Preface

The HIV/AIDS epidemic has spanned the past three-and-a-half decades. During this time, the epidemic has caused suffering on a global scale. In the fight to end this epidemic, researchers, healthcare agencies, and governments have mobilized and, as a result of these efforts, have fundamentally altered the course of the epidemic and transformed the prognosis for millions of individuals living with HIV/AIDS. Research has been central to the effort to control the HIV/AIDS epidemic. Early studies aimed at defining key processes in the viral replication cycle helped promote the identification of antiviral agents that have dramatically altered the outlook for infected individuals. This has created a *status quo* where HIV-1 infection is no longer a death sentence but a manageable, chronic infection. Now the frontier in the fight against HIV/AIDS has shifted to preventing infection, either through use of antivirals or through development of a vaccine. The field has also embarked on seeking ways to eliminate the virus from infected individuals. The hope is that these endeavors will bring an end to the “Age of AIDS.”

The human endeavor around three-and-a-half decades of research on HIV/AIDS has produced a large body of scientific information. There are many excellent treatises that have focused on condensing and highlighting different areas of the HIV/AIDS field. Therefore, why an AIDS Encyclopedia? Do we really need another work to summarize what we know about HIV/AIDS?

The AIDS Encyclopedia represents an AIDS “Wikipedia.” It is a dynamic, online reference work that can be updated by researchers and by editors that will be able to keep pace with developments in the field. The ability to continuously update the encyclopedia essentially means that it will retain its relevance as an easily accessible and important source of information for students, researchers, and clinicians whether they be working in academia, industry, or the hospital sectors.

Work on the encyclopedia began in 2010 and has seen fruition, thanks to the efforts of many individuals. The editors would like to thank Ms. Tina Shelton, Ms. Rita Beck, and Ms. Sunali Mull at Springer for much of the groundwork in structuring the project and maintaining timelines. Thank you for your persistence and commitment to bringing the project to completion. We would also like to thank the sub-editors who took on responsibility for the 282 individual chapters. We hope the research community will further help in keeping the AIDS Encyclopedia an important and current reference work for the

HIV/AIDS field, and we welcome contributions in this regard. Finally, the editors would like to acknowledge individuals living with HIV/AIDS who, by participating in research studies, have been central in the effort to end this epidemic.

List of Topics

Anatomic Compartments

Section Editor: *Babafemi O. Taiwo*

Anatomic Compartments as a Barrier to HIV Cure
Antiretroviral Drug Penetration into Lymphoid Tissue
Antiretroviral Drug Penetration into the CNS Compartment
HIV Compartments and Viral Rebound During Treatment Interruption
HIV Coreceptor Tropism in Different Reservoirs
HIV Reservoirs Within the Lungs
HIV Reservoirs in Lymph Nodes and Spleen
HIV Reservoirs in the Central Nervous System
HIV-1 Pathogenesis in the Gut
Mucosal Pathogenesis in SIV Infection

Behavioral Interventions

Section Editor: *Daniel J. Feaster and Allan E. Rodriguez*

Behavioral Interventions for Adherence
Case Management for Linkage
Nurse-Delivered Interventions for Adherence
Retention in Care Interventions

Behavioral Prevention

Section Editor: *Lisa R. Metsch*

Behavioral Aspects of HIV Mother-to-Child Transmission

Behavioral Aspects of HIV Treatment as Prevention
Combination Approaches to HIV Prevention
Community Viral Load
Delayed Sexual Debut
Faith Based Interventions
Family Interventions
Female Condoms
HIV Prevention Efforts Within Substance Use Disorder Treatment Settings
HIV Prevention and African Americans
HIV Prevention and Asians and Pacific Islanders
HIV Prevention and Hispanics
HIV Prevention and Labor Migration
HIV Prevention and Women
HIV Prevention for MSM
HIV Prevention for Serodiscordant Couples
HIV Prevention for Stimulant Using Men Who Have Sex with Men
HIV Prevention in Persons 50 and Older
HIV Prevention in Transgender Persons
HIV Prevention in Youth
HIV Prevention in the Correctional System
HIV Testing and Counseling
HIV and Sexual Violence
Harm Reduction for Injection Drug Users
Housing as HIV Prevention
Male Condoms
Mass Media and HIV Prevention
Microfinance/Microenterprise Approaches to HIV Prevention
Multilevel Interventions/Structural Approaches to HIV Prevention

Network Interventions
 Peer-Based Intervention Approaches
 Positive Health, Dignity, and Prevention (PHDP)
 Preexposure Prophylaxis (PrEP)
 Prevention Counseling and Other Strategies in the
 HIV Care Setting
 Prevention for People Living with HIV
 Prevention of Alcohol-Related HIV Risk
 Behavior
 Sex Work and HIV Prevention
 Translational Interventions (Intervention
 Technology Transfer)
 Use of Technology and Social Networking in HIV
 Prevention

Circumcision and AIDS

Circumcision and AIDS

Clinical: Opportunistic Infections

Section Editor: *Hansjakob Furrer*

Bacterial Respiratory and Invasive Pneumococcal
 Infections and HIV
 Chagas Disease and HIV
 Cryptococcosis and HIV
 Cryptosporidiosis
 Cystoisosporiasis
 Cytomegalovirus Infection and HIV
 Hepatitis C Virus Infection and HIV
 Leishmaniasis and HIV
M. avium Complex and Other Nontuberculous
 Mycobacteria and HIV
 Microsporidiosis
 Progressive Multifocal Leukoencephalopathy
 and HIV
 Salmonellosis and Other Bacterial Enteric
 Infections and HIV
Talaromyces (Penicillium) marneffeii
 and HIV
 Toxoplasmosis in HIV-Infected Patients
 Treatment of Histoplasmosis,
 Coccidioidomycosis, and
 Paracoccidioidomycosis in Patients with HIV
 Infection
 Tuberculosis and HIV

Clinical: Opportunistic Malignancies

Section Editor: *Robert Yarchoan*

AIDS-Related Primary Central Nervous System
 Lymphoma
 Anal Cancer
 Burkitt and Burkitt-Like Lymphoma
 Cervical Cancer and HIV
 Conjunctival Carcinoma
 Diffuse Large B-Cell Lymphoma
 Epidemic Kaposi Sarcoma, Pathogenesis and
 Presentation
 Epidemiology of AIDS-Defining Malignancies
 Epidemiology of Non-AIDS-Defining
 Malignancies
 Epstein-Barr Virus (EBV)
 HIV Cancers in Resource-Limited Regions
 HIV-Associated Cancers
 Hepatocellular Carcinoma in HIV-Positive
 Patients
 Hodgkin Lymphoma in Patients with HIV Infection
 Human Papillomavirus (HPV)
 Kaposi Sarcoma-Associated Herpesvirus
 (KSHV) or Human Herpesvirus 8 (HHV-8)
 Lung Cancer
 Malignancies in Children with HIV Infection
 Management of AIDS-Related Kaposi's Sarcoma
 Merkel Cell Carcinoma and Other HIV-
 Associated Skin Cancers
 Merkel Cell Polyomavirus (MCV)
 Multicentric Castleman Disease
 Other HPV-Associated Cancers (Oropharyngeal
 and Penile)
 Plasmablastic Lymphoma
 Presentation and Pathogenesis of B-Cell
 Lymphoid Cancers Associated with HIV
 Infection
 Primary Effusion Lymphoma
 Stem Cell Transplantation
 cART and Supportive Care for HIV-Associated
 Malignancies

Vaccine Efforts Against AIDS

About the Editors-in-Chief

Thomas J. Hope Department of Cell and Molecular Biology, Northwestern University, Robert H. Lurie Medical Research Center, Chicago, IL, USA

Thomas J. Hope is currently a Professor at Northwestern University in the Departments of Cell and Molecular Biology and Obstetrics and Gynecology in the Feinberg School of Medicine and Professor in Biomedical Engineering in the Robert R. McCormick School of Engineering in Chicago, IL. He received his Ph.D. from the University of California, Berkeley, in Immunology. Tom began to study HIV in 1988, during his postdoctoral training at UC, San Francisco. He was one of the pioneers to utilizing the methods of cell biology to study HIV. In 2004, Tom was selected as an Elizabeth Glaser Scientist. For more than two decades, Tom has combined this cell biology approach, supplemented with molecular biology, biochemistry, and genetics, to study various aspects of HIV from virus entry, uncoating, and assembly to defining the earliest steps of sexual transmission and developing interventions to decrease transmission. Tom is currently the Editor-in-Chief of *AIDS Research and Human Retroviruses*, a Section Editor of *PLoS Pathogens*, serves on editorial boards and NIH/NIAID review panels, is a past co-organizer of HIVR4P, Keystone HIV, and Cold Spring Harbor retroviruses, and currently presents and teaches worldwide.

Dr. Douglas D. Richman VA San Diego Healthcare System and University of California San Diego, La Jolla, CA, USA

Dr. Douglas D. Richman received his A.B. from Dartmouth College and went on to receive his M.D. at Stanford University where he completed his residency. He was a Research Associate in the Laboratory of Infectious Diseases at the NIH's National Institute of Allergy and Infectious Diseases and Clinical Fellow in the Division of Infectious Diseases, Beth Israel Hospital and Children's Hospital Medical Center of Harvard.

Dr. Richman joined the University of California, San Diego (UCSD), in 1976 and is currently Distinguished Professor of Pathology and Medicine and holds the Florence Seeley Riford Chair in AIDS Research. He is Director of the Center for AIDS Research at UCSD, and he attends in infectious diseases at the San Diego VA Healthcare System. He is a Fellow of the American Association for the Advancement of Science, the American Association of Physicians, and the Infectious Disease Society of America.

Dr. Mario Stevenson Department of Medicine, University of Miami Leonard M. Miller School of Medicine, Miami, FL, USA

Dr. Mario Stevenson is currently Professor in the Department of Medicine, Chief of the Division of Infectious Diseases, Director of the University of Miami AIDS Institute, Director of the Global Virus Network at the University of Miami, and Co-Director of the Center for AIDS Research. Prior to 2011, Dr. Stevenson was the David Frelander Chair for AIDS Research at the University of Massachusetts Medical School and the Director of the Center for AIDS Research at that institution. Dr. Stevenson obtained his B.Sc. (1980)

and Ph.D. (1984) in Glasgow, Scotland. Dr. Stevenson is a molecular virologist who has been working on the viral etiology of AIDS for over 30 years. Dr. Stevenson has provided insight into the mechanisms regulating HIV replication, persistence, and disease pathogenesis. Dr. Stevenson has served as Chair of the HIV AIDS Virology Study Section at the National Institutes of Health, Chair of the Scientific Advisory Board of the National AIDS Conference (CROI), and has served on the NIH Office of AIDS Research that sets AIDS research directives. From 2006 to 2015, he served as Chair of the Scientific Advisory Board and a member of the Board of Trustees of the American Foundation for AIDS Research (amfAR) and a scientific board member of the Elizabeth Glaser Pediatric AIDS Foundation. Dr. Stevenson is a recipient of Harvard Medical School's Shipley Lectureship, recipient of the Gertrude Elion Award, Schally Research Award, and Barcelona's IRSI-Caixa Award for accomplishments in AIDS research.

A

Acetylation

Anna Cereseto
Centre for Integrative Biology, Laboratory of
Molecular Virology, University of Trento, Trento,
Italy

Definition

Acetylation is a protein post translational modification (PTM) catalyzed by a family of cellular enzymes named histone acetyltransferases (HATs). HATs catalyze the transfer of an acetyl group from the acetyl coenzyme A (acetyl-CoA) to the ϵ -amine group of specific lysine residues of protein substrates. The addition of an acetyl group alters the positive charge of specific lysines, thus modifying the electrostatic properties of the proteins targeted by HATs. The protein chemical modification occurring following acetylation results in modified protein functions. Proteins modified by acetylation might be both of cellular or viral origins.

The Diversity of HATs

Acetylation together with other types of PTMs (e.g., sumoylation, phosphorylation) extends the range of possible molecular structures beyond the limits imposed by the twenty encoded amino acids

and, if reversible, gives a means of control and signaling.

In the past decades, protein acetylation has been widely explored starting from histones up to a wide variety of targets either of cellular or viral origins. In fact, although histone acetylation is traditionally linked to transcription activation through histone modification, numerous studies demonstrate that HAT-mediated acetylation is involved in broad cellular and virological functions (Sterner and Berger 2000; Glozak et al. 2005).

HATs are evolutionary conserved from yeast to mammals and are grouped into two general classes: A-type and B-type HATs, depending on their subcellular localizations and functions (Roth et al. 2001). A-type HATs are located in the nucleus, and many are involved in the regulation of gene expression by functioning as transcriptional coactivators. B-type HATs are located in the cytoplasm and are intimately involved in chromatin synthesis and assembly of nascent histones into chromosomes by acetylating de novo synthesized free histones and promoting their nuclear localization and deposition onto newly synthesized DNA. To date, only one B-type HAT has been discovered: the yeast *HAT1* and its homologues in other species. On the contrary most HATs are nuclear, A-type. These HATs acetylate nucleosomal histones within the chromatin and are potentially linked to transcriptional activation through acetylation of transcription factors or by acting as coactivators at the level of gene

promoters. Although most HATs are able to acetylate free histones *in vitro* when assayed as a single polypeptide, in cells they are usually found in high-molecular-weight complexes, containing also several transcription regulators and chromatin-binding proteins (Sterner and Berger 2000).

The A-type HATs are grouped into five families based on their sequence similarities: the GNAT (GCN5-related *N*-acetyltransferase), MYST (MOZ, Ybf2, Sas2, and Tip60), p300/CBP, the general transcription factor HATs (including the TFIID subunit TAF250), and the nuclear-hormone-related HATs SRC1 and ACTR (SRC3).

The GNAT family members include the highly homologous HATs GCN5 (general control nonderepressible-5) and PCAF (p300/CBP-associated factor), as well as other more distantly related enzymes. GCN5 and PCAF appear to primarily function as histone-acetylating transcriptional coactivators but also catalyze the acetylation of nonhistone substrates, leading to changes in their activities.

p300 and CBP were isolated independently as factors interacting with the adenovirus E1A protein or the transcription factor CREB, respectively. These two factors are highly interchangeable in functions and are thus commonly referred as p300/CBP (Chan and La Thangue 2001). Both factors contain a bromodomain and are often found within the same macromolecular complexes. The four core histones (H2A, H2B, H3, and H4) and also a wide variety of nonhistone proteins can be acetylated by p300/CBP; in fact, these HATs seem to have the broadest substrate acceptance for histones and nonhistone proteins as compared to other HATs. p300/CBP is a potent transcriptional coactivator, which is recruited at specific promoters through interaction with a large number of transcription factors, like E1A, c-Jun, c-Myc, c-Fos, TFIID, MyoD, nuclear-hormone receptor, and E2F-1. In addition, lysine-specific acetylation of histones by p300/CBP together with chromatin remodeling and other covalent modifications establishes the active state of chromatin in a gene-specific manner. More in general, p300/CBP has been

implicated in a number of diverse biological functions such as proliferation, cell cycle regulation, apoptosis, differentiation, and DNA damage response (Yang and Seto 2007).

The MYST family of proteins constitutes a third major group of HATs. The acronym MYST derives from its four founding members: human MOZ (monocytic leukemia zinc finger protein), yeast Ybf2/Sas3, yeast Sas2, and mammalian Tip60 (HIV-1 Tat interacting 60 kDa protein). As compared with the GCN5/PCAF and p300/CBP groups, the MYST family is larger and more heterogeneous in domain organization and biological functions (Roth et al. 2001).

Histone Acetylation in the Regulation of Gene Expression

Histones are heavily modified through several pathways including acetylation, methylation, ubiquitination, sumoylation, phosphorylation, and ADPribosylation. These modifications alter chromatin dynamics by influencing histone-DNA interactions, as well as the recruitment and binding of protein factors to chromatin. Histone acetylation affects chromatin mainly in two ways. First, acetylation neutralizes the positive charge of lysine residues within the histone tails, thus reducing their ability to form electrostatic interactions with the negatively charged phosphodiester backbone of associated DNA. The acetylation of histones is therefore associated with chromatin decondensation, which results in an increased accessibility of transcription factors to their target sequences on DNA. Second, histone acetylation provides a platform for the recruitment of transcriptional regulatory proteins through acetyl-lysine interacting motifs, known as bromodomains. The bromodomain, found in HATs and chromatin-associated proteins, functions as the sole protein module known to bind acetyl-lysine motifs. These domains associate with acetylated lysines of both cellular and viral proteins allowing the proper transduction of the molecular information conveyed by lysine acetylation. For instance, transcriptional activation of HIV-1 proviral DNA depends on a molecular

interaction between acetylated Tat and the bromodomain of the cellular coactivator PCAF (see below).

Acetylation of Nonhistone Proteins

In addition to histones, HATs target nonhistone substrates, such as transcription factors and other nuclear proteins. Cytoplasmic structural components (e.g., tubulin), metabolic enzymes, and signaling regulators have also been reported to be modified by acetylation. Emerging evidence demonstrates that acetylation is an important regulatory mechanism for virally encoded proteins. Acetylation of nonhistone factors is important to modulate the affinity of the proteins with DNA, protein-protein interactions, and subcellular localization or stability.

Acetylation of Viral Proteins

Similarly to cellular factors, proteins encoded by viruses can be modified by acetylation. The oncoprotein E1A of the adenovirus was found to be acetylated by p300/CBP and PCAF at a single lysine residue located at position 239 in the C-terminal domain. Even though Lys 239 has a clear role in the interaction between E1A and the transcriptional corepressor C-terminal-binding protein (CtBP), the functional outcome of E1A acetylation has been debated. One report suggests that acetylation of K239 inhibits the interaction between E1A and CtBP, leading to the loss of CtBP-mediated transcriptional repression and consequent increase in the transforming potential of E1A. Conversely, other studies indicate that, rather than interfering with CtBP recruitment, acetylation of K239 prevents the nuclear import of E1A by abrogating its interaction with importin- α . In this case, acetylation would result in attenuation of E1A nuclear functions and redirection of part of the protein to the cytoplasm. Also viral proteins encoded by the Hepatitis delta virus (HDV) are modified by acetylation. In fact, the small hepatitis delta antigen (S-HDAg), a viral nucleocapsid protein

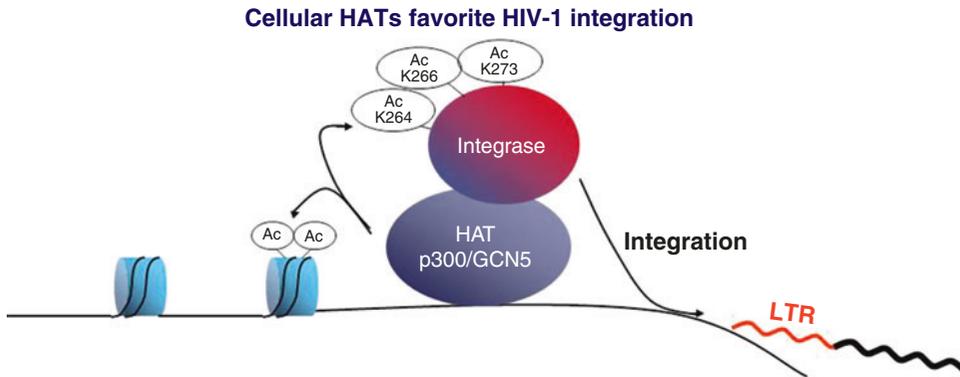

essential for HDV RNA replication, can be acetylated *in vitro* at K72 by the HAT domain of p300/CBP. Most importantly, substitution of K72 with Arg determines a relocalization of the mutated protein from the nucleus, where HDV replicates, to the cytoplasm preventing the accumulation of HDV genomic RNA in the infected cell. Another viral factor functionally modulated by acetylation is the simian virus 40 large T antigen (SV40 T-Ag), a multifunctional protein possessing cellular transforming activity. In this case, acetylation seems to be involved in the regulation of the protein stability, likely enhancing T-Ag degradation through a pathway independent of the ubiquitin-proteasome system.

Cells infected with the human T-cell leukemia virus type 1 (HTLV-1) or overexpressing the HTLV-1 transcriptional activator Tax have been reported to contain a pool of Tax molecules acetylated at a single lysine residue by p300/CBP. Overexpression of p300 markedly increases Tax acetylation and the ability of a wild type HTLV-1 provirus, but not of a mutant provirus encoding an acetylation deficient Tax protein, to activate gene expression from an integrated NF- κ B-controlled promoter. Acetylation together with other PTMs (phosphorylation and sumoylation) controls Tax intracellular localization and its transcriptional activity.

HIV-1 has been described to use the cellular acetylation pathways to regulate viral functions at the nuclear level. Two viral proteins, Tat and integrase, have been reported to be functionally regulated by acetylation through multiple HATs.

Acetylation of HIV-1 Tat

Tat ([► Tat Expression and Function](#)) can be acetylated by three different HATs at three specific lysine residues: K28 is targeted by PCAF, while K50 and K51 are substrates for p300/CBP and GCN5. Most interestingly, the acetylation of each individual lysine differently affects Tat at the molecular level by either increasing Tat affinity to macromolecular complexes (K28 acetylation) or decreasing Tat affinity for its target RNA (K50 acetylation) (Kiernan et al. 1999).

Acetylation, Fig. 1 Model of action of HATs during HIV-1 integration. HATs located at the level of active transcription units acetylated chromatin and integrase

from HIV-1 pre-integration complexes. Acetylation of integrase in turn enhances viral integration

The current model (Nakatani 2002) proposes that acetylation of Tat K28 enhances P-TEFb (► [Cellular Cofactors for HIV-1 Transcription](#)) recruitment on TAR through its interaction with cyclin T1 leading to enhanced RNA Pol II processivity. Subsequently acetylation of Tat K50 leads to Tat recycling by inducing its dissociation from TAR. Tat release from TAR seems to be promoted by the bromodomain of PCAF, through its competition with TAR in binding the acetylated K50. In agreement with the proposed model, the three HATs capable of acetylating Tat efficiently cooperate to stimulate transcription from the 5' LTR of HIV-1 proviral DNA.

Finally, additional functions have been attributed to Tat acetylation. One report shows that acetylation at K50 and K51 increases the affinity of Tat for p32, a cellular splicing factor, thus regulating the splicing efficiency of the HIV-1 transcripts (Berro et al. 2006). Finally, Tat acetylation at K28 increases the affinity for microtubules leading to increased apoptosis in T lymphocytes (Huo et al. 2011).

Acetylation of HIV-1 Integrase

HIV-1 integrase (► [Integration](#)) is acetylated by at least two different cellular HATs, p300/CBP and GCN5 (Cereseto et al. 2005; Terreni et al. 2010). In particular three lysines at the carboxy-terminal domain of the viral enzyme (K264, K266, K273)

are acetylated by both p300 and GCN5, while a fourth lysine, K258, is acetylated exclusively by GCN5.

Similarly to transcription factors, such as p53, E2F, MyoD, c-Myb, and GATA1, acetylated integrase has a higher affinity for DNA which determines increased in vitro catalytic activity (strand transfer activity). Consistently, substitution of acetylatable lysines with arginines (an amino acid with chemical properties similar to lysines) in integrase negatively affects the infectivity of the mutated viruses by specifically reducing their integration efficiencies. A comparative analysis, aimed at establishing the roles of p300/CBP and GCN5 during the HIV-1 replication cycle, revealed that mutated viruses expressing either integrase K264,266,273R or K258,264,266,273R exhibited the same replication deficiency, specifically affecting the step of integration. These results indicate that acetylation of integrase C-terminal lysines 264, 266, and 273 is required for HIV-1 maximal integration efficiency, while acetylation of K258, although observed in vitro, does not appear to play any significant role during infection (Fig. 1).

Similarly integrase of the Moloney murine leukemia virus (M-MuLV), a gammaretrovirus, was demonstrated to be acetylated at Lys 376 by p300 (Schneider et al. 2012). Interestingly, K376 is homologous to the acetylatable K266 in HIV-1. Mutations at K376 decrease retroviral integration; nevertheless, the role of integrase

acetylation has not been clarified yet in this type of retrovirus.

Thus, the same HATs, p300/CBP and GCN5, affecting viral transcription through Tat modification also regulate integration through integrase acetylation.

At the cellular level, acetylation regulates protein functions by modulating protein-protein interactions. Since HIV-1, as all viruses, requires to interact with numerous cellular factors during its replication cycle, acetylation was evaluated as a factor determining differential affinity of integrase with cellular proteins. A yeast two-hybrid screening aimed at identifying factors binding specifically to acetylated integrase led to the discovery of thirteen new integrase-binding partners (Allouch and Cereseto 2011). The identified binding factors are either nuclear or cytoplasmic and are involved in different pathways including chromatin remodeling, nuclear transport, RNA binding, protein synthesis regulation, and microtubule organization. The majority of the two-hybrid hits showed preferential binding for acetylated integrase, while few of them bind with the same affinity the acetylated and the unmodified integrase. One of the factors identified with this screening is KAP1 (also known as TRIM28 or TIF-1 beta), a protein belonging to the TRIM family of antiviral proteins. KAP1 binds acetylated IN and induces its deacetylation through the formation of a protein complex including the deacetylase HDAC1. KAP1-mediated deacetylation results in integrase inactivation and inhibition of viral integration. In fact, modulation of intracellular KAP1 levels through either over expression or knockdown technique (shRNA) revealed that KAP1 curtails viral infectivity by selectively affecting HIV-1 integration (Allouch et al. 2011).

KAP1 has also been described to restrict M-MLV in embryonic carcinoma and embryonic stem cells. However, in the last case viral inhibition occurs at the level of transcription and not during integration (Wolf and Goff 2009).

Conclusions

Acetylation is a PTM that was originally demonstrated at specific lysine residues within the

histone basic N-tail region. Subsequent studies demonstrated that acetylation substrates include also nonhistone proteins of both cellular and viral origins. Two HIV-1 viral proteins are modified by acetylation: Tat and integrase. Both proteins function mainly at the nuclear level. Tat acetylation increases viral transcription efficiency. Acetylation of integrase increases the efficiency of viral integration. Therefore, acetylation of so far identified HIV-1 target proteins positively regulates different stages of viral replication.

Definition

Actin is a ubiquitous highly conserved 42-KDa globular protein in eukaryotic cells. There are three actin isoforms: alpha, beta, and gamma. The alpha actins are mainly found in muscle cells where they form thin filaments, part of the muscle contractile apparatus. The beta and gamma actins are found in most cell types and exist either as a monomeric form (G-actin) or as assembled, double helical, filamentous polymers called filamentous actin (F-actin or microfilaments). In non-muscle cells, the actin cytoskeleton provides mechanical support to cells and is a major driving force for cell motility. Actin also participates in many cellular processes such as cell division, vesicle and organelle movement, and signal transduction.

Introduction

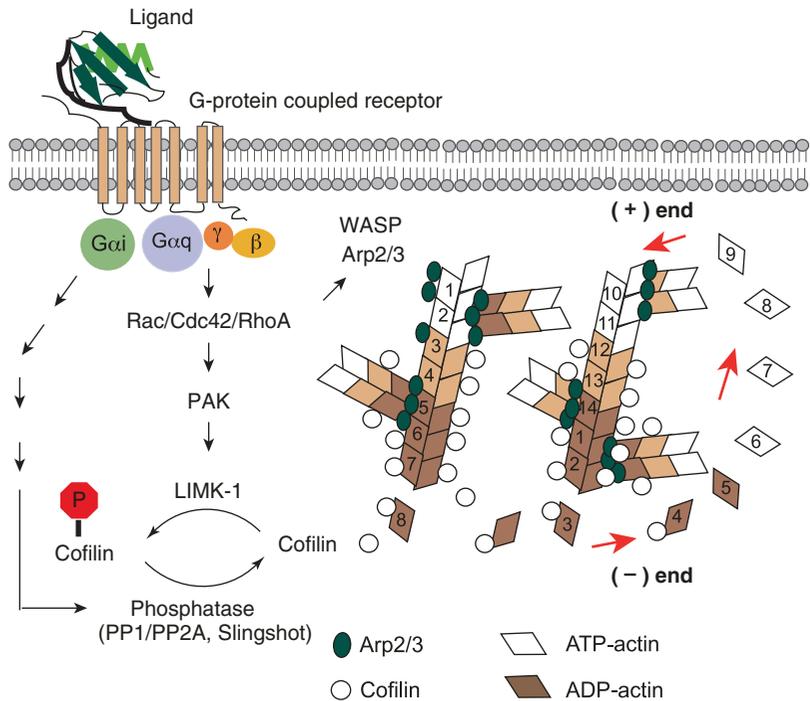

Actin dynamics are regulated through actin polymerization and depolymerization. In vitro, the monomeric G-actin can automatically polymerize in salt solution at concentrations above the critical concentration (C_c) at which actin polymerization

and subunit dissociation reach the equilibrium. Structurally, polymerized actin filaments have polarity, with (+) and (–) ends (or barbed and pointed ends, respectively), as revealed by binding of myosin S1 head domains, which generates directional arrowhead-like decorations pointing towards the (–) end in electron micrographs. In test tubes, the rates of actin polymerization at the (+) and the (–) ends are not the same because the C_c value is lower at the (+) end (100 nM) than at the (–) end (700–800 nM). This results in an elongation rate 5–10 times faster at the (+) end than at the (–) end. When actin polymerization reaches a steady-state phase, the G-actin concentration is between the C_c values of the (+) and (–) ends. This permits selective addition of actin monomers at the (+) end and dissociation of them at the (–) end, and the length of the actin filaments remains constant. This process, called actin treadmilling, resembles a “walking” process of actin subunits moving from the (+) end towards the (–) end along actin filaments (Pollard and Borisy 2003; Fig. 1).

Monomeric G-actin also binds to ATP, and once incorporated into actin filaments, ATP can hydrolyze into ADP-actin through the release of the γ phosphate. Although ATP binding to G-actin is not required for polymerization, the dissociation equilibrium constant (K) for ATP-actin is different, much lower at the (+) end than that at the (–) end. This lower K value promotes ATP-actin addition and actin growth at the (+) end. In contrast, the K value for ADP-actin is similar at both the (+) and (–) ends; this ADP-actin K value is much higher than that of ATP-actin at the (+) end but slightly lower than that of ATP-actin at the (–) end. The difference selectively promotes ADP-actin disassociation from the (–) end (Pollard and Borisy 2003).

In cells, the cytosolic G-actin concentration (0.5 mM) is much higher than the C_c of both (+) and (–) ends. This concentration would trigger the polymerization of almost all G-actin in test tubes, depleting the G-actin pool. However, the intracellular actin pool is stably maintained and actin dynamics are tightly regulated by multiple cellular factors to ensure proper and speedy response to stimulation. G-actin is normally

Actin, Fig. 1 Model of actin treadmilling in cell migration. Extracellular ligand binding to cognate surface receptors such as the G-protein coupled receptors transduces signals to activate actin modulators such as the Arp2/3 complex and cofilin. The Arp2/3 complex binds to the side of an existing filament and serves as an F-actin nucleus, promoting rapid ATP-actin polymerization at the (+) end. With filament growth, the γ phosphate is dissociated from ATP-actin by hydrolysis. Cofilin also promotes phosphate dissociation and servers ADP-actin filaments from the (-) end (Modified from (Wu and Yoder 2009))

associated with factors such as profilin and thymosin β 4. Profilin acts as a nucleotide-exchange factor, allowing the switch from ADP-actin to ATP-actin for actin polymerization. Thymosin β 4 is an actin-sequestering protein and is considered a buffering protein for the maintenance of the monomeric actin pool. Actin filaments (F-actin) are also associated with multiple cellular factors such as the Arp2/3 complex and ADF/cofilin. The Arp2/3 complex is a seven-subunit protein that promotes the growth of new actin filaments. Two of the subunits of the Arp2/3 complex, Arp2 and Arp3, resemble G-actin and serve as nucleation sites for actin growth. ADF/cofilin is a family of actin-severing proteins that depolymerize actin filaments mainly at the (-) end. The Arp2/3 complex and cofilin work together to mediate cytoskeletal actin reorganization and actin dynamics. In addition, actin-capping proteins such as CapZ and gelsolin can cap the ends of actin filaments, preventing actin polymerization or depolymerization. Gelsolin also has a calcium-dependent actin-severing activity that can break actin filaments into shorter fragments (Pollard and Borisov 2003).

In non-muscle cells, the actin cytoskeleton provides mechanical support and drives cell motility. Actin also participates in diverse cellular processes such as cell division, vesicle movement, and signal transduction. In immune cells, actin is involved in multiple processes such as cell adhesion, cell migration, chemotaxis, and T-cell activation. In chemotaxis, directed cell movement towards chemoattractants is controlled by localized cortical actin polymerization. In antigen-specific T-cell activation, the reorganization of the cortical actin plays a critical role in the formation of the immunological synapse. The actin cytoskeleton is the driving force for receptor clustering and the formation of the supramolecular activation cluster (SMAC). This process involves the actin-dependent activation of LFA-1, which is required for sustained signaling to reach full T-cell activation (Wulfing and Davis 1998).

Role of Actin in HIV Entry

HIV entry into cells is mediated through the binding of viral glycoprotein gp120 to the specific cell

receptor and coreceptor, CD4 and CXCR4 or CCR5. This interaction triggers membrane fusion between the virus and the cell and delivers the viral core into the cytoplasm. During entry, gp120 binding to blood resting CD4 T cells also initiates a transient course of actin polymerization and depolymerization, which is important for viral entry and the early postentry process (Vorster et al. 2011; Yoder et al. 2008). For viral entry, actin may be involved in the initial receptor clustering and stabilization. Actin polymerization may also transiently block CXCR4 internalization upon gp120 binding and may provide a support to stabilize the fusion complex (Vorster et al. 2011). In addition, actin may facilitate signal transduction from viral binding to CXCR4 in blood CD4 T cells (Vorster et al. 2011).

Mechanistically, the sequential binding of gp120 to CD4 and the coreceptor is suggested to enhance CD4-CXCR4 or CD4-CCR5 colocalization, which may be dependent on actin activity. However, several studies have demonstrated that CD4 is constitutively associated with or closely (within 100 nm) juxtaposed to CXCR4 or CCR5 in the absence of HIV or gp120. In addition, it has been suggested that gp120 binding to CCR5 requires juxtaposition of CD4 and CCR5, because the engagement has to occur very fast when gp120 is still attached to CD4. These studies suggest that actin may not be involved in the initial gp120-receptor engagement; instead, actin is likely involved in the stabilization of the fusion complex following gp120 binding to CD4 and the coreceptor (Harmon et al. 2010; Vorster et al. 2011). It has been found that the actin inhibitor cytochalasin B inhibits fusion mediated by the CD4-independent gp120, suggesting that steps sensitive to the actin inhibitor may not involve CD4-CXCR4 clustering. In addition, blocking actin activity inhibits gp120-mediated cell-cell fusion at the step of fusion pore formation (Harmon et al. 2010).

Binding of HIV to blood resting CD4 T cells triggers a transient course of actin polymerization and depolymerization mediated through the activation of the signaling pathway Rac1-PAK1/2-LIMK1 (Vorster et al. 2011). The LIM domain kinase 1, or LIMK1, is a cellular serine/threonine

kinase responsible for the phosphorylation of cofilin. Stable shRNA knockdown of LIMK1 decreases cortical actin density and increases the rate of CXCR4 internalization (Vorster et al. 2011). In addition, the entry of HIV is also slightly inhibited at high viral dosages. This LIMK1 knockdown study suggests that HIV-mediated LIMK1 activation and early actin dynamics may be required to block the rapid internalization of CXCR4 following gp120 binding to permit fusion to occur. This LIMK-mediated actin polymerization may also prolong coreceptor signaling to prime postentry events.

Several other actin-binding proteins such as filamin-A and moesin have also been identified as possible factors involved in HIV entry. Filamin-A is an adaptor protein that may anchor both CD4 and CXCR4/CCR5 to F-actin following receptor clustering. siRNA knockdown of filamin-A resulted in a reduction of HIV-1 infection (Jimenez-Baranda et al. 2007). Moesin belongs to the ezrin-radaxin-moesin (ERM) family of proteins that act as cross-linkers between the plasma membrane and actin filaments. HIV gp120 binding to CD4 alone can increase ezrin and moesin phosphorylation, which has been suggested to promote receptor clustering (Barrero-Villar et al. 2009; Naghavi et al. 2007). The siRNA knockdown of moesin has been shown to enhance or inhibit viral infection (Barrero-Villar et al. 2009; Naghavi et al. 2007).

HIV gp120-mediated cell-cell fusion has also been shown to extensively rely on gp120-induced signaling, which is often linked to actin dynamics (Harmon et al. 2010). siRNAs or inhibitors against molecules such as Pyk2, Rac1, GTPase Ras, phospholipase C, protein kinase C, Tiam-1, Abl, IRSp53, and Wave2 have been shown to inhibit gp120-mediated cell-cell fusion (Harmon et al. 2010). siRNA knockdown of the Arp2/3 complex has been shown to inhibit gp120-mediated cell-cell fusion or to have no effect on the cell-cell fusion (Harmon et al. 2010; Komano et al. 2004). However, inhibiting Arp2/3 with an inhibitor, CK548, or through stable shRNA knockdown of Arp3 has been shown to mainly inhibit viral DNA nuclear migration in human CD4 T cells (Spear et al. 2014).

Role of Actin in HIV DNA Synthesis

The involvement of actin cytoskeleton in HIV reverse transcription has been suggested based on multiple actin inhibitor studies and siRNA knockdown of actin modulators. cytochalasins A, D, and E inhibit HIV infection of a HeLa-CD4 indicator cell line at 5 μM (Bukrinskaya et al. 1998). Cytochalasin D reduces viral early DNA synthesis four to fivefold in MT-4 cells (Bukrinskaya et al. 1998). In addition, another actin inhibitor, jasplakinolide, effectively inhibits HIV latent infection of resting CD4 T cells at dosages of 120 nM and above (Cameron et al. 2010; Yoder et al. 2008). The inhibition by jasplakinolide is at the step of viral DNA synthesis and nuclear migration in resting CD4 T cells (Yoder et al. 2008), and this inhibition can be partially overcome by increasing actin dynamics through spinoculation (Guo et al. 2011). The actin inhibitor studies are supported by several siRNA knockdown studies in which the activity of actin modulators such as cofilin and LIMK1 are directly targeted. Inhibition of cofilin activity in blood CD4 T cells through siRNA triggers a drastic increase in the cortical actin density, and this increase correlates with an increase in HIV DNA synthesis (Yoder et al. 2008). In addition, siRNA knockdown of LIMK1 decreases cortical actin density, and this decrease is also associated with the inhibition of viral DNA synthesis (Vorster et al. 2011).

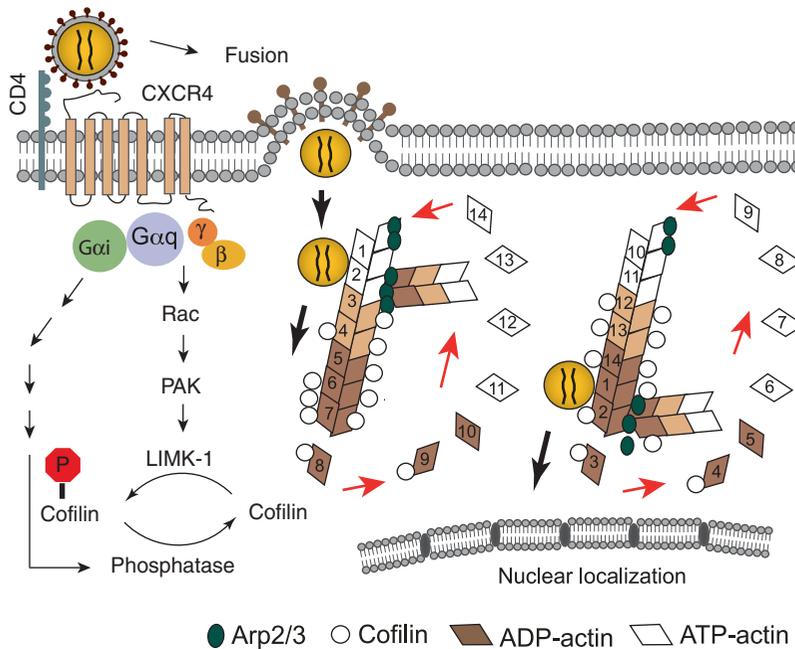

The mechanism of how actin is involved in HIV DNA synthesis remains unclear. It has been proposed that the process of actin polymerization may simply act as a driving force for viral uncoating, and thus, decreasing actin dynamics may impair proper uncoating (Vorster et al. 2011). Alternatively or additionally, the cortical actin may function as an anchorage for the viral reverse transcription complex, and a decrease in the actin cortex density may result in less contact time and suboptimal reverse transcription (Vorster et al. 2011). The actin cytoskeleton has been proposed to be a major site for viral reverse transcription in infected cells (Bukrinskaya et al. 1998; Vorster et al. 2011; Yoder et al. 2008). Multiple viral proteins in the preintegration complex are found to interact with

actin. These proteins include the Gag nucleocapsid protein (NC), the large subunit of viral reverse transcriptase, the viral integrase, and Nef. Among these actin interacting proteins, Nef, in particular, has been shown to enhance viral DNA synthesis. This positive effect of Nef is diminished by actin inhibitors, indicating that the Nef-mediated enhancement of viral DNA synthesis may be related to the cortical actin (Wu and Yoder 2009).

In HIV infection of blood resting CD4 T cells, viral DNA synthesis is a slow process that takes about two days to maximize (Yoder et al. 2008). This slower viral DNA synthesis may be attributed a lower deoxynucleoside level in resting T cells. It has also been suggested that the slower synthesis of viral DNA correlates with lower cortical actin dynamics in resting T cells (Yoder et al. 2008). Pre-stimulation of resting CD4 T cells with anti-CD4/CXCR4 antibody-coated magnetic beads reorganizes the cortical actin and increases actin dynamics, and this stimulation enhances viral DNA synthesis and nuclear migration (Yoder et al. 2008). In addition, spinoculation triggers dynamic actin and cofilin activity, and this process dramatically increases viral DNA synthesis and nuclear migration in resting CD4 T cells (Guo et al. 2011). It has also been shown that stimulation of resting CD4 T cells with chemokine CCL2 augments gp120-induced F-actin polymerization, which enhances viral DNA synthesis about fivefold (Campbell and Spector 2008).

Role of Actin in HIV Intracellular Migration

It has been observed, using live cell imaging, that HIV may use the cytoskeleton, particularly microtubules, to move inside epithelial cells. However, treatment of CD4 T cells with multiple microtubule modulators such as taxol (1 μM), vinblastine (1 and 10 μM), colchicine (10 and 100 μM), and nocodazole (10 and 100 μM) is not able to block HIV infection of CD4 T cells (Yoder et al. 2011). In contrast, actin inhibitors such as cytochalasins and jasplakinolide inhibit HIV infection of CD4 T cells (Yoder et al. 2008, 2011). It has been suggested that HIV may mainly use actin-based mobility for

Actin, Fig. 2 Model of HIV-mediated actin dynamics in the initiation of viral infection. HIV binding to CD4 and the chemokine coreceptor, CXCR4 or CCR5, mediates entry and signal transduction that activates actin modulators such as LIMK and cofilin. HIV-mediated actin dynamics may facilitate viral entry, and postentry DNA synthesis. The viral preintegration complex (*PIC*) may also be

anchored onto F-actin for reverse transcription. HIV-mediated cofilin activity increases actin treadmilling which may promote the migration of viral PIC across the cortical actin layer, facilitating PIC localization to the perinuclear or nuclear region (Modified from (Wu and Yoder 2009))

intracellular migration in T cells (Yoder et al. 2008, 2011). It has also been proposed that in blood resting CD4 T cells, the cortical actin is relatively static in the absence of T-cell activation or chemotactic stimulation. This lack of actin activity may represent a realistic limitation for viral early processes such as intracellular migration; HIV uses the chemokine receptor CXCR4 to trigger the activation of actin modulators such as LIMK1 and cofilin to increase actin dynamics (Vorster et al. 2011; Yoder et al. 2008). The cortical actin may function as an anchorage for the viral preintegration complex, and HIV may rely on active actin treadmilling to cross the cortical actin layer (Vorster et al. 2011; Yoder et al. 2008; Fig. 2). In support of this model, inhibition of HIV-mediated chemotactic signaling through pertussis toxin inhibits viral nuclear migration (Yoder et al. 2008); treatment of cells with jasplakinolide also diminishes viral DNA synthesis and nuclear migration (Yoder et al. 2008). In addition, siRNA knockdown of cofilin increases early

HIV DNA synthesis but simultaneously decreases HIV nuclear migration (Yoder et al. 2008); siRNA knockdown of LIMK1 also decreases HIV DNA synthesis and viral nuclear migration (Vorster et al. 2011). Induction of actin dynamics through transient treatment with latrunculin A, a cofilin-activating peptide S3, or with anti-CD4/CXCR4 antibody-coated magnetic beads enhances HIV latent infection of CD4 T cells (Yoder et al. 2008). In addition, spinoculation triggers both cofilin activation and actin dynamics in transformed and resting CD4 T cells (Guo et al. 2011). This leads to the upregulation of the CXCR4 receptor and a marked enhancement of HIV-1 DNA synthesis and nuclear migration (Guo et al. 2011).

In HIV-1 latent infection of resting memory CD4 T cells, pretreatment of cells with the chemokine CCL19, CXCL9, CXCL10, and CCL20 significantly increases viral DNA integration (Cameron et al. 2010). It has been suggested that chemokines such as CCL19 trigger cofilin

activation and changes in actin filaments that enhance viral nuclear localization (Cameron et al. 2010). These studies suggest that chemokine-mediated actin dynamics are required for HIV-1 nuclear migration and the establishment of viral latent infection in resting memory T cells.

Role of Actin in HIV Assembly and Release

Cytoskeletal actin is implicated in HIV assembly and release from several actin inhibitor studies (Jolly et al. 2007). Cytochalasin D only partially inhibited HIV-1 release from infected T cells, but mycalolide B potently inhibited HIV-1 release. Treatment of T cells with actin inhibitors such as latrunculin A also results in a decrease in Env-Gag colocalization at polarized actin caps on the plasma membrane, suggesting that actin is required for Env and Gag transportation to the plasma membrane for assembly. In addition, wortmannin and KT5926, a myosin light-chain kinase inhibitor, also inhibit viral release. It is suggested that myosin-actin interaction may be required to drive viral budding. HIV-1 Gag directly binds to F-actin through its nucleocapsid region. Nevertheless, viral nucleocapsid association with F-actin does not appear to be critical for viral budding; rather, active actin treadmill has been proposed to be important for driving viral budding at proper speed. HIV Gag is also found to bind to the actin cross-linking protein filamin A, suggesting that filamin A may also function to facilitate the transport and anchorage of Gag to the plasma membrane for viral assembly. Recently, the cofilin kinase, LIMK1, has been suggested to regulate HIV particle release; disrupting of LIMK1 activity led to the accumulation of virion particles on the plasma membrane (Wen et al. 2014).

