

There are many challenges surrounding HAND, diagnosis is difficult, and the identification of biomarkers in low-resource settings still requires investigation. In Africa, the region with the highest disease burden, there are many obstacles such as poor health-care infrastructure, a lack of trained staff, and increased comorbidity, such as tuberculosis and malaria (Robertson et al. 2010). In resource-poor settings, screening tools (e.g., the IHDS) are more frequently employed than neuropsychological test batteries with less severe forms of HAND likely to be missed and the burden of HAND likely to be underestimated (Habib et al. 2013). There is, therefore, a need in low-resource settings to validate screening and neuropsychological assessments that can be administered by nonspecialists, are culturally appropriate and time efficient, and incorporate biomarkers of HAND. There is also a need for well-powered trials to assess the efficacy of adjunctive pharmacological agents (e.g., neuroprotective, anti-inflammatory agents) in reducing the considerable clinical and economic burden associated with HAND.

Acknowledgments Support for this work has been provided by the South African Research Chairs Initiative funded by the Department of Science and Technology and the National Research Foundation of South Africa and the National Institutes of Health Grant for the HIV Neurobehavioral Research Center (HNRC; P30-MH62512).

Neuro-AIDS, Immunopathogenesis of

Kenneth C. Williams and Tricia H. Burdo
Department of Biology, Boston College, Chestnut Hill, MA, USA

Definition

The immune pathogenesis of Neuro-AIDS entails immune responses inside and outside the central nervous system (CNS) that begin immediately with infection in the periphery and occur throughout infection. Immune pathogenesis of Neuro-AIDS is a result of histopathogenesis. Histopathogenesis manifests in neurological symptoms of AIDS under the umbrella term HIV-associated neurocognitive disorders (HAND). Therefore, components of immune pathogenesis include early viral entry to the CNS, viral replication in inflammatory cells and resident CNS cells, release of toxic proteins by inflammatory and resident CNS cells, and perhaps viral proteins, glial cell responses, perivascular macrophage cuffing, the formation of HIV syncytia, and macrophage nodules. Hallmarks of immune pathogenesis of HIV include the presence of viral RNA, DNA, and proteins in myeloid lineage cells and nonproductive infection of astrocytes. Additionally, there are perivascular macrophage accumulations around CNS blood vessels (cuffing,) reactive astrocytes (astrogliosis), and elevated proteins including sCD14, sCD163, neopterin, and neurofilament light (NFL) shed from activated myeloid and glial cells and nerve cells.

Elevated levels of biomarkers shed from activated and infected myeloid cells, activated glia, or damaged neurons/axons are found in the plasma and cerebral spinal fluid (CSF) and are considered markers of active disease as well as viral replication.

Early Virus Entry Into The CNS

The immune pathogenesis of Neuro-AIDS, by definition, is comprised of the immune responses within the CNS that occur with HIV infection. The immune responses are a result of both virus entering the CNS and cells responding to CNS infection. In simian immunodeficiency virus (SIV) infection of rhesus monkeys, the virus is detected as early as 3 days postinfection (Williams and Burdo 2012). In human iatrogenic infection, virus was detected 24 h postinfection. HIV infection is found as early as 8 days postinfection in the CSF of normally infected individuals (Zayyad and Spudich 2015).

Mechanisms of Viral Entry and Establishment of CNS Reservoir

Mechanisms by which the CNS is infected are not clear. Virus can theoretically enter as free virus or cell-associated virus within CD4⁺ T cells or monocytes programmed to become CNS and perivascular macrophages (Campbell et al. 2014a). In experimental infection of monkeys, SIV DNA and RNA are found within cuffs of macrophages 1–3 days postinfection (Williams and Burdo 2012). SIV DNA is then found throughout the course of infection, but viral RNA and protein are not detected after primary infection, until animals develop AIDS. Whether virus reemergence with AIDS represents recrudescence of virus that entered during primary infection or new waves of entry with immune activation and development of AIDS is not clear. Emerging viral sequence data support the later contention (Zayyad and Spudich 2015). In addition to the presence of SIV and

HIV DNA and RNA early after infection and perivascular cuffs of myeloid cells including perivascular macrophages and inflammatory MAC387⁺ macrophages, CD8⁺ T lymphocytes are evident in perivascular cuffs, with SIV encephalitic (SIVE) and HIV encephalitic (HIVE) lesion. CD8⁺ T lymphocytes comprise approximately 5% or less of the cells in the lesions, where the remaining cells in the lesions are inflammatory macrophages, parenchymal macrophages (microglia), and recruited CD163⁺ perivascular macrophages. Experimental depletion of CD8⁺ lymphocytes in monkeys results in rapid AIDS and severe SIVE. Studies using SIV-gag tetramer complexes and immunohistochemistry demonstrate the presence of SIV-gag-specific CD8 T lymphocytes and CD8 T lymphocytes in the CNS juxtaposed with SIV-p28⁺ macrophages. Depletion of CD4⁺ T cells in SIV-infected monkeys also results in severe CNS infection with numerous multinucleated giant cells (MNGCs) and infected macrophages and microglia, underscoring the importance of CD4 T cell immunity, CD8 T cell immunity, and immune deficiency, in the development of Neuro-AIDS (Micci et al. 2014).

Peripheral Immune Correlates of Brain Inflammation

Early infection (primary infection) and accumulation of inflammatory cells in late infection (chronic infection) correlate with white matter changes measured by MR spectroscopy (MRS) and diffusion tensor imaging (DTI) in humans and monkeys (Ances and Hammoud 2014). Activated monocytes in blood correlate with decreased NAA/Cr in monkeys, which is a measurement of neuronal injury (Crews et al. 2008). Elevation in the numbers of activated monocytes and CD8 lymphocytes correlates with decreased NAA/Cr in HIV infection (Crews et al. 2008). DTI demonstrates early white matter changes that correlate with blood-brain barrier (BBB) disruption that is an early hallmark of CNS pathogenesis and likely subsequent monocyte/

macrophage recruitment (Ances and Hammoud 2014).

Brain Macrophages Are Primary Targets of HIV and SIV Infection

Cells of the myeloid lineage are the most common cell type found latently and productively infected in the CNS (Williams and Hickey 2002; Williams et al. 2011). The CD14⁺ CD163⁺ perivascular macrophages are the most commonly identified infected cell. These cells are continually replaced from the bone marrow normally at a rate that is accelerated with inflammation and AIDS (Williams and Burdo 2012). Perivascular macrophages are repopulated in the CNS from bone marrow-derived monocyte precursors and CD34⁺ stem cells (Williams and Burdo 2012). The resident CNS macrophage, parenchymal microglia, can be infected *in vivo*, but the prevalence of these infected cells is much lower than perivascular macrophages (Williams et al. 2001). Astrocytes were demonstrated to be latently HIV and SIV infected but do not appear to replicate the virus. Prior to combination antiretroviral therapy, multinucleated giant cells (MNGCs) were found in human CNS with fulminant disease. They are routinely found in the CNS of SIV-infected monkeys with AIDS and are in fact a hallmark of SIVE. These cells replicate high levels of HIV and SIV RNA and proteins. They share CD14, CD16, and CD163 immune markers found on perivascular macrophages, have numerous nuclei, and likely arise from a fusion of perivascular macrophages when immune dysregulation of macrophages occur with AIDS (Williams et al. 2001).

Activation of Peripheral Monocytes and Trafficking to the Brain

Outside the CNS, monocyte activation occurs with HIV and SIV infection early and then again late in infection, in a biphasic pattern. Interestingly, this biphasic pattern of monocyte activation

occurs whether infection results in rapid progression and disease, slow progression, and regardless of the rate of development of AIDS. The absolute number or relative percentage of activated CD14⁺ CD16⁺ monocytes correlate with the development of HIV-associated dementia (HAD) in humans and neuronal injury and development of SIVE in SIV-infected monkeys (Campbell et al. 2014a). CD14⁺ CD16⁺ monocytes in humans and monkeys have been demonstrated that are HIV and SIV infected, even in humans on anti retroviral therapy (ART). CD14⁺ CD16⁺ monocytes have varying levels of CD163 and are immune phenotypically similar to CNS perivascular macrophages. Bacterial translocation from the gut is suggested to correlate with monocyte activation and HAND. Bromodeoxyuridine (BrdU) label studies find the magnitude of BrdU⁺ monocytes in blood, which are derived from BrdU-labeled monocyte precursors in the bone marrow and blood, and correlate with the rate of development of AIDS and level of CNS tissue pathogenesis in SIV-infected monkeys (Williams and Burdo 2012). Experimental studies in SIV-infected monkeys, using an antibody against alpha-4 integrin at the time of SIV infection, result in lack of productive and latent SIV infection of the CNS (Campbell et al. 2014b). Using the same experimental paradigm, administering anti-alpha-4 integrin antibody at a time where fulminant CNS has occurred and productively infected macrophages are present in the CNS with neuronal damage results in reversal of neuronal damage, non-detectable SIV DNA or RNA in the brain, and resolution of macrophage nodules (Campbell et al. 2014b). These results underscore the role of monocyte/macrophage infiltration of the CNS in Neuro-AIDS. Different immune fluorescent-tagged dextran dyes experimentally injected into the CSF and taken up by perivascular macrophages at early infection, asymptomatic infection, and AIDS demonstrate turnover of perivascular macrophages at a rate that accelerates with the severity of and rate of development of Neuro-AIDS. Perivascular macrophages labeled with dextran dyes early, prior to the development of SIVE lesions, make up the majority of cells in

SIVE lesions demonstrating perivascular macrophage traffic from justavascular sites to CNS lesions (Williams and Burdo 2012; Williams et al. 2012). Despite this, the role of inflammatory macrophages in the CNS with Neuro-AIDS is critical.

Accumulation of Monocyte/Macrophage and Histopathological Changes in the Brain

In patients with HIV and SIV infection, perivascular macrophages accumulate in CNS vessels and some are infected. Recently recruited MAC387⁺ monocytes/macrophages are also present and are only found in the CNS with inflammation (Williams and Burdo 2012; Williams et al. 2012). The ratio of the number of MAC387⁺ macrophages that are of M1 pro-inflammatory immune phenotype and CD163⁺ perivascular macrophages that are of M2 anti-inflammatory repair phenotype is >1 in early lesions that are active and forming. The ratio of MAC387⁺ macrophages to CD163⁺ macrophages is <1 in established, chronic lesions, consistent with CD163⁺ macrophages functioning to down-regulate CNS and MAC387⁺ macrophages amplifying antiretroviral responses. Overall, the number of inflammatory macrophages is the histopathologic correlate of HAND as well as the degree of neuronal injury (Williams and Burdo 2012; Williams et al. 2012).