Actin and Actin Cytoskeletal Proteins Present in HIV Virion Particles

Actin and several actin regulatory proteins have been found in virions purified from sucrose

gradient centrifugation (Ott et al. 1996). Three types of actin-related factors are present inside HIV virions in various molar ratios to HIV Gag: actin, 10–15%; ezrin and moesin, 2%; and cofilin, 2–10%. The packaged actin filaments are found to be specifically associated with the nucleocapsid. The packaging of cytoskeletal proteins may result from the direct involvement of actin in the viral assembly process. Nevertheless, the functional importance of cytoskeletal proteins' presence in virions remains to be studied.

Role of Actin in HIV Cell-Cell Transmission

HIV-1 cell-cell transmission is proposed to occur through a structure called virological synapse (VS), which requires both actin and microtubules for polarized viral budding and viral cell-cell transfer (Sattentau 2010). Formation of the VS involves HIV gp120-induced clustering of gp120 with CD4/CXCR4, and ICAM-1 with LFA-1 on the effector and target cells, respectively. Actin is involved in the clustering and polarization of Env-Gag on the effector cells; actin is also involved in the stabilization of the CD4/CXCR4 and LFA-1 clusters on target cells. In addition, using a cell-free lipid-bilayer system, gp120 is shown to induce signal transduction to create an F-actin-depleted zone on target cells, possibly facilitating viral transfer and post transfer events. The cofilin kinase, LIMK1, and its regulator ROCK1 have also been shown to modulate HIV cell-cell transmission (Wen et al. 2014).

Potential Role of Actin in Viral Pathogenesis

In vitro, HIV-1 gp120 is suggested to act as a viral chemokine to attract or repel CD4 or CD8 T cells through triggering actin activity. Gp120 is also shown to alter T-cell chemotactic response to CCL20, CCL21, and sphingosine-1-phosphate (SIP), which may inhibit CCL21-mediated lymphatic entry and SIP-mediated egress. In addition, gp120 has been shown to promote T-cell

non-responsiveness to SDF-1 through deregulation of cofilin. HIV-1 Nef has also been shown to inhibit SDF-1-mediated chemotaxis and to inhibit the activity of cofilin. In HIV-1-infected patients, cofilin activity in their blood resting CD4 T cells is found to be aberrantly upregulated, suggesting that dysregulation of actin modulators such as cofilin may have a profound effect on T-cell activity and functionality (Wu and Yoder 2009).

In HIV-infected patients, there is also a strong positive correlation between HIV viremia and the chemokine CCL2. Treatment of resting CD4 T cells with CCL2 leads to an increase in gp120-induced actin polymerization that enhances viral entry and viral early DNA synthesis (approximately fivefold) (Campbell and Spector 2008). Similarly, in patients, the T-cell homing and inflammatory chemokines CCL19 and CCL21 are markedly increased at early stages of infection. Treatment of resting CD4 T cells with CCL19 or CCL21 triggers cofilin and actin activities that promote high levels of HIV-1 DNA integration (Cameron et al. 2010). These studies suggest that the infection and establishment of viral reservoirs in resting T cells likely involves chemokines and chemokine-mediated actin dynamics (Wu and Yoder 2009).

Conclusion

HIV-mediated actin dynamics have recently been shown to be important for viral entry, reverse transcription, and efficient nuclear migration. In addition, actin cytoskeleton may also be involved in viral assembly and HIV cell-cell transmission. In blood CD4 T cells, HIV-mediated chemotactic signaling and actin dynamics not only facilitate viral infection but may also contribute to viral pathogenesis through disruption of normal chemotactic responses and T-cell activity. Furthermore, HIV-mediated chemotactic signaling may interact or interfere with signal transduction from chemokines, and this interaction is expected to have a profound impact on HIV infection and pathogenesis.

Definition

Primary central nervous system lymphoma (PCNSL) is a rare extra-nodal B-cell non-Hodgkin lymphoma, which arises in the brain, spinal cord, meninges, or eyes. In individuals infected with HIV, PCNSL occurs with advanced immunosuppression and low CD4 T-cell count. It is considered an AIDS-defining malignancy. Unlike PCNSL in immune-competent hosts, AIDS-related PCNSL

(AR-PCNSL) is almost exclusively caused by a cancer-causing herpesvirus, Epstein Barr Virus (EBV, also known as human herpesvirus-4). While PCNSL in immune-competent patients and AR-PCNSL have pathological and clinical overlap, AR-PCNSL is distinguished by its strong association with immunosuppression and viral etiology.

Introduction

Primary central nervous system lymphoma (PCNSL) is a rare extra-nodal non-Hodgkin lymphoma, which accounts for approximately 3–5% of primary brain tumors. Prior to effective therapy for HIV, a large proportion of cases of PCNSL, especially in younger individuals, occurred in severely immune-compromised patients with acquired immunodeficiency syndrome (AIDS) (Ziegler et al. 1984); therefore, PCNSL is considered an AIDS-defining malignancy. However, after the broad availability of highly activated antiretroviral therapy (HAART) in 1996, the incidence of PCNSL in HIV-infected individuals has decreased by nearly 90%. Nonetheless, the incidence of AIDS-related (AR)-PCNSL in the USA remains significantly elevated at an estimated 26 cases per 100,000 person-years among people with AIDS and continues to affect mainly patients under the age of 50 (Shiels et al. 2011). In areas where HAART is available, most patients with AR-PCNSL are not taking HAART either because they are not aware they are HIV infected or because of poor adherence to HAART. At the same time that incidence of AR-PCNSL has decreased and there has been an increase in the incidence of PCNSL in immune-competent elderly patients, highlighting a changing epidemiology of PCNSL in the USA related to differences in the underlying pathogenic processes (Shiels et al. 2011).

Histopathology and Pathogenesis

PCNSL is a B-cell lymphoma with diffuse large-cell morphology. The diagnosis should be

distinguished from systemic lymphoma with CNS involvement, dural-based low-grade lymphomas, and other rare histologies presenting in the CNS. PCNSL in HIV-infected and HIV-uninfected patients shares some clinical and morphologic characteristics; however, pathogenesis differs in important ways.

Both AR-PCNSL and PCNSL in immune-competent hosts are multifocal angiocentric tumors that express pan-B-cell markers (CD20, CD19, CD22, and CD79a). These tumors are highly proliferative with high expression of Ki-67. PCNSL generally has a post-germinal center phenotype. In immune-competent patients, immunohistochemistry suggests a majority of tumors have activated B-cell differentiation based on the lack of CD10 and common expression of IRF4 (90%), a transcription factor associated with lymphocyte activation. However, the germinal center-associated transcription factor BCL6 is also expressed in 60–80% of cases. In contrast, in AR-PCNSL, the immunophenotype is generally BCL6 negative and IRF4 positive (Carbone et al. 1998). This immunophenotype is also noted in posttransplant lymphoproliferative disorder (PTLD). Additional characteristics of AR-PCNSL include expression of the plasma cell marker CD138, the activation marker CD30, and adhesion molecules CD11a and ICAM-1 (CD54) that may contribute to homing to cerebral blood vessels.

There are several similarities between AR-PCNSL and PTLD. PTLD is a disorder of proliferating latently EBV-infected B cells that may be clonal and sometimes presents with CNS-only manifestations. PTLD can occur either after solid organ (SOT) or hematopoietic stem cell transplants (HSCT) as a result of medical immunosuppression. In HSCT it usually occurs within 6 months posttransplant and the lymphoproliferation is of donor-cell origin prior to EBV-specific cytotoxic T-cell reconstitution, while in SOT >90% is of recipient-cell origin and may have a longer latency due to long-term T-cell suppression to prevent organ rejection (Heslop 2009). Both AR-PCNSL and PTLD often have immunoblastic features (Castellano-Sanchez et al. 2004). Like PTLD, AR-PCNSL

tumor cells almost always have evidence of EBV infection, as noted by staining for EBV-encoded small RNA (EBER1) transcripts (MacMahon et al. 1991). AR-PCNSL is usually clonal based on polymerase chain reaction (PCR) evaluation of the immunoglobulin heavy-chain gene (IgH).

Acquired T-cell immunosuppression is a common risk factor for both AR-PCNSL and PTLD. In patients with HIV, the majority of cases of AR-PCNSL occur in severely immune-compromised patients with AIDS and CD4 counts <50 cells/uL. AR-PCNSL patients have been shown to lack EBV-specific CD4+ T cells, irrespective of absolute CD4 counts, supporting the lack of immune regulation of EBV-infected B cells as a critical mechanism of EBV-driven oncogenesis (Gasser et al. 2007). This is in contrast to PCNSL in immune-competent patients, in which evidence of EBV infection of the tumor cells is rare (MacMahon et al. 1991). A range of EBV viral proteins are expressed in both AR-PCNSL and PTLD, including the EBV-associated nuclear antigens (EBNAs) 1, 2, 3A, 3B, and 3C, latent membrane proteins (LMP) 1 and 2, and leader protein (LP). This pattern of EBV protein expression is referred to as latency III and is remarkable among EBV-associated tumors for the broadest expression of viral proteins. EBV-encoded genes may play an important role in lymphomagenesis, and at the same time, EBV latency III lymphoproliferations are also the most immunogenic EBV-associated tumors and responsive to immune-based therapies.

At the molecular level, a high level of aberrant somatic hypermutations has been detected both in PCNSL in immune-competent patients and in AR-PCNSL (Table 1) (Gaidano et al. 2003). In AR-PCNSL, recurrent mutations have been noted in 5' noncoding region of *BCL6*, *c-MYC*, and *TTF*. Additional insight into the molecular pathogenesis of PCNSL has mainly been evaluated in tumors from immune-competent subjects. In PCNSL not associated with AIDS, additional recurrent mutations have been identified (Table 1). Also, chromosomal abnormalities involving either *IgH* or *BCL6* breakpoints detectable by fluorescence in situ hybridization (FISH) or gains and losses of genetic materials detectable

	12q gains	
Human gene expression studies	Compared to systemic DLBCL: high expression of <i>XBPI</i> , <i>c-MYC</i> , <i>PIMI</i> , IL-4-induced genes (Rubenstein et al. 2006), as well as extracellular matrix and adhesion-related genes <i>osteopontin</i> , <i>CXCL13</i> , and <i>IL-8</i>	Unknown
Human microRNA (miRNA)	Compared to systemic DLBCL, further upregulation of miRNA associated with germinal center B-cell lymphomas (miR17-5p, miR-20a, miR-155), as well as those blocking B-cell differentiation (miR-9, miR-30b/c)	High miR-155 expression (Wang et al. 2011)
EBV–human gene interactions	Not applicable	EBV-encoded LMP1 interacts with cellular TRAFs, activating NFkB (Kung 2010)
		LMP1 induces IRF4, these proteins are co-expressed in AR-PCNSL (Xu et al. 2008)
		LMP1 upregulates adhesion molecules LFA1 and ICAM-1, leading to tumor necrosis and vascular destruction as seen in AR-PCNSL (Cherney et al. 1998)
EBV-encoded miRNA	Not applicable	EBV-encoded BHRF1 miRNA cluster enhances EBV's transforming potential

by comparative genomic hybridization (CGH) have been noted in PCNSL not associated with AIDS. One study conducted in HIV-uninfected patients comparing lymphomas limited to immune-privileged sites (IP-testis and CNS) to systemic DLBCL identified a loss in 6p21.32-p35.3 in IP-DLBCL. Analysis of candidate genes encoded in that region identified two separate clusters: one involved in apoptosis and a second involved in the immune response, including the regulation of HLA expression. More recently, L265P gain-of-function point mutation in *MYD88* has been noted to be a common recurrent mutation in PCNSL. This point mutation is also noted in a subset of activated diffuse large B-cell lymphomas and Waldenstrom's macroglobulinemia. Point mutations in the coiled region of *CARD11* have also been noted. These later two genes are implicated in NFkB dysregulation in B-cell lymphomas.

Gene expression profiling in PCNSL has been limited due to relatively small sample sizes ($n < 25$) and have been mainly performed on tumors from HIV-uninfected patients. Three published studies have demonstrated a transcriptional signature that somewhat resembles systemic DLBCL. However, several genes of interest have been identified as being significantly upregulated in PCNSL compared to systemic DLBCL, including genes encoding adhesion-related proteins (*CXCL13*), extracellular matrix genes (*SSP1*, *osteopontin*) (Tun et al. 2008), and the oncogenes *Pim-1*, *c-MYC*, and *Mina53*. Interestingly, increased expression of the transcription factors *XBPI* and *ATF6*, which are genes that regulate unfolded protein responses, were noted in one study. Transcriptional upregulation appears to be associated with paracrine interactions with CNS vasculature, which is in part driven by tumor and endothelial IL-4 expression (Rubenstein et al. 2006).

The role of microRNAs in normal lymphoid development as well as lymphomagenesis is an area of active research. miR-155, which plays an important role in germinal center biology and is associated with B-cell proliferation and lymphomagenesis, appears to be even more highly expressed in PCNSL than systemic DLBCL. Additional microRNAs that are upregulated compared to systemic DLBCL include miR-17-5p and miR-20a, which target the *c-MYC* pathway, as well as those blocking B-cell differentiation (miR-9, miR-30b/c), while several putative tumor-suppressor miRNAs (miR-199a, miR-214, miR-193b, miR-145) may be downregulated.

Further research is required to evaluate molecular similarities and differences between AR-PCNSL and PCNSL in immune-competent hosts. It remains unknown which of the genetic abnormalities seen in PCNSL also exist in AR-PCNSL, but it is likely that some molecular abnormalities in AR-PCNSL are due to interactions between EBV-encoded genes, microRNAs, and lymphomagenic human signaling pathways. For example, latency membrane protein-1 (*LMP1*) is a viral oncogene that encodes a homologue to CD40 that is constitutively activated. Interactions between the C-terminal-activating regions of LMP1 and tumor necrosis factor receptor-associated factors (TRAFs) can lead to the upregulation of NF κ B. LMP1 also upregulates IRF4, a hallmark of AR-PCNSL, while downregulating the transcription factor BLIMP1, which is required for plasma cell differentiation. LMP1 itself is upregulated by IL-4, and therefore IL-4-dependent signaling appears to be important in both types of PCNSL. Interestingly, mouse models of lymphomas expressing LMP1 are notable for a high degree of tumor necrosis and vascular destruction and in some cases tumor regression, mirroring what is noted in AR-PCNSL. These findings may be mediated by the upregulation of adhesion molecules and induction of chemokine antitumor responses (Cherney et al. 1998). Furthermore, miR-155, which is transcriptionally targeted by IRF4, is highly expressed in the latency III pattern of EBV-infected B cells as well as PTLD and is associated with cellular proliferation (Wang

et al. 2011). Additional epigenetic mechanisms of lymphomagenesis attributable to dysregulated expression of EBV-encoded proteins and microRNAs in B cells, as well as abnormal innate and acquired immune responses in AIDS patients, are also likely.

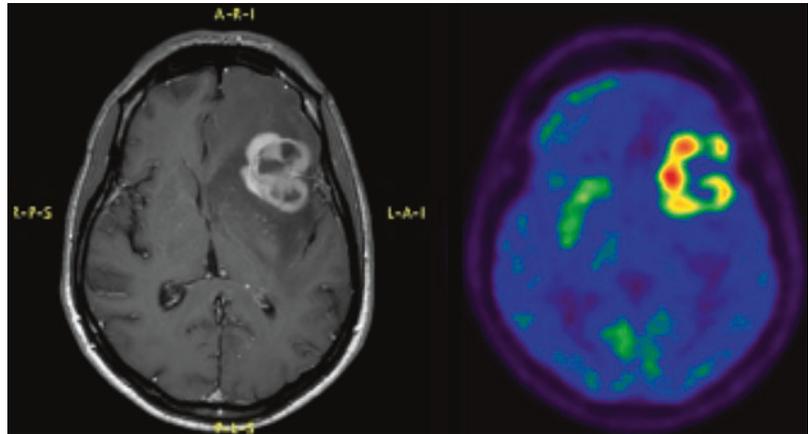

Clinical Presentation, Diagnosis, and Baseline Evaluation

Neurologic disorders are prevalent in AIDS patients and may be due to HIV-associated pathology, opportunistic infections, neoplasms, drug effects, and cerebrovascular disease. AR-PCNSL most often presents with neurologic symptoms such as headaches, lethargy, confusion, visual complaints, seizures, or focal neurologic symptoms such as cranial nerve dysfunction or hemiparesis. It occurs most of the time in patients with CD4 counts less than 50 cells/mL. CT scans usually show ring-enhancing CNS mass lesions. The main differential diagnosis of such lesions in patients with AIDS includes toxoplasma encephalitis, the most common cause, followed by PCNSL. Other causes of mass lesions are cryptococcal meningoencephalitis and tuberculosis. Before HAART, toxoplasmosis encephalitis occurred in 3–10% of patients in the USA. However, toxoplasmosis is much less frequent with HAART as well as medicines commonly used in patients with CD4 counts less than 200 to prevent *pneumocystis* pneumonia such as trimethoprim–sulfamethoxazole. In the HAART era, toxoplasmosis incidence is less than 1%, but like AR-PCNSL, it is most commonly seen in medically underserved HIV-infected populations not on HAART.

AR-PCNSL occurs primarily in the brain parenchyma and may disseminate to the leptomeninges. Spinal cord, ocular, and cranial nerve involvement are rare. Given advanced immunosuppression in this population, patients with AR-PCNSL are also at risk for concurrent opportunistic infections, including CNS infections such as toxoplasmosis, cryptococcus, or CMV. The preferred initial imaging in patients with HIV and neurologic symptoms is contrast-

A

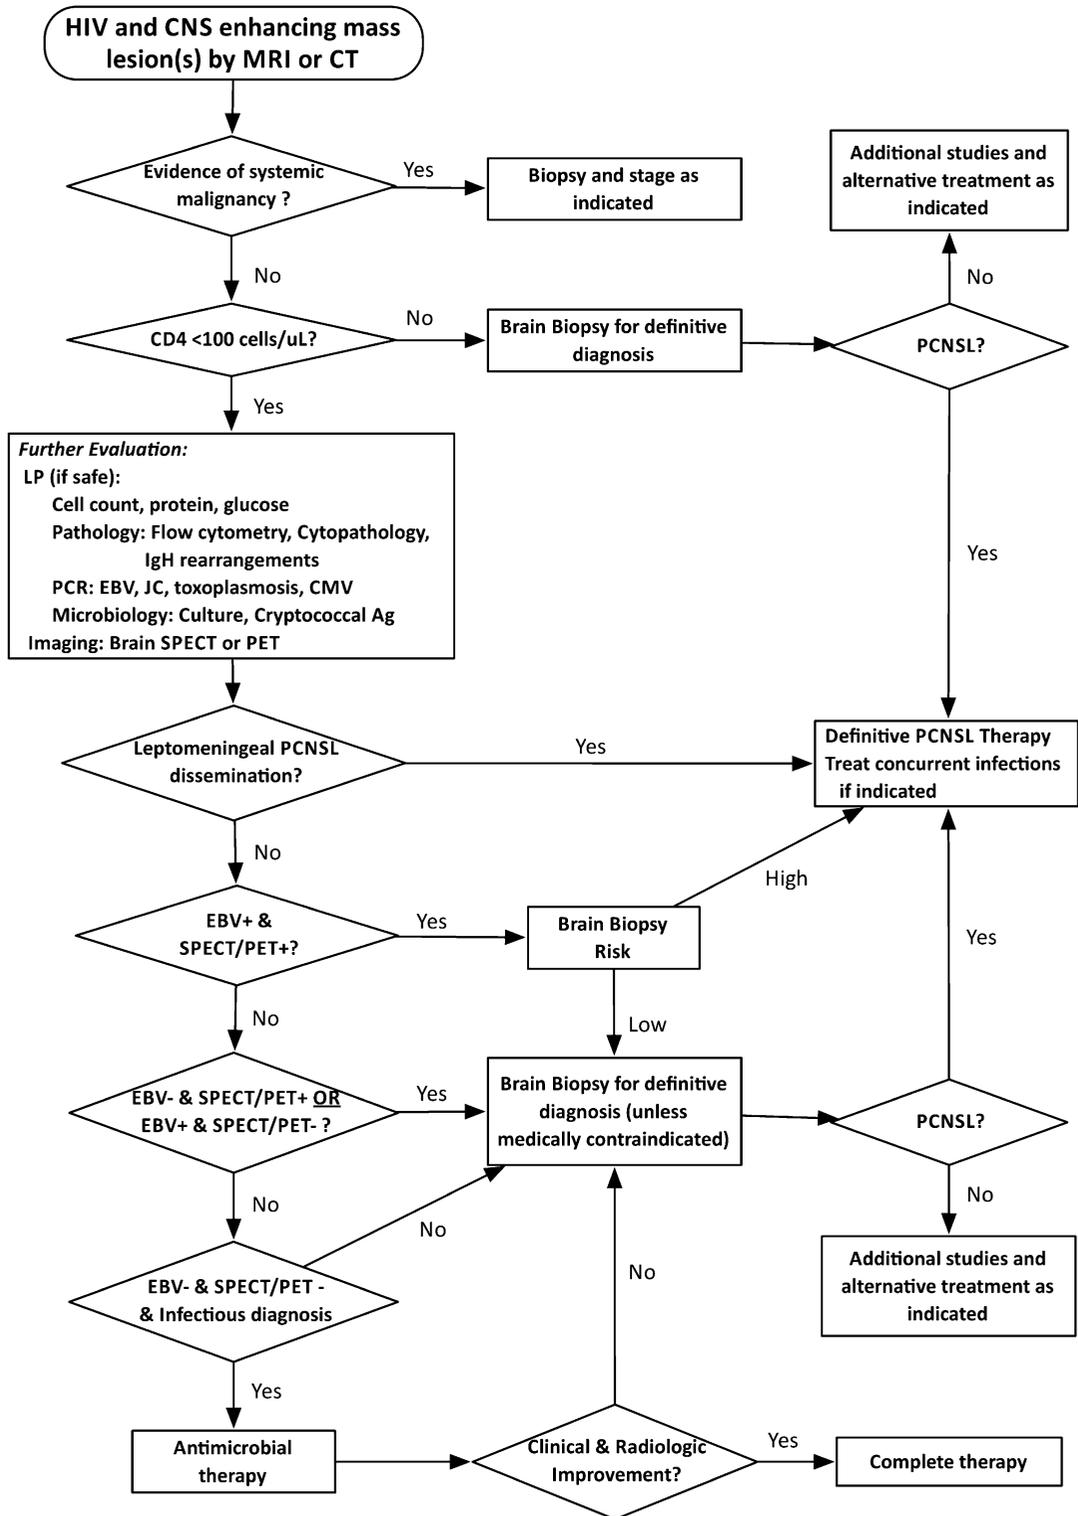

enhanced magnetic resonance imaging (MRI), although CT with contrast can be used if MRI is not available. In AR-PCNSL, these imaging studies can identify single or multiple CNS masses, which are generally ring enhancing with central necrosis, but may also have diffuse or nodular enhancement (Fig. 1). Mass-associated edema is also common and can be best noted on MRI fluid-attenuated inversion recovery (FLAIR) sequence imaging. CT and MRI are useful in excluding significant midline shift that may make a lumbar puncture unsafe. Toxoplasmosis and AR-PCNSL have similar presentations and cannot be reliably distinguished based on imaging and clinical features.

Establishing a definitive diagnosis of cerebral mass lesions in patients with known or suspected HIV (Fig. 2) requires a medical history focusing on HIV and opportunistic infections, use of prophylactic antibiotics with anti-toxoplasmosis activity, and risk factors for systemic malignancies, as well as physical exam including professional ophthalmology evaluation. Expedited evaluation should include the following studies: HIV ELISA and viral load, CD4 count, CNS and body imaging to evaluate for systemic infections or malignancies, toxoplasmosis serology, and lumbar puncture to evaluate the cerebral spinal fluid (CSF) for leptomenigeal dissemination and/or CNS infection. In cases of suspected ocular involvement, vitrectomy is indicated (Abrey et al. 2005).

Lumbar puncture with CSF studies and nuclear imaging provides important diagnostic

information to help differentiate between AR-PCNSL and CNS infection and identify concurrent pathologies. The discovery of an almost universal association of AR-PCNSL with EBV infection (MacMahon et al. 1991) has led to the use of polymerase chain reaction (PCR) to detect EBV DNA in the cerebral spinal fluid (CSF) in patients with suspected AR-PCNSL. Additional initial CSF studies to evaluate for leptomenigeal dissemination and/or infections include opening pressure, cell count, protein, glucose, gram stain, cryptococcal Ag, cytopathology, flow cytometry and PCR evaluation for immunoglobulin heavy-chain (IgH) clonal rearrangements, EBV (quantitative) viral load, JC virus, cytomegalovirus (CMV, also known as human herpesvirus-5), and toxoplasmosis (Fig. 1). Other microbiology studies may be indicated in some cases based on MRI findings and patient history.

Two nuclear imaging modalities have been evaluated in patients with AR-PCNSL, thallium-201 (Tl-201) single-photon emission CT (SPECT) and ^{18}F -fluorodeoxyglucose positron emission tomography (FDG-PET). With either nuclear imaging modality, infections usually appear as hypometabolic lesions, whereas PCNSL or other tumors are hypermetabolic (Fig. 1). In patients with HIV/AIDS and low CD4 count (generally less than 100 cells/uL), the sensitivity and specificity of nuclear imaging range between 80% and 100%. Combining imaging findings with data on toxoplasmosis serology and CSF EBV viral load can further increase

AIDS-Related Primary Central Nervous System Lymphoma, Fig. 2 An approach for evaluating HIV-infected patients with central nervous system-enhancing mass lesions

diagnostic accuracy. The combination of Tl-201 SPECT with CSF-based testing increased the specificity and positive predictive value to nearly 100% in one study (Antinori et al. 1999). However, it should be noted that EBV can be detected frequently in the CSF of patients with HIV/AIDS with systemic non-Hodgkin lymphoma or other diseases, and is not specific for AR-PCNSL. Furthermore, anti-toxoplasmosis titers can be elevated in patients with AR-PCNSL, and do not exclude concurrent pathology. For these reasons, despite technical advances in minimally invasive diagnostic tools for evaluation of intracranial masses in AIDS patients, the diagnosis of AR-PCNSL is done by pathological examination in nearly all cases.

CSF cytopathology as well as flow cytometry and IgH rearrangement studies may be useful in the diagnosis of AR-PCNSL. The impetus for using CSF cytopathology as a diagnostic tool in PCNSL comes from studies utilizing this as adjunct in diagnosis of leptomeningeal involvement. CSF cytopathology can detect leptomeningeal spread in 15–40% of untreated immune-competent PCNSL patients and is associated with higher tumor burden (Balmaceda et al. 1995; Ferreri et al. 2003; Fischer et al. 2008). Multiparameter flow cytometry is also useful for detecting leptomeningeal involvement of both systemic diffuse large B-cell lymphoma and PCNSL and is more sensitive than cytopathology. IgH PCR studies of CSF can also detect clonal IgH rearrangements in patients with PCNSL and provide important information that can be integrated with cytopathology and flow cytometric findings. It should be noted that the utility of flow cytometry and IgH PCR in AR-PCNSL remains to be fully defined; still it is reasonable to integrate these minimally invasive studies into the initial diagnostic evaluation of patients with AIDS and ring-enhancing CNS masses. In AIDS patients with ring-enhancing CNS masses, the pathological demonstration of leptomeningeal dissemination of lymphoma can establish a definitive diagnosis.

Despite these advances in minimally invasive diagnostic tools, histologic diagnosis remains the gold standard for diagnosis of AR-PCNSL, and

biopsy is required in many cases for definitive diagnosis. As AR-PCNSL is a multifocal malignancy, craniotomy with resection of a lesion is generally not performed unless there is another indication such as decompression of mass effect or concern for an abscess. Stereotactic brain biopsy has a diagnostic yield of 85–90% in the evaluation of cerebral lesions in patients with AIDS and is generally associated with low mortality, although the overall morbidity rate is approximately 8–10% mainly due to intracranial bleeding. However, thalamic or basal ganglia lesions are associated with a significantly increased risk of morbidity, often from bleeding. In AIDS patients with a CD4 count less than 100 cells/uL, positive EBV viral load in the CSF, and lesions consistent with AR-PCNSL by nuclear imaging, biopsy of such high-risk lesions may be relatively contraindicated. In such cases, diagnosis of AR-PCNSL can usually be established based on the results of these established noninvasive studies (Fig. 2).

In 1998, the American Academy of Neurology issued recommendations to guide diagnostic evaluation of AIDS patients with ring-enhancing lesions (1998). However, this algorithm does not include more recent molecular diagnostics or flow cytometry, which is sensitive for detecting B-cell malignancies in the CSF. Furthermore, this and other algorithms include a trial of empiric antibiotics for toxoplasmosis, which is no longer advisable given diagnostic advances and dramatically improved survival of patients with AIDS in the HAART era. An alternative algorithm for patients with AIDS and enhancing CNS masses that takes into account these new findings is proposed in Fig. 2. It should be noted that evaluation in some patients, for example, those with inconclusive imaging and laboratory studies in which brain biopsy is felt to be dangerous, can be challenging and the best approach will require balancing various risks. Also, this algorithm should be considered a suggested guide, and readers should be alert for new developments or new official guidelines in this area.

AR-PCNSL and other CNS infections occurring in patients with AIDS can be associated with a rapid deterioration of functional and neurologic

function. Patient performance status should be assessed using an Eastern Cooperative Oncology Group (ECOG) performance scale. Cognitive function should be monitored using serial scoring of the Mini-Mental State Examination (MMSE). Given the rapid and sometimes irreversible decline in performance status in patients with untreated AR-PCNSL or untreated CNS infections and improved long-term outcomes in AIDS patients treated with HAART, expedited evaluation is crucial. Long-term neurologic function, quality of life, and survival are likely affected by the course of action taken during the initial diagnostic evaluation (Abrey et al. 2005).

Treatment and Prognosis

The advent of effective combination antiretroviral therapy, also known as highly active antiretroviral therapy (HAART), heralded a new era for HIV-infected patients. The control of HIV replication and associated immune reconstitution leads to a decrease in deaths from opportunistic infections and dramatically improved overall survival for many AIDS patients. Studies of outcomes for HIV-related diseases are usually divided between the pre-HAART era (before 1996) and the era when HAART became broadly available in the USA and Europe (after 1996). Among populations with access to HAART, one of the great advances has been the prevention of malignancies occurring in the setting of very low CD4 counts, such as AR-PCNSL. However, despite improvement in overall survival attributable to HAART (Hoffmann et al. 2001), patients who do develop AR-PCNSL still have an overall mortality close to 90% at 2 years (Norden et al. 2011).

HAART is a necessary part of the treatment of AR-PCNSL, and immune reconstitution is considered the main driver of this effect. The control of HIV viremia allows for T-cell immune reconstitution and improved immunosurveillance against this immunogenic, virally associated malignancy. In rare cases, HAART alone has even been associated with complete resolution of PCNSL, presumably due to improved T-cell function.

Pilot and retrospective studies (Hoffmann et al. 2001) suggest further improvements in outcomes may be possible in this patient population with lymphoma-directed therapeutics and appropriate supportive care that includes prophylaxis and treatment of opportunistic infections and in some cases, short courses of steroids to manage neurologic symptoms. However, delayed diagnosis, heterogeneous approaches to diagnosis, poor performance status, and infectious or malignant comorbidities may be significant additional risk factors that affect overall survival. Unlike systemic non-Hodgkin lymphoma in patients with AIDS, for which dramatic improvements in overall survival have been achieved through prospective therapeutic studies, advances in AR-PCNSL have been limited by the lack of prospective studies. As such, there is no consensus on how to treat AR-PCNSL.

The major definitive treatment modalities for PCNSL are whole-brain radiotherapy (WBRT), chemotherapy, and the anti-CD20 monoclonal antibody, rituximab. However, there are no completed prospective lymphoma-directed studies that have been performed in patients with AR-PCNSL in the HAART era. With the exception of HAART, which is indicated based on evidence showing improved overall survival, therapeutic interventions for AR-PCNSL are based on case series and expert opinion or extrapolation from studies performed in immune-competent patients with PCNSL.

In AR-PCNSL, radiotherapy has been the predominant treatment modality since the beginning of the AIDS epidemic. Radiation has good activity against PCNSL. However, focal radiotherapy is associated with high recurrence rates and hence whole-brain radiotherapy (WBRT) is recommended. Even WBRT is unlikely to treat leptomeningeal disease outside the radiation field. In retrospective studies performed in the pre-HAART era, median overall survival with WBRT alone was less than 6 months; death was generally from either other complications of AIDS or from progressive PCNSL. A more recent study performed in the HAART era has demonstrated a 3-year survival of 64% in patients with pathologically confirmed AR-PCNSL treated

with HAART and WBRT (>30 Gy). Doses of WBRT (~40 Gy) recommended for better and more durable disease control, however, are associated with debilitating and at times life-threatening neurotoxicity (Correa et al. 2004). Therefore, radiation-sparing approaches to AR-PCNSL are highly desirable.

High-dose methotrexate, either alone or in combination regimens, is the best-studied radiation-sparing approach to PCNSL in patients without HIV. However, many regimens evaluated in PCNSL in immune-competent patients also contain high-dose cytarabine, which adds substantial toxicity and may not be appropriate for patients with AIDS. A pilot study of high-dose methotrexate 3 g/m² performed in ten patients with histologically confirmed AR-PCNSL in the pre-HAART era (Jacomet et al. 1997) demonstrated a complete response rate of 30%; however, median overall survival was only 2 months. Further evaluation of radiation-sparing approaches is required in the HAART era.

Rituximab, a monoclonal antibody directed against CD20, is an important immunotherapy that has been evaluated in the treatment of PCNSL and PTLD and is a rational agent in AR-PCNSL, in which 100% of lymphoma cells express CD20. One challenge has been determining whether a therapeutic concentration rituximab can be obtained in the central nervous system. Pharmacokinetic studies have shown that CSF levels are approximately 0.1–1% that of serum during peripheral administration. Though this may appear to be an insufficient concentration, it represents one to ten times more than needed to saturate 80–95% of CD20-positive cell surface. Furthermore, tumor-associated breakdown of the blood-brain barrier likely allows for increased accumulation at the site of the tumor. Indeed tumor accumulation of yttrium-90-labeled anti-CD20 antibodies can be demonstrated in a majority of patients with PCNSL.

Clinically, a retrospective study examined the addition of rituximab to high-dose methotrexate and ifosfamide on outcomes in newly diagnosed PCNSL in HIV-negative patients. The addition of rituximab increased the CR rate (100% vs. 68.4%; $p = 0.02$) and 6-month progression-free survival

(94.1% vs. 63.2%; $p = 0.04$) (Birbaum et al. 2012). A subsequent prospective multicenter study evaluating rituximab in combination with high-dose methotrexate and temozolomide had a 63% complete response rate. Patients went on to receive consolidation therapy with high-dose cytarabine and etoposide, and mature results from this study are forthcoming.

Overall, the results of trials in HIV-uninfected patients with PCNSL suggest that radiation-sparing modalities can achieve good results. While patients with AR-PCNSL may be more susceptible to toxicities from such regimens because of their severe underlying acquired immunodeficiency, such approaches are appropriate to consider at the HAART era. However, there are no completed studies of radiation-sparing approaches with HAART in AR-PCNSL. Curative-intent, radiation-sparing treatment of AR-PCNSL is currently under investigation in a prospective study evaluating rituximab, high-dose methotrexate, and HAART in patients with AR-PCNSL (NCT00267865).

Conclusion

AR-PCNSL is a rare AIDS-defining malignancy with a high mortality. The advent of the widespread distribution of HAART has led to a substantial decline in incidence and a modest improvement in overall survival. For AIDS patients who develop AR-PCNSL, diagnostic as well as therapeutic challenges exist. A streamlined evaluation of CNS masses (Fig. 2) may lead to earlier diagnoses and treatments and improved outcomes. All patients should be started on HAART and, given the lack of a standard therapy, should also receive curative-intent lymphoma-directed therapy, ideally within a clinical trial.

Anal Cancer

Joel Palefsky

Department of Infectious Diseases, University of California, San Francisco, CA, USA

Definition

Anal cancer is a squamous cell cancer of the anal canal and perianal region that is very similar biologically to cervical cancer in terms of its

association with oncogenic human papillomavirus (HPV), particularly HPV 16. Like cervical cancer, anal cancer occurs most often in a squamocolumnar transformation zone and is preceded by squamous intraepithelial lesions. The incidence of anal cancer is considerably higher in HIV-infected men and women than in the general population and has increased since the introduction of highly active antiretroviral therapy. Now one of the most common cancers occurring in HIV-positive men and women, and unlike most other cancers occurring in the HIV-positive population, anal cancer is also potentially preventable through primary prevention (vaccination against HPV) and secondary prevention (screening for and removal of high-grade anal squamous intraepithelial lesions).

Introduction

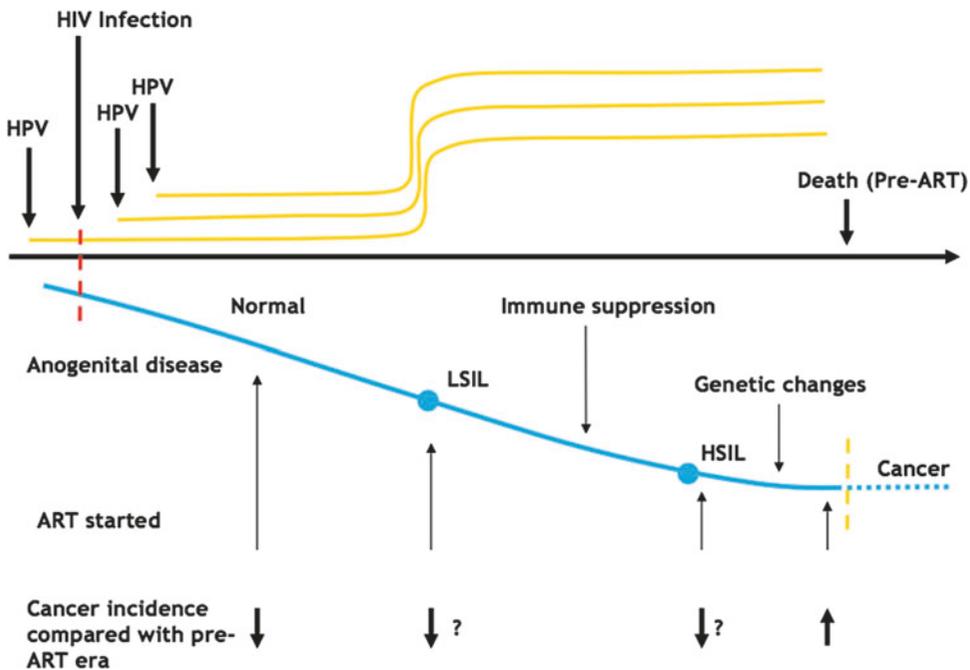

Recently, malignancies have become one of the most common causes of mortality in HIV-infected men and women. Unlike the most common HIV-associated malignancies, Kaposi's sarcoma and non-Hodgkin's lymphoma, the incidence of anal cancer has continued to increase among HIV-infected individuals well after the introduction of highly active antiretroviral therapy (HAART) (Fig. 1). HIV infection may also accelerate the natural history of anal cancer, for which the mean age of diagnosis among HIV-infected individuals is lower than among HIV-uninfected individuals. Among the more common malignancies occurring in HIV-infected individuals, anal cancer has one additional distinguishing feature – it is likely to be preventable.

Given the biological similarity between cervical and anal cancer and the well-established success of cervical cancer prevention programs, it is possible that anal cancer may similarly be preventable. Like cervical cancer programs, anal cancer prevention programs may take the form of primary prevention or secondary prevention. Primary prevention consists of prevention of infection with the underlying etiologic agent, HPV, through prophylactic vaccination. Secondary prevention efforts are focused on those who have

already been exposed to HPV and who have developed anal high-grade squamous intraepithelial lesions (HSIL), also called high-grade anal intraepithelial neoplasia (HGAIN). Identification of anal HSIL and removal of that lesion through a variety of methods is performed in an effort to reduce the risk of progression of that lesion to cancer. Secondary prevention has been shown to work very well to prevent cervical cancer and is the basis of cervical cytology screening programs, with colposcopy and biopsy to diagnose cervical HSIL, and ablate it to reduce the risk of progression to cervical cancer. A similar approach to prevention of anal cancer has been advocated by several experts in the field (Palefsky 2009). Although it seems probable that adaptation of cervical techniques to the anal canal would be successful to reduce the risk of anal cancer, there are several challenges, particularly in HIV-infected individuals. These include large lesions, multifocal lesions, high incidence of new lesions, and high recurrence rate after treatment. Well-designed clinical trials to demonstrate the efficacy of this approach have not yet been done and are urgently needed.

Incidence of Anal Cancer in HIV-Positive Men and Women

Anal cancer is biologically similar to cervical cancer in several ways. Like cervical cancer, anal cancer is associated with HPV infection, primarily HPV 16. The anal canal has a transformation zone at the anorectal junction that is similar to the main target of HPV infection in the cervix, the cervical transformation zone. At both of these anatomic sites, HPV infection leads to a series of epithelial changes that reflect various stages of HPV infection and HPV-associated transformation. HSIL includes loss of epithelial differentiation and abnormal mitotic activity and is considered to be the precursor lesion to both cervical and anal cancer. Natural history studies show that the time from HPV infection to development of HSIL is relatively short and usually occurs within just a few years. It would therefore appear that the long latency period to development of

Anal Cancer, Fig. 1 Relationship between highly active antiretroviral therapy (HAART) initiation, anal squamous intraepithelial lesions, and incidence of anal cancer. Data suggest that immune response plays an important role in preventing development of low-grade squamous intraepithelial lesions (LSIL) and high-grade squamous intraepithelial lesions (HSIL). HSIL that persists accumulates genetic changes over time that are not reversible by antiretroviral therapy-induced immune reconstitution. With sufficient time and accumulation of cancer-inducing genetic changes, these lesions may progress to cancer. In the pre-HAART era, the incidence of anal cancer among HIV-infected MSM was modestly higher than among HIV-uninfected MSM. In the pre-HAART era, MSM may have died of competing causes before they had sufficient time to progress from HSIL to cancer, and this may have limited the number of cases of cancer that developed. Since the introduction of ART, the incidence of anal cancer has increased among HIV-infected MSM. Initiation of

HAART if the patient has no disease or LSIL at either a low or high CD4 level may prevent progression to HSIL and may lead to reduced incidence of anal cancer compared to those who initiate HAART after having HSIL for a long period of time. The incidence of anal cancer may or may not be higher in this group compared with the pre-HAART era. Initiation of ART if the patient has early HSIL at either a low or high CD4 level may induce regression of HSIL and may or may not lead to reduced incidence of anal cancer compared to those who initiate ART after having HSIL for a long period of time. The incidence of anal cancer may or may not be higher in this group compared with the pre-HAART era. Initiation of ART after HSIL has persisted for several years may not induce lesion regression whether the CD4 level is high or low, and the longer survival time in the absence of ASIL screening will allow the incidence of anal cancer to increase compared with the pre-HAART era

anal cancer primarily reflects the long period of time required for HSIL to progress to cancer.

Several studies have shown that anal HPV infection in women is as common or more common than cervical HPV infection (Machalek et al. 2012). Given the ease in which women acquire anal HPV infection, it is not surprising that in the general population anal cancer occurs more commonly among women than men. The incidence of anal cancer in the general population

has been rising by about 2% among both men and women. With a nearly 60% rate of anal HPV infection among HIV-uninfected men who have sex with men (MSM), it is also unsurprising that the incidence of anal cancer in this group of men is much higher than men with no history of receptive anal intercourse. The rate of anal HPV infection is even higher among HIV-infected MSM, and this group has the highest incidence of anal cancer of all.

Given the many competing causes of mortality prior to the advent of HAART and the long latency period typically required for HSIL to progression to anal cancer, the incidence of anal cancer was only modestly increased among HIV-infected MSM compared with HIV-uninfected MSM. When HAART was introduced, it was hoped that it would have the same beneficial effect on anal cancer incidence as on KS and NHL, reflecting immune reconstitution and improved immune response to the etiologic agents. However, it quickly became clear that individuals with prevalent HSIL were not undergoing regression to normal after initiating effective HAART, HPV infection was not being cleared, and the incidence of HSIL was continuing unabated. Combined with the increasing survival due to fewer competing causes of mortality and absence of organized screening or prevention programs for anal cancer, the incidence of anal cancer has increased, not decreased, in the HAART era (Shiels et al. 2012). Several HIV-anal cancer database matches showed an incidence of anal cancer of 70/100,000 or more. More recent data from the NA-ACCORD study show an incidence of 131/100,000 HIV-infected MSM (Silverberg et al. 2002) rendering the incidence of anal cancer well above the highest incidences of cervical cancer anywhere in the world. Recent data from the Swiss Cohort study suggest that the increase may be leveling off.

It is not clear whether the incidence of anal cancer will continue to increase at the same rate in the future or whether it may level off or even decrease. There are several competing factors that will ultimately determine the incidence of anal cancer in HIV-infected men and women. A factor that may reduce the incidence of anal cancer in the future is vaccination to prevent anal HPV infection with HPV 16 and HPV 18. However, it will be several decades before any reduction in the incidence of anal cancer due to vaccination is seen. Current uptake of the vaccine among males is very low, and the full benefit of the vaccine may take even longer to realize unless vaccination uptake is improved. Another factor that may lead to a lower incidence of anal cancer in the future compared with current rates is

changes in practice regarding higher threshold CD4 levels for initiation of HAART. We hypothesize that immune response may be useful to control HPV replication and progression from HPV infection to HSIL. Those whose immune systems are less damaged by HIV might have a lower incidence of HSIL and ultimately a lower incidence of anal cancer. Although not consistent from study to study, some have shown that men and women started on HAART have more clearance of existing HPV infection and lower incident of HSIL. With the current clinical standard of practice moving increasingly toward initiating HAART earlier in the course of HIV infection and at higher CD4 levels, it is possible that this will have a long-term beneficial effect in reducing incident HSIL and cancer. Unfortunately most HIV-infected individuals were initiated on HAART at CD4 levels well below current guidelines, and they may not benefit from the earlier initiation of HAART described above. As described previously, aging of the HIV-infected population may also contribute to an increase in the burden of anal cancer in the future.

Pathogenesis of Anal Cancer

Consistent with their shared etiologic association with HPV, anal cancer and cervical cancer are both preceded with a series of intraepithelial changes ranging from low grade to high grade. Low-grade changes are associated with few signs of cell transformation but instead primarily reflect cytopathic changes due to high levels of HPV replication. These changes are not believed to be precancerous. Low-grade anal squamous intraepithelial lesion (LSIL) is the most common form of ASIL associated with a wide variety of HPV types, both oncogenic and non-oncogenic (Hoots et al. 2009). Condyloma acuminatum is most often associated with HPV 6 or 11, but in HIV-infected individuals, a high proportion may be coinfecting with HPV 16 or 18. Rather than reflect coinfection of individual cells with more than one HPV type, these probably reflect separate foci of clinically subtle HSIL, with HPV 6 or 11 causing the condyloma and HPV 16 causing

the HSIL. HSIL is believed to be the true cancer precursor of anal cancer, similar to the role of cervical HSIL as the precursor to cervical cancer. Unlike anal LSIL, a high proportion of anal HSIL contain oncogenic HPV types. Infection with multiple HPV types is particularly common in HIV-infected individuals, but it is relatively uncommon to detect only non-oncogenic HPV types in these lesions. The rate at which these lesions progress to cancer is unknown and likely varies highly from person to person. Since the mean age at which HIV-infected individuals develop anal cancer is lower than the general population, it is likely that the time of progression from anal HSIL to invasive cancer is shorter in this group.