Plasma and CSF Biomarkers of CNS Inflammation

A series of proteins including chemoattractants, immune molecules, and in some cases viral proteins are secreted into the plasma or CSF where they are considered biomarkers of CNS Neuro-AIDS disease. Numerous studies support the examination of CSF HIV RNA, soluble CSF and plasma markers of immune activation (MCP-1, sCD14, sCD163, osteopontin (OPN), neopterin), markers of neuronal injury (NFL), and

neuroimaging markers as biomarkers of HAND (Letendre and Ellis 2012). The majority of these markers are shed from activated or infected myeloid cells or are involved in the chemoattraction of myeloid cell traffic to their retention in the CNS. In plasma, soluble CD14 (sCD14) and CD163 (sCD163) are elevated in SIV- and HIV-infected monkeys as well as humans prior to and on durable ART (Williams and Burdo 2012). sCD163 levels in plasma correlate with HIV RNA in acute and chronically infected individuals prior to and after effective ART. Plasma neopterin, an indicator of macrophage activation, is also elevated in untreated HIV⁺ patients. Plasma sCD163 levels correlate with the degree of neurologic deficits in HAND. Plasma LPS that can activate innate immune responses including monocytes and macrophages correlates with the prevalence of HAND (Williams and Burdo 2012; Williams et al. 2012). Plasma OPN (secreted by macrophages) levels are significantly increased in individuals with HIV-associated dementia and increase prior to SIV-induced neurological and clinical abnormalities.

Neopterin, β 2-microglobulin, macrophage chemoattractant protein-1 (MCP-1), quinolinic acid, neurofilament light (NFL), TNF- α and soluble TNF receptor, chemokine receptor-5 (CCR5) ligands (MIP-1 α , MIP-1 β , and RANTES), S100 β , and glutamate are all elevated in CSF with HIV infection and correlate with HAND (Letendre and Ellis 2012). Many of these correlations were found in the pre-ART era. With ART to date, none of these markers are used for clinical studies. But sCD163 in plasma still functions. Neurofilament protein (NFL) levels are elevated in HAD patients. NFL levels predict the onset of HAD, and effective ART reduces NFL CSF levels (Zayyad and Spudich 2015). Measurement of single-copy HIV RNA shows a low level of viral persistence in some ART patients with persistent neuroimpairment. Macrophage activation, reflected by increased levels of CSF neopterin, is also an important factor in neuropathogenesis. In untreated HIV-infected patients, CSF neopterin is elevated and increases as suppression worsens and CD4⁺ T cell counts decrease. Effective ART

does not consistently normalize macrophage activation. ART initially reduces neuroinflammation, but reduced MCP-1 CSF levels often rebound (Letendre and Ellis 2012). Neuroimaging techniques demonstrate neuronal injury, inflammatory response, gliosis, brain atrophy, and decreased cerebral blood flow in the brains of HIV-infected patients using magnetic resonance spectroscopy (MRS), volumetric MRI, diffusion tensor imaging (DTI), and functional MRI (fMRI) (Ances and Hammoud 2014).

Conclusion

The presence of virus in the CNS early after infection in the periphery initiates Neuro-AIDS. Hallmarks of Neuro-AIDS include activated monocytes and increased numbers of these cells in the blood, the presence of replicating virus in the CNS, and then latent infection with reemergence with AIDS. Cuffs of perivascular macrophages that are CD14⁺ CD16⁺ CD163⁺ cells that can be virally infected are present. Additionally, MAC387⁺ macrophages that are not infected accumulate early in disease. Accumulation of macrophages, some of which are infected, is a histopathologic hallmark of Neuro-AIDS, as elevated myeloid shed sCD163 and CD14 in the plasma and proteins shed in the CSF. Blips of viral RNA are detected in the CSF of individuals on ART, which demonstrates that there is likely an ongoing low-level CNS infection in individuals on durable ART. Functional neuroimaging demonstrates changes in BBB permeability early with infection and white matter changes consistent with pathogenesis. CD8 T lymphocytes and CD4 T cells both regulate immune activation that can result in Neuro-AIDS.

Definition

This entry summarizes neurocognitive research on HIV+ individuals who have past or current substance use disorders. This entry focuses on findings since the introduction of combination antiretroviral therapy. We focus on neurocognitive correlates of specific drugs of abuse, placing special emphasis on the independent and additive effects of these drugs on the brain and cognition and on implications for clinical management. Finally, strategies for treating this vulnerable population are provided, with a specific focus on neurocognition.

Introduction

The frequency of substance use disorders (SUDs) among HIV+ individuals often makes it difficult to distinguish substance-related neuropathological and cognitive effects from those effects due to HIV-associated neurocognitive disorders (HAND). Detecting the presence of HAND in individuals with a concurrent SUD is further complicated by multiple SUD-associated comorbid conditions, including head injury, psychiatric illness, cerebrovascular risk, and attention deficit/hyperactivity disorder. Neurocognitive impairment, whether secondary to HIV, substance abuse, or both, complicates clinical management, increases high-risk sexual and injection practices with exacerbation in the risk of HIV transmission

and superinfection, and limits the capacity for successful treatment adherence and ability to function independently. Additionally, the clinical management of HIV+ substance-dependent individuals is further complicated by psychosocial consequences such as chaotic living environments, homelessness, and risk of incarceration. Therefore, understanding the complex relationship between SUD and HAND is critical in both the clinical and research milieu. Herein, we summarize relevant research regarding neurocognitive impairment among HIV+ individuals with past or current SUDs. We focus our review on studies conducted since the introduction of combination antiretroviral therapy (cART), with special emphasis on their independent and additive effects on the brain and cognition and their translational implications for clinical management.

Alcohol

Comorbid alcohol dependence in HIV+ persons can disrupt multiple cognitive functions, most evident among those with chronic heavy drinking. Heavy drinking (e.g., average consumption of at least 100 (80 for women) standard alcoholic drinks per month) and a positive HIV serostatus are individually associated with poorer neurocognitive test scores, and these together result in an additive or even synergistic effect on tasks requiring speeded information processing (Levine et al. 2012). Importantly, neurocognitive impairment can be attenuated with adequate antiretroviral treatment among alcohol users (Rothlind et al. 2005). Additional evidence of additive or synergistic effects of alcohol and HIV have been reported in recent years, including greater impairment on measures of immediate episodic memory, psychomotor speed, sustained attention, and associative learning (Levine et al. 2012).

Overall, studies have consistently demonstrated a greater risk of neurocognitive impairment among HIV+ individuals with heavy alcohol use, particularly among heavy drinkers who have consumed alcohol within the past 12 months and who have poorer viral suppression. It is also inferred that some degree of cognitive impairment could persist for up to one year following cessation of drinking, with most

prominent disruption in information processing. However, since psychomotor slowing is a prominent neurocognitive deficit among HIV+ individuals, it may be difficult to distinguish alcohol effects from those of HIV.

Cannabis

In recent years, there has been a growing trend to facilitate access to cannabis for individuals living with HIV/AIDS in order to help alleviate various symptoms associated with the disease. While recent research suggests promising therapeutic applications for smoked cannabis in the context of HIV/AIDS, including treating AIDS-associated anorexia and neuropathic pain, such studies have not addressed the long-term implications of cannabis use on neurocognitive functioning. It is important to note that dronabinol, an orally consumed synthetic tetrahydrocannabinol (the main psychoactive ingredient in cannabis), has been approved by the Food and Drug Administration for AIDS-associated anorexia since 1992. Nonetheless, FDA approval of dronabinol has not diminished the demand and research for botanical cannabis and pharmaceutical compounds that may mimic more closely the effects of smoked cannabis, as dronabinol is orally consumed and possesses different metabolism and drug action compared to smoked cannabis.

Studies examining the acute effects of dronabinol and smoked cannabis on the neurocognitive performance of HIV+ individuals are conflicting. One found that smoked cannabis had no acute impact on any of the neurocognitive tasks, but 30 mg of dronabinol adversely affected neurocognitive performance, and 20 mg of dronabinol adversely affected neurocognitive performance among a group with low body fat composition. However, another study concluded that both oral dronabinol and smoked cannabis use did not significantly change performance on cognitive measures compared to placebo (Levine et al. 2012).

The few published studies to date that have specifically examined the effects of longer-term cannabis use on the brain functioning of HIV+ individuals are also equivocal. One group found that symptomatic HIV+ individuals that used

cannabis frequently performed more poorly on a global measure of neuropsychological functioning compared to those with a history of minimal or no cannabis use. In contrast, a separate group found that the use of cannabis did not affect the neuropsychological performance among HIV+ subjects, as they reported no significant interactions between HIV serostatus and history of cannabis use. However, when they compared brain metabolite levels across groups using magnetic resonance spectroscopy, they found evidence of negative additive effects of cannabis use and HIV for some (but not all) metabolites in the basal ganglia and thalamus. In the third of existing studies, the researchers examined procedural learning (PL; i.e., acquisition of motor skills and habits) among HIV+ adults with a history of substance use disorders. Both positive HIV serostatus and a history of cannabis dependence were independently associated with poorer performance in complex motor skills with significant adverse additive effects of HIV and cannabis use history on performance.

Nicotine

Rates of cigarette smoking have been estimated at up to 88% among individuals in substance abuse treatment, and HIV+ individuals are three times as likely to smoke as the general population. However, there are minimal data regarding the neurocognitive consequences of nicotine use among HIV+ smokers. Compared with HIV-seronegative individuals, scans of non-smoking HIV+ persons with heavy alcohol use show significantly smaller volume in the prefrontal cortex; however, HIV+ persons with both chronic cigarette use and heavy drinking show significantly lower volumes in the frontal, temporal, and parietal cortex and also show poor performance on tests of memory and learning as compared to HIV+, nonsmoking, heavy drinkers. These findings illustrate the need to address the history of nicotine dependence as a source of additional neurocognitive and neurobiological burden among HIV+ subjects with alcohol dependence.

There may be seemingly paradoxical effects of nicotine use on the neurocognitive functioning in

HIV+ patients. A recent study of HIV-seronegative and HIV+ women found that current cigarette smoking was associated with higher plasma HIV viral burden and greater immunosuppression; however, no associations between neurocognitive functioning and either current or past history of smoking were found (Levine et al. 2012). Additionally, when analyses were restricted to the HIV+ women, individuals with a history of smoking performed significantly higher on measures of frontal/executive functioning. While this finding may seem counterintuitive, it is consistent with reports from animal studies that nicotine has protective effects. Currently, the mixed findings regarding nicotine use and neurocognitive functioning in HIV make it impossible to make conclusions regarding nicotine use in HIV. However, considering the multiple health hazards associated with cigarette smoking, cessation programs are likely to be beneficial for HIV+ persons.

Cocaine

The use of crack or powder cocaine is common among HIV+ drug users, but surprisingly few studies have evaluated their neurocognitive effects. Large studies have failed to find an increased risk for neurocognitive impairment in HIV+ cocaine users as compared to those with HIV or cocaine use alone (Durvasula et al. 2000). However, this may be due to lack of adequate measures or narrow demographic inclusion criteria, as others have found deficits specifically in sustained attention, verbal memory, and visuospatial functioning among active HIV+ cocaine users as compared to HIV+ nonusers (Levine et al. 2006). Neuroimaging studies have found neurophysiological differences, with HIV+ cocaine users having decreased dopamine transporter in the caudate as compared to HIV+ nonusers and HIV-negative controls; however, no clinical correlation was detected with neurocognitive tests (Chang et al. 2008).