The mechanisms that trigger invasion of the underlying basement membrane are not known. Ongoing HPV oncogenic protein expression, particularly E6 and E7, is necessary for maintenance of the transformed phenotype. Induction of angiogenesis may play a role in progression to cancer, although it is not clear if it is the cause or effect. The role of HIV in the process is also not known. HIV proteins may be present in the epithelial microenvironment of HIV-infected individuals, even if they have well-controlled HIV viral loads on HAART. An inflammatory microenvironment may also be present in HIV-infected individuals, in which there may be elevations of cellular immune response proteins such as tumor necrosis factor-alpha and interferon-gamma. These proteins may be potentiating the oncogenic effects of HPV proteins, but their exact role is still unclear.

Primary Prevention of Anal Cancer Through HPV Vaccination

The quadrivalent (qHPV) and bivalent HPV vaccines have both been shown to be highly effective at preventing persistent cervical HPV infection and high-grade cervical squamous intraepithelial lesions (CSIL) due to the types of HPV in the vaccines. The quadrivalent vaccine is also effective at preventing genital warts in women due to HPV 6 or 11. Recent studies have shown early

evidence of effectiveness at the population level. Australian sexually transmitted infection clinics have reported a reduction in the proportion of women presenting with genital warts (Read et al. 2011), and in the United States, the proportion of women with high-grade CSIL that contain HPV 16 or 18 has declined (Powell et al. 2012). Based on these and other data, the quadrivalent and bivalent HPV vaccines were approved for routine use in females aged 9–26 years.

Recently the qHPV vaccine was shown to be effective at reducing the incidence of external genital warts in HIV-uninfected heterosexual men and MSM (Giuliano et al. 2011). In a sub-study of anal canal HPV infection and anal canal anal squamous intraepithelial lesions (ASIL), the qHPV vaccine was also effective at reducing intra-anal persistent infection with vaccine HPV types and anal HSIL due to vaccine types (Palefsky et al. 2011). Based on these and other data, qHPV was approved for routine use in males aged 11–21 years. Vaccination is also approved for routine use in MSM and immunosuppressed males aged 22–26 years and is approved but not for routine use in non-immunosuppressed males aged 22–26 years.

Although studies of HPV vaccination to prevent anal HPV infection, ASIL, and anal cancer have not been done in women, the qHPV vaccine was approved for this indication in women based on similarity of anal cancer between men and women and the data from the Merck 020 protocol in men. The bivalent vaccine has not been studied for prevention of anal cancer, and the qHPV vaccine is the only vaccine approved for prevention of anal cancer in men or women. However, in a post hoc analysis of Costa Rican women vaccinated with the bivalent vaccine to prevent cervical HPV infection, CSIL, and cervical cancer, there was a reduction in infection with HPV 16 and 18 in the anal canal of vaccinated women (Kreimer et al. 2011). These data provide encouragement that the bivalent vaccine may reduce the risk of ASIL and cancer in addition to CSIL and cervical cancer but studies are needed to demonstrate this.

HIV infection is not a contraindication to HPV vaccination, and given their high risk of anal HPV

infection and ASIL, HIV-infected men and women of vaccine-eligible age should be vaccinated. Several studies have shown that vaccination in HIV-infected men and women is safe (Wilkin et al. 2010). Nearly all HIV-infected individuals seroconvert in response to vaccination regardless of CD4 level. Titers may be lower in HIV-infected people and similarly aged HIV-negative individuals, but nearly all have titers well above those seen after natural HPV infection. Studies of the efficacy of HPV vaccination to prevent anogenital disease in HIV-infected individuals have not yet been reported, and the duration of protection is unknown.

The qHPV and bivalent vaccines are preventive vaccines and work to prevent initial HPV infection. Consequently HPV vaccination is most effective among those who have not been exposed to vaccine types previously, i.e., those who are naïve to a given HPV type, as defined by being DNA negative and seronegative to that type. Studies have shown that despite a large number of previous sexual partners, a high proportion of HIV-infected MSM over the age of 26 years are HPV DNA negative and seronegative to vaccine HPV types and would be considered “naïve” to these types (Wilkin et al. 2010). However, we speculate that many men who would currently be classified as “naïve” to HPV 16 or HPV 18 were previously seropositive to these types and sero-reverted to negative, a process that has been demonstrated to occur over time in healthy women.

Despite the high rate of “naivete” to vaccine types and incidence of HPV infection in HIV-positive MSM over the age of 26 years, vaccination of HIV-infected individuals over the age of 26 years is controversial. If these men were previously seropositive, the value of vaccination is not clear, and studies are needed to determine if vaccination affords these men the same protection that they would have received if they were truly naïve.

Secondary Prevention of Anal Cancer

In cervical cancer secondary prevention programs, cervical cytology, and, to an increasing

extent, adjunctive tests such as HPV DNA or RNA are used to identify women at risk of high-grade CSIL. The next step in the evaluation of these women is to visualize the cervix and vulvovaginal epithelium to localize the source of abnormal cells on cytology or positive HPV test, using a technique known as colposcopy. With the aid of the magnification provided by the colposcope and topically applied solutions such as 5% acetic acid or iodine-based Lugol’s solution, areas likely to be lesional are targeted for biopsy. Histologically confirmed high-grade CSIL is then removed using techniques such as loop electro-excision procedure or cryotherapy, depending on the setting. There is good evidence that high-grade ASIL is the precursor to anal cancer, and it is likely, although unproven, that removal of anal HSIL will reduce the incidence of anal cancer. Given the similarity between ASIL and CSIL, methods to identify those with anal HSIL are largely based on those used for cervical screening (Palefsky 2012). To identify anal HSIL, a technique known as high-resolution anoscopy (HRA) can be performed, in which patients are examined under magnification with a colposcope and with topical solutions such as 5% acetic acid or Lugol’s iodine to identify areas of ASIL visually. A biopsy of visible lesions is then performed for histologic confirmation.

Individuals at high risk of anal cancer can be considered for testing to identify anal HSIL (Palefsky 2009). These include HIV-infected men and women, regardless of mode of HIV acquisition, HIV-uninfected MSM, those with perianal HPV-related lesions, women with a history of high-grade vulvar squamous intraepithelial lesions and vulvar and cervical cancer, and those who are immunosuppressed due to causes other than HIV. In the interest of minimizing morbidity, consideration should be given to screening only after the age of 30 years given the low incidence of anal cancer among those younger than 30 years of age.

Similar to cervical screening, there remains room for improvement in screening for anal HSIL. The most direct screening method is to perform HRA. However, HRA requires extensive training and experience, and for optimal results an

interdisciplinary team is needed that includes an anoscopist, pathologist, surgeon, and counselor/educator. Currently the number of clinicians performing HRA is limited given the extensive infrastructure and training required, and there are too few well-trained clinicians performing this technique to allow it be used as a true screening tool.

One of the more easily performed screening tools that may identify individuals who would benefit from HRA is anal cytology. Anal cytology is performed in a manner similar to cervical cytology, but unlike cervical cytology, it may also be performed by patients themselves. Those with abnormal cytology are then referred for HRA. Like cervical cytology, the sensitivity of anal cytology is limited, and it tends to under-call the grade of lesion shown on HRA-guided biopsy. Given the high proportion of HIV-infected individuals expected to have abnormal anal cytology, the grade of cytology may also be used to triage patients. Ultimately all patients with any abnormality, including atypical squamous cells of undetermined significance (ASC-US), should be considered for HRA. However, the positive predictive value for anal HSIL on cytology is highest for those with anal HSIL on cytology, followed by those with atypical squamous cells – cannot rule out high-grade lesion (ASC-H) and low-grade squamous intraepithelial lesions (LSIL). Cost-effectiveness studies have shown that HIV-infected MSM should be screened annually with anal cytology if their cytology is normal, and that HIV-uninfected MSM should be screened every 2–3 years (Goldie et al. 1999). Although there are fewer data for the other at-risk groups, at the University of California San Francisco, we recommend similar screening intervals for these groups according to their HIV status.

HPV testing is being used in the cervix as an adjunct to cervical cytology or as a primary screening test to identify women who should have cervical colposcopy. Given the limitations of anal cytology, some have advocated anal HPV testing to identify those who should have HRA. However, given the high prevalence of oncogenic HPV in HIV-infected patients, HPV testing may be more useful for its negative predictive

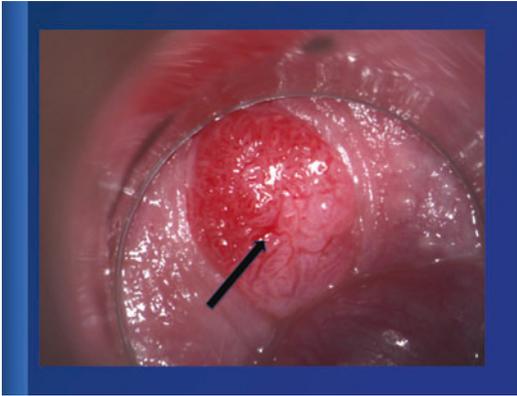

value. Further studies are needed to define the best use of HPV-based tests.

Once identified on biopsy, every effort should be made to ablate or remove the lesion with the primary goal of reducing the risk of progression to cancer. However, to date no clinical trials have been performed that define the efficacy of anal HSIL treatment to reduce the incidence of anal cancer. Currently all clinicians who choose to screen for and treat anal HSIL are doing so based on the similarity between anal cancer and cervical cancer and the proven efficacy of treatment of cervical HSIL to prevent cervical cancer. Studies to determine if this approach is effective are urgently needed.

Another goal of anal HSIL treatment is relief of symptoms. In the perianal region, anal HSIL may cause bleeding, burning, or itching, and patients may experience psychological distress due to its cosmetic appearance. Anal low-grade squamous intraepithelial lesions (LSIL) including condyloma acuminatum may also cause these symptoms. Unlike HSIL, LSIL is not believed to be precancerous. While treatment of LSIL will not likely reduce cancer risk, it is reasonable to treat it for symptom relief.

Diagnosis of Anal Cancer

Anal cytology and HRA-guided biopsy are primarily aimed at identifying anal HSIL, these should therefore be considered to be methods of anal “precancer” screening. In contrast, digital anorectal exams (DARE) with palpation for intra-anal and perianal masses is a key element of anal cancer screening. Some anal cancers may also be detected at HRA (Fig. 2). Like cervical cancer, survival after treatment of anal cancer correlates inversely with the stage of diagnosis. Five-year survival after treatment of stage I disease is as high as 70% and declines to about 20% after diagnosis of stage IV disease. In the absence of any organized anal cancer or HSIL screening program, diagnosis of anal cancer is often made when the patient presents with new anal pain that is not explained by any other obvious source of pain such as hemorrhoids, fissures, or infections.

Anal Cancer, Fig. 2 Large area of anal cancer, as seen after application of 5% acetic acid at high-resolution anoscopy, indicated by *black arrow*. Cancerous lesion is raised and has clear borders, erythema, and atypical vessels

Lesions such as HSIL are usually painless, and when patients develop pain, it may be a sign of progression to cancer that is involving pain nerve fibers. Patients may also present with new patterns of bleeding, discomfort upon defecation or anal intercourse, or rapid growth of a mass. In those areas where active screening of HSIL is in place, a new category of anal cancer is being diagnosed, i.e., very early cancers that are too small to be palpable on DARE and which are asymptomatic. These cancers are detected only on biopsy at HRA and are suspected when ulcers or highly atypical blood vessels are noted. Occasionally these may be unsuspected, with the appearance of otherwise unremarkable HSIL. This new category of anal cancer was adopted as part of the Lower Anogenital Squamous Terminology Project of the College of American Pathologists and American Society for Colposcopy and Cervical Pathology, called “Superficially Invasive Squamous Cell Carcinoma of the Anus” (SISCCA). SISCCA is defined as a lesion with less than 3 mm in depth and 7 mm in width (Darragh et al. 2012).

Treatment of Anal HSIL

Treatment for anal HSIL generally falls into two categories: (1) local treatment with clinician – or

patient-applied creams or liquids and (2) clinician-applied ablative techniques such as electrocautery, laser, or infrared coagulation (IRC) and surgery. The choice of treatments will vary with the preference of the clinician, the clinical setting, the size and number of lesions, and the location of the lesions.

Treatment of Perianal HSIL

For smaller lesions (less than 1 cm in diameter) that are also limited in number (less than 3), 85% trichloroacetic acid (TCA) or liquid nitrogen or a combination of the two may be used. These modalities may be reapplied up to four times at 2–3-week intervals, and if not successful, a different modality should be tried. Some clinicians would use hyfrecation in the office or infrared coagulation. Studies in Europe have shown modest success with imiquimod for treatment of anal HSIL, but HIV-positive patients may not respond as well to imiquimod as HIV-negative patients since the mechanism of action is immune mediated through toll-like receptors. Like other topical treatments, imiquimod has not been approved by the US Food and Drug Administration for treatment of ASIL. Recently a phase I study showed that topical cidofovir is safe for treatment of perianal HSIL and showed signs of modest efficacy that should be confirmed in phase II/phase III studies. An additional option for extensive perianal disease is application of 5-fluorouracil (5-FU) cream. This drug has been used topically for many years to treat vulvar and vaginal SIL. It may be used to reduce the size lesions to permit treatment of remaining lesional areas with more targeted therapies such as IRC or electrocautery. Its toxicities include local pain, inflammation, and ulceration, which can range from mild to severe.

In general, surgery is reserved for treating those with the most extensive disease, those who require an examination under anesthesia to permit biopsies large enough to definitely exclude invasive cancer, or rarely, treatment of complications of office-based procedures such as bleeding or infection. Larger perianal HSIL often requires more aggressive approaches in the setting of the operating room, such as IRC, electrocautery, laser, and surgical excision with skin flaps.

Treatment of Intra-anal HSIL

Treatment approaches for intra-anal HSIL are similar to those described for perianal HSIL but there are fewer options. Smaller lesions may be treated with 85% TCA, but most require IRC, electrocautery, or laser surgery. A high proportion of larger lesions may be treated with IRC, although the recurrence rate is high, as is the development of new lesions in areas that were not treated. A multicenter phase I safety study indicated that the efficacy of IRC to treat individual HSIL was about 65% within a year, with up to three treatments, similar to results of previously published retrospective chart reviews. Electrocautery appears to have similar safety and efficacy to IRC. Recently a randomized controlled trial of 156 patients with ASIL comparing imiquimod, topical 5-fluorouracil, and electrocautery showed that of the three modalities, electrocautery was the most effective for intra-anal lesions. However, each modality was associated with a high risk of lesion recurrence (Richel et al. 2013). There was little difference between the modalities for treatment of perianal ASIL. As with perianal HSIL, the most extensive disease may require surgical excision and/or fulguration in an operating theater. When performed in conjunction with HRA, surgery was effective to treat extensive anal HSIL in a retrospective chart review, particularly when combined with post-surgery IRC to treat remaining lesions or early recurrences.

Treatment of Anal Cancer

Treatment of anal cancer is based on the stage of the disease. Stages 1, 2 and 3 are typically treated with combined modality therapy (CMT) consisting of 5-fluorouracil and mitomycin, with radiation therapy. The National Comprehensive Cancer Network (NCCN) recommends 5-FU IV on days 1–4 and 29–32 with mitomycin IV on days 1–29. A minimum of 45 Gy radiation therapy is given over 5 weeks with an additional 9–14 Gy considered for patients with T3, T4, or node-positive disease or for those with residual disease after the initial 45 Gy. At some centers, intensity modulated radiation therapy is used

instead of 3-D conformal radiation in an effort to reduce radiation-associated toxicity. Cisplatin has been assessed in place of mitomycin, but clinical trials have shown insufficient benefit to recommend that it replace mitomycin as the first-line chemotherapeutic agent in combination with 5-FU (Gunderson et al. 2012).

However, cisplatin may be useful as first-line therapy with 5-FU for patients who are expected to be intolerant of the hematologic toxicity associated with mitomycin-based regimen.

Prior to the advent of HAART, HIV-infected patients had poor survival rates for anal cancer with many unable to tolerate a full regimen of CMT. In recent years, however, HIV-infected patients with good HIV control on HAART and high CD4 levels have been shown to tolerate full-dose therapy and have similar survival rates to HIV-negative individuals. The current recommendation is to treat HIV-infected patients with the standard regimen, although careful monitoring for toxicity is required and treatment breaks may be needed.

The primary role for surgery in the treatment of anal cancer is abdominoperineal resection for patients who fail CMT. In addition, local excision may be used to treat anal margin/perianal cancer provided that the surgery does not compromise anal sphincter function. With the recent recognition of SISCCA as a very early stage of invasive cancer that may develop in the perianal region or anal canal, there is substantial interest in determining whether SISCCA can be safely treated with wide local excision regardless of where in the anus it is diagnosed. Clinical trials will be needed to determine if this can become standard of care. If it does, then efforts to identify anal cancer at this very early stage will be important to effect a cure while minimizing the risk of toxicity associated with CMT.

Conclusion

Anal cancer is a problem of growing importance among HIV-infected men and women, and its incidence may continue to rise as an increasing number of HIV-infected men and women reach advanced age. Efforts need to be made to diagnose anal

cancers as early as possible given the improved morbidity and mortality outcomes associated with earlier diagnosis. It is possible that routine performance of simple techniques such as DARE will lead to earlier anal cancer diagnosis, as will performance of HRA in some at-risk individuals. Despite the high likelihood of surviving anal cancer when detected early, prevention is highly desirable given the high rates of morbidity associated with successful treatment of anal cancer.

Fortunately, unlike many other cancers that occur in HIV-infected men and women, many cases of anal cancer are potentially preventable through primary prevention in the form of vaccination against HPV 16 and 18. However, the impact of vaccination on anal cancer incidence will not be seen for several decades given the time required for those of vaccination age to reach the age at which anal cancer is typically diagnosed, and the high proportion of at-risk individuals who were exposed to HPV before vaccination became available. Further, the potential for vaccination to reduce anal cancer incidence is somewhat mitigated by relatively low vaccine uptake in the targeted age groups, especially in boys.

For those who have already been exposed to HPV, secondary prevention in the form of anal cytology screening and treatment of anal HSIL diagnosed on HRA-guided biopsy may be the best approach to reducing their risk of anal cancer. However, randomized, controlled trials of HSIL treatment to reduce the incidence of anal cancer are needed to assess the risk-benefit ratio of this approach before screening in at-risk populations will become standard of care. In the long term, reduction of the incidence of anal cancer will likely be achieved through all three approaches – DARE, anal screening for and treatment of anal HSIL, and HPV vaccination.

Anatomic Compartments as a Barrier to HIV Cure

Steven A. Yukl and Joseph K. Wong
 Department of Medicine, University of California, San Francisco (UCSF) and San Francisco VA Medical Center, San Francisco, CA, USA

Definition

Anatomic compartments as a barrier to HIV cure: organs, tissues, or tissue cells that allow persistence of HIV despite immune responses and/or antiretroviral therapy

Introduction

Anatomic compartments other than the blood represent a major site of HIV persistence on combination antiretroviral therapy (ART) and a major obstacle to efforts directed at eradication of HIV.

Though ART can block viral replication and reduce plasma HIV RNA levels below the detection limit of commercial assays (“suppression”), it does not eradicate HIV, which rebounds rapidly after interruption of ART in the vast majority of patients. Despite years of suppressive ART, HIV can usually be detected as low levels of HIV RNA in the plasma, higher levels of cell-associated HIV DNA and RNA in blood and tissues, and infectious virus in latently infected CD4⁺ T cells from the blood, which are widely regarded as a major barrier to the eradication of HIV.

However, compelling evidence also suggests that HIV persists in anatomic compartments outside of the blood (Svicher et al. 2014), which represent another barrier to HIV eradication. One of the main reasons that the tissues are an obstacle to eradication is that in both untreated and ART-treated individuals, most HIV-infected cells reside in the tissues. HIV primarily infects activated CD4⁺ T cells, but activated CD4⁺ T cells home to and are more abundant in the lymphoid tissues and gut. In addition, almost all organs contain CD4⁺ T cells, and while <2% of the body’s CD4⁺ T cells are found in the blood, most of the body’s CD4⁺ T cells reside in the gut and the lymphoid tissues. Moreover, CD4⁺ T cells from some tissues (such as gut) are more susceptible to HIV infection *in vitro*, and cell-to-cell spread in the tissues may enhance viral replication or decrease the efficacy of antiretrovirals. Consequently, infected cell frequencies are higher in certain tissues, such as gut and lymph nodes, than in the blood. In discussing HIV-infected cells and organs, some authors use the term “reservoir” to refer to a significant site of infection, while others reserve it specifically for HIV-infected tissues or cells that persist despite long-term suppressive ART (likely due to long life span or proliferative renewal) or more specifically for those that can produce virus or infectious virus. Using the second definition, the main tissue reservoirs are probably the gut, lymph nodes, spleen, genital tract, brain, lung, and kidney (Table 1).

A second major barrier to eradication posed by the tissues is that the distribution of infected cell types may differ between the tissues and blood. Aside from infecting CD4⁺ T cells, HIV can

Anatomic Compartments as a Barrier to HIV Cure, Table 2 Evidence for HIV or SIV infection in cells other than CD4+ T cells

Tissue and cell type	In vitro infection	Untreated HIV+				Treated HIV+					
		HIV DNA	HIV RNA	Infectious virus	HIV DNA	HIV RNA	Infectious virus	Protein

enter or infect many other cell types (Alexaki et al. 2008), including other hematopoietic cells, endothelial cells, epithelial cells, mesenchymal cells, and germ cells (Table 2). Some cell types constitutively produce free virus (“productive” infection), while others (including some CD4+ T cells and possibly mast cell progenitors or astrocytes) produce virus only upon stimulation (“latent” infection), and other cell types do not produce free virus but can internalize viral particles and transmit infection to neighboring cells. In ART-treated individuals, CD4+ T cells are almost certainly the largest and most important reservoir, but some evidence also suggests that other cell types may be reservoirs, including hematopoietic/mast cell progenitors, T memory stem cells, tissue macrophages, dendritic cells, and possibly astrocytes or microglial cells.

A third main barrier posed by the tissues is that certain tissues may harbor virus that differs in sequence from that in the blood, which may contribute to phenotypic differences such as cell tropism, resistance to ART, or evasion of immune responses. The terms “compartment” and “compartmentalization” have been used to refer to organs or cell types containing viruses that differ significantly in sequence and/or phenotype from viruses found in the blood. The organ with the greatest evidence for compartmentalization is probably the brain, followed by male and female genital tracts and possibly the lung, kidney, liver, gut, and lymph nodes (Table 1). A fourth potential barrier posed by the tissues is that immune responses to HIV may differ in certain tissues (such as brain and testes) compared to blood. Fifth, penetration of antiretroviral drugs may be reduced in certain tissues (including brain, spleen, lymph nodes, gut, and genital tissues) compared to blood. Finally, these differences between the blood and tissues in the number and phenotype of infected cells, viral variants, immune responses, and drug levels suggest that mechanisms of HIV persistence may vary between the tissues and blood and that the tissues may respond differently to therapies aimed at treating or eradicating HIV.

The following sections review HIV infection by organ system, including the nature of the infected cell types, evidence for infection in

untreated and (where it exists) ART-treated individuals, evidence for compartmentalization, and evidence for differences in immune responses or ART levels. This entry concludes with a discussion of the cell and anatomic origins of the low-level residual plasma virus that persists on ART and the virus that rebounds after interruption of ART.

Lymph Nodes

In untreated as well as ART-treated patients, the lymph nodes (LN) are one of the largest reservoirs of infected cells. HIV infection has long been associated with lymphadenopathy and pathologic changes in the LN (Wood 1990). In 1986, HIV proteins and viral particles were detected in the germinal centers of LN in follicular dendritic cells (FDCs) and the extracellular network of immune complexes, leading to the first suggestion that FDCs may be a reservoir for antigen (Tenner-Racz et al. 1986) and may spread virus to new T cells or nodes (Spiegel et al. 1992). Though one study did not find convincing evidence of viral replication in sorted FDCs (Tenner-Racz et al. 1994), human FDC can be productively infected *in vitro*, and FDCs from infected rhesus monkeys show budding virus and can infect donor cells (Sprenger et al. 1995). Moreover, HIV particles have been detected between FDCs and in endosomes and the cytoplasm of FDCs, where they could escape recognition by CD8 + T cells (Tacchetti et al. 1997). One early study detected p24 in high endothelial cells of the paracortical postcapillary venules and in mononucleated cells of paracortex and germinal center (Baroni and Pezzella 1987), while another study found HIV RNA in FDCs, lymphocytes, and rare macrophages but not endothelial cells (Spiegel et al. 1992). In Thai patients infected with HIV subtype E, Langerhans cells and Langerhans-related dendritic cells appear to harbor most HIV RNA and protein in LN (Bhoopat et al. 2006). Several studies also suggest that the location of the virus may also change over the course of the disease (Tenner-Racz et al. 1989; Fox et al. 1991; Hurtrel et al. 1994) and that the LN may contain

large numbers of latently infected CD4⁺ T cells (Embretson et al. 1993; Peng et al. 1995).

In untreated humans and primates, the LN are infected early and contain a particularly large burden of HIV. After mucosal infection of rhesus monkeys, LN are seeded within 3 days of infection, prior to systemic viremia (Whitney et al. 2014). In a postmortem autopsy study of multiple tissues from 16 AIDS patients, HIV DNA was detected most often in LN (100%) and spleen (100%), followed by lung (93.8%) and colon (87.5%) (Sei et al. 1994). Several studies have suggested that the LN contain substantially higher copies of HIV RNA and DNA than the blood (Chun et al. 1997). One study reported that the HIV RNA level in the LN was 110-fold greater than in blood, which was attributed to higher CCR5 and CXCR4 expression in the LN (Nokta et al. 2001). The burden of HIV in the LN may also affect pathogenesis (Beer et al. 1996) and disease progression (Chakrabarti et al. 1994; Pantaleo et al. 1994).

Despite suppressive ART, HIV DNA and RNA persist in the LN. Though 3-drug therapy results in an exponential 3-log decrease in HIV RNA in LN, with a half-life only slightly longer than the blood (6 vs. 1.9 days) (Lafeuillade et al. 1996), HIV RNA and DNA can still be detected in the LN after years of ART (Wong et al. 1997a; Gunthard et al. 2001; Lafeuillade et al. 2001). One study also detected abundant amounts of HIV p24, p17, and gp120/gp41 in the germinal centers of LN after 5–13 months of suppressive ART, although HIV RNA was not detected in this study (Popovic et al. 2005). Several studies of ART-treated macaques have demonstrated that viral DNA and/or RNA levels are highest in LN and spleen (North et al. 2010; Horiike et al. 2012; Kline et al. 2013). In one study, SIV RNA levels in LN and spleen decreased much less than in plasma and gut, which was attributed to lower drug levels in these secondary lymphoid tissues (Bourry et al. 2010). Studies from humans also suggest that levels of some antiretrovirals may be low in LN (Cohen 2011).

It is unclear whether there is compartmentalization of virus between LN and blood. Some studies found differences between LN and blood

in viral sequences and drug resistance mutations (Haddad et al. 2000; Gunthard et al. 2001), while other studies have shown that HIV sequences in lymphoid tissues are similar to blood (Ball et al. 1994; van't Wout et al. 1998).

Spleen

Several studies from ART-treated primates suggest that the spleen is among the organs with the highest burden of residual infection. HIV DNA can be detected in CD4⁺ T cells and macrophages of spleens removed from HIV⁺ patients (McIlroy et al. 1996) and autopsied spleens of patients who die from AIDS (van't Wout et al. 1998), while HIV RNA can be detected in splenic macrophages of rhesus monkeys infected with SHIV (Igarashi et al. 2001). In one study of ART-suppressed, RT-SHIV-infected macaques, the highest levels of viral RNA and DNA were detected in the spleen, lymph nodes, and gut (North et al. 2010). In another study of macaques treated with ART after peak viremia, SIV RNA persisted in the spleen and lymph nodes despite significant decreases in the gut, and levels of lamivudine and indinavir were much lower in spleen compared to gut (Bourry et al. 2010).

Bone Marrow

HIV can infect various cells in the bone marrow, and HIV DNA can be detected in the bone marrow of ART-treated individuals. CD34⁺ progenitor cells (Folks et al. 1988), eosinophil precursors (Freedman et al. 1991), stromal fibroblasts (Scadden et al. 1990), and stromal macrophages (Gill et al. 1996) from human bone marrow can be infected with HIV-1 *in vitro*, leading to the first suggestion that the bone marrow may be a reservoir for HIV (Folks et al. 1988). During acute infection of rhesus macaques, bone marrow samples from days 3–14 showed SIV infection in marrow monocyte/macrophages of all animals, whereas low numbers of infected marrow CD3⁺ T cells were detected in some animals (Mandell et al. 1995).

In untreated HIV+ humans, infectious virus has been cultured from the bone marrow, although the primary source appeared to be the nonadherent fraction containing CD4+ T cells (McElrath et al. 1989). HIV DNA has been detected in different bone marrow populations, including CD4+ T cells, monocytes, CD4– lymphocytes, and rarely CD34+ progenitor cells (von Laer et al. 1990; Davis et al. 1991; Stanley et al. 1992) but not colony-forming cells of the granulocyte–macrophage lineage (Davis et al. 1991). In another study, HIV RNA was detected in bone marrow biopsies of 6/37 individuals, but localized to cells of the macrophage lineage (Weiser et al. 1996).

In humans on suppressive ART, HIV has been detected in the marrow but it is unclear whether progenitor cells constitute a reservoir. In ART-suppressed individuals, three studies detected HIV in cells from the bone marrow, but two studies did not detect HIV DNA in CD34+ progenitor cells (Durand et al. 2012; Josefsson et al. 2012), while another detected HIV DNA in CD133+ bone marrow progenitor cells from 6/11 patients (McNamara et al. 2013). Bone marrow mast cell progenitors can be latently infected with HIV, and one study detected infected mast cells in the placenta of ART-treated women (Sundstrom et al. 2007), although another study found no evidence of infected mast cells in multiple other organs (Nelson et al. 2009).

Thymus

Many studies in untreated individuals have demonstrated that HIV and SIV can infect different cells in the thymus. As early as 1987, HIV antigens were detected in the thymus of AIDS patients in cells that included multinucleated giant cells (Pekovic et al. 1987). In vitro, HIV can infect different human thymocyte populations (De Rossi et al. 1990; Schnittman et al. 1990) and possibly thymic epithelial cells (Numazaki et al. 1989a, b; Braun et al. 1996).

In untreated SIV-infected primates, viral DNA and RNA have been detected in the thymus (Baskin et al. 1991), and infectious virus can be

cultured from thymic tissue (Baskin et al. 1991), including thymic stromal cells (Muller et al. 1994); in one study, the main infected organs at 2 weeks were the thymus and spleen (Lackner et al. 1994). In untreated humans, HIV DNA (Mano and Chermann 1991), RNA (Burke et al. 1995) and infectious virus (Mano and Chermann 1991; Calabro et al. 1995) have also been detected in thymic tissue, and several studies found tissue-specific variants in the thymus (Calabro et al. 1995; Scinicariello et al. 2010). Thymic infection may also play a role in evolution of CXCR4-tropic virus (Salemi et al. 2007), disease progression (Rosenberg et al. 1994), and CD4 depletion or reconstitution on ART (Douek et al. 1998).

However, little evidence exists to support persistence of HIV or SIV infection in the thymus of ART-suppressed individuals. In one study of ART-suppressed macaques, neither SIV DNA nor replication-competent virus was detected in the thymus, although SIV DNA was detected in spleen and LN, and infectious virus was isolated from LN (Shen et al. 2003). In another study of SHIV-infected macaques on suppressive ART, Gag RNA was detected in the thymus in only 1 of 6 animals, and multiply spliced HIV RNA was not detected in the thymus (Deere et al. 2014).

Liver

Studies in untreated individuals have shown that HIV can infect cells in the liver, including Kupffer cells. Human liver sinusoid endothelial cells and macrophages express CD4 (Scoazec et al. 1990), and both can be infected with HIV-1 in vitro, while human Kupffer cells can be productively infected in vitro (Schmitt et al. 1990a, b). In rhesus monkeys infected with SHIV or SIVmac251, SHIV RNA can be detected in liver macrophages (Igarashi et al. 2001), and SIV protein as well as lentiviral particles can be detected in hepatic Kupffer cells and lymphocytes; in animals with advanced disease, Kupffer cells were the main cell type with HIV protein (Persidsky et al. 1994). In humans, one study detected HIV in the liver of some patients who died of AIDS (van't

Wout et al. 1998), while a second detected HIV RNA in 9/16 HIV+ participants (Blackard et al. 2011); the latter study also found evidence of compartmentalization between plasma and liver.

Gastrointestinal Tract

The gut may be among the earliest targets of HIV infection and one of the organs with highest numbers of infected cells, even in ART-treated individuals. It has long been recognized that HIV infection is associated with gastrointestinal symptoms, and as early as 1988, infectious virus was cultured from the gut of AIDS patients (Mathijs et al. 1988; Nelson et al. 1988). *In vitro*, HIV can productively infect colorectal carcinoma cell lines (Adachi et al. 1987), human ileal and colonic epithelial cells (Moyer et al. 1990), and submucosal mesenchymal cells (Moyer and Gendelman 1991). Intestinal epithelial cells express CCR5 and can transfer CCR5-tropic virus to other cells (Smith et al. 2003). The gut also contains a large proportion of the lymphoid tissue (up to 85%) and lymphocytes (up to 90%) in the body (Cerf-Bensussan and Guy-Grand 1991; Mowat and Viney 1997). Compared to CD4+ T cells from the blood, primary gut mucosal CD4+ T cells show increased susceptibility to *in vitro* infection with HIV (Lapenta et al. 1999; Poles et al. 2001a) and support higher levels of viral replication (Anton et al. 2000; Poles et al. 2001a), which has been attributed to greater CCR5 expression (Lapenta et al. 1999; Anton et al. 2000), T cell activation (Lapenta et al. 1999), and expression of CTLA-4. Human jejunal macrophages can also be infected with HIV and can produce virus, although they produce 2–3 logs less p24 than blood monocytes (Smith et al. 1997).

In untreated HIV+ patients, HIV has been detected in multiple different gut cell types. HIV RNA has been detected on cells that appeared to be enterochromaffin cells (Mathijs et al. 1988; Nelson et al. 1988; Levy et al. 1989), macrophages (Fox et al. 1989; Heise et al. 1993), giant cells (Heise et al. 1993), T lymphocytes (Fox et al. 1989; Heise et al. 1993), jejunal villus

enterocytes (Heise et al. 1991), and gastric epithelial cells (Liu et al. 2013). HIV proteins have been detected in gastric epithelial cells (Liu et al. 2013) and in duodenal and rectal cells (Ullrich et al. 1989; Jarry et al. 1990), including lymphocytes, macrophages, dendritic cells, and, in two patients, rectal gland cells that could be epithelial cells or immune cells (Jarry et al. 1990). Esophageal Langerhans cells are depleted in patients with stage 4 disease, suggesting that they also may be targets for HIV (Charton-Bain et al. 1999). In ART-suppressed patients, HIV DNA and RNA have been detected in gut CD4+ T cells and cells other than CD4+ T cells (Yukl et al. 2013), including CD13+ myeloid cells (Yukl et al. 2014); HIV DNA and p24 have also been detected in duodenal macrophages (Zalar et al. 2010).

Studies in untreated humans or primates have suggested that HIV infection of the gut occurs earlier and to a greater extent than infection in the blood or even the lymphoid tissues. In HIV-infected patients, CD4+ T cell depletion in the gut precedes that in the blood and is more pronounced (Lim et al. 1993; Schneider et al. 1995). In SIV-infected rhesus macaques, profound and rapid (within 7 days) loss of CD4+ T cells was observed in the lamina propria of the small and large bowel, prior to CD4+ T cell depletion in the blood, lymph nodes, or spleen, and more SIV RNA+ cells were observed in the intestine than in lymph nodes (Veazey et al. 1998). One study found that levels of HIV p24 were much higher in intestinal biopsies compared to serum, although HIV DNA (normalized to total cells) did not appear to differ between the intestine and blood (Fackler et al. 1998). In contrast, a study of patients with acute/early infection demonstrated that colonic CD4+ T cells harbor on average 13 times more HIV DNA and 10 times more HIV RNA than CD4+ T cells in peripheral blood (Mehandru et al. 2007), and a study of chronically infected patients found that HIV DNA levels are higher in the rectum compared to blood (d’Ettorre et al. 2011).

In ART-treated patients, multiple studies have documented persistence of HIV in the gut, and some have suggested differences from blood in responses to ART, levels of HIV-infected cells,

and mechanisms of persistence. One early study showed that ART did not seem to reduce the frequency of detection of HIV DNA, RNA, or infectious virus from rectal biopsies (Di Stefano et al. 2001). Another study found that early initiation of ART resulted in comparable reduction in HIV RNA in blood and rectum at 6 months, although clearance of HIV DNA was substantially reduced in rectum (Tincati et al. 2009). Two other studies detected HIV RNA in the gut (duodenum or rectum) of some ART-suppressed patients and found that HIV levels were not substantially different from those of untreated patients (Belmonte et al. 2007; Lafeuillade et al. 2009). Poles et al. (2001a, b) showed that HIV RNA and DNA levels in rectal biopsies appeared stable over 1 year of ART and calculated that the gut contained two times more HIV DNA+ cells than the blood (Poles et al. 2006). In patients suppressed on ART for up to 10 years, Chun et al. reported that HIV DNA levels per million CD4+ T cells were on average five to six times higher in the ileum compared to blood (Chun et al. 2008). A subsequent study of four different regions of the gastrointestinal tract determined that levels of HIV DNA and unspliced HIV RNA per million CD4+ T cells were higher (up to 12-fold) in all four gut sites compared to blood; differences in average transcription and the relation to immune activation suggested that different mechanisms control HIV persistence in the blood and gut (Yukl et al. 2010a). Based on the average level of HIV DNA across the four gut sites, this study estimated that the gut harbors 1.2×10^9 infected CD4+ T cells, or 83–95% of all HIV-infected cells in the body. Another study of 1–2 drug ART intensification suggested that the ileum, but not blood or other gut sites, might be a site of ongoing replication in some patients on ART (Yukl et al. 2010b). Finally, a recent study of RT-SHIV-infected, ART-suppressed macaques showed that gut tissues had the highest levels of multiply spliced HIV RNA and the ratio of multiply spliced to Gag RNA, while Gag RNA tended to be highest in the mesenteric lymph nodes (Deere et al. 2014).

Evidence suggests decreased penetration of certain antiretrovirals into the gut (Cohen 2011),

but it is unclear whether there is compartmentalization between virus in the gut and blood. Several studies have suggested compartmentalization between gut and blood (Poles et al. 2001a, b; Katzenstein et al. 2010; Lewis et al. 2013) and even between different regions of the gut (van Marle et al. 2007; McElrath et al. 2013), while other studies found no compartmentalization between gut and blood (Chun et al. 2008; Avettand-Fenoel et al. 2011; Imamichi et al. 2011).

Nervous System

HIV can infect different cell types in the brain and nervous system, and multiple studies suggest compartmentalization from blood. The frequent association between HIV infection and neurologic impairment has been recognized since the early days of the epidemic, and as far back as 1985, infectious HIV was cultured from cerebrospinal fluid (CSF) and brain of HIV+ men (Ho et al. 1985; Levy et al. 1985). In vitro, HIV can infect many different types of brain cells, including astrocytes (Rytik et al. 1991; Tornatore et al. 1991) and fetal neural cells (Harouse et al. 1989); productive infection has been demonstrated in fetal glial cells (Christofinis et al. 1987), human brain microglia (Watkins et al. 1990), and human brain capillary endothelial cells (Moses et al. 1993). One study found that astrocytes could not be productively infected (Sharpless et al. 1992), while another found that human fetal brain astroglial cells produce virus for a few days, but then revert to a latent state that can be reactivated to produce virus (Tornatore et al. 1991). Astrocyte infection has also been associated with disruption of the blood–brain barrier (Eugenin et al. 2011).

Infectious virus has been cultured from the CSF, brain, spinal cord, and peripheral nerves of untreated patients (Ho et al. 1985; Levy et al. 1985; Gabuzda et al. 1986); in one case, monocytoïd cells from the brain produced virus for as long as 100 days (Gartner et al. 1986). HIV DNA has been detected in the brain of AIDS patients (Pang et al. 1990), and HIV RNA has

been detected in brain macrophages, microglia, giant cells, astrocytes, oligodendroglia, and rarely neurons (Stoler et al. 1986; Rostad et al. 1987). One study detected HIV RNA and protein in brain capillary endothelial cells, mononuclear inflammatory cells, giant cells, and (in one patient) astrocytes and neurons (Wiley et al. 1986), while in other studies, HIV protein localized primarily to monocyte/macrophages (Gabuzda et al. 1986) and cells of the macrophage/microglial lineage (Kure et al. 1990). Several studies found that astrocytes harbored HIV nucleic acids and Nef or Rev protein but no Gag/Env (Saito et al. 1994; Tornatore et al. 1994) or rare mRNA for Gag/Pol (Ranki et al. 1995), suggesting a nonproductive infection limited to early regulatory genes, while Env protein could also be detected in macrophages and multinucleated giant cells.

One early study noted that isolation of infectious HIV from CSF did not correlate with isolation of virus from serum, suggesting that the brain may be a site of preferential viral replication (Hollander and Levy 1987). Many other studies have reported compartmentalization of HIV infection in the brain from that in the blood (Koyanagi et al. 1987; Cheng-Mayer and Levy 1988; Chiodi et al. 1989; Korber et al. 1994; Wong et al. 1997b; Strain et al. 2005; Harrington et al. 2009; Schnell et al. 2009). Moreover, HIV antibody levels and activity differ between the CSF and serum (Diederich et al. 1988).

HIV DNA and RNA have also been detected in the brain of ART-treated individuals. In one study, ART reduced the CSF HIV RNA to or near the limit of detection in nearly all patients, although the viral decay in CSF was slower than that in plasma (Spudich et al. 2005). However, HIV RNA has been detected in the CSF of patients on suppressive ART (Spudich et al. 2006; Kumar et al. 2007; Canestri et al. 2010), and both HIV DNA (Smit et al. 2004) and HIV RNA (Langford et al. 2006; Kumar et al. 2007) have been detected in brain tissue obtained at autopsy from individuals on ART. In two of these studies, viruses from brain (Smit et al. 2004) and CSF (Canestri et al. 2010) contained drug resistance mutations not found in the blood, further suggesting

compartmentalization in the nervous system. Finally, HIV persistence in the brain is suggested by several small case series of patients presenting with new neurologic symptoms (including encephalitis) associated with rebound of CSF virus despite up to 8 years of suppressive ART (Bingham et al. 2011; Peluso et al. 2012).

Lung

HIV DNA and RNA have been detected in lung cells from both untreated and ART-suppressed individuals, and limited evidence suggests compartmentalization from blood. *In vitro*, human embryo lung fibroblasts (Dolei et al. 1994) and alveolar macrophages can be infected with HIV (Coffey et al. 1997). In untreated individuals, HIV has been detected in lung CD8 + T cells (Semenzato et al. 1995) and macrophages obtained by bronchoalveolar lavage (BAL) (Sierra-Madero et al. 1994), and infection of alveolar macrophages has been associated with impairments in phagocytic and/or proteolytic function (Jambo et al. 2014; Cribbs et al. 2015). Another study detected HIV DNA in cells from BAL in 86% of HIV+ patients and found that levels of cell-free HIV RNA in BAL could be higher than serum, particularly in patients with opportunistic lung infections (Koziel et al. 1999). In one autopsy study of AIDS patients, HIV DNA was detected in the lung tissues and Env sequences showed compartmentalization from blood (van't Wout et al. 1998). HIV DNA and RNA have also been detected in alveolar macrophages from some ART-treated patients (Cribbs et al. 2015).

Vascular System and Heart

HIV can also enter endothelial cells from some tissues. *In vitro*, HIV can infect endothelial cells from human brain (productive) (Moses et al. 1993) and liver sinusoids (Steffan et al. 1992), but not lung (Kanmogne et al. 2001); umbilical vein cells are less permissive to infection (Lafon et al. 1993) but can

harbor HIV DNA and transmit infectious virus to CD4+ T cells (Scheglovitova et al. 1993). Human endothelial cells can enhance HIV replication in CD4+ T cells by 50,000-fold and can promote HIV replication in minimally activated (Choi et al. 2005) or resting CD4+ T cells (Shen et al. 2013). In untreated patients, one study detected HIV p24 in high endothelial cells of lymph node postcapillary venules (Baroni and Pezzella 1987), while another found no evidence of HIV RNA in lymph node endothelial cells (Spiegel et al. 1992). HIV DNA has also been detected in cardiac tissue obtained at autopsy from some patients with AIDS, and the infected cells resembled cardiac myocytes (Grody et al. 1990).

Kidney and Urine

HIV-infected cells can be found in the kidney, and limited evidence suggests compartmentalization as well as persistence on ART. HIV can enter HK2 cells and primary human renal proximal tubular epithelial cells in vitro, and these cells can transmit infectious virus to CD4+ T cells (Hatsukari et al. 2007; Mikulak et al. 2009). In rhesus macaques infected with SHIV or SIVmac251, viral RNA can be detected in renal macrophages (Igarashi et al. 2001), and SIV DNA can be detected in cultured primary kidney cells, which do not produce free virus but can transmit infectious virus to lymphoid cell lines (Lena and Luciw 2001). In small case series of untreated HIV-infected humans, HIV DNA and RNA were detected in renal glomerular and tubular epithelial cells as well as infiltrating leukocytes (Bruggeman et al. 2000; Marras et al. 2002). In two patients, HIV DNA Env sequences from infected renal epithelial cells showed clustering from viral sequences in the blood (Marras et al. 2002), and in one patient, HIV RNA was detected in tubular epithelial cells and glomerular podocytes after 3 months of suppressive ART (Winston et al. 2001). In one study of ART-suppressed individuals, HIV DNA was detected in the urine of 23% of patients (Chakrabarti et al. 2009). In another study of 19 ART-suppressed patients who

received renal transplants, HIV nucleic acids and viral particles were detected in podocytes and tubular cells of renal biopsies, and HIV DNA and RNA were detected in the urine (Canaud et al. 2014).