Clearly, more detailed studies are needed to determine what factors are associated with neurocognitive deficits among HIV+ users of cocaine. Among these is sex; current evidence has raised the question of increased vulnerability

to neurocognitive impairment among HIV+ female crack users. The literature on gender differences in drug dependence has shown that compared with men, women are more highly responsive to cocaine/crack effects and that crack use is highly predictive of high-risk sexual behavior among women but not men. It has been reported that compared with women with no or non-crack drug abuse history, persistent crack users had significantly lower CD4 counts and higher HIV RNA levels; further, persistent users were three times as likely to die from AIDS-related causes (Levine et al. 2012). Recently, neuroimaging studies among HIV+ women have revealed aberrant functioning in the anterior cingulate and left dorsolateral prefrontal cortex and associated verbal memory deficits (Meyer et al. 2014).

Methamphetamine

Perhaps the most commonly studied drug in the context of neuroAIDS, studies suggest an additive and synergistic effect of HIV and methamphetamine use on neurocognition and biochemical, structural, and functional brain imaging. The risk of neurocognitive impairment increases with each additional risk factor (HIV and methamphetamine abuse) (Rippeth et al. 2004). Clinicopathological studies indicate that global neurocognitive impairment and memory scores are significant predictors of the severity of neuronal damage, which was significantly more extensive for HIV+ methamphetamine users with HIV encephalitis compared with methamphetamine users without HIV encephalitis and with HIV+ non-methamphetamine users without HIV encephalitis (Chana et al. 2006). While these findings suggest an additive effect, others found evidence for the synergistic impact on brain functioning affecting physiological parameters such as decreased baseline cerebral blood flow (CBF) (Ances et al. 2011). Still, the impact of methamphetamine on everyday functioning is less clear. For example, comorbid HIV and methamphetamine dependence did not increase the likelihood of complaints about problems with everyday functions, such as driving and managing finances, beyond

that found with either HIV or methamphetamine dependence alone (Sadek et al. 2007). The results suggest that the consistent neurocognitive deficits detected in the aforementioned studies may not necessarily translate to everyday functioning.

Club Drugs

“Club drugs” are those that have traditionally been used at dance clubs and raves and include 3,4-methylenedioxymethamphetamine (MDMA, or “ecstasy”), ketamine (“special K”), and gamma-hydroxybutyrate (GHB). Club-drug use is more prevalent among men who have sex with men (MSM) as compared to the general population. Despite the high rate of club-drug use among MSM, there are no published studies that examine the cognitive effects of these substances in the context of neuroAIDS. Still, based on their actions on the catecholamine system, as well as their high potential for abuse among HIV-prone populations, there are numerous reasons to suspect an interactive or additive effect of these drugs with HIV (Levine et al. 2012).

Neurobehavioral Treatment Issues in HIV+ Substance Users

HIV+ individuals with comorbid SUD present unique treatment challenges. Those with untreated SUD are less likely to receive cART therapy or achieve viral suppression even when cART is prescribed. These individuals often face a difficult road; the dual stigma of HIV and substance abuse makes access to treatment more difficult, and the lack of effective and consistent medical care may make abstinence more difficult. Further, both researchers and clinicians must contend with direct and indirect medical consequences of drug abuse, such as head injury, stroke, and malnutrition. Additionally, SUDs are frequently accompanied by a spectrum of neuropsychiatric conditions, including mood disorders, anxiety disorders such as PTSD and social phobia, ADHD and learning disabilities, and personality disorders, adding to the complexities and challenges of treatment. Clinicians should be mindful

of comorbid conditions and make appropriate referrals to substance use clinics and mental health professionals.

Adherence

Viral suppression requires optimal adherence to cART. While the definition of optimal adherence varies across studies, it generally can be said that at least 80% of scheduled doses must be taken (Malta et al. 2008). Adherence rates among active substance users have consistently been found to be suboptimal (Levine et al. 2012). Fortunately, abstinent drug users or individuals with access to substance use and mental health treatment have better adherence rates (Hinkin et al. 2007). While active substance use is associated with poorer adherence, various treatments improved this (Malta et al. 2008). For example, higher adherence rates were found among individuals receiving care in structured settings, as well as those in drug substitution therapy (e.g., methadone treatment). Additional factors resulting in poor adherence included poor self-esteem, recent incarceration, and negative outcome expectations.

Studies examining the interaction between neurocognitive impairment and adherence in substance users have shown that neurocognitive functioning is an intermediary between drug abuse and adherence (Levine et al. 2012). Findings from such studies have led to remediation and compensatory programs, as discussed in the following section.

Managing Neurocognitive Deficits in the Treatment of HIV+ Substance Using Individuals (SUI)

Fortunately, there has been considerable interest in the treatment for SUDs in HIV+ individuals, including those with neurocognitive deficits. There are several ways in which neurocognitive deficits common among HIV+ individuals may have a detrimental effect upon HIV-preventive behavior (Norman et al. 2009). For example, cognitive-behavioral techniques commonly used with substance abusers might be difficult to

remember and implement in the face of learning and executive deficits experienced by HIV+ individuals. To counter this, Norman et al. (Norman et al. 2009) suggested cognitive remediation strategies, including the frequent use of multimodal presentation of materials in order to facilitate learning and consistent training in a distraction-free environment to overcome impairments in retention and attention. Patients should be assessed frequently so that they have the opportunity to evaluate the efficacy of their treatment regimen. In order to facilitate the generalization of skill learning to day-to-day life, treatment should include real-world scenarios and situations. Assistance from the patients' social support network and other health-care providers may also improve the chance of success. In fact, group treatment may be the preferred treatment modality for neurocognitively impaired HIV+ SUIs, as this context encourages and strengthens prosocial behaviors. Group treatment could also reduce feelings of isolation and provide interpersonal support from peers with similar backgrounds.

From a medical standpoint, arguably the most important aspect of HIV treatment is maintaining strict adherence to cART. Thorough knowledge of potential obstacles could improve treatment outcomes. Wood et al. (2008) undertook a substantive review in order to summarize the evidence regarding barriers and facilitators to cART adherence among IDUs, which can also be applied to SUIs in general (Wood et al. 2008). They identified decreased access to treatment and poor adherence to treatment as existing challenges. Within each of these are sociopolitical, individual, and provider-based barriers. For example, adherence to medication among SUIs includes sociopolitical barriers such as incarceration and financial constraints, individual barriers such as fear of side effects and psychiatric illness, and provider-based barriers such as physicians' belief that SUIs will not be able to adhere to their regimen. In the context of this review, cognitive deficits would fall under individual barriers. A number of evidence-based interventions have been developed that are aimed at reducing these specific barriers to treatment. Examples of strategies

aimed at addressing sociopolitical barriers include outreach programs and meeting SUIs on their own terms (e.g., through needle exchange programs). Examples of strategies that address individual-based concerns include increased efforts to improve health insurance coverage and free access to medical care, utilizing HIV-experienced physicians in order to improve the treatment relationship and providing substance abuse treatment and housing support in order to reduce physicians' reluctance to prescribe cART. The recommendations put forth by Norman et al. (2009), described above, can also be considered individual-based strategies. Finally, provider-related strategies include modifications of clinics in order to improve uptake and adherence to cART by being highly flexible, comprehensive, and interdisciplinary. Key features of such programs include on-site pharmacists, HIV specialist nurses, drop-in services, geographic proximity, and case management services. A final important strategy mentioned by Woods et al. is the linking of addiction treatment (e.g., substitution therapy) with cART. Such "directly administered therapy programs," which also provide daily supervision of antiretroviral intake, are associated with improved adherence. Note, however, that there are potential difficulties with substitution therapies. For example, concurrent psychoactive medication and opioid substitution therapies such as methadone have been associated with impaired cognitive performance (Mintzer and Stitzer 2002). Further, pharmacokinetic studies of various ARTs and methadone or buprenorphine indicate that, when taken together, there are alterations in metabolic concentrations of both drug classes that may have adverse consequences on HIV disease status and opioid-therapy effectiveness. However, findings from a 5-year longitudinal study provide a more sanguine outlook, indicating that consistent opioid substitution therapy is predictive of virologic suppression (Bruce et al. 2010). Clinicians' awareness of such research will help facilitate its application and development.

Finally, integrated behavioral and medical interventions have been successfully applied to HIV+

substance users, although the optimal structure remains unclear. For example, variations in ease of communication between health-care providers, availability of office space, professional autonomy, and available services exist between integrated HIV clinics/substance use treatment centers and those that are simply collocated (Lombard et al. 2009). However, some essential features emerge from the literature, including the need for both conditions to be treated simultaneously by health care with proper experience/training, minimizing the stigma associated with either condition, installing valid methods for detecting the presence of either condition, and providing other key services for clients within a single location.

Conclusion

Despite the information provided in this entry regarding the putative additive risk of substance abuse on neurocognitive functioning in those with HIV, the interaction between substance abuse and HAND has not been well detailed among numerous commonly abused drugs. Despite their high prevalence among those with HIV, drugs such as marijuana, cocaine, and the class collectively known as “club drugs” have received relatively little attention. Further, research across different substance types among HIV+ individuals has not been balanced; most post-cART studies focus on stimulants such as methamphetamine. In addition, studies examining drug combinations with synergistic neurotoxic effects (e.g., alcohol and cocaine) are necessary. Finally, the available literature indicates the importance of additional studies of sex differences in neuroAIDS and substance use, which have potentially critical implications for clinical practice and treatment.

Continued research into evidence-based treatment strategies must occur in tandem with the investigation of mechanisms of HAND neuropathogenesis among SUIs. The treatment hurdles associated with each condition alone are difficult to overcome; individuals with comorbid SUD and HAND represent an especially difficult population. However, identifying the individual

barriers to treatment makes it possible to address each simultaneously and effectively.

Neurocognitive Outcomes in HIV-Infected Children and Adolescents

Richard M. Rutstein¹ and Renee Smith²

¹Division of General Pediatrics, Children's Hospital of Philadelphia, Philadelphia, PA, USA

²Department of Pediatrics, University of Illinois at Chicago, Chicago, USA

Introduction

Perinatally acquired HIV (PAH) infection was first described in 1981. Within a short time, it became clear that, as with adults, PAH could lead to devastating central nervous system damage in infants and children. Through the early years of the epidemic it also became clear that many infected infants had more subtle static neurocognitive deficits and behavioral disorders.