Male Reproductive Tract

HIV can infect different cells in the male reproductive tract, and some but not all studies suggest compartmentalization from the blood. HIV particles have been detected in the cell-free semen of AIDS patients at up to 10^8 particles/ml, levels higher than the plasma, leading to the suggestion that the male reproductive tract may be a reservoir (Borzy et al. 1988). Viral-like particles have also been detected in the prostate and testicle (Lecatsas et al. 1985) and in spermatozoa (Baccetti et al. 1991) of AIDS patients. HIV antigens have been detected in the testis, epididymis, and prostate of some AIDS patients in lymphocytic/monocytic cells, macrophages (Pudney and Anderson 1991), and, in one study (da Silva et al. 1990) but not others, rare positive foci that were thought to be degenerating germ cells and prostate glandular epithelial cells. HIV DNA has been detected in seminal mononuclear cells and in germ cells at all stages of differentiation (Muciaccia et al. 1998a, b; Shevchuk et al. 1998), including sperm (Bagasra et al. 1994), while HIV RNA (genomic, multiply spliced) has been detected in spermatogonia, spermatocytes, and rare spermatids and macrophages (Nuovo et al. 1994).

In macaques, SIV RNA and protein have been detected in the testes, epididymis, prostate, and seminal vesicles (Miller et al. 1994; Shehu-Xhilaga et al. 2007; Le Tortorec et al. 2008) within 14 days of infection; infected cells included macrophages, dendritic cells, T cells, germ cells (including spermatogonia), and, in one animal, Langerhans cells in the foreskin. Interestingly, immune responses varied by tissue and the testes showed little evidence of inflammation (Le Tortorec et al. 2008). HIV antibody levels are lower in semen compared to blood (Wolff et al. 1992), and testicular SIV-specific CD8+ T cells have reduced cytokine responses to

mitogens (Winnall et al. 2015), suggesting local immunosuppression in the testis.

In humans and primates on suppressive ART, several studies have demonstrated that HIV and/or SIV can still be detected in genital tissues and secretions. Despite suppression of HIV RNA in plasma, HIV RNA can be detected in the semen in 2–48% of men (Lafeuillade et al. 2002; Marcelin et al. 2008; Sheth et al. 2009; Halfon et al. 2010; Politch et al. 2012), sometimes in association with drug resistance mutations (Lafeuillade et al. 2002). Similarly, a subset of ART-treated, SIV-infected macaques continued to shed SIV in semen despite suppression in the plasma (Matusali et al. 2015). In this study, ART resulted in large decreases in SIV RNA in the prostate and vas deferens, smaller decreases in SIV RNA in the epididymis and seminal vesicle, and no decrease in SIV RNA in the urethra, where SIV RNA⁺ macrophages could be detected. However, ART had little to no effect on SIV DNA in any genital tissue, suggesting the presence of nonproductively infected cells.

It is unclear whether seminal fluid HIV RNA comes from genital tissues or blood, but multiple studies have suggested a local source and/or compartmentalization from plasma (van't Wout et al. 1998; Paranjpe et al. 2002; Smith et al. 2004; Coombs et al. 2006), suggesting a distinct reservoir. In contrast, one study in macaques showed that SIV RNA sequences were evenly distributed between the blood, LN, and genital tract (Fieni et al. 2013).

Female Reproductive Tract

HIV DNA and RNA can be detected in female genital secretions from untreated and ART-treated women, and some but not all studies suggest compartmentalization from the blood. The endometrial epithelial cell line HEC-1A can endocytose viral particles and infect underlying cells (Saidi et al. 2007), suggesting that epithelial cells may be involved in transmission. In vaginal biopsies of untreated Thai women infected with HIV subtype E, HIV p24 was detected in all patients; infected cells included Langerhans cells, Langerhans-related dendritic cells, and T lymphocytes (Bhoopat et al. 2001).

HIV can be detected in female cervical cells (Iversen et al. 2004) and genital secretions (Kovacs et al. 2001) of most untreated patients. In addition, HIV can be detected in genital secretions of 8–87.5% women on suppressive ART (Kovacs et al. 2001; Nunnari et al. 2005; Launay et al. 2011; Wahl et al. 2011; Fiscus et al. 2013), suggesting that some women may have a separate reservoir of HIV in the genital tract, perhaps due to reduced penetration of certain antiretrovirals (Taylor and Davies 2010; Else et al. 2011). Multiple studies have found evidence for compartmentalization between blood and female genital organs (Overbaugh et al. 1996; Tirado et al. 2004; Chomont et al. 2007; Bull et al. 2009), although another study found that compartmentalization in drug resistance mutations was not sustained over time (Kelley et al. 2010).

Breast and Breast Milk

It has long been known that HIV can be transmitted through breast feeding, though it is unclear whether HIV-infected cells in the breast milk arise from blood or breast tissue. Human mammary epithelial cells can internalize viral particles and transmit infection to activated CD4⁺ T cells (Dorosko and Connor 2010). Breast milk CD4⁺ T cells produce more HIV virus than CD4⁺ T cells from blood (Becquart et al. 2006), and the frequency of resting CD4⁺ T cells that can be induced to express HIV antigen is higher in breast milk than blood (Petitjean et al. 2007). In another study using breast milk from both untreated and ART-treated women, breast milk CD4⁺ T cells showed spontaneous expression of HIV antigens and could be induced by activation to produce supernatant HIV RNA (Valea et al. 2011), suggesting that spontaneous reactivation of latently infected breast milk CD4⁺ T cells may allow HIV transmission despite ART. Short courses of ART have been shown to reduce cell-free and cell-associated HIV RNA, but not HIV DNA, in breast milk (Lehman et al. 2008). One study of breast milk Env sequences demonstrated limited or no compartmentalization from plasma (Salazar-Gonzalez et al. 2011).

Skin and Adipose Tissue

In untreated HIV+ individuals, spliced HIV RNA (Giannetti et al. 1993), HIV antigens, and viral particles (Rappersberger et al. 1988) have been detected in epidermal Langerhans cells, though one study found equivocal evidence for HIV in these cells (Kalter et al. 1991). HIV DNA has been detected in the epidermis (Dusserre et al. 1992) and dermis, and virus has been cultured from skin (Rappersberger et al. 1988). A recent study also detected HIV DNA in CD4+ T cells from adipose tissue of ART-treated individuals (Couturier et al. 2015).

Origin of the Residual Virus and Rebound Virus

Two very important questions in understanding HIV persistence are the cellular and anatomic origins of the low-level plasma virus that persists on ART and the virus that rebounds after interruption of ART. One study found that the residual plasma HIV RNA sequences were rarely found in resting CD4+ T cells in blood, raising the question of whether the residual virus arises from other cell types or tissues, or whether it may have arisen from resting CD4+ T cells not sampled (Bailey et al. 2006). Some studies have suggested that the rebound virus arises from blood cells (Imamichi et al. 2001), while other studies have shown that in some patients, the rebounding plasma HIV RNA was distinct from sequences found in circulating latently infected cells (Chun et al. 2000; Zhang et al. 2000) and closest to virus in lymphoid tissues (Zhang et al. 2000). Another study found that the rebounding plasma HIV RNA did not match HIV DNA sequences found in a limited number of gut biopsies, although it is difficult to exclude an origin from elsewhere in the gut (Lerner et al. 2011). In one recent study, multiple foci of HIV RNA+ cells were detected in the gut or lymph nodes in half of the participants (often in more than one tissue) as soon as plasma HIV RNA was detectable, and sequence analysis of the blood revealed a large number of rebounding/founder viruses, suggesting the rebound virus arises simultaneously from many

cells at multiple sites (Rothenberger et al. 2015). However, the observation that different viral clones dominate in rebounding plasma virus during successive treatment interruptions (Joos et al. 2008) would require that, in the face of multicentric viral reactivation, stochastic or incompletely understood selective forces favor outgrowth of one or another viral population. It is unclear whether there is a dependence on the anatomic origins of individual clones and how well those particular tissues can amplify local viral populations.

Conclusion

Tissue reservoirs of HIV in the setting of suppressive ART are important both for their size and the diversity of the latently and chronically infected cell populations found in different sites, but their assessment is hampered by limited access to many tissues. Important differences in types of infected cells, viral genetic composition, local immune surveillance, drug levels, and mechanisms of persistence in different tissues are suggested by some studies but require confirmation and perhaps more systematic study. The development of new tools and approaches to quantify and characterize these tissue reservoirs would greatly facilitate development of future strategies for HIV eradication and permit more comprehensive assessment of responses to interventions aimed at cure.

bNAbs and have a greater magnitude of the intratype antiviral activity of ADCMI.

Introduction

Many HIV-2-infected patients are able to control the progression of the infection more effectively than most HIV-1-infected subjects. In many HIV-2-infected patients, the viral load remains below limits of detection and CD4 T-cell counts remain normal; therefore, the disease progression may take decades (Marlink et al. 1994). Although HIV-1 and HIV-2 share several biological features, such as the ability to bind to CD4 molecules, T-cell and mononuclear cell tropism, and a high degree of genetic variability (Huang et al. 1991), the two viruses have differences in immunogenicity and evolution. Most HIV-2-infected patients generate high titers of broadly neutralizing antibodies (nAbs), whereas this is relatively rare in HIV-1 infection. This could be due to structural differences of the envelope (Env) between HIV-1 and HIV-2 and their effect on the antibody responses, consequently their impact on Env evolution, control of viral replication, and clinical outcome.

Similar to HIV-1 infection, there is a correlation between B-cell activation and depletion with CD4 cell loss in HIV-2 infection (Marcelino et al. 2008). However, in HIV-2-positive patients, polyclonal activation and total IgA antibody production do not increase (Marcelino et al. 2008). Furthermore, in HIV-2 infection, most of the IgA-producing B cells are activated in the intestinal lymphoid tissue and the production of total and HIV-2-specific IgA functions at a normal level, suggesting that in HIV-2 infection the gastrointestinal immune system is not as severely infected as in HIV-1 infection (Gordon et al. 2007).

In HIV-2 infection IgG1 and IgG2 are the predominant responding antibody subclasses (Marcelino et al. 2008). In most chronically HIV-2 patients, IgG1, IgG3, and IgA responses are generated against gp36 and the C2V3C3 region (Marcelino et al. 2008). The C2V3C3 region of HIV-2 envelope can exert an

Antibody Response to HIV-2

Definition

Neutralizing antibodies (nAbs) inhibit or neutralize the infectiveness of a virus or bacteria. **Broadly neutralizing antibodies (bNAbs)** are neutralizing antibodies, which are able to neutralize multiple strains of HIV. **Antibody-dependent complement-mediated inactivation (ADCMI)** is a cell mediated mechanism whereby an effector cell actively lyses a target cell, which has been bound by a specific antibody. It is one of the mechanisms through which antibodies control HIV infection. Compared to HIV-1-infected patients, more HIV-2-infected subjects develop

immunosuppressive activity on CD4 and CD8 T cells (Cavaleiro et al. 2007), which may result in the lower rates of immune activation and CD4 cell loss in most HIV-2-infected patients.

Neutralizing Antibody (nAb) Responses to HIV-2 Infection

A much greater proportion of HIV-2-infected patients develop nAbs, particularly broadly neutralizing antibodies, than do HIV-1-infected patients, and the pattern of neutralization over time differs between the two viruses (Bjorling et al. 1994). In HIV-1 patients the optimal titers of nAbs capable of neutralizing the autologous infecting HIV-1 strain were observed only briefly, approximately 5 weeks after primary HIV-1 infection. However, later in the infection most plasma samples fail to neutralize the patients' own circulating virus. In contrast, the neutralizing activity of HIV-2-infected patients against contemporaneous isolates is maintained at different stages of infection (Bjorling et al. 1994). One study showed that 68% of HIV-2-infected patients elicited nAb against R5 isolates, compared to 10–31% of HIV-1-infected patients (van Gils et al. 2009).

Potent neutralizing antibody activity against primary HIV-2 envelopes is mediated by IgG antibodies (Kong et al. 2012). It was demonstrated that there are significantly fewer glycosylation sites in the V4 region of several HIV-2 isolates, suggesting the reduced glycan shielding is an important factor in increasing the accessibility of HIV-2 envelope to neutralizing antibodies. In a cohort study, heterologous and autologous nAb responses were assessed over the course of 15 years. In this cohort, all the patients possessed high heterologous nAb titers, which were several log units higher than similar antibodies in HIV-1 infection, and a positive association between the nAb titer and viral load was observed. Furthermore, 78% of the patients exhibited high autologous nAb titers, suggesting high levels of antigenic stimulation (Bailey et al. 2006).

To this date only very few epitopes targeted by nAbs in HIV-2 have been identified and their sensitivity to neutralization verified. Many of the

HIV-2-specific monoclonal antibodies were shown to react potently with epitopes on the base of V3, V4, and the CD4-binding site (Kong et al. 2012). These nAbs frequently exhibited IC50s of 0.1 g/ml or less, suggesting that these epitopes in HIV-2 envelopes are more readily accessible to nAbs. Antibodies with these specificities may contribute significantly to the broad and potent neutralization observed in HIV-2-infected individuals. The V3 region of HIV-2 has only two glycosylation sites, whereas the same region in HIV-1 has four to five glycosylation sites to shield the virus from nAbs (Shi et al. 2005).

Antibody-Dependent Complement-Mediated Inactivation (ADDCMI) in HIV-2 Infection

Only very few studies have been conducted on antibody-dependent complement-mediated inactivation of HIV-2. A greater magnitude of the intratype antiviral activity of samples from HIV-2-infected subjects was contributed by antibody-dependent complement-mediated inactivation (ADDCMI) than seen in HIV-1 infection (Ozkaya Sahin et al. 2012). In the presence of complement, the antiviral activity was increased by 32-fold in HIV-2 intratype reactions, presumably due to the number and accessibility of Env spikes on HIV-2 virions. Compared to HIV-1, the spike on HIV-2 is more stable after budding (Ozkaya Sahin et al.); its Env is more accessible and has a thinner glycan shield (Shi et al. 2005). Furthermore, the coreceptor-binding site of the HIV-2 Env spike was shown to have a more open configuration, regardless of CD4 binding, compared to HIV-1 (Thomas et al. 2003). More efficient ADCMI in HIV-2 infection could be one of the main contributing factors to better host control of this infection.

Effect of Antibodies on Diversification of HIV-2 Envelope

Despite high evolutionary rates, there are more structural and functional constraints placed on

the HIV-2 envelope than for HIV-1. The mutations in gp125 and the C2V3C3 region (Skar et al. 2010; Barroso and Taveira 2005) mostly occur in synonymous sites in HIV-2, and they are rarely associated with the escape of the virus from nAbs (Skar et al. 2010). This could be related to weaker positive selection or even to negative selection (Barroso and Taveira 2005). Genetic diversification within HIV-2 occurs predominantly in the gp120 variable loops, V1/V2, V3, and V4. V1/V2 and V4 are the most prone to mutation. The variation in V3 is more prominent among isolates that utilize CXCR4 as a coreceptor (Lin et al. 2007). Unlike V1/V2 and V4 regions, which are able to tolerate insertions and deletions (Huang et al. 2005), the V3 length is highly conserved, i.e., 34–35 amino acid long (Ren et al. 2005), due to its critical role in HIV-2 interaction with the chemokine receptors (Lin et al. 2007; Huang et al. 2005). X4 isolates, which have a longer V3 loop by 1–3 amino acids, are more resistant to nAbs compared to R5 isolates (Marcelino et al. 2010). Amino acids FHSQ, located at V3 loop positions 315–318, interact with residues WCR, located at V3 stem positions 329–331, to form a conformational neutralizing epitope (Bjorling et al. 1994). The insertion of the 1–3 amino acids immediately after the FHSQ sequence results in the inappropriate assembly of this target epitope and consequently resistance to nAbs (Marcelino et al. 2010). Thus during the R5 to X4 transition in HIV-2 infection, significant changes occur in the charge, size, and conformation of the HIV-2 V3 loop, resulting in prevention of nAb binding to target epitopes (Shi et al. 2005). Since the C2 and C3 regions are well exposed in HIV-2, they are under strong selection for diversification and hence may be presumed to harbor nAb epitopes (Barroso and Taveira 2005). Observations suggested that 22% of the amino acids in C2, 24% in V3, and 36% in C3 were exposed to antibody recognition. Among amino acids 319/320 and 328 in the V3 loop, which are involved in coreceptor binding, only amino acid 319 was reasonably well exposed. Generally, C2 and C3 diversification in HIV-2 are subject to more structural and functional constraints, and consequently, mutations are thought to have a

negative effect on virus fitness (Barroso and Taveira 2005). This could be one of the essential differences in the biology of the two HIVs and their interactions with the host immune system and consequently the outcome of the disease.

Conclusion

Production of bNAbs and ADCMI response are higher in HIV-2-infected patients than in HIV-1 positive subjects. Furthermore, many mutations in HIV-2 envelope occur in synonymous site, resulting in either weaker positive selection or even negative selection, which could have an adverse effect on the fitness of the virus. All these factors can contribute to an effective immune control of viral replication in many HIV-2 positive individuals.

Definition

Drug distribution through the body is not homogenous. Restricted penetration of antiretroviral drugs into anatomic compartments, such as the secondary lymph nodes and gut-associated lymphoid tissue that are primary sites of HIV replication, may be a mechanism of viral persistence in HIV-infected persons despite potent suppression of HIV replication in plasma with antiretroviral therapy. Strategies to increase antiretroviral drug delivery to reservoir compartments that improve pharmacokinetics and enhance pharmacodynamics may achieve the full suppression of HIV production, which is a prerequisite to long-term remission or eradication of HIV infection.

Introduction

In the fourth decade of the HIV epidemic, and despite remarkable advances in the treatment of HIV, the ability to eradicate the virus from an

infected individual still evades us. Combination antiretroviral therapy (ART) can achieve long-term suppression of plasma viral load to <50 copies/mL, the current goal of ART, and has reduced mortality and dramatically improved quality of life for HIV-infected persons. But immune reconstitution is incomplete, and these HIV-infected individuals continue to have abnormal vaccine responses, a higher-than-normal incidence of non-AIDS cancers and an increased risk of clinical diseases associated with chronic inflammation (e.g., cardiac disease) (Fletcher et al. 2014). The secondary lymph nodes (LN) and gut-associated lymphoid tissue (GALT) are the primary sites of HIV replication and where the latent pool of virus is maintained. This chapter will describe the physiology and HIV-associated pathophysiology of the lymphoid system, mechanisms of drug penetration into lymphoid tissues, present current human data on antiretroviral (ARV) penetration into lymphoid tissues, and discuss strategies to enhance ARV concentrations into lymphoid tissues.

Physiology and HIV-Associated Pathophysiology of the Lymphoid System

The lymphoid organs, lymphatic vessels, and the lymph comprise the lymphatic system. The bone marrow and thymus are the two primary lymphoid organs where lymphocytes originate or mature. Secondary lymphoid organs are LN, spleen, and mucosal-associated lymphoid tissues (MALT), of which the GALT is the largest and best defined component, and bronchial-associated lymphoid tissues (BALT). These secondary lymphoid organs maintain mature naïve lymphocytes and are where acquired immune responses are initiated. They are located in areas more likely to be invaded by pathogens, such as the gastrointestinal tract, respiratory tract, and genitourinary tract. The lymphatic vessels comprise a one-way transport system for fluid and proteins by collecting them from the interstitial space and returning to the blood circulation (Yanez et al. 2011). Lymph forms as interstitial fluid moves into the lymphatic capillaries and then drains into the collecting

vessels, which pass through at least one but usually several clusters of LN. Lymph nodes are small encapsulated organs located along the pathway of lymphatic vessels. They serve as filters through which lymph percolates on its way to the blood. Collecting vessels drain into larger trunks, which lead into the lymphatic ducts. The lymphatic ducts return the lymph back to the bloodstream, completing the circuit of fluid transport. The major functions of the lymphatic system are maintenance of normal tissue fluid balance, absorption of lipids and fat-soluble vitamins from the intestine, and attraction and transport of immune cells.

HIV causes a persistent, chronic infection in LT, which becomes a significant reservoir where virus is produced, stored, and persists in latently infected cells capable of virus production upon reactivation (Fletcher et al. 2014). The LT compartment is also the major site where CD4⁺ T cell depletion occurs and pathologic changes from virus replication significantly limit the ability of ART to fully reconstitute the immune system. Normal immune function is dependent on the anatomic structure of secondary LN. The anatomy of the paracortical T cell zone of secondary LN is of particular importance. Viral replication primarily occurs in resting and activated CD4⁺ T cells of the paracortical T cell zone in LN and GALT and triggers an inflammatory response. The persistent state of immune activation initiates and maintains collagen formation in the paracortical T cell zone. Collagen deposition into the parafollicular T cell zone and the resulting fibrosis are a significant cause of CD4⁺ T cell depletion in the untreated individual and a significant cause of impaired immune reconstitution despite good control of viral replication. Collagen deposition and immune dysfunction occur in a disease stage-dependent fashion; increasing levels are directly correlated with progression toward AIDS and inversely with the degree of immune reconstitution that can be expected when ART is implemented.

Lymphoid Tissues as Reservoirs for HIV

The secondary LN and GALT are the primary sites of HIV replication and where the latent pool of

virus is maintained (Fletcher et al. 2014). The reservoir of latently infected resting memory CD4⁺ T cells is established very early in the course of HIV infection. These resting cells do not actively produce virus, are not susceptible to the mechanisms of action of current antiretroviral drugs, and are a major barrier to a cure of HIV infection. Intermittent virus production from reactivation of latently infected CD4⁺ T cells is thought to be a source of low-level persistent or “blips” of virus detected in blood in well-suppressed patients on treatment. However, emerging evidence suggests it may be possible for cells in tissues such as the secondary LN and GALT to continue to produce low levels of HIV, despite ART suppression of plasma HIV RNA to undetectable levels (Chun and Fauci 2012). For example, in aviremic HIV-infected persons who had received long-term ART, there was incomplete recovery of CD4⁺ T cells in the GALT, and significantly higher levels of HIV-1 DNA normalized to CD4⁺ T cell count in GALT tissue than in either resting or activated CD4⁺ T cells in the blood (Chun et al. 2008). Additionally, there was a high degree of sequence similarity between virus in the GALT and virus in PBMCs, suggesting cross infection between the GALT and PBMCs. Others have shown similarity between HIV-1 sequences in the guts and plasma in HIV-1-positive individuals, suggesting that even with undetectable HIV-1 RNA in plasma, subjects still have ongoing replication in the gut and that there is equilibrium between these two compartments (Imamichi et al. 2011). Viral concentrations were higher along the entire GI tract as compared with the blood of HIV-infected subjects treated with ART, and ratios of unspliced RNA to DNA were lower in the colon and rectum of these subjects, compared with PBMCs, suggesting a low rate of HIV transcription (Yukl et al. 2010). Studies in SIV-infected macaques have identified mesenteric LN as a sanctuary site. For example, while effective suppression of plasma viral RNA was achieved in SIV-infected macaques treated with ART, detectable levels of virus in the spleens and LN were found (Horiike et al. 2012). Detectable vDNA and vRNA in LT, including mesenteric, axial, inguinal, iliac, and cervical LNs,

collected at necropsy have also been shown in aviremic ART-treated macaques infected with RT-SHIV and treated with efavirenz, emtricitabine, and tenofovir for 26 weeks (North et al. 2010). Recently, a sensitive immuno-PET radiotracer and whole-body imaging have been used in chronically SIV-infected, ART-suppressed macaques to detect and visualize areas of ongoing virus replication (Santangelo et al. 2015). After treatment, imaging studies revealed residual virus remained in the colon, spleen, male genital tract, nasal-associated LT, and individual LNs. qRT-PCR on these tissue samples confirmed the presence of residual virus or infected cells. Collectively, these human and animal data suggest there is persistence of viral replication in LT despite long-term, potent suppression of plasma viremia, and that such low-level continued viral replication could be sufficient to re-seed the reservoir and maintain a state of immune activation that impairs immune reconstitution.

Drug Penetration in Lymphatic Tissues

Drugs do not distribute evenly throughout the whole body. The reasons for this are complex and multifactorial. Absorption and distribution vary by drug and by location depending on the physicochemical properties of the drug, the size and rate of perfusion of the target site, and protein binding of the drug. Additional factors include whether a drug is a substrate of influx or efflux transporters, metabolic enzymes, and patient-specific polymorphisms for transporters and metabolic enzymes. These complex factors can lead to significant differences in drug concentrations in different compartments, as well as different drug concentrations in these compartments between patients.

Following oral administration, drugs enter the systemic circulation either through the portal vein or the intestinal lymphatic system. The majority of absorbed drugs are preferentially diverted into the portal blood because the rate of fluid flow in the portal blood is approximately 500-fold higher than the intestinal lymph. Drugs that enter the

systemic circulation through the portal vein are subject to hepatic first-pass metabolism, which can substantially reduce bioavailability. To penetrate into the lymphatic system, a drug appearing first in the blood must cross blood-lymphatic barriers. The fraction of drug that enters the LN can diffuse out with little resistance. In contrast, drugs successfully transported in the lymph avoid hepatic first-pass metabolism, and therefore lymphatic system transport can enhance oral bioavailability. Factors associated with greater intestinal lymphatic system absorption are higher molecular weights, particle size, lipophilicity (log octanol/water partition coefficients [log P values]), and long-chain triglyceride solubility (Yanez et al. 2011). Factors described in the literature particularly associated with greater absorption via the intestinal lymphatic system are higher molecular weights, particle size, and a log P value greater than five. All current oral ARVs are low molecular weight drugs (ranging from 247–776 Da.), and most have an experimental log p value <5. A series of studies with the protease inhibitor indinavir are illustrative of the importance of physicochemical properties in LT penetration. Indinavir (low molecular weight, log P value <5) is more rapidly cleared from lymph than plasma following oral administration to rats. LN mononuclear cell concentrations in three HIV-infected patients were only 25% those in blood and very similar to cerebrospinal fluid (CSF) (Freeling et al. 2015). Administration to macaques of a lipid-associated indinavir formulation with higher molecular weight, greater lipophilicity, and a larger particle size, all factors that favor distribution into lymph flow and accumulation in LN, increased concentrations in LN to >250% in those of blood and increased *in vitro* anti-HIV potency by twofold (Freeling et al. 2015).

Membrane transporters and drug-metabolizing enzymes play a significant role in drug disposition, clinical therapeutic responses both desired and adverse, and drug interactions. The small intestine (duodenum, jejunum, and ileum) is the primary site of oral absorption for most drugs and has been studied for the expression of drug influx and efflux transporters (Bruyere et al. 2010).

Various drug efflux transporters [e.g., P-glycoprotein (P-gp) and breast cancer resistance protein (BCRP)] and drug influx transporters (e.g., OATP1B1) have been identified in intestinal tissues. Considerable differences in expression for transporters including P-gp, BCRP, and MRP2 exist among patients and different sections of the gut. P-gp expression, for example, has been shown to increase from the duodenum to the ileum. The colon has higher expression of MCT1, OCTN2, and MRP3 than the small intestine. Human studies have shown considerable variation in cytochrome P450 (CYP) drug-metabolizing enzymes, including CYP3A4 expression, along the length of the gastrointestinal tract with the amount of CYP3A4 decreasing from the duodenum to the ileum and to the colon. Taken together, these studies show the expression of drug transporters and metabolizing enzymes is not uniform within the small intestine and along the gastrointestinal tract. Furthermore, a number of genetic polymorphisms in the drug transporter and drug-metabolizing enzyme genes have been identified. These data, therefore, provide a pharmacologic basis for inter-patient variability in ARV concentrations in LN and GALT, as well as regional differences in ARV concentrations such as between the ileum and rectum.

Multiple ARVs have been studied in various LT in humans. The available data, however, are sparse, and confirmatory studies of reported concentrations are generally lacking. This arises in part because while measurements of drug concentrations in plasma are easy to obtain, the concentrations in LT for a given drug are considerably more difficult to obtain and more complex to quantify. The lack of agreement on the best tissue matrix for quantitation of an ARV and the lack of standardization of analytical methodology for quantifying ARVs in LT among laboratories are additional challenges in interpreting the data and comparing reported values for the same drug of interest in tissue of similar anatomic origin. There are two commonly used strategies for measuring ARVs in LT: first, measuring drug concentrations within homogenates of tissue biopsies and, second, measuring ARV concentrations in mononuclear cells extracted from LT biopsies. homogenates are easier to obtain and to prepare for sample analysis. Cells extracted from tissue biopsies allow measurement of drug at the pharmacologic site of action within the target cell. Table 1 summarizes current LT concentration data of

ARVs obtained from human studies with orally administered ARVs that have been published. Data are from both single-dose and multiple-dose studies in HIV-infected persons as well as volunteers not infected with HIV. Ratios of tissue

(or cellular) concentrations of ARVs to blood plasma (or PBMC) concentrations widely vary. Nonetheless, some general observations can be drawn from these data. First, the penetration of ARVs into LT appears to be drug specific and not class specific as seen, for example, with the finding of substantially higher tenofovir-diphosphate (TFV-DP) concentrations in the ileum and rectum compared with emtricitabine-triphosphate (FTC-TP). Second, ARV penetration into LN appears to be lower than the ileum and rectum. With the exception of TFV-DP, tissue-derived MNC ARV concentrations have not been shown to exceed those in PBMC for any of the ARVs studied. Many of the tissue-to-blood plasma ratios derived by analyzing tissue homogenates for ARVs yield ratios >1 ; however, caution must be used when interpreting tissue homogenate concentrations as tissue homogenate may overestimate the amount of drug present at the pharmacologic site of action. Despite methodologic limitations, pharmacodynamic correlates with LT ARV concentrations exist. Multiple pharmacokinetic studies have found high concentrations of tenofovir (TFV) and in rectal cells and tissue homogenates (Table 1). Clinical studies have shown that orally administered tenofovir disoproxil fumarate (TDF) and emtricitabine (FTC) are highly effective in the prevention of HIV transmission among men who have sex with men, where the tissue of greatest pharmacodynamic relevance for prevention of HIV transmission is rectal (Grant et al. 2010).

The different physicochemical properties of the ARVs that affect penetration into the intestinal LT provide a pharmacologic basis to expect differences in concentrations compared with peripheral blood. The relevant physicochemical properties would generally predict poorer penetration into LN. Patient-specific factors, such as host genetic variability in drug-metabolizing enzymes or transporter function, are quite likely to be determinants of drug penetration as well. Finally, LN fibrosis as a pathophysiologic consequence of HIV infection might also contribute to ARV penetration into the LN. The emerging evidence that low-level replication of HIV may persist in tissues such as the secondary LN and GALT, despite ART suppression of plasma HIV

RNA to undetectable levels, and data that shows poorer penetration of ARVs into these tissues allow the hypothesis that virus might continue to replicate because ARV concentrations are insufficient to suppress replication fully.

Strategies to Enhance Drug Delivery to Lymphatic Tissues

The unique anatomy and physiology of the lymphatic system provide a number of drug delivery advantages over drug absorption via the portal blood. Some advantages include the ability to enhance bioavailability and systemic concentrations by bypassing hepatic first-pass metabolism, the delivery of sustained-release drugs, and, because of the role the lymphatic system plays in certain cancer metastasis, the ability to improve effectiveness of antineoplastic and immunomodulatory agents by achieving high concentrations and targeted delivery. The treatment of HIV infection might also be advanced by improved LT delivery of ARVs because of the role the secondary LN and GALT play in HIV pathogenesis. Strategies to enhance drug delivery to LT include (but are not limited to) structural modification of existing drugs, transporter or metabolism blockade, and targeted drug delivery with nanoformulations.

Structural Modification of Existing Drugs

Modifying the chemical structure of existing ARVs that have established safety and efficacy is an attractive approach to improve pharmacokinetic/pharmacodynamic properties in sanctuary sites. Tenofovir alafenamide (TAF; GS-7340) is a prodrug of tenofovir presently in clinical development that has improved penetration into LT. The drug displays variable absorption, with larger doses resulting in a greater percentage of the dose being absorbed than with lower doses, and is very stable in intestinal tissue. This is believed to be due to the ability of the drug to saturate intestinal transporters, including P-glycoprotein. After a single oral dose to beagle dogs, LN concentrations were 5–15-fold higher than after oral administration of TDF. TAF

achieved concentrations in PBMCs that were approximately 25-fold higher than a dose of 300 mg of TDF after oral administration to HIV-infected persons at a dose of 40 mg (Ruane et al. 2013). The significantly increased concentrations in PBMCs and in LT in animals (which is yet to be demonstrated in humans) observed with TAF appear to provide a clear illustration of the promise of structural modification of existing drugs to enhance antiviral activity in tissue compartments.

Transporter and Metabolism Blockage

Strategies to increase concentrations in sanctuary sites include use of drugs to block influx and efflux transporters or the metabolism of ARVs (Cory et al. 2013). Ritonavir and cobicistat have established roles in HIV pharmacotherapy as CYP3A enzyme inhibitors. *In vitro* research suggests that ritonavir and cobicistat also enhance intestinal absorption. Studies with Caco-2 monolayers (a cell line derived from human epithelial colorectal adenocarcinoma cells, commonly used in *in vitro* absorption studies) show increased transport of antiretrovirals including atazanavir, darunavir, and TAF across the monolayers. This is accomplished in part by inhibition of P-gp and BCRP. Similar findings have been observed for ritonavir. This inhibition of efflux transporters in the gut may lead to increased concentrations in plasma, but little is known if this will increase drug concentrations in compartments. The data discussed above for TAF and its ability to saturate intestinal P-gp efflux and achieve increased LT concentrations seems to provide such evidence. An abacavir prodrug dimer that can inhibit P-gp efflux has been designed to increase abacavir CNS penetration. *In vitro* assays, as well as a brain capillary model, found this molecule was able to inhibit P-gp in the cell culture system and is converted back to abacavir inside cells. This approach may be utilized for other ARVs as a means to increase penetration past the blood–brain barrier and perhaps other blood–tissue barriers. P-gp blockers have been studied as adjunctive treatment in cancer, but no clinical therapeutic benefit has been established to date.

Targeted Drug Delivery with Nanoformulations

The targeted delivery of drugs to increase therapeutic efficacy and limit off target toxicities is one of the most important objectives in modern pharmaceutical research. One approach is the incorporation of drugs into nanocarriers or nanoformulations. Nanoscale antiretroviral therapies, usually defined as ARVs formulated into particles with a size of less than 100 nm, have been proposed as an approach to increase concentrations and sustain delivery (i.e., increase the half-life) of ARVs in tissues and sanctuary sites. Human monocyte-derived macrophages (MDM) exposed to nanoformulations consisting of atazanavir, efavirenz, and ritonavir show rapid uptake of the ARVs and slow release over an extended time period (15–20 days) (Nowacek et al. 2010). These ARV nanoformulations can be utilized to establish drug depots for a sustained response, allowing for weekly and even less-frequent administration. Significant concentrations of ARVs are found in a variety of tissues, including the liver, spleen, kidneys, and lungs of animals for a number of days post-administration. As circulating monocytes and macrophages distribute throughout the body, including to the brain and secondary LT, this has been proposed as a means to overcome barriers preventing access of antiretrovirals (Nowacek et al. 2010). A folic acid-coated nanoformulation of atazanavir and ritonavir achieved higher and more sustained plasma and certain tissue concentrations of atazanavir at lower doses compared with a non-folic acid-coated nanoformulation (Gautam et al. 2014). A lipid nanoformulation containing lopinavir, ritonavir, and tenofovir has been evaluated in macaques (Freeling et al. 2015). Plasma and PBMC concentrations were higher and sustained for up to 7 days beyond that with free drug formulations. Importantly, the LN concentrations of lopinavir and ritonavir were substantially increased: lopinavir and ritonavir LN concentrations increased 1200-fold and 50-fold, respectively. In contrast, there was no difference in LN concentrations of tenofovir when given in the nanoformulation compared with the administration as free drug, probably because of limited encapsulation of this hydrophilic drug. No serious adverse

reactions were reported over 7 days of administration of this triple-ARV nanoformulation to macaques. The development of ARV nanoformulations may play an important role in overcoming barriers to achieving adequate concentrations of some ARVs in LT, and further study is clearly warranted.

Conclusions

Latently HIV-infected, resting CD4⁺ T cells are clearly a major impediment to eradication of HIV. However, sensitive HIV-1 RNA assays show viral production persists in some individuals with plasma viral load <50 copies/mL. LT have been shown to be viral reservoirs in nonhuman primate studies, and HIV RNA has been detected in human rectal samples and HIV DNA detected in GALT tissue of well-suppressed patients. Collectively, these findings indicate the existence of a reservoir of low-level viral replication in peripheral blood and LT. The different physicochemical properties of the ARVs that affect penetration into the intestinal LT provide a pharmacologic basis to expect differences in concentrations compared with peripheral blood. The relevant physicochemical properties and pharmacologic characteristics would generally predict poorer penetration into LT. Studies in HIV-infected persons and in animals have shown low concentrations of some ARVs in LT. These data provide a pharmacologic basis to hypothesize that inadequate concentrations of ARVs in LT allow low-level viral replication in LT of HIV-infected persons despite plasma viral load <50 copies/mL. Therefore, improving the pharmacokinetic and pharmacodynamic conditions of ARVs in LT seems to be a necessary antecedent to achieve the goals of complete remission or eradication of HIV infection.

Antiretroviral Drug Penetration into the CNS Compartment

Andrea Calcagno

Unit of Infectious Diseases, Department of Medical Sciences, University of Torino, Torino, Italy

Definition

The central nervous system is reached and infected a few hours after HIV infection. Viral replication occurs in perivascular macrophages, in microglia, and, although restricted, in astrocytes: neuronal damage is believed to be a consequence of neurotoxin production by the aforementioned cells of the immune system. Such cells are reached by antiretroviral drugs either directly (crossing blood–brain and blood–cerebrospinal fluid barriers) or through cerebral extracellular fluid (drained into cerebrospinal fluid); for several drugs, cerebrospinal fluid concentrations have been shown to reflect cerebral interstitial fluid concentrations. The penetration of several compounds into the central nervous system has been shown to be highly variable and to depend on drugs’ (molecular weight, lipophilicity, ionization, plasma protein binding, transport mechanisms) and patients’

characteristics (age, blood flow, blood–brain barrier permeability). Although the exact amount of drug necessary to inhibit viral replication in the central nervous system is currently unknown, antiretrovirals have been ranked according to their concentration/penetration effectiveness: higher scores have been repeatedly associated with lower cerebrospinal fluid HIV viral loads.

Introduction

HIV RNA has been recovered from the cerebrospinal fluid (CSF) few days after systemic infection and central nervous system (CNS) involvement parallels this event (Valcour et al. 2012). The presence of viral replication in perivascular macrophages, microglia, and astrocytes (restricted) is eventually associated with neuronal damage due to persistent immune activation and cytokine production. Inflammatory cytokines and chemokines have been found to be abnormally elevated in HIV-positive patients and they have been linked to the alteration of the blood–brain barrier (BBB) (Gannon et al. 2011). An impaired BBB might facilitate the penetration of HIV-infected monocytes, thus increasing the viral biomass in the CNS. Furthermore, CNS has been recognized as a site of compartmentalized viral replication: HIV may harbor different resistance-associated mutations in the CSF as compared to plasma (Canestri et al. 2010). Approximately 10% of treated patients have detectable HIV RNA in the CSF despite plasma viral control; the clinical and immunological consequences of this event in the absence of resistance-associated mutations are currently unclear (Edén et al. 2010).

The clinical endpoint of untreated CNS infection is the appearance of HIV-associated dementia (HAD). With the introduction of highly active antiretroviral therapy (HAART), the incidence of dementia significantly declined; nevertheless, cognitive impairment (asymptomatic and moderate according to the impact on everyday life and globally defined as HIV-associated neurocognitive disorders, HAND) remains highly

prevalent (Clifford and Ances 2013). Furthermore, 19–22.7% of subjects may progress to symptomatic neurocognitive impairment over a two-year follow up (Heaton et al. 2015).

Mechanisms of Drug Passage and Drug Measurement in the CNS

To be efficacious, drugs must reach adequate concentrations at the site of action: in the case of CNS infection by HIV, the targets are macrophages, microglia, and astrocytes within the brain parenchyma. After intestinal absorption, orally administered antiretrovirals (ARVs) (the vast majority of available drugs, with the exception of intravenous zidovudine and subcutaneous enfuvirtide) are transported by plasma proteins in the bloodstream and distributed to organs and tissues. The CNS receives approximately 14% of cardiac output, but two anatomical barriers can be found that prevent the free passage of drugs into the brain: the blood–brain barrier and the blood–CSF barrier. The first one is characterized by endothelial cells connected by tight junctions and by the presence of astrocytes end feet: several substances are restricted from crossing the BBB (Varatharajan and Thomas 2009). Nevertheless, in some areas in the brain (hypothalamus, area postrema, subfornical organ), tight junctions are not present and direct diffusion is possible.

The study of antiretroviral pharmacokinetics in the CNS has several methodological obstacles. For instance, data on tissue and intracellular drug concentrations are limited and most of the knowledge derives from cerebrospinal fluid measurements. Cerebrospinal fluid is believed to be produced by filtration from blood plasma (two thirds) and from brain extracellular fluid (one third). Several animal studies have suggested that cerebrospinal fluid is a surrogate reliable marker for most of the studied drugs although a significant variability in tissue levels prediction was observed. For instance, data in nonhuman primates suggest a good correlation between zidovudine CSF and brain parenchyma concentrations, while data for other ARVs are scarce.

Factors Affecting Antiretroviral Penetration into the CNS

Patient-related factors include age (older age may affect the passage of several drugs into the CNS due to reduced blood efflux, permissive BBB, and altered CSF flow) and BBB permeability. BBB impairment is often observed in HIV-positive patients: a permissive barrier may allow the passage of both drugs and plasma proteins, thus increasing the CSF total concentration but reducing the free drug levels, thus questioning its clinical impact; however, it has been shown to be significant for tenofovir, emtricitabine, and raltegravir.

Four chemical characteristics that affect drug passage have been identified: molecular weight (the smaller, the higher), lipophilicity (the higher, the higher, measured as octanol water distribution coefficient, LogP), ionization (the higher, the lower), and plasma protein binding (the lower, the higher). Several data confirm the effect of such drug-related features: a near direct linear correlation has been shown between plasma protein binding and CSF-to-plasma drug concentration ratios.

Several transporting proteins have been shown to be expressed at the BBB and at the blood–cerebrospinal fluid barrier (BCB) and to be involved in drug transport into the CNS: p-glycoprotein (P-gp); organic anion transporter 1, 2, and 3 (OAT1, 2, and 3); breast cancer resistance protein (BCRP); and others. Single nucleotide polymorphisms affecting such enzymes may affect drug penetration into the CNS although data showing such influence are very limited.

Antiretroviral Penetration in the CNS

Antiretrovirals' molecular weight, plasma protein binding, CSF-to-plasma ratios, and concentration/penetration effectiveness score (CPE, discussed below) are shown in Table 1 (Yilmaz et al. 2012; Eisfeld et al. 2013).

- NRTIs are small, poorly bound, hydrophilic molecules reaching very variable CSF-to-

plasma ratios. Tenofovir is ionized at physiological pH and this limits its uptake by membrane transporters. NRTIs are transported by organic anion transporters (OATs) that have been shown to be present at the choroid plexus (OAT1 and OAT3); the modulation of their activity (either by other drugs such as probenecid or by genetic polymorphisms in the encoding genes) may be relevant for zidovudine, stavudine, lamivudine, and tenofovir passage. With the exception of didanosine (whose CSF exposure has been found to be undetectable or very low), the other NRTIs have been associated with therapeutic CSF concentrations. Animal data suggested a good tenofovir CSF passage (through the blood–CSF barrier and independently of OATs) but a poor penetration into deep brain tissue; CSF tenofovir levels in humans are low and often undetectable.

- NNRTIs are small, lipophilic, highly protein-bound (with the exception of nevirapine) compounds. Efavirenz CSF levels are low (very close to the limit of detection of the instruments, thus suggesting undetectable concentrations) but frequently above 50% inhibitory concentrations (IC_{50}). While data on rilpivirine and etravirine are still limited, nevirapine high CSF-to-plasma ratios have been confirmed: the compound properties as well as the *in vivo* data suggest that nevirapine is one of the ARVs with the best CSF penetration.
- PIs are large, lipophilic, highly protein-bound (with the exception of indinavir) compounds with CSF-to-plasma ratios around 1%; they have been recognized as substrate of p-glycoprotein as well as OAT1A2 and this may limit drug accumulation into the CNS (as well as into other key tissues such as lymph nodes). Nowadays, the comparison among the three most used protease inhibitors favors darunavir and lopinavir since atazanavir was associated with low or undetectable CSF concentrations.
- Enfuvirtide is a synthetic 36-amino-acid oligopeptide (interacting with viral gp41) with a very large molecular weight: a single study and a case report confirmed CSF is very

low or undetectable in majority of patient samples.

- Maraviroc is a small, lipophilic, intermediately protein-bound compound that targets the human co-receptor CCR5 and is effective in preventing R5-tropic HIV virus entry. It is substrate of both cytochrome P450 3A4 and p-glycoprotein and drug-to-drug interaction, potentially affecting CSF concentrations, have been reported. The available data have been obtained with twice-daily different dosages (150 mg with PIs, 300 mg with NRTIs and nevirapine, and 600 mg with efavirenz or
- Integrase inhibitors are the latest ARV drug class and they are somehow heterogeneous: while all are small molecules and highly bound to plasma proteins, lipophilicity varies considerably (raltegravir is hydrophilic, while elvitegravir is lipophilic). So far, no data has been released on elvitegravir CSF exposure (a study is currently ongoing: ClinicalTrials.gov Identifier: NCT02251236) while a single study reported low dolutegravir CSF-to-plasma ratios (0.4%) but CSF concentrations

above IC_{50} in all samples (Letendre et al. 2014). Given raltegravir peculiar pharmacokinetics properties such as very wide inter- and intraindividual variability and an unclear concentration-dependant efficacy, its effectiveness in the CNS is still unknown.

Target Levels

The study of the pharmacodynamic effect of ARVs in the CNS is complicated by the absence of a clear pharmacodynamic target. The optimal marker would be the inhibition of HIV tissue replication in the whole brain parenchyma, although such marker is not currently available. Several other markers of CNS efficacy are currently being studied: CSF biomarkers, magnetic resonance imaging, astrocytes targeted positron emission tomography, and electroencephalographic rhythms. CSF HIV RNA and neurocognitive testing are currently used in clinical practice (Garvey et al. 2014).

The use of CSF HIV RNA as a marker of antiviral activity is the most commonly used marker since it is dramatically affected by HAART introduction and since the decrease in CSF replication parallels cognitive improvement in patients with HAD. Nevertheless, HIV replication may differ in different brain areas not accurately reflecting CSF levels. Furthermore, commercial kits for measuring HIV RNA have not been validated in the CSF and the threshold is unclear: second-generation methods can quantify as low as 20 copies/mL; very sensitive experimental techniques (quantifying 0.3–1 copies/mL) have been assessed showing residual CSF HIV RNA in a high proportion of subjects. This low-level HIV RNA in the CSF did not change after treatment intensification. However, subjects having the lowest viral load in the cerebrospinal fluid had the lowest levels of biomarkers of immune activation (such as neopterin, produced by macrophage-derived cells and believed to be a sensitive marker of CNS immune activation) (Dahl et al. 2014).

Cognitive function is analysed and monitored with neurocognitive tests; nevertheless, complete testing is time-consuming and it may be influenced by the choice of the control group and by learning effect (patients repeating slightly modified tests may perform better).