With the advent of effective antiretroviral therapies and earlier initiation of therapy for infected children, the incidence of more serious HIV-related neurocognitive effects decreased dramatically, and they are rarely seen today. In regions with access to effective pediatric antiretroviral therapy (ART), the vast majority of youth with PAH have learning and behavioral profiles similar to age and sociodemographically matched uninfected youth. With the ability now to achieve lifelong control of the infection, the hope is to develop treatment strategies that best ensure optimal long-term neurocognitive and behavioral outcomes.

Pathophysiology

The exact mechanisms by which HIV enters and damages the central nervous system is still under study. As mentioned elsewhere (refer to entries on neuropathology), HIV-related neurologic changes are a direct consequence of HIV infection and subsequent immune activation.

Very early in the course of HIV infection, the virus spreads to the brain across the blood-brain

barrier, most likely carried by CD14+/CD16+ monocytes. Using a SIV infection model in primates, viral infection of the CNS was found within 1–3 days of an oral challenge with a high titer of SIV. In adults, HIV entrance into the CNS has been shown to occur as early as 2 weeks to 3 months after infection and most likely occurs even earlier. Among adults with acute HIV infection, 80% had measurable HIV RNA (>100 cpm) in the CSF at a median of 18 days postexposure (Peluso et al. 2015). In perinatally infected infants, systemic infection is estimated to occur within 2 months prior to delivery for a third of exposed infants, while the remainder of infections occur during the intrapartum period (in the absence of breastfeeding). CNS infection may also occur in utero or in the early perinatal period. Because of an immature blood-brain barrier in neonates and very young infants, they are at higher risk for early and severe CNS manifestations compared to older children and adults.

Infection of CNS microglial and macrophage cells leads to established infection. Infection of astrocytes, and possibly neurons, can occur as well, but their involvement in the neuropathogenesis of HIV encephalopathy is less clear. The interplay between characteristics of viral infection and replication, ongoing immune activation and host genetic factors and responses leads to the symptomatology seen among individuals.

Multiple markers of brain inflammation, immune activation and CNS neuronal damage have been shown to correlate with the level of neurologic impairment. These include serum and CNS markers of monocyte and macrophage activation (increased percentage of CD14+/CD16+ monocytes and levels of sCD14, sCD163, and quinolinic acid and TNF-alpha), as well as neuronal cell injury (CSF neurofilament light (NFL)). Several of these products, such as TNF-alpha and quinolinic acid, are neurotoxic. In addition, plasma levels of P-selectin and fibrinogen (markers of vascular dysfunction) have also been associated with pediatric cognitive outcome (CO) (Kapetanovic et al. 2010).

Most of these markers have been best studied in adults, and appear to correlate with ongoing CNS activation, viral replication and cellular

damage. The prospective use of these markers to identify children and adults most at risk for ongoing CNS infection/damage, and receive potential adjunct therapies to preserve CO, have not been clinically studied.

Neuroimaging of HIV-infected adults shows subtle changes within months of initial HIV seroconversion. The severity of changes seen on later imaging correlate with clinical severity of CNS disease in both children and adults. Similarly, employing magnetic resonance spectroscopy (MRS), findings in symptomatic PAH revealed changes associated with neuronal cell loss and inflammation. In addition, MRS studies in asymptomatic PAH were consistent with delayed brain development and neuro-inflammation. In infants with rapidly progressive CNS disease, cerebral atrophy and secondary compensatory enlargement of ventricles, with/without basal ganglion calcifications, can be seen in the first year of life and correlate with neurodevelopmental outcomes.

The issue of viral/host interactions in the pathogenesis of HIV-related CNS disease has been an area of intense interest. Differences exist in the reported incidence of HIV-related neurocognitive disease between HIV-1 and HIV-2, as well as between different HIV-1 viral clades and subtypes. So-called macrophage trophic viral strains appear to have an increased propensity for CNS infection, compared to T-cell trophic viral strains (though it appears that both viral strains can establish productive CNS infection). In addition, within subtypes, specific viral strains with increased neuro-tropism has been demonstrated. Finally, studies in adults and children have noted different rates of HIV-related CNS disease among infected individuals based on genetic-based differences in chemokine receptor density. For instance, among HIV-infected children and adults who are heterozygous or homozygous for a mutation (delta 32), that results in a decreased density of CCR5 receptors on cell surfaces, the incidence of HIV-related CNS disease appears decreased. Other specific genetic polymorphisms (such as polymorphisms in the gene coding for the CXCR2 receptor) have also been identified that appear to play a role in individual patient susceptibility to HIV-related CNS disease.

Among the early hypotheses of the pathogenesis of HIV-related CNS disease, was the possible contribution of other CNS infections acting synergistically with HIV infection. In the pre-ARV era, studies suggested that HIV-infected adults and infants co-infected with CMV were at increased risk of CNS disease and poor neurocognitive outcomes. However, data from the HAART era indicate that cognitive outcomes are the same for co-infected children compared to those who are only HIV-infected.

Clinical Presentation

The most catastrophic CNS aspect of pediatric HIV infection is a progressive encephalopathy (PE), characterized by Belman, Epstein and others (Belman et al. 1985; Epstein et al. 1985). The definition of PE was generally accepted to include at least two of three of the following: loss of previously acquired skills (or a confirmed >15 point loss in full-scale IQ testing), or a prolonged plateau period without any developmental advancement, with an acquired microcephaly and/or neuroimaging with evidence of cerebral atrophy with/without basal ganglion calcifications, and/ or corticospinal tract signs (paresis/spasticity/weakness). As noted, the severity of the changes on neuroimaging (atrophy and calcifications) were generally associated with a worse clinical status. Several patterns of the course (trajectory) of PE were eventually appreciated. In many infants, after a normal developmental trajectory at first, the disease ran a rapidly progressive and fatal course, with a rapid loss of skills; in pretreatment studies, average survival was 12 months following a diagnosis of PE. However, other children were noted to have a prolonged plateau phase of developmental advancement, followed by a slow increase in skills. Still others exhibited a pattern of rapid loss of skills interspersed with plateau or stabilization phases. Seizures were relatively rare, and generally seen late in the course of the disease.

The incidence rate of PE was greatest in the first 3 years of life (as high as 10% in the first year of life), falling to around 0.5–1%/year after age

3. In general, the onset of symptoms occur in the first years of life (with >50% diagnosed by age 3, and 75% by 4–5 years of age). Cumulative rates of PE in the USA, prior to HAART, were 20–35%, with a 4%–10% incidence rate by age 1 (Patel et al. 2009).

Infants infected in utero (as defined by a positive HIV PCR DNR, RNA or culture or day 1 of life) were at high risk for a rapid progressive disease trajectory, including peak viral loads (>5–5.5 log₁₀ cpm) and lower CD8 percentages in the first year of life, significant HIV-related symptoms within 24 months of life, and death by age 4. From the pre-ARV error, infants with PE were generally those with this more rapid progression pattern in the first 2 years of life. It should be noted however that not all of the infants with these high-risk markers developed HIV-related CNS disease.

Among infected children without the rapid progression pattern, PE was unusual, except as a very late event. The incidence of HIV-related encephalopathy among PAH, after infancy, is comparable to that among recently infected adults at about 1% per year. This led to the consideration that PE represented an in utero CNS infection, or infection with a more neurotrophic/pathogenic viral strain, as discussed above.

In addition to PE, in the pre-HAART era, an additional 20% of children were noted to have a static chronic encephalopathy (SE). In these children there was a stable delay in acquisition of cognitive and motor skills, but without loss of previously acquired milestones. Overall, prior to the advent of antiretroviral therapies, 40% of PAH developed either PE or SE CNS manifestations of HIV infection.

As noted, it was unusual to diagnose new-onset PE in children after age 4 or 5, except as a very late, preterminal event. One longitudinal study noted that among children who had neither PE nor SE at first testing (mean age 4 years), full-scale IQ results were not statistically different after a median follow-up of 4.75 years (Shanbhag et al. 2005). A more recent study from the same site determined that those PAH patients surviving to at least age 13 (mean age 15 years) had a mean full-scale IQ not

significantly different from those tested at a median age of 8 years (87 vs. 92) (Wood et al. 2009).

Treatment of Pediatric HIV-Related CNS Disease

Surprising results were seen in the original pediatric HIV treatment study using zidovudine, conducted at the National Cancer Institute. There, Pizzo and colleagues treated HIV-infected children with a 6-month course of a continuous infusion of zidovudine (Pizzo et al. 1988). Infants who entered the study with neurologic abnormalities improved over the 6-month treatment period; in addition, infants thought to be within the normal range also showed significant gains in developmental testing following the 6-month treatment period. There was also surprising improvement in the results of neuroimaging of these children. Among children with ventricular enlargement and cerebral atrophy noted on CT imaging prior to zidovudine treatment, several had a marked improvement in the degree of ventricular enlargement and cerebral atrophy while on therapy. Unfortunately, these gains dissipated over the ensuing months of treatment from what we now understand to be viral resistance developing in the setting of monotherapy.

In addition, there were scattered reports that prednisone could also temporarily reverse or stabilize CNS symptomatology, with improvement of cerebral atrophy and ventricular enlargement noted on neuroimaging. The fact that both therapies (zidovudine and prednisone) could lead to temporary improvement in function and neuroimaging led to the realization that pediatric HIV encephalopathy was a more plastic, dynamic process than originally thought and that even in children with evidence of brain volume loss, the process might be slowed and potentially partially reversed with treatment. As with prednisone or zidovudine therapy, however, treatment with other mono-, or dual-, ARV regimens only transiently affected the course of HIV-related CNS disease.

However with the advent of HAART in the late 1990s, it became clear that early aggressive

treatment, besides delaying or halting progression to AIDS in PAH, could prevent the onset of PE. The cumulative incidence of HIV encephalopathy by age 5 dropped to 2–10% in the early years of HAART compared with a pre-HAART rate of 20–35%. Since 2000, with the widespread use of HAART at the time of diagnosis in infants, the incidence rates of PE have further decreased, to less than 0.4/100 patient years in the USA (Nachman et al. 2009; Patel et al. 2009).

With substantial evidence that HAART initiated early in life can prevent PE, a major question still to be answered is whether HAART improves the neurocognitive outcome in those children without a diagnosis of progressive encephalopathy, and, if so, is there a threshold age by which HAART must be initiated to preserve cognitive outcome (CO). Recent studies, mostly in adults, have examined ARV's effectiveness in protecting and possibly improving CO by looking at the relationship between specific ARV's CNS penetration effectiveness (termed CPE) rating and changes in CO and neurologic status. Although data is conflicting, it seems those agents with higher CPE are more effective in sustaining or improving CO.

In pediatrics, less data is available on the utility of higher CPE regimens. One study found a decreased incidence of new cases of PE with HAART, versus non-HAART regimens, and that higher CPE regimens prolonged survival among those with preexisting PE (Patel et al. 2009). The few studies to date have not been able to find a convincing effect of CPE scores on CO for PAH; any HAART has been shown to be protective against progression to AIDS.

Two US studies retrospectively reviewed the age of initiation of HAART, CPE scores, age of virologic suppression and CO among PAH. In both studies, though there was no relationship found between treatment regimen CPE scores and CO, virologic suppression at an early age was associated with a trend toward improved CO (Crowell et al. 2015; Lazarus et al. 2015). These studies both suffered from a retrospective analysis, and compared to adult studies, were underpowered to detect smaller differences in outcomes. In addition, among HIV-infected

children, there are a limited number of treatment options, compared to those available for treatment of adults, so that CPE scores of the treated children may not have varied as widely as those in adult studies.

Abundant evidence exists to indicate that it is through suppression of CNS HIV viral replication that HAART preserves CO. Pretreatment CNS levels of viral replication have been associated with the presence of neurocognitive abnormalities, and the risk of progression of CNS symptoms is decreased in those with CNS viral suppression. Recent studies of adults find that up to 10% of those with suppressed plasma viral load have ongoing CNS viral replication. This ongoing CNS viral replication has been associated with continued CNS immune activation and risk of neurocognitive decline. In the pediatric literature, there are anecdotal reports of children with worsening neurocognitive function despite plasma viral suppression and without evidence of other causes of the deterioration. The supposition is that among these individuals there is compartmentalization between plasma and CNS viral populations, where the CNS viral strain replicates independently of the plasma compartment, and possibly due to inadequate CNS drug levels, develops resistance to the HAART regimen. In these situations, it might be critical to ensure adequate CNS penetration of the HAART regimen.

The age of initiation of HAART may be crucial. In a southern African population, infants randomized to very early therapy (commencing before 12 weeks of age) versus deferred therapy (CD4 guided) had significantly better performance on neurodevelopmental testing, at a mean age of 11 months, than those on the deferred arm, and the scores in the early treatment cohort mirrored that of HIV-uninfected infants (Laughton et al. 2012). Conversely, the PREDICT study found that when initiating therapy in Thai treatment-naïve children 1–12 years of age, starting therapy at a CD4 range of 15–25% versus initiating therapy for CD4 <15% did not improve the CO at week 144, and both groups scored worse than a control group of HEU and HU children (Puthanakit et al. 2013). From combined studies, it can be inferred that treatment before the

development of an AIDS diagnosis may be critical in preserving optimal CO. So it becomes an issue of starting therapy before immunologic decline, to prevent the development of AIDS; the age that this may occur is highly variable among a population of infants and children with PAH. The decision as to when to initiate therapy however is now less controversial, as most treatment guidelines recommend initiating therapy for all diagnosed infants and children less than 5 years of age, regardless of immunologic status, and strong consideration of treatment initiation at the time of diagnosis in older children and youth as well.

With increasing numbers of HIV-exposed neonates being exposed to multidrug ARV regimens in utero, it is important to note that a number of large cohort follow-up studies on HIV-exposed, but uninfected, infants and children (HEU) support the overall safety of in utero exposure to ARVs on the developing fetal brain. Early reports of very small numbers of exposed infants suggested mitochondria-related symptomology compared to infants without exposure to in utero ARVs; however, those concerns have not been found in other large cohorts. The increased risk of CNS-related mitochondrial disease or toxicity, related to in utero exposure to ARVs, has not been noted in the USA or elsewhere, when reviewing data from treatment networks.

Neuropsychological Profiles

There are multiple methodological issues with studies of neurocognitive outcome in PAH. Studies from the USA and international areas with access to HAART are generally retrospective in design and include heterogeneous populations, with youth identified at different ages and stages of illness, and during different periods of ARV availability and treatment initiation guidelines. In addition, the assessment tools employed differ over time, populations, and countries of origin.

PAH, particularly in young children and prior to advances in HIV treatments, was associated with global deficits, ranging from mild to severe. Domains of particular vulnerability included general cognition, receptive and particularly

expressive language, visual-spatial integration, and gross motor functioning (Smith and Wilkins 2015). As treatments advanced and youth survived into adolescence, the profile of impairments changed significantly, shifting to a profile of more subtle and specific deficits. Although there is increased risk for overall lower cognitive functioning, most studies agree that comparisons of mean performance show little to no differences when compared to PHEU, who are sociodemographically similar.

As noted above, when comparing PAH without PE to noninfected youth and when the groups were well matched in socioeconomic and family factors, the overall CO has approached that of same age-vulnerable youth (those that were HIV exposed in utero but uninfected). However, both groups on average perform lower than expected compared to normative samples, with standardized scores in the average to low-average range, suggesting that concomitant environmental risk factors contribute greater risk than HIV itself.

These groups' mean scores approach those reported of other cohorts of high-risk urban children. For example, in a longitudinal study of inner city youth with and without gestational cocaine exposure, but no HIV exposure, the mean FSIQ of both groups was about one standard deviation below national population mean, and in line with that reported from a longitudinal study of PAH adolescents followed in the same city over the same time period (Hurt et al. 1997; Wood et al. 2009).

Concomitant risk factors that youth with PAH may be exposed to include urban poverty, family instability, and disadvantaged minority status. Compared to the general population, PAH are more frequently exposed to maternal substance use, suboptimal prenatal care and nutrition, and are at higher risk for prematurity (protease inhibitor-based therapy may increase risk of prematurity), and lower birth weights. All of these birth-related factors have been associated with an increased risk of poorer CO among HIV-uninfected populations. Exposures after birth, including community- and family-related stressors (poor educational environments, maternal mental health and substance use problems, inadequate/unsafe housing, exposure to domestic and community violence, food and financial

instability), also impact on cognitive, behavioral, and mental health outcomes as well.

Over the last two decades, accumulating information describes the profound effect that these socioeconomic and emotional stressors can have on the developing brain. Lower cognitive score, achievement results, school success, and components of EF/WM have been well documented. With the advent of HAART, HIV-infected youth appear close to their SES matched peers in a number of neuropsychological domains.

While overall cognitive functioning appears to be fairly stable for older youth, more recent investigations have focused on specific neurocognitive functioning and its impact on daily living, including executive functioning, processing speed, memory, achievement, and adaptive functioning.

Executive functions are the cognitive processes involved in self-monitoring of emotions and behaviors and planning and execution of problem solving. It includes processes such as inhibition, working memory, and flexibility in shifting thoughts and behaviors. These processes are of particular concern as youth age into adolescence, when impairment of these skills may have serious implications for decision-making processes that could lead to high-risk behaviors, poor medication management, delayed vocational planning, and transmission of the virus. Findings have been mixed and interpretation has been difficult due to methodological differences among and within studies. Most studies support the finding that youth with PAH demonstrate impairments in EF abilities. However, studies with appropriate control groups and those that were able to control for psychosocial risk factors suggested that those impairments were not due to PAH infection.

An important area that has consistently been found to be of particular vulnerability in adults and youth is processing speed, and studies suggest that this impairment is highly associated with disease markers such as high viral load (VL) and having a previous Class C (AIDS-defining) diagnosis. This finding holds even after controlling for psychosocial influences. Impairments in this area have implications for a youth's ability to focus, process, and respond in an appropriate and timely manner in a broad range of circumstances.

Other domains of neuropsychological functioning are similar in nature to the neurocognitive findings; average to low-average functioning compared to normative samples, but comparable to youth who are not HIV-infected and have similar psychosocial demographics. Academic achievement and adaptive functioning, two domains that contribute to a youth's quality of life, are two of the domains with similar findings. Language is also a domain considered particularly vulnerable to PAH infection, but post-HAART studies again suggest that although youth exhibit high rates of impairment, they are not consistently attributable to PAH. Lastly, although motor impairment was highly prevalent in the pre-HAART era, it is not a common finding in youth who have access and are adherent to treatment.

One subgroup of youth with PAH are at greater risk for poor neuropsychological outcomes even after controlling for psychosocial contributions. Youth who experienced an early AIDS-defining illness (prior to 3–5 years), despite current virologic and immunologic recovery, continue to demonstrate deficits in several areas, even into adolescence, including cognition, EF, language, processing speed, and achievement (Smith and Wilkins 2015). Additionally, those who experienced HIV encephalopathy in early childhood are at even greater risk for moderate-to-severe neurocognitive impairments, indicating that although the process can be arrested, full return to normal function is generally not achieved. This suggests that the CNS may have less recovery potential and/or that recovery is different from the peripheral system possibly due to the evolution of viral replication in this independent reservoir. In addition, it may be that these youth experienced earlier infection (i.e., in utero) and were exposed to high viral loads and neurotoxic immune responses during critical periods of brain development.

Mental Health/Behavioral Health

Early studies, without control groups, suggested an increased incidence of MH disorders (among them depression, anxiety, and ADHD) and more importantly, psychiatric hospitalizations, among

PAH. Several studies have reported that children and adolescents with a past diagnosis of AIDS are more at risk for psychiatric illness and hospitalization, compared to national population incidence.

More recent work indicates that compared to control groups of PHEU and HIV-negative but at-risk youth, rates of mental health diagnoses are not significantly different for PAH youth, but generally higher than rates among the general population. Again, methodological issues make solid conclusions difficult, including differences in study design/confounding issues, different tools for assessing risk/diagnosis, and selection bias among those consenting for inclusion in a study.

As stated previously, environmental conditions under which one develops is one of the greatest influences to neurocognitive and MH outcomes. Youth with PAH face a number of concomitant risk factors including urban poverty which may bring increased exposure to stress, community and domestic violence, suboptimal education systems, and resource instability. In addition there are stressors unique to living with PAH that may increase the cumulative contributions of risk to overall mental health. Stigma is a complex societal process for people living with HIV. It can result in devaluation and discrimination and often influences a youth's decision to disclose their diagnosis to peers and intimate partners. Parental loss, either in the form of death, unstable family dynamic, or impaired functioning due to HIV, is another common stressor experienced by youth with PAH. Many of these stressful life experiences have been shown to be contributory factors in poor physical and mental health outcomes for children (Elliot-DeSorbo et al. 2009).

Mental health problems and high-risk behaviors often co-occur in adolescents, including those with PAH, and have been associated with poor adherence, substance use, and risky sexual behaviors (Mellins and Malee 2013; Mellins et al. 2011). Adherence can be a significant challenge for adolescents with any chronic illness, however for youth with PAH, adherence is often complicated with the increased risk of inadvertent disclosure to others. Additionally, many PAH adolescents are aging into adult care after more than a decade of personalized pediatric care and

often disengage from consistent medical care. The majority have been treated with ARVs for more than 15–20 years, frequently initially on what is now known to be suboptimal regimens. Therefore, many have resistance to multiple drugs, pill-taking fatigue, and poor family or community supports for medical adherence.

Many PAH voice a fear of sexual intimacy, related to need of disclosure, and fear of transmission of the virus. Others plunge into multiple relationships without disclosure of their status to anyone. In the few studies examining sexual activity among youth with PAH, rates of sexual intercourse were comparable to national averages and to PHEU youth, however the majority of youth with PAH had unprotected sex (with significantly higher rates of sexually transmitted infections) and did not disclose their status to their partners (Tassiopoulos et al. 2013).