Given the inaccessibility of *in vivo* brain tissue, CSF inhibitory concentrations (IC_{50} , IC_{90} , and IC_{95}) have been used to compare the adequacy of ARVs exposure: these concentrations represent the level at which 50%, 90%, or 95% of viral replication is inhibited *in vitro* using wild-type viruses. However, these *in vitro* protein-free values have significantly variable values, and the same drug has been judged to reach optimal or insufficient concentrations in different studies when compared to different thresholds. Using standardized ICs, 95% inhibitory quotients (as CSF exposure divided by IC_{95}) have been described for several antiretrovirals: they represent how many times a drug overcomes the target level in a single patient. Patients with higher inhibitory quotients and detectable NRTIs had a better CSF viral control (Calcagno et al. 2015).

The CPE Score

The CNS penetration effectiveness score (CPE score) has been proposed by a large collaborative study group in the USA (the CHARTER group): in the revised 2010 version, ARVs were scored 1–4 (where 4 is the most neuro-effective drug, Table 1) according to drug characteristics, pharmacokinetics, and pharmacodynamic properties. In the last available analysis, several other demographic (race), clinical (current depression, current adherence to medications), and virological variables (plasma HIV RNA and duration of current HAART) have been added to CPE strata (<5, 5–10, ≥ 10), thus creating a “cerebrospinal fluid HIV risk score” (Hammond et al. 2014).

While in the original study it nicely correlated with the prevalence of CSF HIV RNA above 50 copies/mL, several other investigators have studied the composite CPE (obtained adding single drug scores to obtain a treatment score). Most

of the studies found a lower CSF HIV RNA with higher CPE score, while the effect on immune activation, MRI cerebral metabolite levels, and neurocognitive testing were less concordant among studies. Furthermore, only one study (out of three) found a correlation with CSF escape and CPE cutoffs are still debated.

Some limitations of the CPE score must be highlighted: the limited amount of evidence regarding PD data and regarding drugs' standard dosages, the absence of a clear cutoff, and the validation in patients receiving triple therapies and with fully sensitive viruses. As an example, a CPE corrected for plasma resistance-associated mutations was a better predictor (compared to standard CPE) of HAND in a cross-sectional study. For these reasons, some authors prefer not to use the aggregate CPE, but they suggest that treatment optimization in patients with CNS diseases may include drugs with individual elevated CPE score.

The CPE score may be a useful tool for choosing neuroactive antiretroviral drugs although with some limitations. Nevertheless, a recent review using rigorous methods found that neuro-HAART (i.e., a combination including ARVs with high CPE scores) was effective in improving neurocognitive function and decreasing CSF viral load (although only two of the included studies were adequately powered): this confirms the possible optimization of CNS treatment and calls for prospective, randomized, adequately powered studies (Cysique et al. 2011). The only randomized controlled trial trying to answer this question was prematurely interrupted for slow accrual (326 patients screened and 59 enrolled): CNS-targeted HAART was not associated with neither virological nor neurocognitive improvements although in patients with baseline-suppressed viral load, a trend for improved cognitive performances over time was observed (Ellis et al. 2014).

Efficacy in Monocytes, Macrophages, and Astrocytes

In vitro data suggest that the endogenous nucleoside pool in resting macrophages is smaller than

the one in activated lymphocytes and therefore that the effective phosphorylated NRTI levels required to inhibit HIV replication are lower. Some authors used in vitro effective concentration in acutely infected macrophages (EC_{50}) to calculate a "monocyte efficacy score": the obtained composite score was associated with neurocognitive performances and with the presence of HAND or minor motor cognitive disorders (Shikuma et al. 2012). Recent data challenging infected astrocytes with several NRTIs, NNRTIs, and raltegravir found that some drugs (zidovudine, lamivudine, and stavudine) may have inadequate inhibitory activity in astrocytes, with 90% inhibitory concentrations (EC_{90}) exceeding those achievable in the CSF.

These preliminary observations warrant further studies on the differential efficacy of ARVs according to target cells. Furthermore, the repeated association between HIV reservoir size (measured as PBMC- or monocyte-associated quantitative HIV DNA) and the prevalence of HAND support the implementation of specific drug strategies in selected patients (those with low CD4+ cells nadir, high HIV RNA zenith, and high cumulative viremia, for instance) (Valcour et al. 2013).

Conclusion

The infection of central nervous system immune cells by HIV is associated with severe long-term consequences. With the widespread use of highly active antiretroviral therapy, HIV-associated dementia is currently a rare AIDS-defining condition; less severe forms are however still common with multifactorial pathogenesis. Incomplete antiretroviral penetration into the central nervous system might be one of the reasons for compartmentalized infections and residual indirect neuronal damage. Several data has now associated lower central nervous system exposure (either measuring cerebrospinal fluid concentrations, ranking drugs according to the CPE, or monocyte activity scores) with detectable cerebrospinal fluid HIV RNA.

Antiretroviral Medications, Adult Care, and Treatment

C. William Wester

Vanderbilt Institute for Global Health (VIGH),
Vanderbilt University School of Medicine,
Nashville, TN, USA

Definition

Antiretroviral medication(s): There are currently five main groups of antiretroviral (ARV) medications used to treat HIV. They are called ARV medications because they act against the life cycle of the retrovirus HIV. The five groups are as follows (of note, they are categorized by how they interfere with the HIV life cycle with the sixth group/designation “multi-class combination products” containing different combinations of ARV medications from the main groups working against various components of the HIV life cycle):

1. *Entry inhibitors*: ARV medications in this class of ARVs effectively interfere with the receptor-mediated entry of the HIV virus into a cell. One subclass of entry inhibitors is the CCR5 antagonists; and the one medication approved for use currently in this subclass is maraviroc, with *viroc* standing for *virus occupying*. A new medication in this class, cenicriviroc, is currently in preclinical studies and may be available soon.
2. *Fusion inhibitors*: ARV medications in this class of ARVs effectively interfere with the receptor-mediated entry of the HIV virus into a cell. One subclass of entry inhibitors is the fusion inhibitors; and the one medication approved for use currently in this subclass is enfuvirtide (or T-20, Fuzeon); but this specific medication is only available in parenteral (subcutaneous injection) form.
3. *Reverse transcriptase inhibitors* (of which there are two types):
 - (i) *Nucleoside reverse transcriptase inhibitors (NRTIs)*: ARV medications in this class of ARVs are based on molecules that are converted in the cell to structures analogous to DNA bases, which are incorporated into the DNA strand transcribed by HIV polymerase (or reverse transcriptase) from HIV RNA but block the DNA from further elongation.
 - (ii) *Non-nucleoside reverse transcriptase inhibitors (NNRTIs)*: ARV medications in this class of ARVs are molecules that block the action of HIV reverse transcriptase by binding a pocket of the reverse transcriptase and distorting the shape of the molecule.
4. *Protease inhibitors (PIs)*: ARV medications in this class of ARVs inhibit the activity of the HIV protease, which is required by HIV to cleave the precursor HIV proteins produced by the infected cell to the smaller proteins required for the assembly of new HIV virions.
5. *Integrase strand inhibitors (ISIs)*: ARV medications in this class block the integration of viral DNA into the nucleus (host genome) of cells.
6. *Multi-class combination products*: multiple classes of ARV medications are available in

these multi-class combination products, with are widely utilized in resource-replete settings as follows:

- Genvoya™ (tenofovir alafenamide + emtricitabine + cobicistat + elvitegravir)
- Triumeq™ (abacavir + lamivudine + dolutegravir)
- Stribild™ (tenofovir + emtricitabine + cobicistat + elvitegravir)
- Odefsey™ (tenofovir alafenamide + emtricitabine + rilpivirine)
- Complera™ (tenofovir + emtricitabine + rilpivirine)
- Atripla™ (tenofovir + emtricitabine + efavirenz)

Combination antiretroviral therapy (commonly referred to as ART): The use of three or more active ARV medications that act on different stages of the HIV life cycle. ART promotes immunologic recovery (CD4+ cell count increase) and virologic control (markedly reducing/suppressing viral burden as measured/quantified by circulating plasma HIV-1 RNA or viral load levels) and helps prevent the development of potentially debilitating and life-threatening opportunistic infections (OIs).

NOTE: The summary text that follows is based on care and management of HIV-infected adults residing in resource-replete settings and is based on the most current “Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents (July 14, 2016)” (Panel on Antiretroviral Guidelines for Adults and Adolescents 2016).

HIV-infected adults residing in resource-limited settings (RLS) receive comprehensive care and treatment, and the summary text that follows is based on the World Health Organization’s (WHO) “Consolidated Guidelines on the Use of Antiretroviral Drugs for Treating and Preventing HIV Infection; Recommendations for a Public Health Approach” (release date June 2016) (Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection 2016). Of note, in these guidelines, based largely on published data from the recently completed START and TEMPRANO clinical

trials (TEMPRANO ANRS Study Group et al. 2015; INSIGHT START Study Group et al. 2015), the recommendation for care of HIV-infected persons residing in resource-limited settings is to provide lifelong ART to all children, adolescents, and adults, including all pregnant and breastfeeding women living with HIV, regardless of CD4+ cell count (Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection 2016). This is a significant change, and it is important to note that although numerous countries within sub-Saharan Africa and other resource-constrained settings have adopted *test-and-start* (also referred to as *test-and-treat*) strategies (specifically the initiation of ART in HIV-infected children, adolescents, and adults regardless of immune status/CD4+ cell count), some countries still recommend ART initiation based on a person's immune status and/or clinical disease staging, i.e., HIV-infected adult having a CD4+ cell count less than 500 cells/mm³ and/or having a WHO clinical stage 3 or 4 condition. Within the next few years, it is anticipated that these remaining countries in RLS will all have transitioned to *test-and-start*.

In addition, in RLS, the ARV medication options, especially when it comes to second-line therapy, are considerably more limited, with few protease inhibitors (primarily lopinavir/ritonavir (provided in heat-stable Aluvia™ capsules or Kaletra™ tablets) as well as atazanavir/ritonavir being available for second-line therapy in many settings with integrase strand inhibitors just beginning to be available in some settings. Laboratory monitoring also differs in that in many RLS, plasma viral load monitoring is still not uniformly available, so response to therapy as well as suboptimal response to therapy decisions is largely based on clinical (the development of an incident WHO clinical stage 3 or 4 condition) and/or immunologic (suboptimal CD4+ cell count response) criteria.

Introduction

Without therapy, most HIV-infected adults will develop progressive immunosuppression, as evidenced by markedly reduced CD4+ cell

count values and significantly elevated levels of circulating plasma virus (i.e., very high plasma HIV-1 RNA levels), leading to the development of AIDS-defining illness(es) and premature death (Panel on Antiretroviral Guidelines for Adults and Adolescents 2016; Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection 2016).

The availability of ART for the treatment of HIV infection has improved dramatically since the advent of highly active antiretroviral therapy (formerly referred to as HAART) in 1996 (Panel on Antiretroviral Guidelines for Adults and Adolescents 2016; Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection 2016). Due to the widespread availability of ART, millions of HIV-infected persons are now receiving lifelong ART and benefiting from significant reductions in HIV-/AIDS-associated morbidity and mortality (Panel on Antiretroviral Guidelines for Adults and Adolescents 2016; Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection 2016). In fact, as per the most recent UNAIDS data, at the end of 2016, there were an impressive 19.5 million persons accessing ART (Cohen et al. 2011). As a result, markedly fewer proportions of HIV-infected persons are dying from AIDS-related conditions, and what we are witnessing is a burgeoning epidemic of noncommunicable diseases (NCDs), specifically cardiovascular, kidney, liver, and other end-organ complications (including non-AIDS-associated malignancies) among persons receiving these potentially life-saving ARV regimens. In addition, due to slow progress in HIV vaccine development in light of very impressive ARV medication treatment efficacy data, ARV medications are now also being recommended to prevent HIV transmission or acquisition. Landmark clinical trials originally presented in 2011 documented the impact of ARVs in preventing HIV sexual transmission (Thigpen et al. 2013; Grant et al. 2010; UNAIDS fact sheet 2017). The HIV Prevention Trials Network (HPTN) 052 study found that HIV-infected persons initiating ART with CD4+ cell counts between 350 and 550 cells/

mm³ had an unprecedented 96% reduced risk of transmitting HIV to uninfected, stable sexual partners (Cohen et al. 2011). Clinical and prevention synergy was confirmed when early ART also reduced disease progression in infected individuals. Knowledge of one's HIV status is critical for personal decision-making. If one's HIV-infected partner does not take ART or an HIV-uninfected person is potentially exposed by a non-stable partner, ARV medications can be used orally or topically (microbicide) by uninfected, vulnerable persons themselves to prevent infection, i.e., pre-exposure prophylaxis (PrEP).

“When to Start” Based on the results of these and related treatment as prevention studies, current practice in resource-replete settings of the world is to initiate ART in all adults found to be HIV-infected regardless of their CD4+ cell count (Panel on Antiretroviral Guidelines for Adults and Adolescents 2016). There are certain priority medical conditions and/or clinical scenarios when HIV-infected adults should be offered immediate ART; these conditions/scenarios are listed below: (Panel on Antiretroviral Guidelines for Adults and Adolescents 2016; Panel on Opportunistic Infections in HIV-Infected Adults and Adolescents 2017; Zolopa et al. 2009; Makadzange et al. 2010; Boulware et al. 2014)

- *Pregnancy.*
- *AIDS-defining conditions* including HIV-associated dementia (HAD) and

AIDS-associated malignancies [**NOTE:** cryptococcal meningitis is a special case as based on published studies (Zolopa et al. 2009; Makadzange et al. 2010; Boulware et al. 2014) and on expert opinion, it is prudent to delay initiation of ART at least until after completion of antifungal induction therapy (the first 2 weeks) and possibly until the total induction/consolidation phase (10 weeks) has been completed (Panel on Opportunistic Infections in HIV-Infected Adults and Adolescents 2017). In addition, delay of ART may be particularly important in patients with evidence of increased intracranial pressure and/or in those patients with low

CSF white blood cell counts (Panel on Opportunistic Infections in HIV-Infected Adults and Adolescents 2017)].

- *Acute opportunistic infections.*
- *Lower CD4+ cell counts* (e.g., <200 cells/mm³).
- *HIV-associated nephropathy* (HIVAN).
- *Acute/early HIV infection* (if/when identified).
- *HIV/Hepatitis B co-infection.*
- *HIV/Hepatitis C co-infection.*

In terms of resource-constrained settings, numerous national public initiatives offering first-line combination antiretroviral therapy (ART) for HIV infection have commenced in sub-Saharan Africa since 2002 (Wester et al. 2009). In the African region (comprising the most current UNAIDS data from West, Central, East, and Southern Africa), which continues to bear the brunt of the HIV epidemic, more than 13.8 million persons were receiving potentially life-saving treatment at the end of 2016 compared to 50,000 persons approximately 14 years earlier (Cohen et al. 2011). Analyses from the region report favorable clinical/treatment outcomes and impressive declines in AIDS-related mortality among HIV-infected adults and children receiving ART (Wester et al. 2009).

HIV-infected adults residing in resource-limited settings (RLS) receive comprehensive care and treatment, and the summary text that follows is based on the World Health Organization's (WHO) “Consolidated Guidelines on the Use of Antiretroviral Drugs for Treating and Preventing HIV Infection; Recommendations for a Public Health Approach” (release date June 2016) (Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection 2016). HIV treatment recommendations in the current version of the WHO consolidated guidelines are largely based on published data from the recently completed TEMPRANO and START clinical trials (TEMPRANO ANRS Study Group et al. 2015; INSIGHT START Study Group et al. 2015), which showed the net benefit of initiating ART in HIV-infected adults having a CD4+ cell count of greater than 500 cells/mm³ compared to waiting until their CD4+ cell count

had declined to less than 350 cells/mm³. Specifically, in the START trial (INSIGHT START Study Group et al. 2015), a total of 4,685 patients were followed for a mean of 3.0 years. At study entry, their median viral load was 12,759 copies/ml, and the median CD4+ count was 651. Primary endpoint (serious AIDS events, serious non-AIDS events, or death) occurred in 1.8% of persons in the immediate group (immediate ART initiation – regardless of CD4+ cell count) versus 4.1% in deferred group (deferred initiation group – waiting until their CD4+ cell count declined to <350 cells/mm³), for a risk reduction of 57% (INSIGHT START Study Group et al. 2015). The protective effects/risk reduction of the immediate group was evident for both serious AIDS and serious non-AIDS events (greater for serious AIDS, TB, and cancer), and these findings were consistent regardless of age, sex, race, region of the world, as well as CD4+ cell count and viral load at entry (INSIGHT START Study Group et al. 2015) (NOTE: 54% of START trial participants were from low- and middle-income countries, and all 100% of TEMPRANO trial participants were enrolled in a West African setting, specifically Cote D’Ivoire (TEMPRANO ANRS Study Group et al. 2015; INSIGHT START Study Group et al. 2015)). In the TEMPRANO trial (TEMPRANO ANRS Study Group et al. 2015), immediate ART and 6 months of isoniazid preventive therapy (IPT) to eligible adults led to lower rates of severe illness than did deferred ART and no IPT, both overall and among patients with CD4+ cell count values of at least 500 cells/mm³. In summary, for HIV-infected children, adolescents, and adults residing in resource-constrained settings, the WHO consolidated guidelines (updated in June 2016) recommend the provision of lifelong ART to all children, adolescents, and adults, including all pregnant and breastfeeding women living with HIV, regardless of CD4+ cell count (Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection 2016). This is a significant change, and it is important to note that although numerous countries within sub-Saharan Africa and other resource-constrained settings have adopted *test-and-start* (also referred to as *test-and-treat*) strategies (specifically the

initiation of ART in HIV-infected children, adolescents, and adults regardless of immune status/CD4+ cell count), some countries still recommend ART initiation based on a person’s immune status and/or clinical disease staging, i.e., HIV-infected adult having a CD4+ cell count less than 500 cells/mm³ and/or having a WHO clinical stage 3 or 4 condition. Within the next few years, it is anticipated that these remaining countries in RLS will all have transitioned to *test-and-start*. The WHO has also expanded earlier recommendations to offer PrEP to selected people at substantial risk of acquiring HIV (Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection 2016). Alternative first-line ARV treatment regimens are also recommended, including an integrase inhibitor as an option in resource-limited settings and reduced dosage of a key recommended first-line drug, efavirenz, to improve tolerability and reduce costs (Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection 2016). Implementing these guidelines fully will have an unprecedented impact on preventing people from becoming newly infected and reducing the number of people dying from HIV-related causes over the coming years (Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection 2016). Based on these new *test-and-treat* (or *test-and-start*) strategy, initiating ART in all HIV-infected persons regardless of their immune status, the number of people eligible for ART increases significantly from 28 million to all 37 million people currently living with HIV globally (Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection 2016; UNAIDS fact sheet 2017). The new recommendations are aimed to aggressively address the lofty UNAIDS 90-90-90 goals, which aim to end the AIDS epidemic as a public health threat by 2030 (Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection 2016). Specifically, the 90–90–90 goals include i) 90% of the people living with HIV knowing their HIV status, ii) 90% of the people who know their HIV status receiving ART, and iii) 90% of the people receiving ART having fully suppressed viral loads (Consolidated

Antiretroviral Medications, Adult Care, and Treatment,

Fig. 1 Guidelines to start ART in Adults

4.3.1 When to start ART in adults (>19 years old)

Recommendation

- ART should be initiated in all adults living with HIV, regardless of WHO clinical stage and at any CD4 cell count (strong recommendation, moderate-quality evidence).
- As a priority, ART should be initiated in all adults with severe or advanced HIV clinical disease (WHO clinical stage 3 or 4) and adults with CD4 count ≤ 350 cells/mm³ (strong recommendation, moderate-quality evidence).

A

guidelines on the use of antiretroviral drugs for treating and preventing HIV infection 2016).

Please refer to the inserted Table below from the “Consolidated Guidelines on the Use of Antiretroviral Drugs for Treating and Preventing HIV Infection: Recommendations for a Public Health Approach; June 2016 (World Health Organization)” (Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection 2016).

All patients initiating ART, regardless of setting, should be willing and able to commit to treatment and understand the benefits and risks of therapy and the importance of adherence.

“What to Start” Resource-replete settings: In resource-replete settings, the current recommendations for first-line ART in adults are as follows:

Recommended First-Line Regimens (Panel on Antiretroviral Guidelines for Adults and Adolescents 2016):

1. **One integrase strand inhibitor (INSTI) + two nucleotide/nucleoside reverse transcriptase inhibitors (NtRTIs/NRTIs):**
 - DTG/ABC/3TC (TriumeqTM) — if HLA-B*5701 negative
 - DTG (TivicayTM) plus either TDF/FTC (TruvadaTM) or TAF/FTC (DescovyTM)
 - EVG/c/TAF/FTC (GenvoyaTM) or EVG/c/TDF/FTC (StribildTM)
 - RAL (IsentressTM) plus either TDF/FTC (TruvadaTM) or TAF/FTC (DescovyTM)

2. **Boosted PI + two NRTIs:**

- DRV/r (PrezistaTM) plus either TDF/FTC (TruvadaTM) or TAF/FTC (DescovyTM)

Alternative First-Line Regimens (Panel on Antiretroviral Guidelines for Adults and Adolescents 2016):

1. **One non-nucleoside reverse transcriptase inhibitor (NNRTI) + two nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs):**

- EFV/TDF/FTC (AtriplaTM)
- EFV plus TAF/FTC (DescovyTM)
- RPV/TDF/FTC (CompleraTM) or RPV/TAF/FTC (OdefseyTM)
(IF VL <100,000 AND CD4+ cell count >200)

2. **Boosted protease inhibitor (PI) plus two NRTIs**

- ATV/c (EvotazTM) or ATV/r (ReyatazTM) plus either TDF/FTC (TruvadaTM) or TAF/FTC (DescovyTM)
- DRV/c (PrezcobixTM) or DRV/r (PrezistaTM) plus ABC/3TC
(IF HLA-B*5701 negative)
- DRV/c (PrezcobixTM) plus either TDF/FTC (TruvadaTM) or TAF/FTC (DescovyTM)

Legend:

Integrase strand inhibitors (INSTIs)

DTG = dolutegravir

RAL = raltegravir

EVG = elvitegravir

Antiretroviral Medications, Adult Care, and Treatment,

Fig. 2 First-line ART for Adults

4.4.1 First-line ART for adults

Recommendations

- First-line ART for adults^a should consist of two nucleoside reverse-transcriptase inhibitors (NRTIs) plus a non-nucleoside reverse-transcriptase inhibitor (NNRTI) or an integrase inhibitor (INSTI).
- TDF + 3TC (or FTC) + EFV as a fixed-dose combination is recommended as the preferred option to initiate ART (strong recommendation, moderate-quality evidence).
- If TDF + 3TC (or FTC) + EFV is contraindicated or not available, one of the following alternative options is recommended:
 - AZT + 3TC + EFV
 - AZT + 3TC + NVP
 - TDF + 3TC (or FTC) + NVP (strong recommendation, moderate-quality evidence).
- TDF + 3TC (or FTC) + DTG or TDF + 3TC (or FTC) + EFV 400 mg/day may be used as alternative options to initiate ART (conditional recommendation, moderate-quality evidence). 
- Countries should discontinue d4T use in first-line regimens because of its well-recognized metabolic toxicities (strong recommendation, moderate-quality evidence).

^a Adults include pregnant and breastfeeding women, for whom additional guidance is found in Box 4.3.

3TC lamivudine, AZT zidovudine, d4T stavudine, DTG dolutegravir, EFV efavirenz, FTC emtricitabine, NVP nevirapine, TDF tenofovir
Source: Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection: recommendations for a public health approach. Geneva: World Health Organization; 2013 (<http://www.who.int/hiv/pub/guidelines/arv2013/download/en>).

Nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs/NtRTIs)

ABC = abacavir

3TC = lamivudine

FTC = emtricitabine

TAF = tenofovir alafenamide

TDF = tenofovir fumarate

Non-nucleoside reverse transcriptase inhibitors (NNRTIs)

EFV = efavirenz

RPV = rilpivirine

Protease inhibitors (PIs)

DRV = darunavir

ATV = atazanavir

Pharmacologic boosters

r = ritonavir (pharmacologic booster with intrinsic HIV activity but only at high doses)

c = cobicistat (pharmacologic booster without any intrinsic HIV activity)

NOTE: In terms of genetic testing, in resource-replete settings, ALL patients need to undergo HLA-B*5701 genetic testing prior to initiating abacavir to avoid the risk of potentially life-threatening hypersensitivity reactions that have been strongly associated with persons carrying the major histocompatibility complex (MHC) class I risk allele, specifically within the HLA-B serotype at position 57 (aptly named the HLA-B*5701 risk allele) (Panel on Antiretroviral Guidelines for Adults and Adolescents 2016; Mallal et al. 2008; Martin et al. 2007).

Resource-Limited Settings

For a summary of “what to start” among HIV-infected adults residing in resource-limited settings of the world, please refer to the most recent Consolidated Guidelines on the Use of Antiretroviral Drugs for Treating and Preventing HIV

Antiretroviral Medications, Adult Care, and Treatment,
Fig. 3 First-line ART Regimens for Adults

Table 4.2. First-line ART regimens for adults (see Annex 11 for doses)

Preferred regimen	TDF + 3TC (or FTC) + EFV
Alternative regimens	AZT + 3TC + EFV (or NVP) TDF + 3TC (or FTC) + DTG ^a TDF + 3TC (or FTC) + EFV ₄₀₀ ^b TDF + 3TC (or FTC) +NVP
Special circumstances ^{c,d}	Regimens containing ABC and boosted PIs

^a Safety and efficacy data on DTG for pregnant and breastfeeding women and TB coinfection are still pending.
^b Efficacy data for EFV at a lower dose of 400 mg/day in the case of pregnant and breastfeeding women and TB coinfection are still pending.
^c Special circumstances may include situations where preferred or alternative regimens may not be available or suitable because of significant toxicities, anticipated drug–drug interactions, drug procurement and supply management issues, or for other reasons.
^d Using stavudine (d4T) as an option in first-line treatment should be discontinued.
 3TC lamivudine, ABC abacavir, AZT zidovudine, DTG dolutegravir, EFV efavirenz, FTC emtricitabine, NVP nevirapine, PI protease inhibitor, TDF tenofovir.

A

Infection: Recommendations for a Public Health Approach; June 2016 (World Health Organization) (Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection 2016). The major “what to start” recommendations for adults are summarized in this table below:

Second-Line ART

Second-line ART for adults should consist of two nucleoside reverse-transcriptase inhibitors (NRTIs) + a ritonavir-boosted protease inhibitor (PI) (Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection 2016).

- After failure on a TDF + 3TC (or FTC)-based first-line regimen, use AZT + 3TC as the NRTI backbone in second-line regimens (Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection 2016).
- After failure on an AZT or d4T + 3TC-based first-line regimen, use TDF + 3TC (or FTC) as the NRTI backbone in second-line regimens (Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection 2016).

Use of NRTI backbones as a fixed-dose combination is recommended as the preferred approach (*strong recommendation, moderate-*

quality evidence) (Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection 2016).

- Heat-stable fixed-dose combinations LPV/r and ATV/r are the preferred boosted PI options for second-line ART (*strong recommendation, moderate-quality evidence*) (Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection 2016). **NOTE:** Presently, the most widely used boosted PI for 2nd line ART is heat-stable lopinavir/ritonavir (Aluvia™).

Please see below summary for second-line ART in resource-limited settings as outlined in the WHO consolidated guidelines (June 2016 revised version) (Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection 2016).

New Patient (Baseline Assessments)

Patients newly identified as being HIV-infected require an in-depth initial visit or two to determine their disease status (how much damage has been done to date to their immune system including identification of key comorbid medical conditions) as well as assess their overall psychological status (readiness to initiate ART).

Antiretroviral Medications, Adult Care, and Treatment,

Fig. 4 Summary of preferred second-line ART Regimens for Adults and Adolescents

Table 4.16. Summary of preferred second-line ART regimens for adults and adolescents

Target population	Preferred second-line regimen ^a	
Adults and adolescents	If d4T or AZT was used in first-line ART	TDF + 3TC (or FTC) + ATV/r or LPV/r ^{b,c}
	If TDF was used in first-line ART	AZT + 3TC + ATV/r or LPV/r ^{b,c}
Pregnant or breastfeeding women	Same regimens as recommended for adults and adolescents	
HIV and TB coinfection	If rifabutin is available	Standard PI-containing regimens as recommended for adults and adolescents
	If rifabutin is not available	Same NRTI backbones as recommended for adults and adolescents plus double-dose LPV/r (that is, LPV/r 800 mg/200 mg twice daily) ^d
HIV and HBV coinfection	AZT + TDF + 3TC (or FTC) + (ATV/r or LPV/r) ^b	

^a ABC and didanosine (ddI) can be used as NRTI back-up options but add complexity and cost without clinical advantages.

^b DRV/r can be used as an alternative PI option.

^c RAL + LPV/r can be used as an alternative second-line regimen (conditional recommendation, low-quality evidence).

^d Standard LPV/r and RTV-boosted saquinavir (SQV/r) doses with an adjusted dose of RTV (that is, LPV 400 mg/ RTV 400 mg or SQV 400 mg /RTV 400 mg twice daily) can be used as alternative options.

3TC lamivudine, ATV atazanavir, AZT zidovudine, d4T stavudine, FTC emtricitabine, LPV lopinavir, NRTI nucleoside reverse-transcriptase inhibitor, NVP nevirapine, PI protease inhibitor, r or RTV ritonavir, TDF tenofovir.

Antiretroviral Medications, Adult Care, and Treatment,

Fig. 5 Second-line ART in resource-limited settings

Recommendations

- Second-line ART in adults should consist of two nucleoside reverse-transcriptase inhibitors (NRTIs) plus a ritonavir-boosted protease inhibitor (PI).
- The following sequence of second-line NRTI options is recommended:
 - After failure on a TDF + 3TC (or FTC)-based first-line regimen, use AZT + 3TC as the NRTI backbone in second-line regimens.
 - After failure on an AZT or d4T + 3TC-based first-line regimen, use TDF + 3TC (or FTC) as the NRTI backbone in second-line regimens.
- Use of NRTI backbones as a fixed-dose combination is recommended as the preferred approach (strong recommendation, moderate-quality evidence).
- Heat-stable fixed-dose combinations of ATV/r and LPV/r are the preferred boosted PI options for second-line ART (strong recommendation, moderate-quality evidence).
- Heat-stable fixed-dose combinations of DRV/r can be used as an alternative boosted PI option for second-line ART (conditional recommendation, low-quality evidence). 
- A combination of RAL plus LPV/r can be used as an alternative second-line ART regimen (conditional recommendation, low-quality evidence). 

Source: Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection; recommendations for a public health approach. Geneva: World Health Organization; 2013 (<http://www.who.int/hiv/pub/guidelines/arv2013/download/en>).

At the time of initial evaluation, the following baseline assessments should be performed: (Panel on Antiretroviral Guidelines for Adults and Adolescents 2016; Aberg et al. 2014).

Resource-Replete Settings

Baseline laboratory testing (at time of entry into care): (Panel on Antiretroviral Guidelines for Adults and Adolescents 2016; Aberg et al. 2014)

- Comprehensive metabolic panel/chemistry (including blood urea nitrogen plus creatinine).
- Complete blood count (CBC).
- Urinalysis (and calculated creatinine clearance; current recommended formula is CKD-EPI (Inker et al. 2012)).
- Fasting lipid profile (total/HDL and LDL cholesterol + triglycerides).
- Fasting glucose or hemoglobin A1C testing.
- Hepatitis B screening (HBsAg, HBsAb, anti-HBc, or HBcAb) and those who are susceptible to infection should be vaccinated against HBV (**NOTE:** HBsAb should be repeated 1–2 months or at the next scheduled visit after the third vaccine was given to assess for immunogenicity; a second series of vaccine is recommended for patients whose HBsAb levels are negative/not detectable OR <10 IU/mL after the primary vaccine series) (Aberg et al. 2014).
- Hepatitis C screening (HCV antibody).
- Syphilis screening (VDRL/RPR).
- CD4+ cell count (absolute and percentages).
- Plasma HIV-1 RNA (viral load).
- HIV resistance testing (HIV-1 genotype).
- HLA B*5701 screening (**NOTE:** needs to be done before initiating ANY patient on abacavir but often routine practice to obtain in all patients at baseline).
- Toxoplasmosis prior exposure/screening (anti-toxoplasma IgG).
- Morning serum testosterone levels are recommended in adult men with decreased libido, erectile dysfunction, reduced bone mass or low trauma fractures, hot flashes, or sweats and should be considered in the setting of less specific symptoms (i.e., fatigue, depression).

Vaccine recommendations (Panel on Antiretroviral Guidelines for Adults and Adolescents 2016; Aberg et al. 2014) (**NOTE:** please refer to above laboratory testing section for information pertaining to hepatitis B vaccine recommendations):

- Hepatitis A vaccination is recommended for ALL susceptible men who have sex with men (MSM), as well as other susceptible persons (e.g., injection drug users, persons with chronic liver disease, travelers to countries

with high endemicity, *or* patients who are hepatitis B and/or C infected) (**NOTE:** hepatitis A total or IgG Ab should be repeated 1–2 months or at the next scheduled visit after the second vaccine to assess for immunogenicity).

- Varicella primary vaccination may be considered in HIV-infected, VZV-seronegative persons aged >8 years with CD4+ cell count values >200 cells/mm³.
- HPV vaccination is recommended for all females aged 9–26 years and all males aged 9–21 years.
- Pneumococcal vaccine is recommended (all should receive a dose of PCV13 (Pneumovax) followed by a dose of PPV23 (Pneumovax) at least 8 weeks later (**NOTE:** if previously vaccinated with PPV23, give PCV13 at least 1 year after PPV23; a second PPV23 dose is recommended 5 years after the initial/first PPV23 dose).
- Influenza vaccine annually (inactivated recommended; DO NOT use live attenuated intranasal vaccine (FluMist))
- Polio vaccine (for travelers to endemic areas) (**NOTE:** OPV contraindicated; use IPV)
- *Haemophilus influenzae* type B vaccine (**ONLY** if asplenic)

Sexually transmitted infection (STD) screening: (Panel on Antiretroviral Guidelines for Adults and Adolescents 2016; Aberg et al. 2014)

- All women should be screened for trichomoniasis, and all women aged ≤ 25 years of age should be screened for *Chlamydia trachomatis* infection.
- Men and women should be screened for gonorrhea and chlamydia infection at initial presentation and then annually if at risk for infection.

Additional screening:

- Cervical PAP smear (all HIV-infected women at time of entry into care and then repeat at 6 months and then annually if results normal): women with atypia (atypical squamous cells of unknown significance or cannot rule out high-grade intraepithelial lesion, atypical

glandular cells, low- or high-grade squamous intraepithelial lesions, or squamous carcinoma by Pap testing) should undergo colposcopy and directed biopsy, with further treatment as indicated by results of evaluation.

- Baseline chest radiography (CXR) should be done in all HIV-infected persons having a positive TB screening test result (**NOTE:** it may also be useful in other patients likely to have preexisting lung abnormalities).

Resource-Limited Settings

- Comprehensive metabolic panel/chemistry (needs to include at a minimum kidney (creatinine) and liver function (SGPT/ALT) testing)
- Complete blood count (CBC)
- Urinalysis (and calculated creatinine clearance; current recommended formula is CKD-EPI (Inker et al. 2012))
- Fasting lipid profile (total/HDL and LDL cholesterol + triglycerides) (**ONLY** when/if commencing a protease inhibitor-containing regimen)
- Hepatitis B screening
- Syphilis (RPR/VRDL) screening
- CD4+ cell count (absolute and percentage)
- Plasma HIV-1 RNA (viral load) (**when available**)
- Vaccines (pneumococcal, rotavirus, etc. when available/applicable)
- Chest radiography (optional but would consider obtaining in all patients at baseline)

Longitudinal Care/Assessments

Resource-Replete Settings

- Chemistry (every 6–2 months) (**NOTE:** includes serum Na, K, HCO₃, Cl, BUN, creatinine (including calculated estimated glomerular filtration rate (eGFR) using the CKD-EPI formula), glucose (preferably fasting))
- Complete blood count (CBC) with differential (every 3–6 months)
- Urinalysis (every 6 months if on TDF-containing ART)
- Fasting lipid panel (repeat annually if normal)

- Fasting glucose or hemoglobin A1C testing (repeat annually if normal)
- CD4+ cell count testing (every 3–6 months) (**NOTE:** reduce to every 12 months after initiated on ART in presence of consistently suppressed viral load if CD4+ cell count in 300–500 cells/mm³ range; if CD4+ cell count >500 cells/mm³ in a patient with consistently suppressed viral load, then CD4+ cell count testing is **OPTIONAL**)
- HIV-1 RNA (viral load): need to repeat 2–8 weeks after ART initiation or modification and then every 3–6 months (and also at time of treatment failure and/or when clinically indicated)
- Tropism testing (if considering a CCR5 antagonist)
- HLA*B5701 testing (if considering abacavir therapy)

Resource-Limited Settings

At the time of HIV diagnosis:

Recommended:

- HIV testing (serology for adults and children 18 months or older)
- CD4+ cell count
- TB symptom screening

Desirable (if available):

- Hepatitis B (hepatitis B surface antigen (HBsAg)) serology
- Hepatitis C virus (HCV) serology
- Cryptococcal antigen (if CD4+ cell count <100 cells/mm³)
- Screening for sexually transmitted infections (STIs)
- Pregnancy test to assess if ART initiation should be prioritized to prevent HIV transmission to the child
- Assessment for major noncommunicable chronic diseases (NCDs) and comorbidities

Follow-up (pre-ART initiation – if applicable):

- CD4+ cell count (every 6–12 months in circumstances where ART initiation is delayed)

At time of ART initiation:**Desirable:**

- Pregnancy test
- Hemoglobin test for starting AZT/ZDV
- Serum creatinine and calculated estimated glomerular filtration rate (eGFR) OR when starting TDF
- Alanine aminotransferase (ALT/SGPT) for starting nevirapine (NVP)
- Baseline CD4+ cell count

Longitudinally:**Recommended:**

- CD4+ cell count (every 6 months until clinically stable and then every 12 months thereafter)
- HIV-1 RNA (viral load): at 6 and 12 months post ART initiation and then every 12 months thereafter (and also at time of treatment failure and/or when clinically indicated)

Desirable:

- Serum creatinine and eGFR for TDF
- Pregnancy test, especially for women of child-bearing age not receiving family planning and on treatment with DTG or low-dose EFV

Opportunistic Infection Prophylaxis**Resource-Replete Settings**

- In general, all patients in resource-replete settings need to be initiated on routine prophylaxis to protect against *Pneumocystis jiroveci* (formerly *carinii*) (PCP) pneumonia and disseminated *Mycobacterium avium* complex (MAC) infection based on their level of immunosuppression (CD4+ cell count value) (Panel on Antiretroviral Guidelines for Adults and Adolescents 2016).
 - If CD4+ cell count <200 cells/mm³

Commence prophylaxis with one double-strength (DS) Bactrim (160 mgs trimethoprim/800 mgs sulfamethoxazole) per day (**NOTE:** also protects against toxoplasmosis infection)

(**NOTE:** For sulfa allergic patients, provide prophylaxis with oral dapsone 75–100 mgs daily; however, for severely sulfa allergic patients as dapsone still contains a minor sulfa moiety, one needs to prophylax for PCP with monthly aerosolized pentamidine treatments; some care providers may also opt to prophylax with atovaquone/mepron);

PCP prophylaxis may be discontinued in persons having a sustained (two or more successive readings) CD4+ cell count value of >200 cells/mm³.)

- If CD4+ cell count <50 cells/mm³

Commence prophylaxis with azithromycin (1200 mgs orally once per week; typically prescribed every Monday morning)

MAC prophylaxis may be discontinued in persons having a sustained (two or more successive readings) CD4+ cell count value of >100 cells/mm³.

Resource-Limited Settings

***Pneumocystis jiroveci* pneumonia (PJP) prophylaxis:** Cotrimoxazole (CTX) prophylaxis is recommended for adults (including pregnant women) with severe or advanced HIV clinical disease (WHO stage 3 or 4) and/or with a CD4 count ≤350 cells/mm³ (strong recommendation, moderate-quality evidence). In settings where malaria and/or severe bacterial infections are highly prevalent, cotrimoxazole prophylaxis should be initiated regardless of CD4 cell count or WHO stage (conditional recommendation, moderate-quality evidence). Cotrimoxazole prophylaxis may be discontinued in adults (including pregnant women) with HIV who are clinically stable on ART, with evidence of immune recovery and viral suppression (conditional recommendation, low-quality evidence) (Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection 2016).

Continuation of CTX prophylaxis regardless of ART status, age, CD4+ cell count, or WHO clinical stage in settings with a high prevalence of malaria and/or severe bacterial infections (SBIs) is also recommended based on data from randomized controlled trials, which show significant reduction in the risk of hospitalization, malaria,

and diarrhea among adults and children with HIV in settings with a high prevalence of malaria and/or SBIs (Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection 2016; Campbell et al. 2012; Polyak et al. 2014; Bwakura-Dangarembizi et al. 2014). In addition, the recommendation to continue CTX prophylaxis in settings with a high prevalence of malaria and/or SBIs may simplify HIV management, forecasting, and supply management issues. However, in settings where malaria is not endemic and/or the patient has not had evidence of severe bacterial infections, then CTX can be safely discontinued if the ART-treated adult has experienced immunologic recovery and/or viral suppression on ART (Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection 2016).

In settings where malaria and/or severe bacterial infections are highly prevalent, cotrimoxazole prophylaxis should be continued regardless of CD4 cell count or WHO clinical stage (conditional

recommendation, moderate-quality evidence). Routine cotrimoxazole prophylaxis should be given to all HIV-infected patients with active TB disease regardless of CD4+ cell count (strong recommendation, high-quality evidence).

Conclusions

In summary, the care and management of adults receiving potentially life-saving antiretroviral therapy (ART) is complex and requires considerable experience and training. Fortunately, comprehensive and frequently updated HIV ART-specific guidelines exist (Panel on Antiretroviral Guidelines for Adults and Adolescents 2016; Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection 2016) and are routinely available to healthcare providers. For complex care and management questions, it is always advisable to consult an expert/experienced HIV specialist (Table 1).

Antiretroviral Therapy and Drug Resistance in HIV-2 Infection

Francoise Brun-Vezinet¹, Sophie Matheron² and Diane Descamps¹

¹Laboratoire de Virologie, Service de Microbiologie, Bichat-Claude Bernard Hospital and University, Paris, France

²Service de Maladies Infectieuses et Tropicales, Bichat-Claude Bernard Hospital and University, Paris, France

Definition

This entry reports on the susceptibility of HIV-2 to antiretroviral drugs and debates about the management of antiretroviral therapy in HIV-2-infected patients.

Introduction

Human immunodeficiency virus type 2 (HIV-2) is known to be less pathogenic and far less prevalent than HIV type 1 (HIV-1). However, HIV-2 affects an estimated 1–2 million people in West Africa (Gottlieb et al. 2008). HIV-2 has a lower infectivity than HIV-1, which is likely to be related to lower viral RNA levels. Even though its rate of progression is slower than HIV-1 infection, with a greater proportion of long-term nonprogressors (Thiebaut 2010), HIV-2-infected patients may develop advanced immunodeficiency and experience adverse clinical events.

Most antiretroviral drugs have been designed for HIV-1 and may not provide optimal viral suppression of HIV-2 infection. Furthermore, no randomized trials have assessed when and how to treat HIV-2-infected patients. The natural resistance of HIV-2 to non-nucleoside reverse-transcriptase inhibitors (NNRTIs) and the lack of commercially available viral-load assays complicate the treatment and monitoring of HIV-2-infected patients.

Susceptibility of HIV-2 to Antiretroviral Drugs

HIV-1 and HIV-2 are related but differ by ~50–60% at the nucleotide level, with significant differences in amino acid sequences. The structures of reverse transcriptase (RT), protease (PR), and integrase (IN) of the two viruses are relatively similar, especially when the catalytic sites are considered. Many studies have described the development of HIV-1 resistance to all classes of antiretroviral drugs, but there is limited information regarding HIV-2, which is naturally resistant to enfuvirtide (a fusion inhibitor) and to all currently used NNRTIs. In addition, HIV-2 exhibits a low genetic barrier to nucleoside reverse-transcriptase inhibitors (NRTI) with more frequent selection of the Q151M NRTI multidrug resistance mutation, and it is intrinsically or partially resistant to several protease inhibitors.

Entry Inhibitors

The process of HIV-2 entry involves identical steps to HIV-1, including having similar virus–cell interactions, first between the HIV-2 gp105 envelope and CD4 receptor and then between the V3 loop of gp105 and the CCR5 or CXCR4 coreceptors. HIV-2 isolates can use a broad range of coreceptors to produce *in vitro* infection including CCR1, CCR2b, CCR3, CCR8, BOB/GPR15, and BONZO/CXCR6. Genotypic determinants of HIV-2 tropism located in the gp105 V3 loop were recently identified, and a strong association between HIV-2 phenotypic tropism and V3-loop sequences, which allow the prediction of CCR5- and/or CXCR4-tropic viruses in HIV-2 infection, has been reported (Visseaux et al. 2012). The four major genotypic determinants of dual/CXCR4 tropism identified are a mutation at residue 18, the V19K/R mutation, insertions at residue 24, and a V3 global net charge.

Maraviroc works by binding to the CCR5 coreceptor to prevent HIV-1 from entering the cell, but its use is limited to patients with CCR5-tropic viruses. The activity of maraviroc against the HIV-2 CCR5 virus has been recently evaluated using a phenotypic PBMC-based test:

TZM-bl reporter cells showed that maraviroc is active *in vitro* against CCR5 HIV-2 clinical isolates and has similar 50% inhibitory concentration values as HIV-1 (Borrego et al. 2012; Visseaux et al. 2012). However, discrepancies exist between studies and cell-line models with regard to determining tropism: in the Borrego study, the 90% inhibitory concentrations were found to be significantly higher than for HIV-1.

Regarding the fusion inhibitors, HIV-2 displays natural resistance to enfuvirtide. A recent study showed that enfuvirtide was 211-fold less active against primary HIV-2 isolates, which confirms and extends the previous results based on laboratory-adapted viral isolates (Borrego et al. 2012).

Nucleoside Reverse-Transcriptase Inhibitors (NRTIs)

Although most *in vitro* studies have shown that similar concentrations of NRTIs are needed to block both HIV-1 and HIV-2 replication (Witvrouw et al. 2004), a few published studies suggest that some drugs may not be as effective against HIV-2 (Reid et al. 2005). Many of the amino acid substitutions that are associated with NRTI resistance in HIV-1 also seem to be implicated for HIV-2. Amino acids at six positions in wild-type HIV-2 are analogous to secondary or accessory drug-resistant mutations in HIV-1 (69 N, 75I, 118I, 210 N, 215S, 219E). These residues may predispose HIV-2 to distinct evolutionary pathways when responding to drug treatments.

With regard to the thymidine analogues, zidovudine (ZDV) and stavudine, most studies have reported that HIV-2 and HIV-1 are equally sensitive to these in both culture and cell-free biochemical assays, whereas two reports suggest that HIV-2 might be relatively resistant to ZDV (Boyer et al. 2012; Reid et al. 2005). HIV-1 more readily incorporates ZDV and is more susceptible to ZDV than HIV-2, and higher concentrations of ZDV are needed durably to suppress the replication of HIV-2 compared to HIV-1 (Ntemgwa et al. 2009). Resistance to thymidine analogues does not follow the usual pathway of selection of mutations at positions 41, 67, 70, 210,

215, and 219. Instead, the selection of the Q151M multidrug-resistant mutation, which confers various levels of *in vitro* phenotypic resistance to almost all NRTIs except tenofovir, is frequently observed (Descamps et al. 2004). This mutation is also easily selected by didanosine. In combination with the mutation at codon 111 (V111I) – which can also occur as a natural polymorphism – this mutation confers high-level resistance to all NRTIs. Mutations at codon 215 (S215A/C/F/L/P/Y) can also be observed with thymidine analogues. However, mutations are rarely observed at positions 67 and 70 and never at positions 41 and 210. Several years ago, it was suggested that the mechanisms responsible for ZDV resistance are different for HIV-1 and HIV-2 and that the exclusion pathway plays a more important role in HIV-2 than selective excision. Recently, additional experiments have confirmed that although HIV-1 RT can adopt an exclusion- or excision-based resistance mechanism against ZDV, HIV-2 RT can only use the exclusion mechanism (Ntemgwa et al. 2009; Boyer et al. 2012).

Non-nucleoside Reverse-Transcriptase Inhibitors

HIV-2 is naturally resistant to all NNRTIs. Natural resistance of HIV-2 to NNRTIs is thought to be due to the Y188L polymorphism, which is naturally present in all HIV-2 isolates. Reversion to Y188 renders the RT of HIV-2 susceptible to some NNRTIs, including efavirenz and delavirdine. The NNRTIs (nevirapine, delavirdine, and efavirenz) and recently approved etravirine and rilpivirine possess limited activity against HIV-2 and are needed at effective concentrations of at least 50-fold higher than those that inhibit HIV-1, which renders the use of these drugs inappropriate for HIV-2-infected patients.

Integrase Inhibitors

The integrase inhibitors, raltegravir, elvitegravir, and dolutegravir, have shown *in vitro* activity against wild-type HIV-2 strains. The phenotypic susceptibility of clinical HIV-2 isolates to integrase inhibitors is similar to that of HIV-1, and this may be because the key catalytic motifs are fully conserved in HIV-2 at the genomic

positions described for HIV-1. Several naturally occurring amino acids in HIV-2 integrase, which are equivalent to secondary raltegravir or elvitegravir resistant-associated replacements in HIV-1, have been observed.

Recent biochemical and phenotypical studies have shown that HIV-2 resistance to raltegravir involves pathways (Y143C, G140S/Q148R, G140S/Q148H, N155H) previously identified as resistance determinants in the HIV-1 coding sequences. The N155H and G140S/Q148R mutations make similar contributions to resistance in both HIV-1 and HIV-2. The G140S mutation confers little resistance but compensates for the catalytic defect because of the Q148R mutation. Conversely, Y143C alone did not confer resistance to raltegravir unless E92Q was present. Furthermore, the introduction of the Y143C mutation into the N155H-resistant background decreased the resistance level of enzymes containing the N155H mutation. In addition, it was observed *in vitro* that the Y143C, Q148R, and N155H replacements in HIV-2 ROD9 integrase compromised viral replication capacity.

Protease Inhibitors (PIs)

Compared to HIV-1, HIV-2 expresses natural polymorphisms in the PR at positions 10I/V, 20 V, 32I, 33 V, 36I, 46I, 47 V, 63E/K, 71 V, 73A, 77 T, 82I, and 93 L, which may be implicated in drug resistance. Some natural polymorphisms, such as 46I and 47 V, give HIV-2 intrinsic resistance to amprenavir. Indeed, these mutations are also associated with amprenavir resistance in HIV-1, and several studies have shown that HIV-2 wild-type isolates reduce susceptibility to amprenavir compared to HIV-1 (Witvrouw et al. 2004).

Biochemical kinetic studies have demonstrated that protease inhibitors (PIs) bind to HIV-2 with a 10- to 100-fold lower affinity than to HIV-1, depending on the inhibitor. Studies have shown that the differences in phenotypes between wild-type HIV-2 and HIV-1 may depend on the PI being tested. Two independent studies have shown that only saquinavir, lopinavir, and darunavir have similar 50% inhibitory concentration values against the wild-type HIV-2 that are

within the same range as for HIV-1. Relative to the HIV-1 reference strain, the median 50% inhibitory concentrations of the HIV-2 wild-type isolates were 31-fold higher for amprenavir, eightfold higher for atazanavir, and three- to fourfold higher for indinavir and nelfinavir. However, there is controversy regarding tipranavir, with one study reporting natural resistance and another reporting full susceptibility. These data suggest that saquinavir, lopinavir, and darunavir may be preferred therapeutic options for HIV-2-infected patients. Drug selection studies in tissue cultures have shown that PR natural polymorphisms can accelerate the time to the development of resistance to several PIs, with selection of I54M, I82L, I84V, and L90M mutations responsible for reducing phenotypic susceptibility. As regards darunavir, there are currently not enough data on its resistance pathways, which affects the possibility of it being used as a sequential therapy.

To date, only one study has investigated whether mutations at Gag-PR cleavage sites can affect HIV-2 drug resistance in the same way as for HIV-1. Indeed, in HIV-2 PI-experienced patients, the presence at the baseline of A430V substitution in the NC/p1 gag cleavage site is associated with a worse virological response to lopinavir.

When to Start Antiretroviral Therapy

The optimal time to start antiretroviral therapy (ART) still needs to be defined: for many years, recommendations have been based on those used and validated for HIV-1 infection, and no randomized trials have addressed this question for HIV-2.

To date, the following arguments have been put forward for starting ART earlier than in HIV-1 infection:

- (i) The poor immunological response to a combined ART (cART) observed in several retrospective studies. In particular, a study compared HIV-2- and HIV-1-infected patients receiving a first cART and matched for factors associated with disease progression in HIV-1 infection: gender, age, HIV

transmission group, and period of treatment initiation (Drylewicz 2010). This study reported a lower increase in CD4-cell count during the first 2 months of treatment (+25cells/mm³/month for HIV-2 vs. +60 for HIV-1) and for the first year (-3 cells/mm³/year for HIV-2 vs. +46 for HIV-1). In addition, the plasma viral-load drop was three-fold more important in HIV-1 patients: [1.56 log₁₀/ml/month versus 0.62 among HIV-2 patients ($p < 10^{-4}$)]. Of note, there was no difference in baseline CD4-cell count depending on HIV type. Other non-comparative studies have reported a poor immunological response whatever the antiretroviral regimen tested, triple NRTI or a PI combination (Matheron et al. 2006; Benard et al. 2009, 2011). This dramatic difference in response to cART could be explained by the delay in giving therapy to these infected patients: the longer infection time before experiencing a decrease in CD4 compared to those infected by HIV-1 suggests that earlier treatment is needed, even if the ability of the antiretroviral drugs to reduce plasma HIV-2 RNA seems limited.

- (ii) Even if the proportion of HIV-2 long-term nonprogressors in clinical cohorts is higher than among HIV-1-infected patients (6% vs. 0.43%), a decrease in CD4-cell count occurs during the natural history of HIV-2 (Thiebault 2011). However, the slope is probably flatter than that for HIV-1, and the CD4-cell count threshold used for HIV-1 infection to start cART is reached later during the course of HIV-2 disease.
- (iii) Plasma HIV-2 RNA, which is less frequently detected in HIV-2-infected patients and is lower when it is detected (median 2.8 log copies/ml), as well as the lack of a commercially available assay, makes this virological response difficult to monitor. Nevertheless, plasma viral load seems to be predictive of clinical progression when it reaches a peak of 1000 copies/ml, whatever the CD4-cell count.

The current recommendations state that cART should be started in patients with a CDC stage

B or C infection and when the CD4-cell count is $<500/\text{mm}^3$. In patients whose plasma RNA is >1000 copies/ml in two successive samples, a closer follow-up is recommended, and if the slope of the CD4 decrease becomes steeper (even if this remains less steep than that seen in HIV-1 progression, which may be $>50/\text{year}$), then this can be considered as an indication for cART. As a minimum, treatment should be considered earlier in cases of hepatitis B or C coinfection, if the patient is aged >50 years or if there are cardiovascular risk factors, similar to the guidelines for HIV-1 infection (DHSS, Gilleece et al. 2010; Yeni 2010).

What Treatment to Start

Randomized trials are the only way to determine effective antiretroviral combinations for both antiretroviral-naïve and experienced patients; however, most data available for HIV-2 therapy are from small, observational studies (Gottlieb et al. 2008).

Given the resistance of HIV-2 to NNRTIs, the French and British guidelines recommend starting treatment with two NRTIs and a boosted PI, either lopinavir or darunavir (Gilleece et al. 2010; Yeni 2010). The US Department of Health and Human Services (DHHS) HIV treatment guidelines suggest starting with a boosted-PI regimen, but do not specify which drugs should be used – saquinavir, lopinavir, or darunavir performed in vitro against HIV-2 with the same efficacy as HIV-1. Successful treatment has been reported in patients receiving two NRTIs plus lopinavir/ritonavir or indinavir/ritonavir (Benard et al. 2009; Jallow et al. 2009). Lopinavir may select the V47A resistance mutation (Jallow et al. 2009), which makes the virus hypersusceptible to saquinavir but does not affect the efficacy of darunavir, thus suggesting that PIs could be introduced in sequence. With regard to darunavir, there are no data on the resistance mutations selected. The NRTI backbone of this first-line antiretroviral therapy may be tenofovir/emtricitabine (or lamivudine) or zidovudine/lamivudine. As in HIV-1 infection, tenofovir/ emtricitabine may be

preferred on the basis of its tolerability. In cases of failure, tenofovir will select the K65R mutation, which seems to preclude the development of thymidine analogue mutations as described for HIV-1. Finally, a good first-line regimen option would be tenofovir/emtricitabine/boosted lopinavir, as assessed by studies reporting a response rate of 60% in up to 96 weeks, based on CD4 and HIV-2 RNA composite endpoints (Benard et al. 2009).

Although there are no data that recommend the use of raltegravir as a first-line regimen, this compound, which has been proved to be active in vitro against HIV-2, may be a preferred option in association with the NRTI backbone as an initial therapy. Given its low genetic barrier to resistance, it may perform better at an earlier stage than as a second-line therapy, when resistance to NRTIs weakens its potency.

Current WHO guidelines suggest that two triple nucleoside regimens, zidovudine/lamivudine/abacavir and zidovudine/lamivudine/tenofovir, may be considered as alternative first-line treatments. This option can be considered in individuals living in sub-Saharan African countries with concomitant tuberculosis. The PI-sparing nucleoside regimens for treating HIV-2 infection may rapidly select the development of Q151M, K65R, and M184V, resulting in resistance to pan-NRTIs (Descamps et al. 2004). Recent data from retrospective European observational studies show a worse CD4-cell response to triple NRTI cARTs compared to a PI-based regimen (Benard et al. 2011).

Monitoring Treatment Response

Given its low rate of detection, plasma HIV-2 RNA alone cannot be used to assess treatment efficacy; response to treatment is usually evaluated using a composite of both immunological and virological criteria. In practice, the lack of a commercially available viral-load assay makes measurement of viral load more difficult to determine in HIV-2. A collaborative HIV-2 infection study group (ACHIEV2E) evaluated various

HIV-2 RNA assays used in nine different centers and found considerable variation between laboratories, particularly for HIV-2 group B (Damond et al. 2011). The genome of HIV-2 group B is very variable, which leads to possible under-quantification of viral-load assays.

Compared to HIV-1 patients, fewer HIV-2-infected patients have a detectable viral load; for example, the proportion of patients with a detectable viral load at enrolment in the French ANRS HIV-2 cohort was only 37% overall, ranging from 18% in patients with CD4-cell counts $>500/\text{mm}^3$ to 51% in those with counts $<300/\text{mm}^3$. In individuals starting treatment with undetectable HIV-2 RNA, the CD4-cell count may be the only method of monitoring the efficacy of the treatment regimen. However, data from the ANRS CO5 HIV-2 Cohort Study Group showed lower than expected CD4 cell recovery in HIV-2-treated patients, despite most patients achieving virological suppression. In practice, HIV-2 RNA should be interpreted together with the CD4-cell count when both considering and monitoring a treatment. A drop from the peak or a return to a baseline CD4-cell count is indicative, as for HIV-1, of failure.

Monitoring for drug resistance is difficult as commercial assays are not available and it is advisable to send specimens to a reference laboratory. The interpretation of resistance-genotyping results is limited by the absence of clinically validated algorithms, although two publicly available websites have started to establish rules for the interpretation of HIV-2 resistance genotype assays: <http://www.geno2pheno.org/> and <http://www.hivfrenchresistance.org/>.

The transmission of drug resistance in Portuguese HIV-2-infected patients has been reported to account for 3.3% of the drug-naïve population. This result suggests that routine baseline resistance testing should be considered before initiating the treatment of HIV-2-infected patients. Nevertheless, contrary to HIV-1, a standard list of mutations that characterize the epidemiology of HIV-2-transmitted drug resistance has not yet been established.

When and What Treatment to Switch to

As for HIV-1, optimization of sequential treatments must be individualized, and the choice of a second- and third-line therapy will depend on the results of the genotypic resistance assay. The interpretation of HIV-2 mutations, as previously stated, is based on *in vitro* studies, and there are few clinical case reports.

With regard to NRTIs, the choice will depend on whether Q151M and/or K65R have been selected in treatment failure. Tenofovir retains activity against the Q151M mutation selected by zidovudine, and zidovudine may be active when the K65R mutation is developed under the pressure of an initial tenofovir regimen. Although abacavir is probably an option when only the Q151M mutation is present, this will be compromised in the presence of K65R and M184V.

Extensive resistance should be assumed to include Q151M, K65R, and M184V, depending on the NRTIs employed in the first-line ART. For a second-line therapy, tenofovir, zidovudine, or abacavir, depending on the first-line regimen, may be used as the NRTI backbone with lamivudine or emtricitabine in spite of the frequent presence of M184V. There is no evidence that this mutation has the same impact on HIV-2 as it does on HIV-1.

When the first-line therapy is based on a boosted PI, interpretation of the genotypic resistance assay is based on very few data, which makes the choice of a second sequential PI difficult. Saquinavir or darunavir may be an attractive choice for second-line therapy after lopinavir-based ART. The choice of raltegravir as a second-line regimen will depend on the potential efficacy of the NRTI backbone, which is determined from the results of the genotypic resistance assay, although there is a risk of only a transient benefit if the viral load is high and resistance to NRTIs is already present.

Although the clinical efficacy of CCR5 inhibitors is still unknown, they could be considered as part of the third-line regimen if access to an HIV-2

tropism assay is available that allows the use of this ARV class.

Foscarnet may represent a therapeutic option for salvage therapy in patients with HIV-2 infection exhibiting multiclass drug resistance.

Special Circumstances

Mother-to-Child Transmission and Prevention

Several studies have reported a natural HIV-2 mother-to-child transmission (MTCT) rate very much lower than that observed for HIV-1, ranging from 0% to 4% (EPF 1994). Nevertheless, if ART must be started in pregnant women who have predictive factors for HIV progression, in the same way as for nonpregnant individuals, treatment is also recommended to prevent MTCT in all HIV-2-infected mothers: indeed, there is no way to assess case by case whether an undetectable HIV-2 plasma viral load will lead to an absence of MTCT. Even if the risk is very low, it can be reduced still further using a MTCT regimen adapted from those who have HIV-1, using a cART of two NRTIs and a PI whose efficacy has been demonstrated for HIV-2. Maternal cART can be started at weeks 26–28 of the gestation period (or earlier in women who themselves require treatment); zidovudine infusion or repeated zidovudine tablets can be given during labor, and zidovudine can be given to the infant for 4 weeks or for 1 week, depending on the North or South setting. Single-drug prophylaxis with zidovudine alone (during pregnancy and intrapartum) can be considered in case-by-case discussions as an alternative to prevent HIV-2 MTCT, in asymptomatic patients with no predictive factors for progression and an undetectable viral load in repeat assays. Of note, two cases observed among a French perinatal cohort were caused, respectively, by an untreated primary infection and by a regimen not adapted to HIV-2: these remind us of the risk of MTCT during such circumstances and underline the importance of using drugs active against HIV-2 in PMTCT regimens.

Dual Infection HIV-1/HIV-2

Only a few studies report on the response to ART of dually infected patients with both HIV-1 and HIV-2 infection. Even though HIV-1 should be considered the dominant virus, the efficacy of drugs against both viruses needs to be considered when selecting the ART regimen. Under this condition, cART seems to be as effective, in terms of virological and immunological response, as it is for patients infected with HIV-1 alone. In cases of dual infection, a baseline genotypic resistance test for HIV-1, and if possible for HIV-2, should be performed. Immunological and virological follow-up of both HIV-1 and HIV-2 in dually infected patients is highly recommended (Landman et al. 2009).

Tuberculosis

Most HIV-2-infected people live or originate from sub-Saharan African countries where tuberculosis is endemic, and available rifamycin curative therapy is limited to rifampin, which interacts with PIs, contraindicating its concomitant use. A cART regimen that is recommended for coinfection with HIV-1 includes NNRTIs, which do not work against HIV-2. In cases of HIV-2 coinfection, the current WHO recommendation is to consider a triple NNRTI regimen. Nevertheless, this cART regimen was shown to give a poor immuno-virological response in HIV-2-infected people in a retrospective European study; other cART regimens, including integrase inhibitors, provide an alternative that is being used in developed countries, even if this is not yet validated by clinical studies.

Conclusion

Not all antiretrovirals are effective against HIV-2. NNRTIs are inactive and the virus is at least partially resistant to some PIs. NRTIs seem to be equally active against HIV-1 and HIV-2, but different resistance pathways and the apparently easy selection of some resistant mutations make them a fragile backbone of the antiretroviral regimen. The reduced response to ART in HIV-2-infected patients raises the question of an optimal

antiretroviral drug regimen and of the best time to initiate treatment in HIV-2 infection. A better understanding of the differences in pathogenicity between HIV-1 and HIV-2 infections may improve the treatment of both these viruses. In addition, randomized controlled trials are ultimately needed to determine the optimal therapy for HIV-2, given the limited range of drugs available for this virus.

Antiretroviral Therapy for HIV-Infected Infants, Children, and Adolescents in Resource-Rich Settings

Sima S. Toussi¹ and Michael Rosenberg²

¹Division of Pediatric Infectious Diseases, Department of Pediatrics, NY Presbyterian Hospital – Weill Cornell Medical College, New York, NY, USA

²Division of Pediatric Infectious Diseases, Jacobi Medical Center, Albert Einstein College of Medicine, Yeshiva University, Bronx, NY, USA

Definition

The treatment of HIV-infected infants, children, and adolescents (ICA) mandates the use of a combination of antiretroviral drugs (ARVs) from two or more classes targeting different steps in the HIV life cycle. These classes include nucleoside reverse transcriptase inhibitors (NRTIs), nonnucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), integrase strand-transfer inhibitor (INSTI), and attachment/entry inhibitors. There are now 21 Food and Drug Administration (FDA) approved therapeutic agents available for pediatric and adolescent populations ≤ 17 years of age, with several of those medications available in child-friendly formulations such as suspensions, chewable tablets, and powders. In qualifying adolescents, the use of multiple ARVs combined into a single tablet, also known as single tablet regimens (STRs), may also be considered. The goals of combination antiretroviral therapy (cART), recommendations of when and why to initiate therapy, an overview of available ARVs, and relevant management strategies in HIV-infected ICA living in resource-rich countries (RRC) will be addressed in this entry. In this review, RRC are defined as per UN criteria (UN Statistics Division 2015).

Introduction

There are at least 3.2 million children under the age of 15 who are HIV infected, with most living in resource limited settings (RLS), (UNAIDS 2013). The global epidemiology of pediatric HIV has changed dramatically in recent years. While the rate of new HIV infections has decreased in infants worldwide, owing to the expansion and success of programs to prevent maternal to child transmission, the number of children living with HIV continues to expand. Increased access to cART, coupled with the availability of newer drugs with improved formulations, has profoundly decreased the morbidity and mortality associated with this infection and has allowed perinatally HIV-infected children (PHIV) to survive well into adulthood. The penetration of modern cART into pediatrics has helped these children live longer and has fostered the hope that therapy will prevent or at least mitigate the end-organ damage inflicted by long-term HIV infection. In RRC where there are markedly fewer infected newborns, the pediatric HIV population is presently composed of a growing population of aging, treatment-experienced PHIV individuals, and, alarmingly, a burgeoning population of behaviorally infected teenagers. In the USA, many of the new infections in adolescents and young adults are occurring in men who have sex with men (MSM) (DHHS 2015a Adolescent and Adult Guidelines).

Goals of Therapy

The aim of HIV treatment is to preserve immune function and health by effectively maintaining viral suppression. Optimal viral suppression is achieved when the viral load is driven below the limit of detection of the assay employed, typically <20 to <75 copies per milliliter (mL) of plasma. Uncontrolled viral replication leads to an impaired immune system and increases the risk of various infections and malignancies; it also results in chronic immune activation which is centrally implicated in the pathogenesis of HIV-related end-organ disease. In addition to restoring and

preserving immune function and preventing HIV-related morbidity and mortality, other goals of cART include: (1) the prevention and emergence of viral drug resistance; (2) minimization of drug-related toxicity; (3) maintenance of normal physical growth and development, and (4) improvement in quality of life. In the adolescent population, HIV treatment is also important to reduce the risk of sexual transmission to partners. Similarly, cART is essential for adolescent females considering pregnancy in order to prevent perinatal transmission.

Although the pathogenesis of HIV infection and principles of treatment are similar between children and adults, certain characteristics unique to pediatric HIV infection require fundamentally different approaches and strategies. These factors include, but are not limited to, HIV infection in the setting of an immature immune system, lack of appropriate formulations and poor palatability of ARVs, limited pharmacokinetic (PK) and pharmacodynamic (PD) data to inform dosing guidelines, age-specific differences in interpreting CD4 counts, significantly higher baseline viremias in perinatally infected infants, adherence issues, and patient and caregiver resilience and coping mechanisms.

Furthermore, due to advances in treatment, therapeutic goals have changed considerably, since early in the epidemic, from preventing short-term complications of HIV infection to a more long-term view of sustaining children during their entire lifespan. Current treatment guidelines and recommendations reflect this changing philosophy and are updated regularly to remain aligned with advances in the fields of basic and clinical HIV research.

When to Start Antiretroviral Therapy

Table 1 highlights the recommendations of when to start cART in ICA, according to the Paediatric European Network for Treatment of AIDS (PENTA) and the Department of Health and Human Services (DHHS) guidelines, informative resources for pediatric HIV providers (Bamford et al. 2015, DHHS 2015b Pediatric Guidelines).

Antiretroviral Therapy for HIV-Infected Infants, Children, and Adolescents in Resource-Rich Settings, Table 1 When to initiate cART in infants, children, and adolescents

Age	DHHS 2015	PENTA 2015
0–1 year	All	All
1–3 years	CD4 count <1,000 cells/mm, or CDC stage 2	CD4 count ≤1,000 cells/mm; CD4 percentage ≤25%
	Moderate HIV-related symptoms	CDC category B/C ^a , or WHO stage 3 or 4
	HIV VL > 100,000	
3–5 years	CD4 count <1,000 cells/mm, or CDC stage 2	CD4 count <750 cells/mm, CD4 percentage ≤ 25%
	Moderate HIV-related symptoms	CDC category B/C, or WHO stage 3 or 4
	HIV VL > 100,000	
6–17 years	CD4 count <500 cells/mm, or CDC stage 2	CD4 count <350
	Moderate HIV-related symptoms	CDC category B/C, or WHO stage 3 or 4
	HIV VL >100,000	

VL viral load

^aCDC categories B and C have been replaced by “moderate HIV-related symptoms” and “opportunistic illnesses in HIV infection,” respectively

The decision to initiate cART in the pediatric and adolescent population depends on age, clinical status, and immunologic parameters. Clinical status is determined by the presence of HIV-related symptoms which are classified as either moderate or severe in nature (Table 2). Immunological parameters considered in the algorithm of when to begin cART include CD4 count and HIV viral load (VL), which is partially captured in the Center for Disease Control’s (CDC) staging of HIV infection. The staging of HIV infection was revised and simplified in 2014 to include 5 stages: 0 (or early infection), 1, 2, 3 or unknown (Selik et al. 2014). Staging is based primarily on CD4 count for age (with CD4 % as alternative), but patients with a severe opportunistic illness (see Table 2) are automatically classified as stage 3. In the USA, a preference exists for CD4 counts over CD4 percentage since the former is considered to be a more reliable prognostic marker in children of all ages (Selik et al. 2014). The PENTA guideline places less emphasis on HIV viral load in the decision to treat. For those with HIV viral loads greater than 100,000 copies/mL plasma, the DHHS would recommend initiating treatment, whereas according to PENTA, treatment should be considered.

Both PENTA and DHHS recommend urgent initiation of treatment for all children less than 1 year of age due to the risk of rapid disease progression in this population. Urgent initiation,

within 1–2 weeks of diagnosis, is recommended due to the high risk of severe illness and death in infancy. A randomized clinical trial in South Africa found that early antiretroviral therapy in infants by 12 weeks of age reduced early infant mortality by 76% and HIV progression by 75% (Violari et al. 2008). Infants treated earlier also had better neurological outcomes than in those in whom therapy was deferred.

For children 1–5 years of age treatment is recommended if the CD4 count falls below 1,000 (CDC stage 2) or if there are moderate HIV symptoms. In Europe, children ages 3–5 can defer treatment until the CD4 count drops below 750. However, treatment should be started urgently, within 1–2 weeks, for any child in stage 3.

HIV disease progression in children aged 6 years and older is similar to adults. Recent studies in adults have shown that earlier initiation of cART, even before the CD4 count drops below 500, leads to better outcomes. Treatment results in improved immunologic health and decreased morbidity and mortality. The DHHS now endorses initiating cART in all HIV-infected adults, regardless of CD4 count, even if asymptomatic (DHHS 2015a Adolescent and Adult Guidelines). This approach results in improved immunologic function, decreased morbidity and mortality, and provides the added benefit of decreasing the risk of sexual transmission if all

Antiretroviral Therapy for HIV-Infected Infants, Children, and Adolescents in Resource-Rich Settings, Table 2 HIV-related symptoms

Moderate HIV-related symptoms

Anemia (hemoglobin <8/g/dl, neutropenia (white blood cell count <1,000/ μ l) and/or thrombocytopenia (platelet count <100 \times 10 ³ / μ l) persisting for \geq 30 days
Bacterial meningitis, pneumonia, or sepsis (single episode)
Candidiasis, oropharyngeal (thrush), persisting (>2 months) in children >6 months of age
Cardiomyopathy
Cytomegalovirus infection, with onset before 1 month
Diarrhea, recurrent or chronic
Hepatitis
Herpes simplex virus stomatitis, recurrent (>2 episodes within 1 year)
Herpes simplex virus bronchitis, pneumonitis, or esophagitis with onset before 1 month
Herpes zoster (shingles) involving at least 2 distinct episodes or more than 1 dermatome
Leiomyosarcoma
Lymphoid interstitial pneumonia or pulmonary lymphoid hyperplasia complex
Nephropathy
Nocardiosis
Persistent fever (lasting >1 month)
Toxoplasmosis, onset before 1 month
Varicella, disseminated (complicated chickenpox)

Stage 3 defining opportunistic illnesses in HIV infection

Bacterial infections, multiple of recurrent ^a
Candidiasis of bronchi, trachea, or lungs
Candidiasis of esophagus
Cervical cancer, invasive
Coccidiomycosis, disseminated or extrapulmonary
Cryptococcosis, extrapulmonary
Cryptosporidiosis, chronic intestinal (>1 month's duration)
Cytomegalovirus disease (other than liver, spleen, or nodes), onset at age >1 month
Cytomegalovirus retinitis (with loss of vision)
Encephalopathy attributed to HIV
Herpes simplex: chronic ulcers (>1 month's duration), bronchitis, pneumonitis, or esophagitis (onset at age >1 month)
Histoplasmosis, disseminated or extrapulmonary
Isosporiasis, chronic intestinal (>1 month's duration)
Kaposi sarcoma
Lymphoma, Burkitt (or equivalent term)
Lymphoma, immunoblastic (or equivalent term)
Lymphoma, primary, of brain
<i>Mycobacterium avium</i> complex or <i>Mycobacterium kansasii</i> , disseminated or extrapulmonary
<i>Mycobacterium tuberculosis</i> of any site, pulmonary, ^b disseminated, or extrapulmonary
<i>Mycobacterium</i> , other species or unidentified species, disseminated or extrapulmonary
<i>Pneumocystis jirovecii</i> pneumonia
Pneumonia, recurrent ^b
Progressive multifocal leukoencephalopathy
<i>Salmonella</i> septicemia, recurrent
Toxoplasmosis of brain, onset at age >1 month
Wasting syndrome attributed to HIV

^aOnly among children aged <6 years

^bAmong children \geq 6 years, adolescents, and adults

adults are started on cART immediately. In children ages 6–17, the CD4 count threshold at which to recommend cART initiation is unknown. At this time, guidelines recommend starting treatment in children and adolescents ≥ 6 years of age if the CD4 count is below 500 (or < 350 in Europe), in the setting of high-level viremia (VL $> 100,000$), or if there is evidence of moderate HIV-related symptoms. As mentioned previously, all children and adolescents experiencing immunologic decline that reaches CDC stage 3 thresholds should be started on cART immediately.

While these recommendations provide guidance on when to start cART, the DHHS also recommends the consideration of cART in all children aged 1 year and older, even if asymptomatic and at CDC stage 1. The risks and benefits of starting cART in asymptomatic children needs to be carefully considered. While there are many antiretroviral agents available for use in children, choices are still limited and the drugs can be more challenging to administer in children than in adults. Consideration also needs to be given to the ability of the caregiver and the child to adhere to the regimen. Strategies to enhance adherence in these populations have been met with limited success. A recent Cochrane systematic review of interventions to improve ARV adherence in children and adolescents, in which only four out of 2,566 studies met their strict selection criteria, revealed that intensive home based and peer support programs failed to demonstrate any significant impact on adherence (Bain-Brickley et al. 2011). These knowledge gaps support the need for more well-designed studies with novel approaches focused on sustaining lifelong adherence to cART in these vulnerable populations.

What Antiretroviral Therapy to Start

There are five classes of antiretroviral drugs available and two pharmacokinetic enhancers. Table 3 lists significant drug-drug interactions and potential severe adverse effects of ARVs, approved by the FDA, for use in ICA. Combination antiretroviral therapy typically includes at least 3 drugs

from 2 different classes. In children, this should consist of 2 nucleoside reverse transcriptase inhibitors (NRTI) as the backbone, and the third drug should be either a nonnucleoside reverse transcriptase inhibitor (NNRTI) or a protease inhibitor (PI). Regimen selection will need to consider patient characteristics, such as age, comorbidities, coinfections, previous ARV exposures, and drug resistance testing results.

Preferred Regimens for Initial Therapy

The DHHS recognizes those regimens as preferred when clinical trial data has shown that the drug combination is more durable and efficacious (viral load suppression and immunologic improvement) and exhibits acceptable safety and toxicity profiles. These determinations are preferably made on the basis of data derived from pediatric clinical trials, but extrapolation from adult studies is frequently necessary for many of the newer ARV drugs on the market. Alternative drugs or regimens are those that are less favorable than the preferred choices because of various reasons including less experience in children, decreased efficacy and durability, increased toxicity, and/or issues with dosing, administration, or drug interactions for that drug or regimen. A third category is designated for use in special circumstances, drugs or combinations that can be used if a patient cannot be treated with either the preferred or alternate drugs or regimens. Tables outlining regimens that are “not recommended” or “never recommended” due to concerns about inferior virologic responses, safety, pharmacologic antagonism, insufficient clinical data, unacceptable rates of resistance formation, and serious toxicity are also listed in the guidelines. These treatment scenarios will not be addressed in this chapter – please refer to the guidelines (DHHS 2015b Pediatric Guidelines) for more information on this subject.

The first-line regimen in full term infants ≥ 14 days old is lopinavir/ritonavir with zidovudine and either lamivudine or emtricitabine. Infants > 3 months of age can be given abacavir instead of zidovudine. Any patient to be started on

Antiretroviral Therapy for HIV-Infected Infants, Children, and Adolescents in Resource-Rich Settings, Table 3 FDA approved antiretroviral drugs for use in

infants, children, and adolescents (Adapted from Van der Linden et al. 2009)

ARV class	Generic name (abbr.)	Age FDA approval	Significant D:D:I and drug metabolism	Potentially severe toxicities
NRTI	Abacavir (ABC)	≥3 months	None	Hypersensitivity in HLA-B*5701 + individuals
	Didanosine (ddI)	≥2 weeks	TDF ↑ [ddI] – do not coadminister	Peripheral neuropathy, lactic acidosis, pancreatitis
	Emtricitabine (FTC)	Birth	None	Neutropenia, lactic acidosis
	Lamivudine (3TC)	≥3 months	None	Peripheral neuropathy, pancreatitis, lactic acidosis
	Stavudine (d4T)	Birth	ZDV (antagonism) – do not coadminister	Peripheral neuropathy, pancreatitis, lactic acidosis; lipodystrophy/atrophy
	Tenofovir (TDF)	≥2 years	TDF ↑ [ddI] – do not coadminister	Bone and renal
	Zidovudine (ZDV)	Birth	D4T (antagonism) Doxorubicin (decreases ZDV – P levels)	Anemia, neutropenia (common)
NNRTI	Efavirenz (EFV)	≥3 months	CYP3A4 inducer/inhibitor	Skin rash, hepatic transaminase elevations, CNS (abnormal dreams, insomnia)
	Etravirine (ETV)	≥6 years	Complex – multiple CYP450 interactions	Skin rash, hypersensitivity
	Nevirapine (NVP)	≥15 days	Complex – CYP450 induction	Skin rash, hypersensitivity, hepatotoxicity
	Rilpivirine (RPV)	≥18 years	CYP3A4 substrate PPIs, antacids, H2 blockers decrease plasma [RPV]	Depression, mood changes
PIs	Atazanavir (ATV)	≥3 months	CYP3A4 substrate/inhibitor PPIs, antacids, H2 receptor antagonists decrease plasma [ATV]	Indirect hyperbilirubinemia and jaundice; PR interval prolongation
	Darunavir (DRV)	≥3 years	CYP3A4 substrate/inhibitor	Skin rash, hepatic transaminase elevations, hepatic dysfunction
	Fosamprenavir (FPV)	≥6 months	CYP3A4 substrate/inhibitor/inducer	Skin rash, Steven-Johnson syndrome, lipodystrophy, neutropenia
	Indinavir (IDV)	≥18 years	CYP3A4 substrate/inhibitor	Lipid abnormalities, lipodystrophy, nephrolithiasis/urolithiasis
	Lopinavir/ritonavir (LPV/r)	≥14 days	CYP3A4 substrate/inhibitor	Diarrhea, rash, hyperlipidemia (esp. hypertriglyceridemia), lipodystrophy
	Nelfinavir (NFV)	≥2 years	Complex – multiple CYP450 interactions	Diarrhea, lipodystrophy, exacerbation chronic liver disease

(continued)

Antiretroviral Therapy for HIV-Infected Infants, Children, and Adolescents in Resource-Rich Settings, Table 3 (continued)

ARV class	Generic name (abbr.)	Age FDA approval	Significant D:D:I and drug metabolism	Potentially severe toxicities
	Saquinavir (SQV)	≥16 years	CYP3A4 substrate/inhibitor	Rash, lipodystrophy, exacerbation chronic liver disease
	Tipranavir (TPV)	≥2 years	CYP3A4 substrate/inducer	Rash, hepatic dysfunction, lipodystrophy
Entry/attachment inhibitors	Enfuvirtide (T-20)	≥6 years	No known interactions Catabolism to constituent amino acids	Local injection-site reactions, cellulitis, hypersensitivity, pneumonia (unclear association)
	Maraviroc (MVC)	≥16 years	CYP3A4 and Pgp substrate	Hepato- and cardiotoxicity
INSTIs	Dolutegravir (DTG)	≥12 years	UGT1A1 and CYP3A4 substrate	Rash, hypersensitivity
	Elvitegravir (EVG)	≥18 years	CYP3A4 substrate, CYP2C9 inducer	Diarrhea
	Raltegravir (RAL)	≥4 weeks	UGT1A1-mediated glucuronidation Antacids decrease plasma [RAL]	Elevated hepatic transaminases in HBV and/or HCV coinfecting individuals
Pharmacokinetic	Cobicistat (COBI)	>18 years	CYP3A4, CYP2D6, renal organic anion transporter inhibitor	Increased risk of renal dysfunction with concomitant TDF use
Enhancers	Ritonavir (RTV, r)	>14 days	Complex – multiple CYP450 interactions	Exacerbation of chronic liver disease, lipodystrophy

D:D:I drug-drug interactions, *NRTI* nucleoside reverse transcriptase inhibitor, *NNRTI* nonnucleoside reverse transcriptase inhibitor, *PIs* protease inhibitors, *INSTI* integrase strand-transfer inhibitor, *DC* drug concentration, *ZDV-P* phosphorylated ZDV, *CYP450* cytochrome p450 enzyme family, *PPI* proton-pump inhibitors, *Pgp* P glycoprotein, *UGT1A1* UDP glucuronosyltransferase 1 family, polypeptide A1

abacavir should first undergo HLA-B*5701 genetic testing to ensure that it is negative. The advantage of abacavir is the possibility of switching to once daily therapy. Recent recommendations were that children with continued viral suppression and stable CD4 counts for more than 6 months can be switched from twice to once daily dosing with abacavir. In a related development, the FDA recently approved the use of once daily lamivudine and abacavir for all children ≥3 months of age, irrespective of viral load (FDA 2015). Labeling changes such as this, which are informed by pediatric clinical trial results, provide more opportunities to simplify regimens in children and improve adherence without sacrificing potency.

Children 3–6 years of age should be treated with either efavirenz or lopinavir/ritonavir with

2 of the NRTIs mentioned above (abacavir or zidovudine with either lamivudine or emtricitabine). Children ages 6 and older have the option of being treated with the NNRTI efavirenz or the PIs atazanavir/ritonavir or lopinavir/ritonavir. In contrast to NNRTI-based regimens in which a single viral mutation can lead to high-level resistance and cross-resistance with other NNRTIs, PI-based regimens have the advantage of increased virologic potency and less drug resistance development due to the high genetic barrier to resistance that this class of drugs possess. Efavirenz should be avoided in adolescent females due to the potential for teratogenicity in the first trimester of pregnancy. The preferred 2 NRTI backbone can include tenofovir once adolescents reach Tanner stage 4 or 5, combined with either lamivudine or emtricitabine.

Alternative Regimens for Initial Therapy **Adherence to Guidelines**

Nevirapine, in addition to 2 NRTIs, is an alternative therapy for infants ≥ 15 days old and may be more palatable than lopinavir/ritonavir. Nevirapine remains an alternative ARV in older children because of the risk for rare serious adverse events (hypersensitivity reactions, potentially life-threatening hepatitis) and an increased risk of virologic failure when compared to a lopinavir/ritonavir regimen. This drug should be avoided in post-pubertal adolescent females with CD4 counts >250 because of the increased risk of hepatotoxicity in this group.

Atazanavir/ritonavir is an alternative PI for children ≥ 3 months (≥ 10 kg) to <6 years due to limited experience in this population. It is the only PI that can be given once daily in infants and children and is available in powder form. Twice daily fosamprenavir/ritonavir (for infants ≥ 6 months) or darunavir/ritonavir (for children ≥ 3 years) are other options. Once daily darunavir/ritonavir can be given to treatment naive children ≥ 12 years of age.

Raltegravir is an integrase strand-transfer inhibitor (INSTI) that can be given to children ≥ 2 years (chewable or film-coated tablet), in combination with 2 NRTIs. Dolutegravir is another option for children ≥ 12 years and has the advantage of once daily dosing in patients naïve to INSTI. It is well tolerated and has an excellent safety and toxicity profile.

The alternative dual NRTI backbone includes zidovudine, with either abacavir or didanosine, or didanosine with either lamivudine or emtricitabine in infants and young children. In adolescents ≥ 13 years of age zidovudine with either lamivudine or emtricitabine is an alternative option. Children and adolescents who are Tanner stage 1–3 can also be given tenofovir in combination with lamivudine or emtricitabine after weighing the risks and benefits. Tenofovir is considered an alternative drug in younger children in Tanner stage 1–3 because of the potential risk of decreased bone mineral density in the growing child.

Although the DHHS and PENTA guidelines provide foundations for the rational and effective treatment of pediatric HIV infection in RRC, treatment decisions must ultimately be individualized to maximize adherence, minimize toxicity, and optimize patient outcomes. A review published in 2005 examined clinician adherence to DHHS pediatric HIV treatment guidelines in the USA from 1998 to 2003, a period encompassing the introduction and expansion of PI-based cART in children (Brogly et al. 2005). The study population consisted of 766 perinatally HIV-infected (PHIV) children enrolled in the Pediatric AIDS Clinical Trials Group 219C who were prescribed first-line cART outside the confines of an ARV clinical trial. During the 5 year study period, 22% of children initiated a cART regimen not recommended by the guidelines, suggesting that clinicians caring for these children were compelled to include new ARVs that may not yet have been FDA approved or recommended by the DHHS. This theme will be expanded on in later sections describing treatment considerations in special populations.

Treatment Response and Monitoring

At the time of diagnosis, HIV-infected children should be thoroughly evaluated with a baseline assessment that includes history, physical exam, CD4 count, HIV VL, and HIV genotypic resistance testing. Evaluation for coinfections will depend on the history, exam, and specific laboratory data. If cART is initiated, the patient's adherence should be assessed and side effects discussed 1–2 weeks later. Two to 4 weeks into treatment laboratory testing should be performed to verify virologic response and to evaluate for toxicity. Children and adolescents should be assessed every 3–4 months for adherence, side effects, and response to treatment (CD4 count/%, VL). Patients with sustained VL suppression, CD4 counts above opportunistic infection (OI) risk for age, good medication adherence, and stable

clinical status for at least 2 years can have their CD4 counts monitored every 6–12 months. Pediatric patients not on cART should similarly be evaluated every 3–4 months to assess clinical course and immunological health (CD4 count/%, VL). More frequent evaluation may be needed on a case-by-case basis if there is concern for clinical or immunological deterioration.

A systematic review of the literature, that included studies through 2010, found that children residing in RLCs had higher mortality rates than those in RRC, whether cART naïve or on treatment (Peacock-Villada et al 2011). Higher VL and lower CD4% and weight for age at baseline were predictors of mortality in both settings. Children residing in RLC were older and had more advanced disease at time of diagnosis which may partially explain the higher mortality rates. Earlier diagnosis and revised WHO recommendations, to start cART in all children ≤ 5 years old, will likely improve outcomes in RLCs.

Assessment/Management of Treatment Failure

A mutually respectful and trusting relationship between the clinical team, the patient, and his/her family is essential to help establish readiness to start therapy, discuss adherence, and understand the goals of cART. Once a patient starts cART, assessment of adherence and efficacy should occur at least every 3–4 months. At each visit, it is important to reinforce how the medications should be administered (frequency, \pm food) and address any concerns the patient or caregiver may have. Caregivers and adolescent patients may benefit from support networks available at the hospital or in the community. Patients with mental health concerns should be evaluated by a specialist.

If a patient is not virally suppressed, the administration of each drug should be reviewed and adherence explored. If there are concerns with palatability or adverse effects, then other options may need to be considered even if it requires transitioning from a preferred to an alternative regimen. If a once daily regimen is possible, it

should be offered. Adherence issues frequently serve as the biggest impediment to success in children prescribed cART. Many factors, including palatability of the regimen, the child's age, and behavioral and psychosocial factors within the family, can negatively impact adherence to cART. Psychiatric illness and substance abuse can create barriers to adherence in adolescents. Denial and fear of disclosure may prevent them from seeking care or safely taking their cART at home or while in college. There may be a lack of social support, unstable housing, or food insecurity. Careful consideration of these challenges may allow clinicians to offer more personalized guidance to patients and their families on the importance of remaining engaged in care and hopefully empowering them to maintain their health.

If there is ongoing treatment failure, either due to clinical, immunologic, or virologic failure, then drug resistance testing should be performed while on the failing regimen, and consideration should be given to changing or modifying the regimen. Clinical failure is the development of a new OI or clinical progression. Immunologic failure is the inability to achieve or maintain the appropriate CD4 count or % for age. Virologic failure is defined as two or more consecutive VLs >200 after 6 months of therapy or repeated VLs above the level of detection following 12 months of cART, using the most sensitive assay available.

Selection of a new regimen should include a review of the previous treatment history and drug resistance testing. Ideally at least 2 fully active drugs should be chosen and a switch made to another class. For example, if a child was on an NNRTI and 2 NRTIs, he/she should be switched from the NNRTI to either a PI or an INSTI. At times the switch can be made within the class, if the presence of resistance is thought to be unlikely.

Treatment Consideration in Special Populations

Neonates and Infants <12 Months Old

There is very limited knowledge on the safety and dosing of ARVs in young infants, especially

neonates. Zidovudine and nevirapine are the only ARVs in which dosing is available for neonates during the first 2 weeks of life. However, they are used alone or in combination for the prevention of perinatal transmission. Since diagnostic HIV testing typically requires 1–2 weeks to complete, pharmacokinetic studies evaluating dosing and safety in neonates <2 weeks old are lacking. While there was one case of prolonged remission in an infant from Mississippi who was started on therapy at 30 hours of life, it has not been shown that early treatment leads to sustained viral suppression or results in better long-term outcomes (Persaud et al. 2013). Thus, at this time there is insufficient data to make treatment recommendations for newborns during the first 2 weeks of life, and there is the risk of significant toxicity if exposed to cART.

Once infants are 14 days or older cART needs to be initiated urgently. Data from the CHER trial (Violari et al. 2008) and the HIV Paediatric Prognostic Markers Collaborative Study (Dunn et al. 2006) were unequivocal in their documentation of high rates of disease progression and death among asymptomatic HIV-infected infants who deferred therapy until their CD4% fell below 25%. The compelling need to start cART in these infants was further confirmed by a Cochrane intervention review (Penazzato et al. 2014), outlining the significant survival benefit conferred by initiating a PI- or NNRTI-based regimen as soon as possible. Lopinavir/ritonavir-based regimens were superior to NVP-containing cART in terms of risk of virologic failure. Treatment interruption protocols in infants were found to be futile based upon the short length of treatment interruption that such infants could tolerate without having to restart cART.