Summary

With earlier initiation of more tolerable and effective treatment regimens, it is expected that infants with perinatally acquired HIV infection will have much improved CO, and much lower risk of PE, compared to those born in the pre-HAART era. However, for the aging population of PAH, further research into ameliorating the effect of ongoing CNS viral replication and immune activation continues to be a high priority. A major unanswered question is whether they will be affected by the progression of subtle HIV-related neurologic deficits and an accelerated process of CNS aging described in HIV-infected adults. Continued close monitoring of this unique population who have had early and chronic exposure to HIV, and multiple treatment regimens, as well as to significant environmental stressors is critical in hopes of offering targeted CNS therapies and necessary psychological, social, and educational support to best optimize outcomes.

Neuroinflammation and HAND: Therapeutic Targeting

Stephanie A. Cross¹ and Dennis L. Kolson²

¹Department of Psychiatry, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA

²Department of Neurology, University of Pennsylvania, Philadelphia, PA, USA

Definition

Neuroinflammation associated with HIV infection is viewed as a state of glial cell activation and expression of inflammatory molecules and

mediators of oxidative stress within the brain, which can disrupt normal neuronal function and architecture. The severity and temporal expression of such inflammation and associated effects are less predictable in individuals on suppressive antiretroviral therapy (ART), but the severity of clinical manifestations of neurological dysfunction is dramatically and consistently reduced in such individuals. The syndrome of HIV-associated neurocognitive disorders (HAND) represents such a group of cognitive dysfunctional states of graded severity that persist in up to 30–50% of virally suppressed individuals, and possible roles for chronic or episodic neuroinflammation have been suggested as mediators of and therapeutic targets for HAND.

Identifying Neuroinflammation and Associated Pathways Induced by HIV-1 Infection of the CNS

- (a) **Central nervous system (CNS) HIV infection.** HIV infection of the brain occurs within days to weeks of systemic infection, and levels of HIV RNA in the cerebrospinal fluid (CSF) correlate with the severity of HAND in individuals who are ART naïve (Clifford and Ances 2013). Evidence suggests a “Trojan horse” mechanism of entry of HIV-infected CD4⁺ T lymphocytes (Sturdevant et al. 2015) and monocytes into the brain and the establishment of viral reservoirs that are at least partially inaccessible to ART drugs. Thus far, in brain autopsy studies, perivascular macrophages have been identified as a major CNS site of productive HIV replication, although endogenous brain microglia and astrocytes (up to ~15% infection rate) can also contain HIV genomes and possibly express viral proteins (Burdo et al. 2013). Although recent evidence for infiltration into the CNS and compartmentalized evolution of T lymphocyte-tropic, non-macrophage-tropic, HIV strains within the CNS has emerged, the anatomic site of this lymphocyte reservoir has not been identified (Sturdevant et al. 2015).

In ART-naïve subjects, brain HIV infection is associated with robust expression of pro-inflammatory molecules including cytokines and chemokines, production of potentially damaging reactive oxygen species and other markers of oxidative stress, expression of some HIV proteins, and increased production of glutamate and other non-proteinaceous neurotoxins, each of which has been linked to disrupted neuronal function and architecture. However, consistent expression of these inflammation factors and their associated linkage to neuronal injury and dysfunction in individuals on suppressive ART has not been as strongly established. Nonetheless, surprisingly high rates of HIV escape (“blipping”) from suppressive ART, as determined by sequential sampling of CSF and episodic detection of both HIV RNA and markers of immune activation in individuals felt to be in a state of HIV suppression, suggest a role for persistent CNS HIV infection and neuroinflammation, even if intermittent, in HAND pathogenesis in ART-experienced patients (reviewed in Price et al. 2014).

(b) **Oxidative stress within the CNS in HIV infection.** Oxidative stress is observed in both systemic and CNS compartments in HIV-infected individuals. Through effects of immune activation and associated signaling, HIV infection can induce pathological oxidative stress, as suggested by detection of diminished levels of reduced glutathione in plasma, lymphocytes, and PBMCs isolated from HIV-infected individuals, reduction of the thiol antioxidant thioredoxin in HIV-infected cells, and elevated serum levels of the lipid peroxidation products in HIV-infected individuals (Kamat et al. 2012). Oxidative stress can in turn drive immune activation through enhancing NF- κ B-driven HIV replication and release of pro-inflammatory cytokines. Furthermore, glutathione deficiency in CD4+ T lymphocytes in HIV-infected individuals correlates with systemic disease progression and mortality.

HIV infection can induce CNS oxidative stress through chronic immune activation and

production of free radicals and lipid peroxidation products, including pathways generating superoxide anions, peroxynitrite, nitric oxide (NO), ceramide, sphingomyelin, and 4-hydroxynonenal (Reynolds et al. 2007; Steiner et al. 2006). Furthermore, several of these in vivo markers of oxidative stress correlate with neurocognitive impairment as well as systemic disease progression in HIV-infected individuals (Reynolds et al. 2007; Steiner et al. 2006).

Although suppression of HIV replication with ART significantly reduces immune activation and oxidative stress, this suppression is incomplete. Neuroinflammation and neuropathological damage can likely persist to some degree in virally suppressed ART-treated individuals, and persistent systemic and CNS markers of monocyte/macrophage activation predict neurocognitive impairment, even in individuals with virological suppression (Kamat et al. 2012). These findings highlight the potential therapeutic benefit of targeting neuroinflammation and oxidative stress to ameliorate disease progression in ART-treated patients.

(c) **Immune activation and neuroinflammation pathways in CNS HIV infection.** In addition to CNS oxidative stress induced by HIV infection within the CNS compartment, systemic effects of HIV infection likely also contribute to neuroinflammation and associated dysfunction. Persistent chronic immune activation has been linked to early pathological injury to the gut in HIV-infected individuals (Burgener et al. 2015). Such immune activation is thought to result from translocation of microbial products across a damaged gastrointestinal tract, which is rapidly depleted of gut-associated lymphoid tissue after HIV infection. Among the identified translocated microbial products in HIV infection is LPS, which can induce systemic monocyte activation, as indicated by elevated blood levels of soluble CD14 (sCD14) and sCD16, and elevated expression of monocyte-associated CD14 and CD16 (Burgener et al. 2015). Based on accumulating evidence for

associations between the gut microbiome and neuroinflammation-associated CNS disorders such as multiple sclerosis (Wang and Kasper 2014), it is interesting to speculate that some gut microbiomes could associate with CNS disease progression in HIV infection.

Elevated plasma markers of immune activation correlate with systemic morbid events during ART, and some evidence exists for a link between systemic immune activation, CNS immune activation, and HAND. Elevated blood levels of CD16⁺ monocytes, sCD14, sCD163, and total CD14⁺ monocyte HIV DNA content associated with microbial translocation have been shown to correlate with an increased risk for HAND (Valcour et al. 2013). Thus, ART-treated individuals with HIV suppression are at risk for CNS complications of persistent immune activation, particularly monocyte/macrophage activation in the systemic and CNS compartments, which likely puts them at an increased risk for HAND. The pathophysiological factors associated with establishing and maintaining a state of immune activation are important considerations for HAND prevention strategies.

HIV-induced neuronal injury *in vitro* is associated with the release of various immune activators and toxins from HIV-infected macrophages, and immune-activated astrocytes, and glutamate receptor-mediated excitotoxicity may be one common injury pathway, among others. Monocyte and macrophage activation, either due to viral infection or inflammation, results in the production and release of known neurotoxins including glutamate, quinolinic acid, and other glutamate receptor agonists, nitric oxide, platelet-activating factor, reactive oxygen species, TNF- α , and other pro-inflammatory cytokines and chemokines. Subjects with HAND have elevated levels of several such pro-inflammatory cytokines, including IL-1 β , TNF- α , and IL-6 in the brain and/or CSF (Chen et al. 2014). Immune activation of astrocytes could similarly increase expression of these potentially neurotoxic factors, including glutamate, even in the absence of HIV infection.

(d) **Blood-brain barrier breakdown.** Additional mechanisms of HIV-induced CNS inflammation might involve increased permeability of the blood-brain barrier (BBB) and increased entry of infected monocytes and lymphocytes into the CNS mediated by systemic and/or CNS inflammation. Several viral and host factors alter the stability and function of the blood-brain barrier (BBB), and this is believed to contribute to HIV neuroinflammation and neuropathogenesis. Drugs of abuse, including cocaine and methamphetamine, and TNF- α have been proposed to exacerbate neurocognitive impairment in HIV infection through further disruption of the BBB, resulting in enhanced immune cell infiltration, elevated CNS inflammation, and alteration in cellular homeostasis. Cocaine, methamphetamine, and TNF- α also alter tight junction and cell adhesion molecule expression, permeability, and immune cell migration across brain microvascular endothelia (Hauser and Knapp 2014). The host response to HIV replication and drug-mediated BBB dysfunction can promote immune cell (HIV-infected and noninfected) infiltration into the CNS and promote neuroinflammation, which in turn may drive further loss of BBB integrity. Therefore, reducing inflammation in the periphery as well as within the CNS could be expected to improve neurocognitive outcomes in HIV-infected individuals.

Potential therapeutic targeting of neuroinflammation and oxidative stress in HAND.

Considering therapeutic targeting of neuroinflammation and oxidative stress in HIV infection requires identification of pathological activation mechanisms and pathways of immune activation and oxidative stress in the CNS. As discussed, a number of such pathways and mechanisms have been tentatively identified, and some of these have been therapeutically targeted (Table 1), but effective strategies for altering neurological outcomes by such targeting have remained elusive. Whether past therapeutic failures represent misidentification of suitable targets, ineffective drugs, or inadequate clinical trial

Neuroinflammation and HAND: Therapeutic Targeting, Table 1 Proposed therapeutics for HAND with direct and indirect anti-inflammatory, antioxidative effects

Generic (brand) name	Mechanism	Proposed effects	References
Memantine (Namenda)	NMDA receptor antagonist	Prevent NMDA receptor-mediated excitotoxicity	Zhao et al. (2010)
Selegiline (Deprenyl)	MAO-B inhibitor	Reduce oxidative burden of cell	Schifitto et al. (2009a)
Minocycline	Inhibitor of 5-lipoxygenase and others	Anti-inflammatory and antioxidative effects	Zink et al. (2005), Nakasujja et al. (2013)
Lithium, sodium valproate (Depakote)	GSK-3 β inhibitor	Anti-inflammatory and other effects	Schifitto et al. (2009b)
SSRIs: citalopram (Celexa), paroxetine (Paxil)	Serotonin transporter inhibitor	Anti-inflammatory and other effects	Steiner et al. (2015)

designs for clinical outcomes remains to be determined.