Adolescents

Only 53–62% of adolescents in RRC are adherent to cART, and only 70% are successfully linked to care. There are unique challenges in caring for HIV-infected adolescents that can make it difficult to engage and retain them in regular health care and to comply with daily cART (DHHS 2015a Adult and Adolescent Guidelines). Adolescents are at a developmental stage that makes it difficult

to accept chronic illness, seek care, and focus on maintaining their health. Other obstacles to adherence includes concurrent mental illness, lack of family and social support, lack of consistent access to health care, and, in the case of behaviorally infected individuals, fear of parental disclosure if a parent's health insurance is used. PHIV commonly have more drug resistance due to exposure to serial nonsuppressive regimens, extensive treatment exposure, and chronic nonadherence, which may require the use of complex and potentially more toxic treatment regimens. Thus, the decision to start or continue cART in adolescents needs to be individualized, with barriers to treatment and adherence readiness explored at each visit. For newly infected or cART naïve adolescents who are of appropriate weight and Tanner stage, fixed dose combinations of ARVs in the form of single tablet regimens should be considered to foster good adherence (DHHS 2015a Adult and Adolescent Guidelines). If an adolescent practices erratic adherence, then treatment may need to be deferred for a short period of time until the issues compromising adherence are addressed. If a decision is made to modify or completely change the regimen, the clinician may need to avoid choosing ARVs with low genetic resistance barriers to decrease the risk of jeopardizing future treatment options.

All adolescents should be educated about pre-conception care, contraception, and decreasing risk of HIV transmission to partners. Adolescent females should be counseled about possible interactions between cART and hormonal contraceptives. They should also be encouraged to maintain compliance with cART if pregnancy is being considered.

HIV-2 Infection

HIV type 2 infection (HIV-2) originated in West Africa but has since spread to other parts of Africa, Europe, India, and the USA. It needs to be considered in individuals considered at risk based on exposure history, if presentation suggests HIV infection but HIV-1 testing is negative, and if the HIV-1 western blot has an unusual indeterminate result (Campbell-Yesufu et al. 2011). Newer HIV-testing algorithms have eliminated the

western blot as a confirmatory test and incorporate HIV-1/HIV-2 antibody differentiation immunoassays that can readily identify HIV-2 infection. HIV-2 infection tends to have a less virulent course than HIV-1, with a longer asymptomatic period and slower progression to AIDS.

Summary

The treatment of HIV-infected children and adolescents with effective cART has transformed HIV from a potentially fatal disease to, in many cases, a manageable chronic illness. In resource-rich settings, mother to child transmission of HIV has been rendered almost obsolete via the provision of cART to HIV-infected women during pregnancy and the availability of safe and inexpensive sources of infant formula. However, despite these successes, major gaps still exist in our ability to effectively treat HIV infection over the lifespan of the individual. More pediatric clinical trials testing ARVs that are safe, palatable, and potent will be one of many ways to close that gap. Reducing stigma and addressing larger societal issues such as poverty, homelessness, education, untreated mental illness, and substance abuse will also have major collateral impacts on this disease. Finally, translating the advances made in RRS to the global stage will be crucial in attempts to provide universal treatment to all HIV-infected people worldwide.

Antiretroviral Therapy: When to Start

Harjot K. Singh and Marshall J. Glesby
Division of Infectious Diseases, Department of
Medicine, Weill Cornell Medical College,
New York, NY, USA

Definition

Clinicians have debated the optimal time to initiate antiretroviral therapy (ART) since the availability of antiretroviral in the late 1980s. While discussions and guidelines have generally centered around the CD4 cell count, the debate over when to start has seen shifts from waiting for disease progression to AIDS to starting immediately at time of HIV diagnosis. These paradigm shifts have largely been driven by recognition of complications of older antiretroviral regimens; the availability of safer, simpler, and better tolerated antiretroviral regimens; and evidence from both cohort studies and randomized controlled trials. Treatment guidelines are currently provided by several groups and have been updated multiple times to reflect new HIV knowledge and gaps. These groups include the World Health Organization (WHO) (Consolidated strategic information guidelines 2015), the British HIV Association (BHIVA) (BHIVA guidelines for the treatment of HIV-1 2015), the European AIDS Clinical Society (EACS) (2014), the US Department of Health and Human Services (DHHS) (Guidelines for the prevention and treatment 2013; Guidelines for the use of antiretroviral agents 2015), the International Antiviral Society-USA (IAS-USA) (Gunthard et al. 2014), and the Pediatric European Network for the Treatment of AIDS (PENTA) (Bamford et al. 2015). In this entry, the historical

pendulum swings in the *when to start* debate will be discussed, the data as of August 2015 will be examined, and the current guidelines, including special populations and children, will be summarized. While current recommendations on when to start ART vary somewhat in these international and national guidelines, a uniformed approach is anticipated in the near future given newly published data demonstrating the clinical benefit of initiating ART at high CD4 cell counts.

Historical Perspective

In the 1980s, AIDS was a poorly understood, nearly universally fatal illness. When the chemotherapeutic drug zidovudine (AZT) was discovered to have antiviral activity, patients and physicians sought its use even prior to FDA approval. In 1990, the AIDS Clinical Trials Group (ACTG) study 019 of AZT monotherapy showed promise for slowing progression of disease in asymptomatic HIV-infected persons with CD4 cell counts <500 cells/mm³, leading to its widespread use in resource-rich settings. But in 1995, a randomized controlled trial (RCT) of initiating AZT in HIV-infected persons with CD4 cell counts <500 cells/mm³ compared to >500 cells/mm³ failed to find a clinical benefit, and the question of *when to start* antiretroviral therapy became contentious. As additional antiviral drugs entered the market, the therapeutic options were increasing but the optimal time to initiate ART remained unknown. The number of persons dying from HIV infection and AIDS kept growing until 1996 with the advent of protease inhibitors. Use of three-drug therapy, coined *highly active antiretroviral therapy* (HAART), profoundly changed the course of HIV disease from nearly universally fatal into a chronic and treatable illness. While not a cure, morbidity and mortality improved dramatically and shifted the landscape from loss of life to quality of life with increasing concern about side effects, pill burden and adherence, and drug resistance (Jain and Deeks 2010).

The initial set of ART treatment guidelines was published in 1996 by IAS-USA, and additional

US, European, and WHO guidelines soon followed. Each of the guidelines has been revised periodically as new information became available. The initial IAS-USA guidelines recommended ART for all HIV-infected persons with a CD4 cell count <500 cells/mm³. This CD4 cell count cutoff is considered to be in the normal range, and HIV-infected persons were often asymptomatic with this degree of immune function. Because ART was recommended at this high CD4 cell count, this era became known as the *hit hard and hit early* era. However, this period did not last long. With widespread ART use, increasing problems began to emerge with the high pill burdens, complex dosing schedules, and extensive side effects. The promise of improved survival was soon overshadowed by risks of the antiretroviral medications. With these concerns, the pendulum began to shift again to waiting to start ART until more advanced disease to avoid multiple complications.

Then, in 2006, data began to emerge from observational and randomized controlled trials showing morbidity and mortality benefits from starting ART earlier. Newer antiretroviral (ARV) medications were developed and were more tolerable with simpler dosing and frequency. Thus, the threshold of *when to start* ART shifted again to earlier and earlier in HIV infection. Campaigns to bring ART to all eligible HIV-infected persons began. The initial WHO campaign was known as *3 by 5*, a plan to treat three million persons with ART by the year 2005. Now, more than three decades into HIV infection, results from several studies attempting to answer the question of what CD4 threshold to initiate ART have been published. These studies are reviewed in the section below and inform the current treatment recommendations.

Summary of Trial Data: Randomized Controlled Trials

Five large randomized controlled trials have investigated the question *when to start* treatment among HIV-infected adults. Four of these studies evaluated different CD4 cell count thresholds for ART

initiation or continuation (Strategies for Management of Antiretroviral Therapy (SMART) Study Group et al. 2006; Severe et al. 2010; Cohen et al. 2011; INSIGHT START Study Group 2015). One study evaluated early versus delayed treatment initiation in infants (Violari et al. 2008). These studies were conducted in both resource-rich and limited settings. Each of the RCTs was powered to find differences in disease progression/AIDS or prevention of HIV transmission, and each was stopped early by the data safety and monitoring board (DSMB) because of greater risk among those with deferred treatment.

SMART

The Strategies for Management of Antiretroviral therapy (SMART) trial began in 2002. At the time, ARV regimens included high pill burdens with frequent dosing and multiple side effects. Because of the lifelong need for ARVs, this RCT was designed to compare a strategy of treatment interruption (drug conservation arm) with continued therapy (viral suppression arm). At the time of the study design, the WHO guidelines recommended reserving ART for persons with CD4 cell counts <200 cells/mm³, and the 2003 DHHS guidelines recommended treatment for all HIV-infected persons with CD4 cell counts <350 cells/mm³. The study enrolled 5472 HIV-infected persons age >13 years with CD4 >350 cells/mm³ who were currently on therapy, had previously received therapy, or who had never received ART. The study was conducted at 318 sites in 33 countries. The primary end point of this study was new or recurrent opportunistic infection (OI) or death from any cause. In January 2006, the DSMB unexpectedly stopped the study because of safety risk in the drug conservation group. The estimated hazard ratio (HR) for any OI or death was 2.6 (95% CI, 1.9–3.7; $p < 0.001$) in the drug conservation group. In a post hoc analysis focusing on the 240 participants who were treatment naïve at study entry plus 228 who had not received ART in the preceding 6 months, randomization to the drug conservation arm with deferred initiation (or reinitiation) of ART until a CD4 count <250 cells/mm³ was associated with over a threefold greater risk of

opportunistic disease and serious non-AIDS events. These data, along with other analyses from SMART, suggested that early initiation and continuation of ART provided clinical benefit (Strategies for Management of Antiretroviral Therapy (SMART) Study Group et al. 2006, 2008).

CHER

The Children with HIV Early Antiretroviral Therapy (CHER) trial began in 2005 to evaluate reduction in infant mortality with the limited use of early ART initiation as a bridge to delay lifelong continuous ART later in life. At the time of this study, baseline infant mortality rates were high in resource-limited settings and were further magnified with HIV exposure and infection. The management challenges of ART in this time included were the need for lifelong therapy, limited age-appropriate drugs, long-term toxicity, adherence issues, and limited resources. The study enrolled 377 HIV-infected infants, 6–12 weeks of age, with plasma HIV RNA >1000 copies/ml and CD4% >25% into one of three randomized treatment strategies: (1) early limited ART for 96 weeks, (2) early limited ART for 40 weeks, or (3) deferred therapy. Deferred therapy was based on WHO and CDC treatment guidelines at the time. The primary end point of this study was time to death or failure of first-line ART. Results were analyzed by combining both early treatment groups into one combined early treatment group. In June 2007, the DSMB stopped the study and mandated urgent evaluation of the deferred treatment group. In the early treatment group, 11 of 252 infants reached the primary end point compared to 21 of 125 in the deferred group (HR 0.25; 95% CI, 0.12–0.51). In the early group, 4% of the infants died compared to 16% in the deferred group (HR 0.24; 95% CI, 0.11–0.51; $p < 0.001$); 40% of deaths occurred unexpectedly at home, and the rates were higher in the first 26 weeks of life with 15 infants dying before receiving any ART. Similarly, HIV disease progression occurred in 6.3% of the early therapy groups compared to 25.6% of the deferred therapy group (HR 0.25; 95% CI, 0.15–0.41;

$p < 0.001$). In summary, this study demonstrated that early initiation of ART at a median of 7 weeks compared to deferred therapy among HIV-infected infants reduced both mortality and morbidity. The degree of difference in early mortality compared with deferred ART provided strong support for the initiation of ART in infants regardless of CD4 cell count or % (Violari et al. 2008).

CIPRA

The Comprehensive International Program of Research on AIDS-Haiti (CIPRA-HT 001) trial began in 2005 and randomized 816 treatment-naïve subjects with CD4 cell counts of 200–350 cells/mm³ to open-label early initiation of ART within 2 weeks of enrollment versus deferred initiation at CD4 cell count of <200 cells/mm³. At the time of this study, the WHO guidelines recommended waiting until the CD4 cell count ≤ 200 cells/mm³. The primary end point of this study was new or recurrent OI or death from any cause. The median CD4 cell count for the study group overall was 281 cells/mm³. In May 2009, the DSMB recommended that the study be stopped early because there was a fourfold higher risk of death (HR 4.0; 95% CI, 1.6–9.8; $p = 0.001$) among the late treatment group. Later analysis also found smaller increase in CD4 cell count after 5 years (496 cells/mm³; 95% CI 477–515 vs. 373 cells/mm³; 95% CI, 357–389; $p < 0.0001$) and a higher risk of tuberculosis (unadjusted HR 2.41; 95% CI, 1.56–3.74; $p < 0.0001$). In conclusion, earlier ART initiation led to significant reductions in mortality and morbidity, particularly in incident tuberculosis. These results played an influential role in changing the WHO treatment guidelines (Severe et al. 2010; Collins et al. 2015).

HPTN 052

The HIV Prevention and Treatment Network (HPTN) 052 study began in 2007. At that time, the WHO recommended treatment for persons with CD4 cell counts of <200 cells/mm³ and treatment consideration for <350 cells/mm³, and the DHHS suggested treatment for persons with

<350 CD4 cells/mm³. This study was the first large RCT of serodiscordant couples comparing the impact of early versus delayed ART among HIV-infected persons on transmission to their HIV-uninfected partners in stable sexual monogamous relationships. The HIV-infected partner was randomized to either start ART at a CD4 cell count of 500 cells/mm³ (early arm) or wait until 350 cells/mm³ (delayed arm). The study enrolled persons ≥18 years who had never received ART at 13 sites in nine countries, including both resource-rich and limited settings. Viral genetic sequencing was done to assess linkages of seroconversion events. The primary prevention end point of this study was linked HIV-1 transmission in HIV-negative partners. The primary clinical end point was the earliest occurrence of pulmonary tuberculosis, severe bacterial infection, a WHO stage 4 event, or death. Of the 1763 serodiscordant couples enrolled in the study, 50% of HIV-infected participants were men and 97% were heterosexual. In April 2011, the DSMB recommended that the study be stopped early because of the prevention results. Only four transmission events were seen in the early treatment group (incidence 0.3/100 person-years) compared with 35 in the delayed group (incidence 2.2/100 person-years) with resulting HR of 0.11 (95% CI 0.04–0.32; $p < 0.001$). With genetic analyses, 28 transmissions were linked, 27 in the delayed group and one in the early treatment group. Forty HIV-related clinical events or deaths were noted in the early treatment group compared to 65 in the delayed treatment group (HR 0.59; 95% CI, 0.40–0.88; $p = 0.01$). In conclusion, earlier ART initiation at a CD4 cell count of 500 cells/mm³ resulted in 96% reduction in linked HIV transmissions and 89% reduction in overall HIV transmission. In addition to prevention success, there were reductions in clinical outcomes including the cumulative probability of AIDS events over 2 years (HR 0.64; 95% CI, 0.43–0.96, $p = 0.031$) and cumulative probability of TB over 2 years (HR 0.49; 95% CI, 0.28–0.89, $p = 0.018$), but no difference was seen in mortality. This combination of transmission prevention and morbidity reduction further

supported the strategy of earlier initiation of ART (Cohen et al. 2011; Grinsztejn et al. 2014).

START

The Strategic Timing of Antiretroviral Therapy (START) trial is the most recently completed RCT comparing early initiation of ART at a CD4 cell count of >500 cells/mm³ versus delayed therapy when the CD4 cell count reaches 350 cells/mm³. As of 2011, when this study started, the threshold for ART initiation was 350 cells/mm³ according to DHHS guidelines and 200 cells/mm³ according to WHO guidelines. This study enrolled 4685 persons ≥18 years with CD4 cell count ≥500 cells/mm³ who had never received ART at 215 sites in 35 countries. The primary composite end point of this study was serious AIDS event, serious non-AIDS-related event, or death from any cause. In May 2015, the DSMB recommended that the delayed study arm be stopped early and patients be offered ART because of significant differences between the groups. In the early ART arm, 42 (1.8%) subjects reached the primary end point compared with 96 (4.1%) in the delayed arm, corresponding to a 57% reduction in risk attributed to earlier initiation of ART. The risk reductions for serious AIDS-related and non-AIDS-related events were 72% and 39%, respectively. Of note, 68% of primary end point events occurred at CD4 counts of >500 cells/mm³. Life-threatening adverse events and hospitalizations did not differ between study arms. This study provides strong evidence supporting the strategy of treating all HIV-infected persons, including those who have normal CD4 counts of >500 cells/mm³ (INSIGHT START Study Group 2015).

Summary of Cohort Studies

Two large observational studies among HIV-infected adults have also had significant impact on the question *when to start* treatment among HIV-infected adults. These studies evaluated age-related differences in disease progression/AIDS as well as various CD4 cell count thresholds and are summarized below.

NA-ACCORD

Two parallel, observational data analyses from the North American AIDS Cohort Collaboration on Research and Design (NA-ACCORD) have informed the pendulum shifts of when to initiate ART. Investigators analyzed data of over 17,000 HIV-infected adults (~80% men) under medical care from 1996 to 2005 in Canada and the United States who were ART naive and had never had an AIDS-defining illness. The patients were stratified on the CD4 threshold at which they initiated ART – the first analysis compared 351–500 cells/mm³ (early) to ≤350 (deferred) and the second compared >500 cells/mm³ (early) to ≤500 cells/mm³ (deferred). At the time of this study, the WHO guidelines recommended deferring ART until a CD4 cell count ≤200 cells/mm³, and DHHS guidelines suggested starting at 350 cells/mm³. The relative risk of death for the group who deferred ART until CD4 cell count of <350 cells/mm³ (compared to 351–500) was 1.69 (95% CI, 1.26–2.26; *p* < 0.001). Similarly, the relative risk of death for those who started at >500 cells/mm³ (compared to ≤500) was 1.94 (95% CI, 1.37–2.79; *p* < 0.001). In conclusion, deferring ART initiation until lower CD4 cell counts in this observational, non-randomized study was associated with significantly greater risk of all-cause mortality. Published in 2009, this very large observational study supported the shift toward earlier ART initiation (Kitahata et al. 2009).

ART-CC

The Antiretroviral Therapy Cohort Collaboration (ART-CC) was established in Europe and North America in 2000 to evaluate clinical events and death among persons living with HIV infection. At the time of this study, the WHO and DHHS treatment thresholds were <200 cells/mm³ and <350 cells/mm³, respectively. Data on more than 12,574 adult persons starting ART were collected through 2009. One of the many questions evaluated by this group was *when to start* ART. During the follow-up period, 1094 patients developed AIDS or died and 344 patients died. Baseline CD4 cell count was strongly associated with the probability of progression to AIDS or

death. Compared with patients starting ART with the lowest CD4 cell count, <50 CD4 cells/mm³, adjusted HRs for AIDS or death were 0.74 (95% CI, 0.62–0.89) for 50–99 cells/mm³, 0.52 (0.44–0.63) for 100–199 cells/mm³, 0.24 (0.20–0.30) for 200–349 cells/mm³, and 0.18 (0.14–0.22) for ≥350 CD4 cells/mm³, showing benefit with higher CD4 initiation. Although not randomized, this large study provided additional support to starting earlier ART, including CD4 cell counts above the treatment thresholds at the time (When To Start Consortium et al. 2009).

Current Guidelines

There are several groups that promulgate HIV treatment guidelines for adults: the World Health Organization (WHO) (Consolidated strategic information guidelines 2015), the British HIV Association (BHIVA) (BHIVA guidelines 2012), the European AIDS Clinical Society (EACS) (2014), the US Department of Health and Human Services (DHHS) (Guidelines for the use of antiretroviral agents 2015), and the International Antiviral Society-USA (IAS-USA) (Gunthard et al. 2014). Each of these guidelines is available online, and some are updated in real time as new data becomes available. Table 1 summarizes the recommendations of *When to Treat* as of August 2015. The results of the START trial are expected to lead to the alignment of all guidelines in support of offering ART to all HIV-infected adults.

Summary of Recommendations for Infants and Children

When to initiate ART in infants and children has changed over the decades. The CHER trial was a landmark trial that suggested earlier treatment was better than deferred treatment, even in the face of concern over lifelong toxicity, adherence concerns, and lack of age-appropriate ARV options (Violari et al. 2008). The current recommendations for treatment of infants and children are generally in agreement across the guidelines.

Antiretroviral Therapy: When to Start, Table 1 Current treatment guidelines for *when to start*

Guideline	Last updated	CD4 cell count thresholds (cells/mm ³)			
		≤200	<350	350–500	>500
WHO (Consolidated strategic information guidelines 2015)	May 2015	Treat	Treat	Treat	Not discussed
BHIVA (BHIVA guidelines for the treatment 2012)	June 2015	Treat	Treat	Treat	Treat
EACS (2014)	November 2014	Treat	Treat	Consider ^a	Consider ^a
DHHS (Guidelines for the use of antiretroviral agents 2015)	April 2015	Treat	Treat	Treat	Treat
IAS-USA (Gunthard et al. 2014)	June 2014	Treat	Treat	Treat	Treat

Notes

^aIf symptomatic, EACS recommends treatment

The WHO recommends that all HIV-infected infants and children age <5 years be started on ART and that children age ≥5 years with CD4 cell counts ≤500 cells/mm³, WHO clinical stage 3/4, or tuberculosis be initiated on ART (Consolidated strategic information guidelines 2015). The PENTA guidelines also recommend treatment for all infants <1 year of age and for all children who are WHO stage 3/4 or CDC category B/C. Treatment is also recommended for children 1–3 years if CD4 cell counts are ≤1000 cells/mm³ or CD4% ≤25%, for children 3–5 years if CD4 cell counts are ≤750 cells/mm³ or CD4% ≤25%, and for children ages >5 years if CD4 cell counts are ≤350 cells/mm³ (Bamford et al. 2015). The current DHHS guidelines recommend that all infants <1 year of age be initiated on ARV regardless of CD4 cell count, as well as children ages 1 to <6 years with CD4 cell counts <500 cells/mm³ and children aged ≥6 years with CD4 ≤200 cells/mm³. Treatment for children older than 1 year with higher CD4 cell counts should be considered (Guidelines for the prevention and treatment 2013).

Special Populations

While there is general agreement among international and national guidelines for when to initiate ART for the treatment-naïve HIV-infected adult, there are some groups for whom initiation of ART should be prioritized to prevent mother-to-child

Antiretroviral Therapy: When to Start, Table 2 Rationale for prioritizing the initiation of ART among special HIV-infected populations

Patient group	Rationale
Pregnancy	Access to ART to prevent maternal-to-child transmission
Hepatitis C virus infection	Data on HIV and HCV coinfection have shown that each infection can accelerate progression of the other
Hepatitis B virus infection	Treatment of HBV requires the use of antivirals that dually treat HIV infection; fully suppressive ART should be initiated in this setting
Acute HIV infection	Treatment at the time of acute seroconversion may reduce the HIV reservoir size and inflammation from the virus itself
HIV-associated nephropathy	May reduce renal disease progression but usually does not reverse damage
Opportunistic infection ^a	May improve immune response and outcomes

Notes

^aFor majority of opportunistic infections. In persons with tuberculosis, exact timing of ART depends on the CD4 cell count and severity of pulmonary tuberculosis, but in general should begin within 2–8 weeks of tuberculosis treatment. In persons with cryptococcal meningitis, a short delay of 2 weeks is recommended to minimize the IRIS response and increased mortality.

transmission or reduce morbidity and mortality. Table 2 summarizes the DHSS guidance for special populations (Guidelines for the use of antiretroviral agents 2015).

Conclusion

The question of *when to start* ART for HIV-infected persons has been centered on CD4 cell count thresholds since the availability of zidovudine monotherapy. The starting threshold has swung as low as waiting until progression to AIDS at CD4 cell counts ≤ 200 cells/mm³ and as high as starting at the time of diagnosis, regardless of CD4 cell count. Several large clinical trials have informed the timing of initiation based on HIV transmission, morbidity, and mortality. The past concerns of toxicity, pill burdens, adherence, and emergence of resistance had been dampened by better ARV options and improved clinical and public health outcomes from earlier initiation of ART. Taken as a whole, the question of *when to start* seems to be definitely answered – *start now* – ART should be offered regardless of CD4 cell count threshold.

Definition

Antiretroviral therapy (ART) treatment has been proven to slow the progression of disease and reduce the risk of transmission for individuals with human immunodeficiency virus (HIV) infection. The goal of ART treatment is to completely inhibit viral replication in vivo and sustain the effects for as long as possible.

Introduction on Impact

Access to ART in resource-limited settings (RLS) has provided opportunity for infected patients to achieve nearly normal life expectancy with clear health gains. Before 2001, many people in RLS did not have access to ART due to the high cost and lack of availability of antiretroviral drugs (ARVs). Under special terms in international trade law, manufacturers in RLS began to produce generic drugs in 2001. This production expanded ART coverage, and by 2012, 9.7 million individuals representing 61% of all eligible HIV-infected patients under the 2010 World Health Organization (WHO) HIV treatment guidelines were on treatment in RLS. These scale-up efforts resulted in remarkable declines in the annual number of AIDS-related deaths from a high of approximately

2.3 M in 2005 to approximately 1.6 M in 2012 (UNAIDS report 2013). AIDS-related deaths among children born to HIV-infected mothers also declined more rapidly due to the impact of prevention of mother-to-child transmission (PMTCT) programs. However, in order for individuals and societies to benefit optimally from the successes of ART and thereby dramatically alter the trajectory of national epidemics, it is critical to adopt approaches that enhance the continuum of HIV care. This requires enhanced strategies for HIV diagnosis, linkage to care, retention in care, ART receipt, and ultimately plasma viral suppression (IOM 2012).

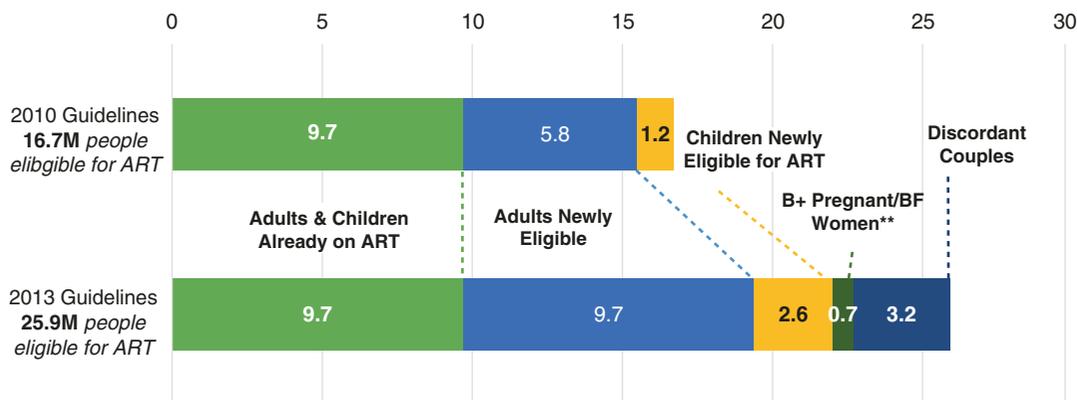

WHO Treatment Guidelines

In 2002, WHO published the first edition of the ART guidelines (WHO 2002). In 2004, guidelines for ART use for PMTCT were published (WHO 2004). The 2006 updated guidelines incorporated a “public health approach,” with simplified standardized tools for the delivery of ART (Gilks et al. 2006; WHO 2006). In 2010, WHO revised the guidelines for ART in adults and adolescents, based on a process of review and synthesis of new and emerging evidence (WHO 2010). Results from research revealed evidence that earlier initiation of ART offered significant benefits by enhancing host immune competence and reducing opportunistic infections, sustaining viral suppression, and thereby prolonging survival (WHO 2011). In 2011, the results of a randomized controlled trial demonstrated that ART can decrease HIV transmission risk in serodiscordant couples. In response to this evidence, in 2013 WHO recommended initiation of treatment when an individual’s CD4 count fell below 500 cells/mm³, immediately for all pregnant women, for HIV-infected partners in serodiscordant couples, for all children younger than 5, and for people with HIV-associated tuberculosis and Hepatitis B (Table 1).

The consolidated guidelines were formulated on the basis of the continuum of HIV prevention, treatment, and care. The recommendations incorporated the facilitation of linkage and

Antiretroviral Treatment in Resource-Limited Settings, Table 1 Consolidated guidelines on when to start ART treatment (WHO 2013)

Population	Recommendation
Adults and adolescents (≥10 years)	<ul style="list-style-type: none"> Initiate ART if CD4 cell count ≤ 500 cells/mm³ <ul style="list-style-type: none"> As a priority initiate ART in all individuals with severe/advanced HIV disease (WHO clinical stage 3 or 4) or CD4 count ≤ 350 cells/mm³ Initiate ART regardless of WHO clinical stage and CD4 cell count for individuals with; <ul style="list-style-type: none"> Active TB disease HBV co-infection with severe chronic liver disease Pregnant and breastfeeding women with HIV HIV-infected individuals in a serodiscordant partnership (to reduce HIV transmission risk)
Children ≥5 years old	Initiate ART if CD4 cell count ≤ 500 cells/mm ³ As a priority, initiate ART in all children with severe/advanced HIV disease (WHO clinical stage 3 or 4) or CD4 count ≤ 350 cells/mm ³ Initiate ART regardless of CD4 cell count for children with; <ul style="list-style-type: none"> WHO clinical stage 3 or 4 Active TB disease
Children 1–5 years old	Initiate ART in all regardless of WHO clinical stage and CD4 cell count As a priority, initiate ART in all HIV-infected children 1–2 years old or with severe/advanced HIV disease (WHO clinical stage 3 or 4) or with CD4 count ≤ 750 cells/mm ³ or $<25\%$, whichever is lower
Infants <1 year old	Initiate ART in all infants regardless of WHO clinical stage and CD4 cell count

*Includes TB and HBV co-infected
 **Only includes CD4>500; others are included under adults
 ** BF - Breast feeding

Antiretroviral Treatment in Resource-Limited Settings, Fig. 1 WHO treatment guidelines, 2010 versus 2013: Earlier initiation of treatment with expanded eligibility (Source: PEPFAR 2015)

promotion of consistency in approaches across the various settings in which ART and related services may be provided, such as specialized HIV care, primary care, community-based care, maternal and child health services, TB services, and services for people who use drugs. Finally, the guidelines enabled key clinical, operational, and programmatic implications of new science

and emerging practice in the use of ARVs to be comprehensively reviewed every 2 years across populations, age-groups, and settings (WHO 2013). With these expanded guidelines, it was estimated that 25.9 M individuals in RLS were eligible for ART compared to an estimated 16.7 M persons using the 2010 guidelines (Fig. 1).

The largest increase of newly eligible individuals was in the adult and adolescent age-groups followed by discordant couples and children. Further, the 2013 guidelines modified PMTCT requirements, ensuring continued access to ART for mothers during the pregnancy and breastfeeding period (Option B/B+). Expanding the eligibility criterion for ART in RLS creates opportunities to save lives and reduce HIV transmission. However, the expansion can also pose significant technical, operational, programmatic, and ethical challenges to policymakers and implementers. Therefore, faster scale-up, innovation, and programmatic adaptation will be required to provide care to all eligible individuals (PEPFAR 2015).

ART Regimen Choices for Adults and Adolescents

First-line Regimens in Adults and Adolescents

First-line ART should consist of two nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs) plus a non-nucleoside reverse transcriptase inhibitor (NNRTI). A fixed-dose combination of tenofovir (TDF), lamivudine (3TC) or emtricitabine (FTC), and efavirenz (EFV) is recommended as the preferred option to initiate ART in adults and adolescents. If TDF + 3TC (or FTC) + EFV is contraindicated or not available, Table 2 provides other options that are recommended.

Second-line Regimens in Adults and Adolescents

Diagnosis and treatment of the patients failing first-line ART in RLS remains challenging. The lack of routine viral load monitoring causes treatment failure to entirely depend on WHO clinical and immunological failure criteria, which have been demonstrated to correlate poorly with virological failure. Due to the potential misclassification of treatment failure resulting from using clinical and immunological failure criteria, limited availability of treatment options, poor laboratory infrastructure, lack of health care provider confidence in making switches, and the high cost of second-line ART, physicians are reluctant in deciding whether and when to switch ART. Delayed treatment switches lead to increased morbidity and mortality, and more extensive ART resistance in patients with unrecognized treatment failures.

WHO recommends the use of two classes of drugs, NRTI and protease inhibitors (PI), for adults, adolescents, and children if NNRTI-containing regimen were used in first-line ART. Unlike the NRTI, the PI may have a relatively high threshold of mutations to confer resistance, and most patients failing first-line ART do not have PI resistance mutations. The drugs most commonly used for second-line ART include tenofovir, abacavir, and lopinavir/ritonavir (LPV/r); atazanavir/ritonavir (ATV/r) can be substituted for LPV/r as needed. The second-line NRTI choice for adolescents and adults depends on the first-line ART; for patients on AZT or

Antiretroviral Treatment in Resource-Limited Settings, Table 2 First-line regimens in adults and adolescents (WHO 2013)

First-line ART	Preferred first-line	Alternative first-line
Adults (including pregnant and breastfeeding women and adults with TB and HBV co-infection)	TDF + 3TC (or FTC) + EFV	AZT + 3TC + EFV AZT + 3TC + NVP TDF + 3TC (or FTC) + NVP
Adolescents (10–19 years) ≥ 35 kg	TDF + 3TC (or FTC) + EFV	AZT + 3TC + EFV AZT + 3TC + NVP TDF + 3TC (or FTC) + NVP ABC + 3TC + EFV (or NVP)

AZT zidovudine, NVP nevirapine, ABC abacavir

Antiretroviral Treatment in Resource-Limited Settings, Table 3 Second-line regimens in adults and adolescents (WHO 2013)

Population	Preferred second-line	Alternative second-line
Adults and adolescents (≥ 10 years), including pregnant and breastfeeding women	AZT + 3TC + LPV/r AZT + 3TC + ATV/r	TDF + 3TC (or FTC) + ATV/r TDF + 3TC (or FTC) + LPV/r ABC + 3TC + LPV/r
HIV and TB co-infection	If rifabutin is available	Standard PI-containing regimens as recommended for adults and adolescents
	If rifabutin is not available	Same NRTI backbones as recommended for adults and adolescents plus double-dose LPV/r (that is, LPV/r 800 mg/200 mg twice daily) or standard LPV dose with an adjusted dose of RTV (that is, LPV/r 400 mg/400 mg twice daily)

stavudine (D4T) in first-line ART, the default second-line option is TDF combined with 3TC or FTC and LPV/r. For patients receiving TDF in first line, the second-line option will be an AZT-based regimen. For those receiving TDF during first line because of intolerance to AZT or D4T, an alternative second-line option will be abacavir (ABC) combined with 3TC or FTC and LPV/r (Table 3).

Monitoring of HIV-Infected Patients

Monitoring of HIV-infected patients is critical to assess patient progress. Due to the cost associated with routine viral load testing, patient monitoring in RLS is done mainly through clinical and WHO immunological criteria assessments, despite the shortcomings of these assessments in recognizing virological failure.

Clinical Monitoring

Assessments include observing the development of clinical events such as unexplained weight loss, herpes zoster infection, diarrhea for more than 1 month, pneumonia, tuberculosis, meningitis, or other AIDS-defining events. These clinical events are then used to classify patients into different WHO stages.

Immunological Monitoring

Periodic 6-month CD4 cell count measurements are performed to identify those with ART treatment failure. WHO immunological failure criteria

include a fall of CD4+ cell count to the pre-ART baseline value or below, a fall of $\geq 50\%$ of peak value CD4+ cell count while on treatment, and a persistently low CD4+ cell count $< 100/\text{mm}^3$.

One of the major challenges of immunological assessments is their relatively low sensitivity and specificity in predicting virological failure. The reported range of sensitivity is 16–58%, with specificity of 21–54%. These low levels of sensitivity and specificity suggest unintended misclassifications are likely to occur and some patients will receive unnecessary switches and those with unrecognized treatment failure will be prone to disease progression. Study results have confirmed these predictions but have not demonstrated a survival benefit for viral load monitoring. Although survival benefits of using viral load testing over clinical and immunological assessment are not apparent, WHO recommends the use of viral load testing whenever available since the latter does allow early detection of treatment failure.

Monitoring for Drug Toxicities

Besides clinical and immunological assessments, laboratory monitoring of drug toxicities is important. The nucleoside/nucleotide reverse transcriptase inhibitors are classes of ARVs widely used in RLS. These drugs may be associated with a variety of side effects, most of which could be monitored by routine laboratory assessments of chemistries to monitor liver and kidney function, and complete blood counts for anemia and neutropenia.

Antiretroviral Treatment in Resource-Limited Settings, Table 4 First-line regimens for children and infants (WHO 2013)

Population	Preferred first-line	Alternative first-line
Children 3 years to less than 10 years and adolescents <35 kg	ABC + 3TC + EFV	ABC + 3TC + NVP AZT + 3TC + EFV AZT + 3TC + NVP TDF + 3TC (or FTC) + EFV TDF + 3TC (or FTC) + NV
Children <3 years	ABC or AZT + 3TC + LPV/ r	ABC + 3TC + NVP AZT + 3TC + NVP

A

Monitoring for Drug Resistance

Monitoring for drug resistance in RLS is not a routine practice due to the costs associated with resistance testing and a lack of laboratory support with capacity to do resistance testing.

The availability of liquid ART formulations for treating infants and children varies between countries.

ART Regimen Choices for Pediatrics

For children infected with HIV age 3 years and older (including adolescents), EFV is the preferred NNRTI for first-line treatment and NVP the alternative. For children infected with HIV 3 years to less than 10 years old (or adolescents less than 35 kg), the NRTI choices for an ART regimen should be one of the following, in preferential order: ABC + 3TC or AZT or TDF + 3TC (or FTC).

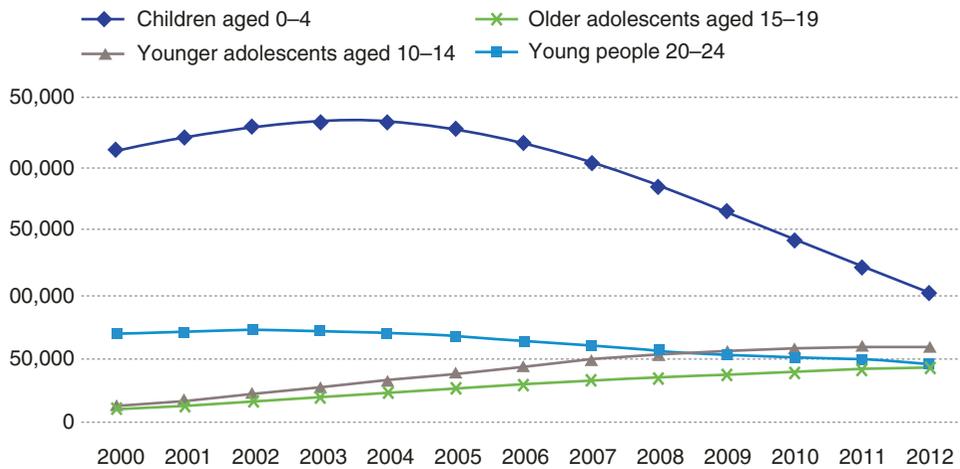

A LPV/r-based regimen should be used as first-line ART for all children infected with HIV younger than 3 years (36 months) of age, regardless of NNRTI exposure. If LPV/r is not feasible, treatment should be initiated with a NVP-based regimen. For infants and children infected with HIV younger than 3 years, the NRTI backbone for an ART regimen should be ABC or AZT + 3TC due to the potential for TDF to be associated with adverse bone effects.

For infants and children infected with HIV younger than 3 years, ABC + 3TC + AZT is recommended as an option for children who develop TB while on an ART regimen containing NVP or LPV/r to avoid drug-drug interactions with anti-TB drugs (Table 4). Once TB therapy has been completed, this regimen should be stopped and the initial regimen restarted.

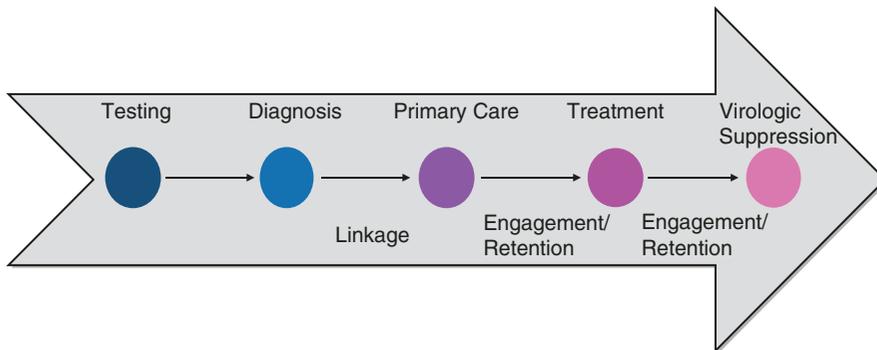

Treatment Challenges for Adolescents

In RLS, an estimated 2.1 million adolescents (10–19 years) were living with HIV in 2012 (UNAIDS 2013). While the number of global AIDS-related deaths for all ages fell by 30% between 2005 and 2012, among adolescents the number increased by 50% in that period (Fig. 2).

Adolescence is recognized as a period of life involving significant physical, physiological, and psychological changes that mark the transition to adulthood. This is also the period of life when social and gender roles are reinforced in many RLS. Adolescents infected with HIV face higher rates of depression, anxiety, and trauma than their uninfected peers. They are often exposed to parental loss and substance abuse. Most come from low-income families and subsequently face inequities in education, food security, and healthcare. Others may enter adolescence unaware of their HIV status. Inadequate access to high-quality, youth-friendly HIV treatment and sexual and reproductive health services and sexual violence against young women and girls hinder effective HIV prevention for adolescents and young people. In addition, limited protection for young people's confidentiality and right to medical privacy may hinder their ability to obtain essential services. Inadequate access to comprehensive sex education, which has been shown to effectively

Antiretroviral Treatment in Resource-Limited Settings, Fig. 2 Estimated number of AIDS-related deaths 2000–2012 (Source: UNICEF analysis of UNAIDS 2012 HIV and AIDS estimates)

Antiretroviral Treatment in Resource-Limited Settings, Fig. 3 Discrete steps in monitoring HIV care (Source: Adapted from IOM – Monitoring HIV Care in the United States)

delay sexual debut and increase condom use among young people, also undermines HIV prevention efforts (UNAIDS 2013). These mental, structural, and psychosocial challenges have negative associations with clinical outcomes. HIV-infected adolescents are more likely to be nonadherent to first- and second-line regimens, hence leading to the observed higher rates of AIDS-related deaths.

Treatment Cascade

The access to and availability of ARVs are not the only ingredients required to reduce mortality and morbidity of HIV/AIDS. In order for individuals

and society to benefit maximally from the successes of ART, it is important to adopt approaches that enhance the continuum of HIV care. Figure 3 illustrates the discrete steps along the HIV care continuum.

The cascade of care was developed to present a continuum of care, from the number of individuals within a population infected with HIV, diagnosed with HIV, linked to and retained in HIV care, on treatment, and having achieved suppression of HIV replication (Mugavero et al. 2010). It reflects the steps needed to improve an individual's health as well as identifies areas of opportunity within a population for interventions to optimize disease management and reduce ongoing HIV transmission. RLS are encouraged

to develop their country-specific national goals for testing, linkage, retention, and viral suppression. With these data, countries will be able to quantitatively track and measure the progress of their HIV programs. Recent studies from RLS have reported poor retention in pre-ART care and substantial losses to follow-up at every step, starting with patients who do not return for their initial CD4 count results and ending with those who do not initiate ART despite eligibility (Rosen and Fox 2011). Delays in diagnosis, poor engagement, and inconsistent retention in HIV care have all been shown to negatively impact both individual and public health outcomes. Therefore an emphasis should be placed on “adherence” to care and not just medications. Benefits of engagement in care for individual patients results in improvements in initiation and adherence to ART, better immunological and virological outcomes, and lower mortality. At the community level due to improvement of virological control and reduction in risky behaviors, there is reduced HIV transmission.

Adherence and Retention Interventions

Adherence

The goal of ART is to reduce the virus to undetectable levels in patients’ blood after being on treatment, and therapeutic levels of ART are essential to reach this goal. Thus adherence to ART is critical if this goal is to be realized. The main concern of interrupted medication use is the development and the spread of resistant strains of viruses leading to treatment failure. Despite the successes of ART, patients, program, and drug-related factors may each contribute to poor ART medication adherence.

Barriers to ART Adherence

HIV-related stigma, poverty, distance to care and treatment centers, alcoholism, substance abuse, being away from home, forgetfulness, depression, and a history of sexual, physical, and mental trauma are some of the notable patient-related factors that negatively impact ART adherence. In practical terms, sustained adherence to ART

requires consistent supply of ART medications. Medication stock-outs and long waiting hours due to staff shortages may impair ART adherence at the programmatic level. Despite the success of ART in reducing morbidity and mortality associated with HIV infection, their unintended adverse effects such as lipodystrophy, peripheral neuropathy, anemia, neutropenia, pancreatitis, hypersensitivity reactions, and kidney and liver toxicities may contribute to poor ART adherence.

Interventions to Improve ART Adherence

Many governments in RLS have tried to remove structural barriers of accessing ART by making ART freely available, as well as decentralizing care and treatment centers to residential areas. In most cases adherence to ART depends on personal behavior, and a number of interventions may result in improved medication adherence. A variety of health care professionals including doctors, pharmacists and nurses, and HIV-infected peers have been used successfully to deliver adherence education. Given that improved adherence may wane with time, counseling about ART adherence should be a continuous process across care and treatment centers. Establishment of peer support may be an important step in improving ART adherence. In addition, simplified treatment regimens with fixed-dose combinations and prescription of less toxic medications may also improve ART adherence.

Retention in Care

One of the greatest challenges facing HIV care and treatment programs in RLS is loss to follow-up. Loss to follow-up may result in increased morbidity, mortality, risk of HIV transmission, and development of resistant strains of viruses, all of which reduce efforts to mitigate HIV infection. Loss to follow-up is higher among those enrolled into care but not on ART than those already on ART, possibly because those not on ART perceive themselves to be clinically stable.

A number of strategies can improve retention of patients in care. For example, decentralization of care and moving treatment centers from

consultant referral hospitals to district and health centers improved patient retention by reducing the distance travel to clinics, as well as long waiting hours patients would have at consultant referral hospitals.

Establishment of community adherence support group improves patient retention into care. With this strategy, groups of 4–6 HIV-infected adults with stable HIV infection are created. Each month one group member attends clinic on behalf of others to collect ART, as well as sending blood samples for CD4 testing. In this way other group members get opportunities to be in the workplace with fewer disruptions and without interfering with ART treatment.

Empowering patients with the skills to prioritize ART use over other sociocultural activities is critical to improve patient retention in care. One of the strategies adopted by the WHO to improve patient retention is integration of health care services by providing services as “one stop shopping.” For example, integrating TB and HIV care at the TB clinic without referring TB/HIV coinfecting patients to specialized HIV clinic improves retention. Similarly antenatal care (ANC) and HIV care are integrated in most programs, and this approach has been shown to improve retention of HIV-infected pregnant mothers. Other strategies proven to improve retention include engagement of peer and family support, specialized services to those with substance abuse and mental illness, provision of reminder services, and systematic monitoring of clinic attendance.