- (a) **CNS HIV replication and ART treatment strategies.** Although ART has significantly decreased the severity of HAND, presumably by lowering systemic and CNS viral loads, the relatively poor penetration of ART drugs into the CNS limits their ability to completely suppress HIV replication in this compartment. Improved CNS penetration of ART drugs into the CNS might reduce HAND prevalence further by more effective suppression of CNS HIV replication, neuroinflammation and oxidative stress pathways associated with infected and activated macrophages/microglia and immune-activated astrocytes. However, clinical trials in patients treated with ART regimens with increased CNS penetration have not demonstrated reduced incidence or progression of HAND. Additionally, increasing ART penetration into the CNS could expose the brain to neurotoxic effects of these drugs. Effective therapies for HAND will likely require combination therapy that not only safely suppresses HIV replication but also addresses the associated neuroinflammation and oxidative stress that contribute to HIV-associated neurodegeneration in ART-treated individuals.
- (b) **Oxidative stress and associated pathways.** Targeting oxidative stress and associated pathways within the CNS can be rationally considered through the use of antioxidants

that might directly correct the cellular glutathione deficiency associated with HIV infection and/or through drugs that induce the endogenous host cellular antioxidant response pathway. The former has already been investigated, and the latter is receiving much current attention. The cellular antioxidant response is initiated through rapid induction of a family of genes driven by the Nrf2 transcriptional factor, which activates an element (the antioxidant response element) within the antioxidant gene promoter. Translocation of Nrf2 from the cytoplasm to the nucleus occurs rapidly after cellular injury and stress and results in antioxidant gene induction and a subsequent cytoprotective response. This cytoprotective response involves the detoxification of the cell's pro-oxidative state that is associated with injury-induced cellular stress. Several previous neuroprotection trials have focused on several therapies that do not directly activate the Nrf2 antioxidant pathway (selegiline, minocycline) but which nonetheless produce antioxidant effect through either glutathione restoration or anti-inflammatory properties. Newer therapies under development target the induction of Nrf2 antioxidant pathways.

Selegiline (Deprenyl), a monoamine oxidase B (MAO-B) inhibitor used in the treatment of early-stage Parkinson's disease, is proposed to act as a neuroprotectant by reducing the oxidative burden within the

cell. However, recent studies of HIV-infected individuals have shown no evidence of improved neurological outcomes with short-term (24 weeks) treatment with selegiline; selegiline also failed to reduce biomarkers of oxidative stress in further analysis of this study, which suggests ineffective drug targeting of oxidative stress pathways *in vivo* (Schifitto et al. 2009a).

Minocycline is a broad-spectrum tetracycline antimicrobial that can cross the blood-brain barrier and that can suppress HIV replication in cultured microglia, macrophages, and lymphocytes (Zink et al. 2005). In addition, minocycline has anti-inflammatory and antioxidative properties as shown by its inhibition of TNF- α , IFN- γ , and IL-2 production by lymphocytes. In SIV-infected macaques, minocycline administration resulted in decreased CSF expression of CCL2, a biomarker of inflammation, and decreased the severity of SIV encephalitis (Zink et al. 2005). However, a short (24 weeks) minocycline neuroprotection trial with ART-naïve, HIV-infected individuals demonstrated no improvement in cognitive functioning (Nakasujja et al. 2013). Notably, however, analysis of CSF from a subset of treated subjects demonstrated a significant reduction in lipid markers of oxidative stress (ceramides), suggesting effective *in vivo* reduction of at least some pathways of oxidative stress. This suggests that a longer treatment period with minocycline should be considered to more effectively evaluate its ultimate neuroprotection potential in HIV-infected individuals.

- (c) **Immune activation and neuroinflammation pathways in CNS HIV infection.** Considerable attention has been paid to the potential neuroprotective effects of statins, which can modulate several neuroinflammation pathways associated with the pathogenesis of HAND. Statins have been prescribed for the treatment of hyperlipidemia, which might be associated with an increased risk of dementia in both HIV-infected and noninfected individuals. Statins also promote cardiovascular and, presumably, cerebrovascular health through

antioxidant and anti-inflammatory effects and improved endothelial function. A recently published systematic review of the role of statins in preventing cognitive decline and dementia reviewed randomized controlled trials and observational studies in HIV-negative cohorts. The conclusion was that initiation of statins in later life does not prevent cognitive decline over the ensuing 3–5 years (Power et al. 2015).

Nonetheless, the potential for statins to provide neuroprotection against HAND requires specific investigation of their effects against associated pathological processes in HIV-infected individuals. These processes include chronic inflammation and the production of excitatory neurotoxins from activated monocytes/macrophages, which are recruited to the CNS during HIV infection. Atorvastatin has been demonstrated to have anti-inflammatory effects in cultured monocytes and in ART-treated HIV-infected individuals, and a double-blind, placebo-controlled crossover pilot clinical trial designed to determine effects of atorvastatin on monocyte activation, gene expression patterns, and neurocognitive outcomes in HIV-infected individuals receiving ART is currently under way (ClinicalTrials.gov Identifier: NCT01600170). Other ongoing research is also examining the role of other statins on monocyte-mediated inflammation and activation in association with neurovascular risk factors in HIV-infected individuals.

Glycogen synthase kinase-3 β inhibitors such as sodium valproate (VPA) and lithium are approved for treatment of bipolar disorder and related mood disorders, and both provide neuroprotection against HIV-induced toxicity *in vitro* and in mouse models of HIV encephalitis. Several small pilot studies have demonstrated improved neuropsychological performance in HAND patients following short-term VPA or lithium therapy (Schifitto et al. 2009b).

Selective serotonin reuptake inhibitors (SSRIs), including paroxetine, citalopram, and fluoxetine, also express some anti-

inflammatory effects and are also under consideration as adjunctive therapies for HAND (Steiner et al. 2015). SSRIs were predicted to directly decrease levels of HIV replication, although clinical trials have not yet found a significant improvement when an SSRI is used as an adjunctive therapy.

- (d) **Glutamate receptor (N-methyl-D-aspartate/NMDA) subtype antagonists.** Noted clinical similarities between the neurodegeneration seen in HIV infection and other neurodegenerative diseases as well as depression have prompted investigations into broadly neuroprotective therapies for the treatment of HAND (Table 1). Because neurodegeneration is often associated with neuroinflammation, oxidative stress, and excitotoxic injury (through glutamate and other NMDA receptor agonists), agents that block the NMDA receptor have been investigated for their neuroprotective properties in several neurodegenerative diseases. Memantine (Namenda) is approved in the treatment for Alzheimer's disease and acts as a noncompetitive NMDA receptor antagonist. *In vitro* and *in vivo* animal studies have shown that memantine can attenuate some features of HIV- and SIV-linked neurotoxicity and neuronal dysfunction, and short-term (20 weeks) and long-term (~1 year) clinical trials in HAND patients demonstrated that memantine improved neuronal metabolism, indicative of neuroprotection, but did not lead to significantly improved neurocognitive outcomes (Zhao et al. 2010). These studies suggest that NMDA receptor targeting, in addition to targeting pathways leading to production of toxic levels of NMDA receptor agonists (glutamate, quinolinic acid) produced in the HIV-infected brain, might provide clinically significant neuroprotection.

Conclusions

Because HIV infection is associated with chronic immune activation and associated inflammation

and oxidative stress, even in individuals with virological suppression due to ART, adjunctive therapies to ART are necessary for improved long-term clinical outcomes. The persistence of HAND in such individuals supports a need for adjunctive therapies capable of penetrating the CNS. Several classes of drugs that might ultimately meet these needs include GSK-3 β inhibitors and drugs that directly or indirectly suppress oxidative stress within the CNS. Some drugs that have antioxidant effects (selegiline, minocycline) have not proved effective, for reasons that might include ineffective CNS modulation of oxidative stress or even because of therapeutic clinical trials of limited duration. Newer approaches to modulating oxidative stress include drugs that can directly activate the host's endogenous antioxidant response. This response, which is mediated Nrf2 transcriptional factor, drives expression of a family of antioxidant genes after stress-associated injury. One major mediator of this host antioxidant response is the inducible enzyme heme oxygenase-1 (HO-1), which is a detoxifying enzyme that is critical for limiting oxidative stress, inflammation, and damage within the CNS and other tissues in response to acute cellular injury. Recent studies demonstrated a unique deficiency of HO-1 within the brains of individuals with HAND and a mechanistic link to HO-1 deficiency and dysregulation of glutamate metabolism, suggesting a potential role for HO-1 deficiency in the pathogenesis of HAND and its potential therapeutic targeting (Gill et al. 2014). Among the drugs known to induce HO-1 expression are statins and a recently-approved drug, dimethyl fumarate (Tecfidera) that has recently been approved for the treatment of multiple sclerosis (Gill et al. 2014). Additional drugs that activate Nrf2-driven gene expression are currently in development as neuroprotectants for various neurodegenerative diseases, which could facilitate their application to HAND neuroprotection. Finally, modified ART regimens with less potential neurotoxicity and with improved CNS penetration might still be feasible for improving neuroprotection against HAND (Clifford and Ances 2013).

Neuropsychological Testing in HIV-Infected Individuals

Robert K. Heaton and Jennifer E. Iudicello
Department of Psychiatry, University of California, San Diego, San Diego, CA, USA

Definition

Recent estimates from the US Centers for Disease Control and Prevention were that 1.2 million individuals were living with HIV/AIDS in the United States and over 35 million worldwide (CDC 2013). The last few decades have witnessed dramatic improvements in the treatment and management of HIV disease, including the advent of combination antiretroviral therapy (cART) in 1996. These advances remarkably improved HIV-related health outcomes and transformed HIV from what was once a condition with very poor prognosis and high mortality rates into a more

chronic, long-term manageable condition. Despite these significant advances, HIV-associated neuropsychological disorders (HAND), particularly in milder forms, remain highly prevalent in the cART era and can have significant adverse effects on everyday functioning and health-related outcomes.

This chapter will provide an overview of neurocognitive (NC) assessment as it pertains to the diagnosis of HAND in clinical and research settings. We will begin with a brief developmental history of the current HAND diagnostic criteria, followed by an overview of the epidemiology and nature of NC disturbances in HIV. We will then review the approaches used to evaluate NC impairment in HIV, which will include methodological considerations (e.g., the selection of NC tests and interpretation of test findings) and will provide brief summaries of methods used to evaluate NC change over time and screen for impairment in clinical or other resource-limited settings.

History of HAND and Current Diagnostic Criteria

Some of the earliest published reports of central nervous system (CNS) consequences due to HIV appeared in the mid-1980s to early 1990s. One of the most common was a neurological condition characterized by moderate to severe cognitive, behavioral, and motor disturbances. Originally termed the AIDS dementia complex (ADC; Navia and Price 1987), and now referred to as HIV-associated dementia (HAD), this constellation of disabling symptoms was observed most typically in the later stages of AIDS and was associated with significant mortality risk. Prevalence estimates of NC impairment in the earlier stages of disease (e.g., medically asymptomatic stage) were more controversial, although a preliminary study by Grant and colleagues (Grant et al. 1987) suggested that, with use of a comprehensive NC test battery with adequate normative standards, increased rates of NC impairment could be documented at each successive stage of infection (including the medically asymptomatic stage). This finding was supported by a

subsequent review (White et al. 1995), which further emphasized the importance of comprehensive assessments covering multiple NC ability areas that could be affected by HAND.

During the early years of the epidemic, several useful classification systems were proposed for the diagnosis of HAND. One of the more widely used early classification systems was developed by an AIDS Task Force of the American Academy of Neurology (AAN; AAN 1991). This system identified two diagnostic categories of HAND: HIV-associated dementia (HAD) and minor cognitive motor disorder (MCMD). In order to meet criteria for HAD, a patient must demonstrate (1) an acquired deficit in two or more non-motor NC domains that cause impairment in work or other activities of daily living (ADLs) and (2) an acquired abnormality in motor function and/or a decline in specific neurobehavioral or psychosocial areas (e.g., motivation, emotional control). If the diagnostic criteria for HAD were not met, a patient could meet criteria for MCMD if they demonstrated acquired impairment in at least two cognitive, motor, or behavioral domains that caused mild impairment in ADLs or at work. These AAN categories were later expanded to include the “sub-syndromic neurocognitive impairment” diagnostic category in response to research suggesting a subgroup of patients with NC disturbances that did not appear to interfere with everyday functioning (Grant and Atkinson 1995).

While the AAN classification system provided a valuable first step toward developing guidelines for classifying the neurological complications of HIV, there were several significant limitations to their applicability in research and clinical settings. One major concern was that the criteria were loosely defined and not operationalized, which can lead to inconsistencies across studies and/or clinics and unreliable estimates of prevalence and nature of HAND across studies. Furthermore, the AAN criteria for HAD with mild functional decline appeared to overlap with the criteria for MCMD, which could also lead to diagnostic inconsistencies.

Another limitation was that the AAN criteria did not emphasize NC (non-motor) impairment as

the essential component of HAND. In fact, given the AAN criteria's emphasis on motor and other noncognitive (e.g., mood, personality) changes, a patient could meet criteria for MCMD without demonstrating any cognitive changes (e.g., motor symptoms and mood/personality changes might meet criteria). This was problematic as motor and/or mood and personality abnormalities frequently are difficult to attribute to HIV.

Significant changes in the HIV epidemic over the years also limited the applicability of the AAN criteria. With the introduction of cART, the nature and course of the HIV epidemic improved dramatically. Effective cART not only improved systemic disease but also decreased the prevalence of severe neurological consequences that often occurred in the pre-cART era, including HAD. The stable, and if anything, increasing prevalence of milder forms of NC impairment (Heaton et al. 2011) warranted more distinct and operationalizable criteria. The changing epidemic also witnessed a growing population of older adults as well as an increase in non-HIV-related comorbid risk factors for NC impairment in HIV, including, but not limited to, traumatic brain injury, metabolic syndrome, coinfection with hepatitis C, serious psychiatric disorders, and substance use disorders (e.g., alcohol and methamphetamine abuse/dependence). As such, there was a need for detailed guidelines regarding how to assess aging and aging-related comorbidities (e.g., vascular disease), as well as other common comorbidities listed above. Careful assessment of the potential NC and functional impact of these comorbid conditions, in addition to the effects of premorbid confounds (e.g., learning disabilities), is required and must be distinguished from the effects of HIV prior to assigning HAND diagnoses.

In response to the abovementioned concerns, in 2005 the NIH supported an international meeting of interdisciplinary neuroAIDS experts in Frascati, Italy, to develop a classification system with more clear and objective guidelines and criteria for diagnosing HAND in research settings. Consensus discussions resulted in the Frascati classification system for the diagnosis of HAND

(Antinori et al. 2007), which defined NC impairment as at least mild impairment in two or more NC ability domains, and described three categories of HAND: (1) asymptomatic neurocognitive impairment (ANI), (2) mild neurocognitive disorder (MND), and (3) HIV-associated dementia (HAD). Formal criteria may be found in Antinori et al. (2007). In brief, to be diagnosed with ANI, a patient must demonstrate at least mild, acquired impairment in at least two NC ability areas, but without any clear evidence that the impairment adversely affects their daily functioning. A diagnosis of MND also requires at least mild impairment in at least two NC ability domains, though unlike ANI, a diagnosis of MND requires evidence that the NC impairment is impacting everyday functioning. A diagnosis of HAD, which in the cART era is rare (i.e., <5%), requires at least moderate impairment in at least two ability areas associated with serious problems with everyday functioning (e.g., incapable of working competitively and/or living independently). For all three HAND classifications, the impairment and/or disability must be attributed at least partly to HIV, rather than solely to other common pre- and/or comorbid conditions (including opportunistic CNS disease and other comorbid conditions mentioned above).

These "Frascati criteria" improved the identification and classification of HAND diagnoses in several ways. First, these criteria included specific operational definitions as well as standardized procedures and algorithms to evaluate the prevalence and severity of both NC impairment and functional decline. For example, for "mild NC impairment" (necessary for ANI and MND classification), a patient's NC performance must be >1 SD below the mean of demographically corrected scores on at least two NC domains; "moderate NC impairment" (necessary for HAD) requires scores >2 SD below the mean on at least two NC domains. Second, the Frascati system emphasized NC impairment as the principal diagnostic criterion rather than other criteria such as motor disorders and/or emotional/personality changes, given consistent findings throughout the literature demonstrating strong associations

between NC abnormalities and underlying pathologic changes in the brain (see Grant and Sacktor 2011). Third, the Frascati classification system was the first to provide detailed operational guidelines for evaluating and interpreting the potential adverse impact of common pre- and comorbid conditions on the expression of HAND and functional declines (see Antinori et al. 2007, Table E-4). This is particularly important, as the Frascati criteria (like prior classification systems) specify that, prior to assigning a HAND diagnosis, the observed NC impairment and functional disability must be attributed at least partly to HIV as opposed to comorbid conditions.

Neuropsychological Assessment in HIV

History of Neuropsychological Assessment

Clinical neuropsychology has long focused on assessment methods to detect and characterize NC impairments in persons with known or suspected brain disorder. In earlier years of the field, NC tests were developed primarily for diagnostic purposes, such as the identification and localization of brain lesions. As the field evolved, the focus of neuropsychology shifted its diagnostic focus to include methods for evaluating the impact of brain damage or dysfunction on NC and behavioral outcomes themselves, which today represents one of the most important and valuable contributions of neuropsychology. Considerable progress has been made in this regard and as a result has expanded the role of NC assessment to include differential diagnosis, assessing change in cognitive functioning over time and predicting everyday functioning outcomes.

Role of Neuropsychological Assessment in HIV

Comprehensive NC assessments have played a major role in detecting and characterizing CNS complications of HIV disease. As mentioned above, HAND remains common in the cART era, even in treated and virally suppressed individuals, with current prevalence estimates of

35–50% (Heaton et al. 2010, 2011). It is most likely to emerge in persons with histories of severe immunosuppression though can even be seen in cases of primary infection. In the cART era, HIV-associated NC deficits are typically mild to moderate in severity and most prominently observed in the domains of executive functions, episodic memory (learning and delayed recall), attention/working memory, speed of information processing, verbal fluency, and fine perceptual-motor skills. HAND is generally nonprogressive, though fluctuations may occur due to disease- or treatment-related factors (e.g., changes in antiretroviral treatment). Importantly, even in its mild forms, HAND has been consistently linked to an array of adverse functional and health-related outcomes, including problems with ADLs (e.g., medication and financial management), vocational difficulties, and reduced overall quality of life (for a review, see Blackstone et al. 2017).

A thorough characterization of NC functioning in HIV requires a detailed (2+ hours) NC assessment covering the seven ability domains mentioned above. This is because of the varied and somewhat “spotty” nature of HIV-associated NC deficits (consistent with neuroimaging findings in this disease; Jernigan et al. 2011), resulting in variable patterns of deficits across patients. Moreover, a comprehensive evaluation of NC functioning not only identifies NC weaknesses, but it also provides information regarding strengths, which together can be highly informative for differential diagnosis and when developing rehabilitation strategies to improve impairment (or at least reduce the impact of impairment in daily life). Relatedly, unlike other measures of CNS integrity (e.g., neuroimaging) NC evaluations are able to detect brain dysfunction that impacts everyday functioning. As mentioned above, NC assessments are also useful tools for detecting and monitoring changes in brain function over time, which may occur with disease progression and/or as a result of treatment (e.g., changes in ART regimens) or comorbidity-related changes (e.g., aging). Lastly, NC evaluations are helpful in determining the impact of incident comorbidities on the expression of HIV-associated NC impairment.

Approaches to Neuropsychological Evaluation

Neuropsychological Test Selection

When considering tests for the assessment and diagnosis of HAND, standardized and well-validated instruments should be selected based on their sensitivity to HIV-associated NC impairment and underlying frontostriatal dysfunction. Selecting multiple and diverse measures sensitive to HAND is necessary for detecting the often mild and “spotty” HIV-associated deficits, even at relatively early stages of disease. Detecting impairment early can have significant implications for treatment, as this may allow for the initiation of directed therapies prior to significant HIV-associated neurological damage. Examples of recommended tests for each of the domains likely to be affected in HAND are provided in Table 1 (for a more comprehensive list with references, see Table E-3 of Antinori et al. 2007).

Another important requirement should be the availability of demographically corrected normative standards appropriate for the individual or population being assessed. Demographically corrected normative data provide guidance with regard to how a particular individual would be expected to perform on a test in the absence of a brain disorder. Demographic factors such as age, education, sex, and ethnicity, can significantly influence NC test performance, so failure to use norms that are corrected for these factors will increase the risk of misclassifying NC impairment (Heaton and Marcotte 2000).

Importantly, although reliable HIV effect sizes can be obtained from group mean comparisons in studies that include demographically comparable HIV-uninfected controls, in the absence of adequate norms, it is not possible to determine the prevalence of HAND in the HIV+ group or determine which HIV+ individuals have HAND. The latter determinations obviously are essential within

Neuropsychological Testing in HIV-Infected Individuals, Table 1 Standardized Neuropsychological Tests Commonly Utilized in HNRP-Associated NC Test Batteries to Document Impairment in NC Ability Domains

Standardized Neuropsychological Assessment (HNRP)	
7 NC Ability Domains	Examples of Neuropsychological Tests
Verbal Fluency	Controlled Oral Word Association Test – Letter Fluency (F-A-S)

Motor Speed & Dexterity	Grooved Pegboard Test (dominant and non-dominant hands)

the clinical context, but also are necessary in research aimed at assessing associations of HAND with disease characteristics, treatment effects, biomarkers related to pathogenesis, and other indications of brain changes (e.g., neuroimaging).

Definitions and Cutpoints for NC Impairment