Treatment as Prevention

In the context of an HIV serodiscordant couple where one member is HIV infected and the other is not, the viral load of the infected partner has long been identified as an important predictor of the risk of sexual transmission. Subsequently cohort studies suggested that treating the infected partner with ART could lead to a decreased risk of sexual transmission. The definitive evidence that ART is successful in decreasing the risk of transmission

came from the results of HPTN 052, published in 2011 (Cohen et al 2011). HPTN 052 studied 1763 HIV serodiscordant couples where the seropositive partner had a CD4 count 350–550, and randomized the HIV-infected partner to either immediate or delayed treatment with fixed-dose combination FTC/TDF/EFV. All participants were provided education regarding prevention of HIV transmission, and given free condoms. The primary outcome was HIV transmission to the seronegative partner, and transmitted virus was sequenced to ascertain whether transmission occurred in the original couple relationship or if a different sexual partner was responsible for transmission. The study was discontinued by the Data Safety and Monitoring Board after a median follow-up period of 1.7 years, and 90% of the couples were still retained in follow-up. The study results were striking; overall there were 39 HIV transmissions, 4 in the early therapy group and 35 in the delayed group. When linked transmission events were determined by sequencing, there was 1 transmission in the early therapy group and 27 in the delayed group, corresponding to a 96% reduction in HIV transmission when the seropositive partner received ART. These findings provide robust evidence to support the 2013 WHO Guidelines recommendation for initiating ART in the seropositive partner of a serodiscordant couple. Researchers are currently studying the impact of this recommendation outside of the context of a clinical trial to see if similar benefits are realized.

Additional uses of treatment as prevention can include pre-exposure prophylaxis (PrEP), postexposure prophylaxis (PEP), and the investigational use of microbicides containing antiretroviral compounds.

Antiretroviral Drug Resistance

Antiretroviral drug resistance is a growing challenge for successful treatment in RLS. A number of factors may be important in the development of drug resistance such as the widespread inability to measure plasma HIV RNA levels and recognize

virological failure, the lack of resistance testing to guide the optimal choice of ART regimens and therefore resulting in incomplete viral suppression, treatment interruptions due to logistical obstacles, poor adherence, and drug interactions. Antiretroviral drug resistance most commonly occurs as a consequence of incomplete suppression of viral replication in HIV-infected persons receiving ART (acquired drug resistance), and it also may occur in the context of transmitted drug resistance when HIV infection first occurs (transmitted drug resistance). These two circumstances will be considered separately.

Acquired Drug Resistance in HIV-Infected Persons Receiving ART

Drug resistance inevitably occurs over time if suppression of HIV replication is incomplete. Resistance to ART in resource-limited settings has been demonstrated in several scenarios listed below:

1. HIV-infected persons beginning ART who fail to fully suppress
2. HIV-infected persons beginning ART who do not adhere to treatment
3. HIV-infected persons who face logistical obstacles to care
4. HIV-infected mothers and infants who are exposed to incompletely suppressive regimens such as single-dose nevirapine

Many studies have addressed drug resistance among patients failing first-line ART in RLS, and nearly all have demonstrated extensive drug resistance by the time that failure was recognized (numerous studies have demonstrated that virological failure is recognized late). Most commonly three-drug regimens containing an NNRTI, 3TC, or FTC and a nucleoside or nucleotide reverse transcriptase inhibitor are employed as first-line treatment. At virological failure of first-line ART, nearly all patients have both NNRTI and 3TC or FTC resistance (Wallis et al. 2014), with consequences for potential cross-resistance in second-line ART choices. Unfortunately, resistance assays to guide second-

line ART choices are rarely available. Similarly, in HIV-infected mothers and infants with past exposure to single-dose nevirapine, NNRTI resistance is common and better treatment outcomes may be achieved when protease inhibitor-containing regimens are used following exposure to single-dose nevirapine.

Transmitted Drug Resistance

Transmitted drug resistance is increasingly recognized in resource-limited setting, especially eastern and southern sub-Saharan Africa. It is now estimated that 5–15% of transmitted HIV has drug resistance mutations, and the percentages with drug resistance are rapidly increasing (an estimated 29% per year in eastern Africa) (Hamers et al. 2013). Transmitted drug resistance does compromise the activity of ART regimens and has been linked to increased virological failure of ART and shorter time to failure (Kantor et al. 2015). These observations underscore the need to ensure successful ART with full suppression of HIV replication, and the need to improve laboratory monitoring of plasma HIV RNA levels and assessment of drug resistance mutations.

Conclusion

ART has been proven to save the lives of people living with HIV and decrease HIV transmission. However, for individuals and communities to reap these benefits, it is critical for health care systems in RLS to improve the delivery of services across the entire continuum of care. Initiatives to support active linkage, engagement, and retention in care have the potential to improve overall patient outcomes.

Definition

The primary targets of HIV-1 (T lymphocytes, macrophages, and monocytes) are able to limit HIV-1 replication by expressing the restriction factors APOBEC3F and APOBEC3G (A3F/G). These two proteins have cytidine deaminase activity and induce mutations during reverse transcription of the genomic RNA that could be lethal for the virus. A3F/G also interfere with the reverse transcription and integration processes independently from this deaminase activity. To counteract this restriction, HIV-1 has evolved the viral infectivity factor (Vif), a multifunctional protein that is able to reduce the cellular A3F/G expression level through two major mechanisms: (1) Vif induces degradation of A3F/G by the proteasome by recruiting an E3 ubiquitin ligase complex, and (2) Vif inhibits A3F/G translation by interacting with the 5' untranslated region (UTR) of their mRNAs. These two mechanisms ultimately reduce the packaging of A3F/G into virions. The intimate relationship between Vif and A3F/G provides new therapeutic targets, and several

functional properties of Vif, such as Vif dimerization, the recruitment of the Vif-E3 ubiquitin ligase complex, and the Vif-A3F/G interaction, could be targeted by drugs.

Introduction

In addition to the three essential protein precursors (structural Pr55^{Gag}, enzymatic Pr160^{Gag-Pol}, and envelope Pr160^{Env}), the HIV-1 genome encodes six auxiliary proteins: Tat, Rev, Nef, Vpr, Vpu, and Vif. Vif (viral infectivity factor) is essential for the infection of the HIV-1 natural targets cells, such as T lymphocytes. Indeed, a *vif*-deleted HIV-1 mutant (HIV-1Δ*vif*) does not replicate in such cells, which are thus termed nonpermissive. Despite this information, the role of Vif remained unclear for a long time, until the identification of CEM15 (Sheehy et al. 2002), a natural cellular antiviral factor counteracted by Vif which has since be renamed APOBEC3G (A3G). A3G belongs to a large family of cytidine deaminases and needs to be packaged into viral particles in order to perturb the next HIV-1 replication cycle. In the first part of this review, A3G and A3F proteins and the processes by which these proteins inactivate HIV-1 replication are described. In the second part, the focus is on Vif and the mechanisms by which Vif counteracts the A3F/G restriction activities. To conclude, the importance of the relationship between A3F/G and Vif is underlined and how it could be used in new therapeutic approaches is indicated.

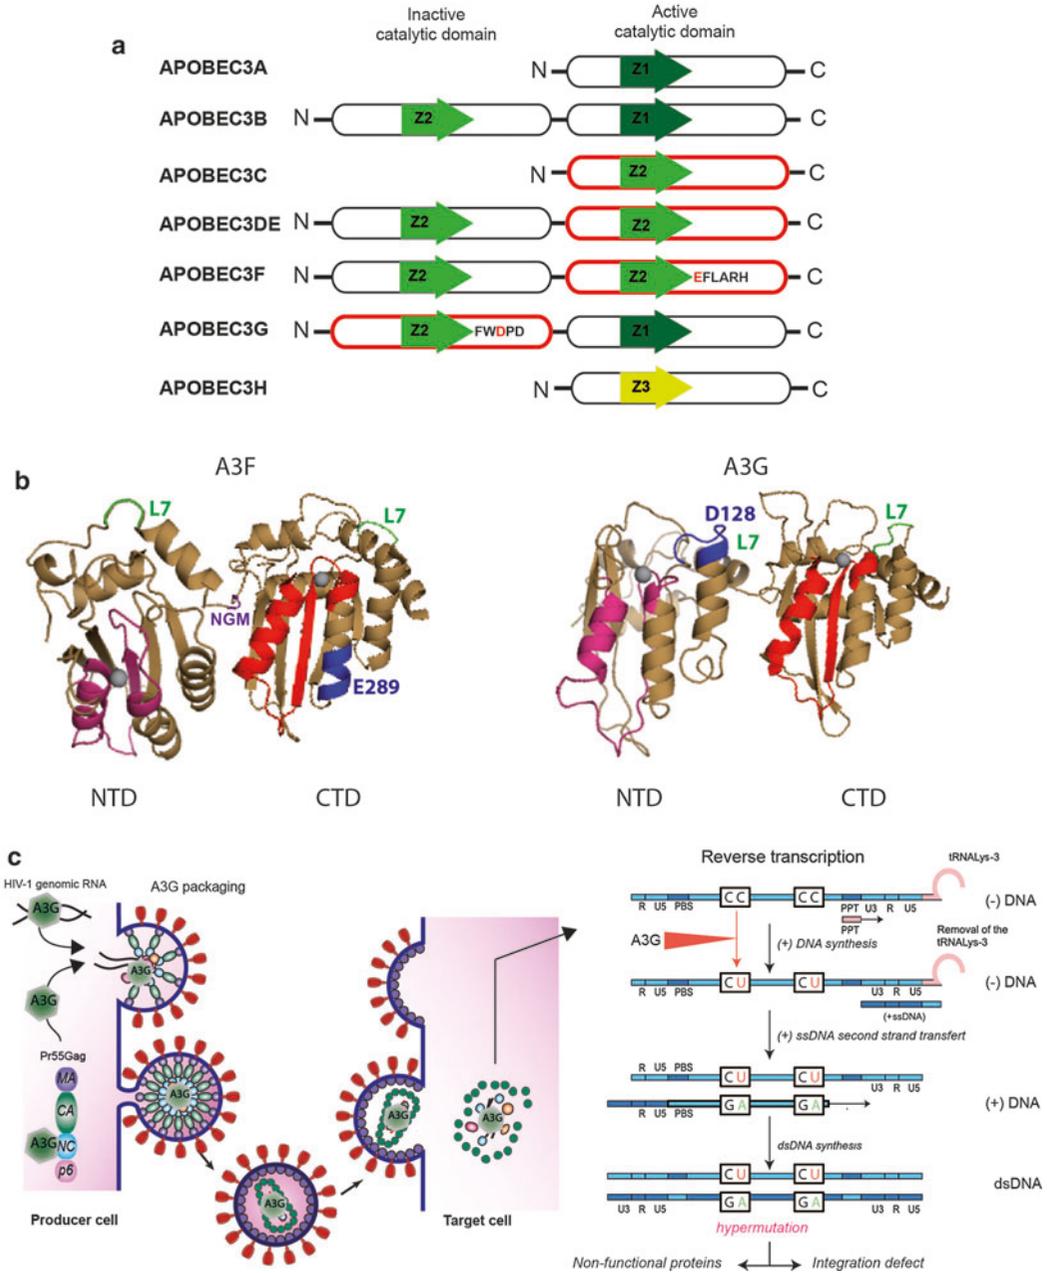

HIV-1 Restriction by APOBEC3 Enzymes

The APOBEC3 Proteins: A Potent Army Against HIV
The APOBEC3 (**apolipoprotein B** mRNA-editing enzyme, catalytic polypeptide-like 3 or A3) family is exclusively present in vertebrates; in humans, it comprises seven members (A3A to A3H), all encoded by genes located on chromosome 22 (Fig. 1a). This family of proteins plays an important role in innate antiviral immunity against retroviruses, most notably HIV-1. Each A3 protein harbors at least one active catalytic domain (CD) constituted by a zinc finger motif sharing the

consensus sequence H-X-E-X_{23–28}-P-C-X_{2–4}-C (where X is any one of the 20 amino acids). A3A, A3C, and A3H have only one zinc finger domain and hence one catalytically active domain. A3D/E, A3F, and A3G have two zinc finger motifs, but only one is catalytically active. A3B is the exception as it has two zinc finger motifs, both of which may be catalytically active. All of these enzymes are involved in the restriction of several viruses/retrotransposons. Among the A3 proteins, A3F and A3G are the most efficient in restricting HIV-1, although A3A, A3D/E, and A3H are also able to affect HIV-1 infectivity to some extent. In A3F and A3G, the active cytidine deaminase domain is located in the C-terminal zinc finger motif (Fig. 1a). The inactive N-terminal zinc finger motif is involved in different functions such as RNA binding, multimerization, or packaging into virions. A3F and A3G are both able to bind Vif, even though the binding sites do not seem to be conserved between the two proteins: the residues involved in Vif binding are located in the N-terminal CD between positions 126–132 of A3G and positions 289–294 in the C-terminal CD of A3F, respectively. Interestingly, both sites of interaction could be disrupted by a single amino acid mutation: D128K and E289K in A3G and A3F, respectively. These mutations alter the ability of the respective protein to reduce HIV-1 infectivity.

Structural information is available for the C-terminal domain of A3F (PDB: 4IOU) and A3G (PDB: 3IQS) revealing highly conserved structures between the two proteins. Both are composed of five β-sheets (β1–β5) with six α-helices (α1–α6) including a coordinated zinc ion. Models of the N-terminal domains have recently been established using the SWISS-MODEL program (Feng et al. 2014). When the two domains are combined (Fig. 1b), A3F/G appear as symmetric proteins exposing a positively charged platform on both domains, allowing binding to negatively charged DNA.

To achieve their restriction activity on HIV-1, A3F/G proteins need to be encapsidated into nascent virions to act during the next round of replication (Fig. 1c). Indeed, despite their cytoplasmic localization in target cells, A3F/G

APOBEC3F/G and Vif: Action and Counteractions, Fig. 1 APOBEC3 family: domains, structure of A3F/G, and restriction mechanisms. (a) Schematic representation of the seven APOBEC3 members. The conserved zinc (Z)-coordinating DNA cytosine deaminase motif Z1, Z2, and Z3 (phylogenetic clusters containing a SW-S/T-C-x₂₋₄-C motif for Z1 and Z2, whereas Z3 proteins have a TW-S-C-x₂-C motif) are shown in *dark green*, *green*, and *yellow*, respectively. The Vif binding domains are indicated by *red ovals*. For A3F/G, the Vif binding sequence is indicated including the crucial residues in *red*

(see text for details). (b) A3F/G structure/models: while the structures of the C-terminal domain of A3F and A3G have both been determined experimentally (PDB: 4I0U and 3IQS), experimental structures of the N-terminal domains are still missing and therefore correspond to models calculated by Feng et al. (2014). The catalytic inactive domain is depicted in *pink*, whereas the active one is in *red*. Residues in *blue* interact with Vif. Loop seven (L7) involved in the processivity and in the recognition of the target sequence to deaminate is depicted in *green* in each domain, whereas A3F NGM residues are in *purple*, at the interface of the

proteins are not able to access the neosynthesized (–) single-stranded (ss) DNA intermediate during reverse transcription of incoming viruses. This is most likely due to the protection of the reverse transcription complex by the HIV-1 capsid and/or sequestration of the A3F/G proteins in storage granules, such as stress granules or processing bodies (P-bodies). A3F/G packaging is mediated by interactions with the nucleocapsid (NC) domain of the Pr55^{Gag} precursor (Alce and Popik 2004). This interaction is also stabilized by the presence of the HIV-1 genomic RNA. Efficient binding of A3G to the HIV-1 genomic RNA requires its oligomerization. Interestingly, both RNA binding and A3G oligomerization are mediated by the N-terminal domain of A3G. Additionally, A3G packaging is favored by the co-encapsidation of 7SL RNA, which is also mediated by the NC domain of HIV-1 Pr55^{Gag}. Once packaged, A3F/G remain associated with the reverse transcription complex after virus entry in target cells where they are able to perform their antiviral activities.

Deamination-Dependent Mechanisms

Once in the cytoplasm of infected cells, A3F/G proteins interfere with reverse transcription by inducing numerous deoxycytidine to deoxyuridine mutations during the synthesis of the (–) ssDNA in a 3′–5′ processive manner (Fig. 1c; Harris et al. 2003). This process ultimately results in dG → dA hypermutations in the (+) strand proviral DNA and in the production of aberrant viral proteins, thus reducing the replicative capacities of the virus. A3F and A3G preferentially deaminate different sequencings in the (–) ssDNA: A3G preferentially deaminates the last cytidine of 5′-CC or 5′-CCC motifs, thus inducing 5′-AG or 5′-AGG mutations on the (+) strand DNA, whereas A3F deaminates 5′-TC or

5′-TTC motifs. Interestingly, the A3G target sequence is part of the unique tryptophan codon (ACC in (–) DNA; TGG in (+) DNA), and its deamination results in the introduction of stop codons (UGA) in the viral coding sequence. In contrast, A3F mainly induces missense mutations that may or may not allow the expression of the corresponding protein. This could explain why A3G has a more drastic effect on HIV-1 infectivity than A3F. Another explanation might reside in the mechanism that the two proteins use to find their target sequence on the (–) ssDNA: while A3G is able to slide very efficiently along the (–) ssDNA substrate to find its target sequence in a processive manner, A3F jumps from one (–) ssDNA substrate to another one in a distributive manner (Ara et al. 2014). The processivity determinants of A3G have been mapped in the loop 7 and helix 6 of the N-terminal non-catalytic domain, which therefore indirectly participate in the deamination activity of A3G. In A3F, the linker between the N- and C-terminal domains (¹⁹⁰NGM¹⁹²) (Fig. 1b) seems to be responsible for its inability to translocate on (–) ssDNA.

Such deamination-induced mutations in the viral genome are lethal to the virus and could lead to the degradation of the hypermutated viral DNA, the production of truncated or non-functional viral proteins, and the impairment of the integration process. Moreover, mutated/truncated proteins expressed from the viral genome may, after processing by the proteasome, serve as HIV antigens and facilitate the immune recognition of HIV-1 (Casartelli et al. 2010).

Deamination-Independent Mechanisms

Several studies using inactive mutants of the CD showed that A3F/G still have residual restriction activity and impair HIV-1 infectivity, indicating that cytidine deaminase activities are not solely

←
APOBEC3F/G and Vif: Action and Counteractions, Fig. 1 (continued) domains (see text for details). Figures were drawn with the PyMOL software (PyMOL Molecular Graphics System, Version 1.5.0, Schrodinger, LLC). (c) Restriction mechanisms of A3G: to exert its

restriction activity, A3F/G needs to be encapsidated into viral particles and released in infected cells (*left panel*). Restriction of HIV-1 replication by A3F/G involves the deaminase activity (*right panel*) and deaminase-independent pathways (not shown)

responsible for their antiviral activities. Deaminase-independent activities target mainly two steps of the HIV-1 replication cycle: reverse transcription and integration. A3F/G are able to interact with reverse transcriptase and limit its efficiency, resulting in diminished viral cDNA levels (Wang et al. 2012), and can also bind HIV-1 integrase and decrease the integration efficiency by 5- to 50-fold (Luo et al. 2007). Such deamination-independent activities might be due to interactions of A3F/G with the viral genome, leading to competition and/or steric hindrance with reverse transcriptase and integrase enzymes. Although this deaminase-independent mechanism seems to contribute less than 1% to the overall restriction capability of A3F/3G, it has nevertheless been observed in primary cells (Gillick et al. 2013).

Overview and Properties of HIV-1 Vif

To counteract the restriction mediated by A3F/G, all lentiviruses except equine infectious anemia virus (EIAV) encode the viral infectivity factor (Vif), which is essential for HIV-1 replication in primary target cells (lymphocytes, macrophages/monocytes, dendritic cells). In these so-called nonpermissive cells, deletion of *vif* from the HIV-1 genome has been associated with a strong reduction of viral infectivity (100- to 1,000-fold) (Strebel et al. 1987). The nonpermissive phenotype is due to the expression of A3F/G proteins in these cell types (Sheehy et al. 2002).

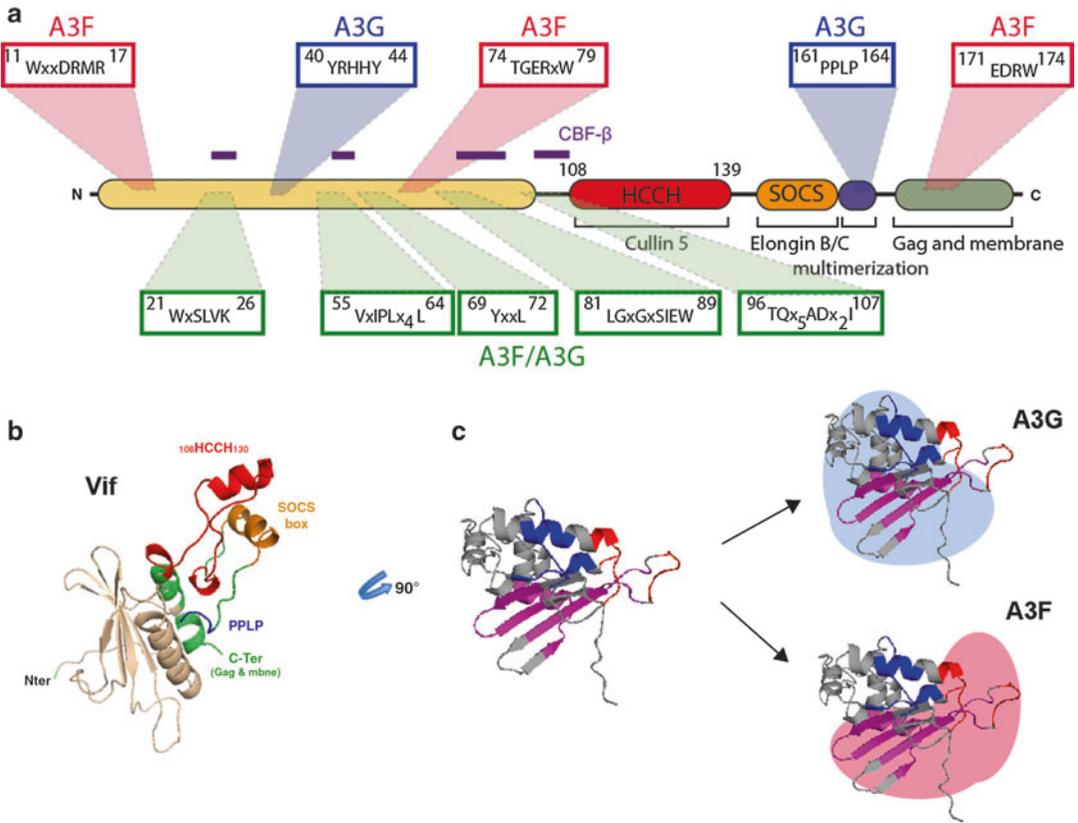

Functional Domains of Vif

Vif is a highly basic protein (pI = 10.7) composed of 192 amino acids (23 kDa). Alignments of lentiviral Vif sequences highlighted several conserved domains suggestive of a multifunctional protein.

- *The N-terminal domain*, enriched in tryptophan residues, is important for the binding of A3 proteins (Fig. 2a). Although A3F and A3G share common interacting motifs with Vif (²¹WKSLVK²⁶, ⁵⁵VxIPLx4L⁶⁴, ⁶⁹YWxL⁷², and ⁸⁵VSIEW⁸⁹), some domains are specific to A3G (⁴⁰YRHHY⁴⁴ and ¹⁶¹PPLP¹⁶⁴) and A3F (¹¹WQxDRMR¹⁷, ⁷⁴TGERxW⁷⁹, and

¹⁷¹EDRW¹⁷⁴). Other domains in the C-terminal domain have been described to be important for A3G and A3F binding, such as the ¹⁶¹PPLP¹⁶⁴ and ¹⁷¹EDRW¹⁷⁴ motifs, respectively (Fig. 2a, b). Such discontinuous interacting sites suggest that the correct folding of Vif is crucial to create the binding platform for A3 proteins. Moreover, Vif residues important for the interaction with A3H, A3C, and A3DE have been identified in the N-terminal region. The N-terminal region of Vif also interacts with the HIV-1 genomic RNA (residues 1–64 and 75–114) both in vitro and in infected cells. Finally, residues W₂₁, W₃₈, ⁸⁴GxSIEW⁸⁹, and ¹⁰²LADQI¹⁰⁷ are involved in the binding of CBF-β (core binding factor β).

- *The central region* of Vif constitutes a platform for the recruitment of an E3 ubiquitin ligase complex composed of Elongin B, Elongin C, CBF-β, Cullin 5, and Rbx2 proteins that targets A3 proteins for degradation by the proteasome. Residues 108–139 constitute a non-consensus HCCH zinc finger motif that binds zinc and Cullin 5; they are followed by a SOCS (suppressor of cytokine signaling) box motif (¹⁴⁴SLQYLA¹⁴⁹). This region promotes the interaction with the Elongin C/Elongin B (BC box) heterodimer through a hydrophobic platform on both proteins involving the SLQ residues and the A₁₄₉ residue of the SOCS box and α helices 3 and 4 of Elongin C. Very recently, the Cullin 5 box and the ¹⁶¹PPLP¹⁶⁴ motif have also been shown to participate to Vif-Elongin C/B binding.
- *The C-terminal region* of Vif starts with a putative Cullin 5 box (residues 159–173) that recruits the Cullin 5 with a lower efficiency than the HCCH zinc finger domain. This region covers the ¹⁶¹PPLP¹⁶⁴ motif involved in Vif multimerization. This PPLP motif is also involved in the binding with various partners such as A3G, Elongin B/Cullin 5, and the cellular kinase Hck. The last 25 residues of Vif are important for its interaction with Pr55^{Gag} and cytoplasmic membranes and interfere with the reverse transcriptase activity. In contrast to other regions of Vif, the C-terminal

structure with A3F (red) and A3G (blue) binding domains. The Vif structure has been rotated to highlight the specific (blue/red) or the common (magenta) interaction areas. The possible orientation of A3G (in light blue) and A3F (pink) proteins is depicted on the Vif structure. Figures were drawn with the PyMOL software (PyMOL Molecular Graphics System, Version 1.5.0, Schrodinger, LLC)

appears to be intrinsically disordered. This property is characteristic of proteins carrying RNA and/or protein chaperone activities: such proteins catalyze the folding of both the chaperone and the target molecules upon binding, reconstituting an active complex. Chaperone activities have been extensively described for several HIV-1 proteins such as NC and Tat and more recently for Vif (Sleiman et al. 2014). The Vif RNA chaperone activity may modulate viral activities such as the structural maturation of the HIV-1 genomic RNA and initiation of its reverse transcription to optimize viral infection and propagation.

Due to its intrinsic biochemical properties, the determination of the 3D structure of Vif has been a real challenge and a matter of intensive research. It is only very recently that the Huang Group successfully crystallized Vif in a pentameric complex (Fig. 3a) including the subunits of the E3 ubiquitin ligase complex: CBF-β, Elongin C/Elongin B, and Cullin 5 (Guo et al. 2014). The crystal structure of Vif has been solved at 3.3 Å resolution (PDB: 4N9F) and showed an elongated conical structure constituting two binding platforms involved in the recruitment of the E3 ubiquitin ligase complex and of A3 proteins (Fig. 2b). This is consistent with previous

APOBEC3F/G and Vif: Action and Counteractions, Fig. 3 Schematic representation of the mechanisms by which Vif reduces the A3G cellular level. (a) Vif binds to A3G and recruits an E3 ubiquitin ligase, leading to the polyubiquitination of A3G and its degradation by the 26S proteasome. (b) Vif impairs the translation of A3G

mRNA through an mRNA-binding mechanism, involving the highly structured 5' UTR of A3G mRNA. These different activities of Vif on translation and degradation not only deplete A3G from virus-producing cells but also prevent A3G from being incorporated into virions

mutational analyses showing that both Cullin 5 and Elongin C interact with the C-terminal domain of Vif, whereas A3F/G and CBF-β bind to the N-terminal domain. Interestingly, while the A3F/G binding motifs appear discontinuous in the linear Vif sequence (Fig. 2a), the Vif structure highlights how the different residues are organized in two different binding domains that overlap in the central part of Vif (Fig. 2c). Of note, the

extreme C-terminal part of Vif does not harbor any defined structures, consistent with an intrinsically disordered region and compatible with the RNA chaperone activity of this region.

Vif Hijacks an E3 Ubiquitin Ligase Complex to Degrade A3 Proteins (Vif/A3 Interactions)

Several mechanisms have been proposed to explain how Vif limits the antiviral activity of

A3F/G by preventing its encapsidation. The first and more documented mechanism so far is the polyubiquitination and proteasomal degradation of A3F/G by Vif (Marin et al. 2003; Sheehy et al. 2003). Proteasomal degradation results in a strong reduction of the intracellular levels of A3F/G. As described above, Vif is able to bind A3F/G through various domains and to recruit an E3 ubiquitin ligase complex, leading to the polyubiquitination and degradation of A3F/G. Vif therefore connects the E3 ubiquitin ligase complex (Elongin B/C, Cullin 5, CBF- β) to its A3G substrate (Fig. 3a). Then, an E2 ubiquitin-conjugating enzyme interacts with Rbx2 and allows the polyubiquitination (⁴⁸K-linked ubiquitins) of A3G that is targeted to the 26S proteasome for degradation. Recently, the transcription cofactor CBF- β has been shown to be an integral component of the ubiquitin ligase complex and required for the Vif-mediated degradation of A3G. Therefore, Vif binds the E3 ubiquitin ligase complex through at least 3 binding domains: the SOCS box allows the interaction with Elongin B/C, the HCCCH zinc finger mediates binding to Cullin 5, and, finally, the N-terminal domain binds to CBF- β .

The A3G lysine residues targeted by the E3 ubiquitin ligase complex are not clearly defined: if one study identified four critical lysines in the C-terminal region of A3G (K₂₉₇, K₃₀₁, K₃₀₃, and K₃₃₄) (Iwatani et al. 2009), others showed that A3G lysines are randomly susceptible to ubiquitination.

Degradation-Independent Inhibition of A3 Proteins

Translation Although the Vif-induced degradation of A3F and A3G by the 26S proteasome has been well studied, it is not the only mechanism by which Vif counteracts A3 proteins. Indeed, Vif decreases the steady-state levels of A3F/G in the presence of proteasome inhibitors in rabbit reticulocyte lysates and cell cultures, suggesting that A3G translation is affected by Vif (Mariani et al. 2003; Stopak et al. 2003). Recently, binding of Vif to the highly structured 5' untranslated region (5' UTR) of A3G mRNA has been shown to be responsible for the inhibition of A3G

translation by Vif (Mercenne et al. 2010; Fig. 3b). Although the exact mechanism is not understood yet, it is possible that Vif relocates A3G mRNA to specialized compartments such as P-Bodies or stress granules where translation is stopped. Indeed, Vif has been shown by immunofluorescence to co-localize with A3 proteins in P-Bodies (Wichroski et al. 2006).

Virion Encapsidation As discussed above, Vif can reduce the expression of A3F/G proteins through the proteasome/degradation pathway and by inhibiting its mRNA translation, ultimately leading to a strong reduction of A3F/G encapsidation into new budding particles. One estimate indicates that 1–2 to 3–11 A3G proteins are encapsidated per virion in the presence or absence of Vif, respectively (Xu et al. 2007). Interestingly, the use of an A3G C97A mutant suggested that degradation and packaging of A3G are independent properties of Vif (Opi et al. 2007). Indeed, although this A3G mutant is resistant to Vif-mediated degradation, less protein is found in virion in the presence of Vif. The molecular mechanism is still not understood but a competition between Vif and A3G toward their specific binding sites, such as the HIV-1 genomic RNA or Pr55^{Gag}, is possible (see also section “[The APOBEC3 Proteins: A Potent Army Against HIV](#)”).

Intravirion Deamination Despite the fact that a few A3G molecules (1–2) are packaged into virions in the presence of Vif, deamination activity per protein is less potent in these viral particles (Britan-Rosich et al. 2011). Several studies have shown that Vif is able to decrease the deaminase-specific activity of A3G and this effect requires Vif binding to the ssDNA that is the substrate of A3G (Feng et al. 2013). The Vif-mediated inhibition of A3G deaminase activity is the consequence of the reduction of A3G processivity. Indeed, A3G performs deaminations on ssDNA using both sliding and jumping mechanisms (see also section “[Deamination-Dependent Mechanisms](#)”). Interestingly, a study reported that Vif from two different HIV-1 isolates (HXB2 and IIB) does not have the same effect on A3G

deaminase activity (Feng et al. 2013). While Vif_{IHXB2} inhibits the jumping of A3G, Vif_{IIB} alters the sliding movements. Moreover, the intravirion deaminase activity of the A3G D128K mutant is unaffected, suggesting that inhibition of this activity requires the interaction between Vif and A3G.

Inhibition of APOBEC3G Degradation: A Therapeutic Perspective

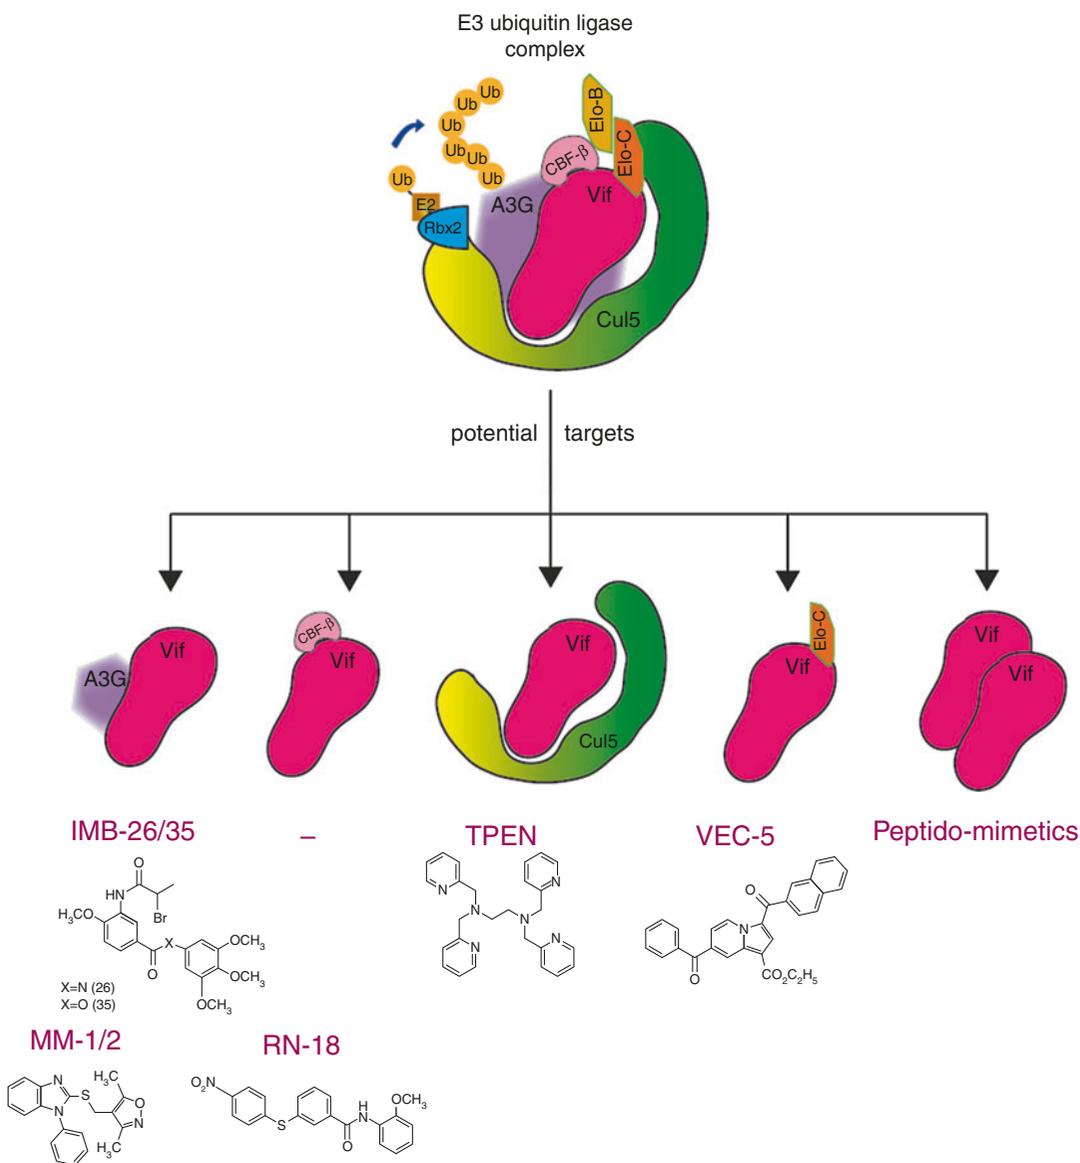

The relationship between Vif and members of the A3 family offers perspectives for developing novel therapeutics. High-throughput screening studies have identified several families of molecules that can restore the A3G intracellular concentration despite the presence of Vif. Some compounds are antagonists of Vif and restore the A3G enzymatic activity (and thus its antiviral property), whereas others block the A3G catalytic activity (Li et al. 2012) and are proposed to decrease the resistance to antivirals due to the reduction of viral quasispecies. There are at least five interfaces that can potentially be targeted to inhibit Vif functions: A3 proteins, CBF- β , Elongin C, Cullin 5, and its dimerization domain (Salter et al. 2014; Fig. 4).

Targeting the interface between Vif and A3 proteins is a real challenge. Indeed, Vif interacts with each of A3 proteins (A3D/F/G/H) through distinct and unique interfaces, and the development of a specific drug targeting each A3 protein is time consuming and thus unlikely. Moreover, another hurdle for the development of such inhibitors is the overlapping of binding sites for different A3 ligands: e.g., the Vif/A3G interface coincides with amino acids required for A3G encapsidation, oligomerization, and processivity (Huthoff et al. 2009). Nevertheless, different classes of compounds have been identified that potentially interfere either directly with the Vif/A3G interaction through binding to the N-terminus of A3G (IMB-26/35) (Cen et al. 2010) or indirectly by stabilizing A3G during the polyubiquitination steps (MM-1/2) (Matsui et al. 2014) or by decreasing Vif expression in the presence of A3F/G (RN-18) (Nathans et al. 2008; Fig. 4). Another strategy to restore the deaminase/antiviral activity would be to block the Vif/E3 ubiquitin ligase

complex and CBF- β interactions. For instance, a zinc chelator named TPEN (N,N,N',N'-tetrakis-(2-pyridylmethyl) ethylenediamine) has been shown to specifically inhibit the Vif-Cullin 5 interaction and to inhibit Vif functions (Xiao et al. 2007). The Vif-Elongin C interaction can also be affected by targeting the Vif SLQ motif with a small molecule (VEC-5) (Zuo et al. 2012). Interestingly, this compound does not only protect A3G but also A3C and A3F from Vif-induced proteasomal degradation, and it enhances A3G incorporation into the progeny virions. Finally, it may be possible to directly target Vif or CBF- β . In the case of Vif, its oligomerization domain provides an attractive target (Fig. 4). Although the molecular mechanism of Vif oligomerization is not clearly defined (Batisse et al. 2013), targeting the ¹⁶¹PPLP¹⁶⁴ motif with peptido-mimetics has been shown to block Vif-Vif interaction in vitro and lead to a decrease of virus replication in nonpermissive cells (Miller et al. 2007). The recent resolution of the Vif/E3 ubiquitin ligase complex structure (Vif/CBF- β /Cul5/EloC/EloB) (Guo et al. 2014) together with in silico screening of small molecules should enhance the number of lead compounds aimed at inhibiting the functions of Vif.

Conclusion

The innate immune system encodes several editing A3 proteins that are involved in the restriction of various retroviruses, viruses, and retrotransposons. Among these deaminases, A3F and A3G are the most potent against HIV-1 replication. These proteins need to be incorporated into new viral particles to induce DNA hypermutation. To prevent the antiretroviral activity of A3F/G, HIV-1 encodes Vif that targets A3F/G and reduces their intracellular concentrations by recruiting an E3 ubiquitin ligase complex to direct them to the proteasome, by inhibiting the A3F/G translation through binding to the 5' UTR of their mRNAs or by competing with A3F/G binding sites to avoid their incorporation into new viral particles. Vif also inhibits intravirion A3F/G

APOBEC3F/G and Vif: Action and Counteractions, Fig. 4 Potential therapeutic strategies and targets to inhibit Vif functions. Targeting one interaction between two partners can be sufficient to prevent the formation of the E3 ubiquitin ligase complex and to inhibit Vif activity. The Vif/A3G interaction can be targeted by IMB-26/35,

MM-1/2, and RN-18. The Vif/CBF-β interaction is a potential target site but no molecules have been identified yet. The Vif/Cul5 and the Vif/E1oC interactions can be inhibited by TPEN and VEC-5, respectively. Finally, the dimerization domain can be counteracted by peptido-mimetics

deamination. Thanks to the recent resolution of the structure of the Vif-E3 ubiquitin ligase complex, new potential therapeutic target sites may be discovered to inhibit Vif functions and restore

antiviral activities of A3 proteins. However, additional studies will be required to make sure the targeted interactions are not involved in essential cellular functions.

 National Center for Biodefense and Infectious
 Diseases, George Mason University, Manassas,
 VA, USA

Definition

Arp2/3 is a heptameric complex composed of the Arp complex proteins (ARPC) 1–5 and the actin-related proteins Arp2 and Arp3 (Higgs and Pollard 1999, 2001). The Arp2/3 complex is highly conserved among eukaryotes, is a key regulator of cytoskeletal actin dynamics, and plays significant roles in cell motility, filopodia formation, cell adhesion, endocytosis, T-cell activation, and metastasis. Additionally, the Arp2/3 complex is utilized by several pathogens, including vaccinia virus, *Listeria monocytogenes*, baculovirus, and enteropathogenic *Escherichia coli* (EPEC) for

intracellular motility or, in the case of EPEC, the creation of an actin pedestal (Haglund and Welch 2011). Recently, the Arp2/3 complex and its upstream signaling regulator, WAVE2, have also been implicated in HIV infection of primary CD4 T cells and macrophages (Spear et al. 2014).

Introduction

In cells, spontaneous actin nucleation is prevented by G-actin-binding proteins such as thymosin β 4. Additionally, the kinetic instability of actin oligomers that are fewer than 3 actin subunits long renders spontaneous actin nucleation unfavorable. The Arp2/3 complex serves as an actin nucleator by overcoming the kinetic barriers to nucleation in a highly regulated manner (Higgs and Pollard 1999). Following activation by nucleation-promoting factors (NPFs), the Arp2/3 complex binds to the side of an existing filament through Arp3 and ARPC2, with Arp2 and Arp3 in close juxtaposition (Higgs and Pollard 2001). The Arp2:Arp3 dimer functions as an F-actin nucleus, promoting de novo actin polymerization with the aid of the associated NPFs (Higgs and Pollard 2001). As a result, a new actin filament is created, deviating from the original filament, or “mother” filament, by an angle of approximately 70° (Higgs and Pollard 2001).

The Arp2/3 complex is highly regulated by NPFs, which serve the roles of signal integrators, activators, and facilitators. Known NPFs include N-WASP, WASP, WAVE 1–3, WASH, WHAMM, and JMY (Padrick and Rosen 2010). All NPFs share an Arp2/3-activating motif, called the WCA, at their C-terminus (Padrick and Rosen 2010). The WCA is composed of a WASP homology 2 (WH2) domain, connector domain, and acidic domain (Higgs and Pollard 1999; Padrick and Rosen 2010). The consensus mechanism of NPF activation involves the release of inhibitory contacts engaging the WCA, which is followed by WCA exposure. The exposed WH2 domain binds to G-actin, and the CA domain binds to and activates Arp2/3, priming the Arp2/3 complex for nucleation (Higgs and Pollard 2001; Takenawa and Suetsugu 2007).

Regulation of the Arp2/3 Complex by WASP/N-WASP and WAVE NPFs

WASP/N-WASP: Wiskott-Aldrich syndrome protein (WASP) was identified as mutated in many patients with WAS, characterized by defects in platelet and leukocyte development and function. WASP is expressed primarily in cells of hematopoietic origin, whereas the related neural WASP, or N-WASP, is expressed in most tissues (Takenawa and Suetsugu 2007). Structurally, WASP and N-WASP share an N-terminal EVH1 domain (Ena/VASP homology 1), a basic domain, a GTPase-binding domain (GBD), a proline-rich domain (PRD) that interacts with SH3-containing adaptor proteins, and a C-terminal WCA domain (Padrick and Rosen 2010). The isolated WCA domain of all NPFs is capable of activating Arp2/3 in vitro (Higgs and Pollard 2001). However, in vivo, both WASP and N-WASP are inhibited by intramolecular interactions between the GBD and WCA domains; however, upon activation, the WCA is exposed (Padrick and Rosen 2010). Activation of WASP/N-WASP is often cooperative, with full activation occurring when the GBD, basic domain, and PRD are engaged by their respective ligands (Padrick and Rosen 2010). The GBD engages a Rho-family GTPase, *cdc42*, in its active, GTP-bound form; the basic domain binds to PIP₂ and other negatively charged phospholipids; and the PRD binds to several known ligands including Grb2, Nck, amphiphysin, and many others (Padrick and Rosen 2010; Takenawa and Suetsugu 2007). However, the details of cooperative activation differ between N-WASP and WASP (Padrick and Rosen 2010). Tyrosine phosphorylation by Src-family kinases may potentiate activation (Padrick and Rosen 2010). The oligomerization of WASP/N-WASP through PRD ligands may also potentiate Arp2/3 activation (Padrick and Rosen 2010).

WAVE1–3: WAVE (WASP-family verprolin-homologous protein) 1, 2, and 3 are structurally similar to the WASP-type NPFs, including a basic domain, PRD, and C-terminal WCA. In contrast, the N-terminus of WAVE proteins contains a WAVE homology domain (WHD), which is responsible for recruiting components of the

WAVE regulatory complex (WRC), composed of HSPC300, Abi1, Nap1, and Sra-1 (Padrick and Rosen 2010) (Takenawa and Suetsugu 2007). The WRC, much like native WASP, is inactive and is activated by binding to the GTP-bound form of Rac, PIP₃, the PRB binding to SH3-domain containing proteins (especially IRSp53), and phosphorylation (Padrick and Rosen 2010; Takenawa and Suetsugu 2007). Rac, another Rho-family GTPase, in its GTP-bound form binds indirectly to WAVE via Sra-1 (Takenawa and Suetsugu 2007). IRSp53 may also promote WAVE activation in a manner dependent on WAVE oligomerization and binding of Rac:GTP (Takenawa and Suetsugu 2007). WAVE1 and WAVE 2 play a significant role in generating the protrusive actin dynamics during cell motility.

Roles of Arp2/3 in Cellular Cytoskeletal Dynamics

As a result of signal transduction events, upstream regulators of the various NPFs are activated, resulting in WCA exposure and Arp2/3 activation. In migrating cells, this often results in a protrusive structure called the lamellipodium at the leading edge of the cell (Le Clainche and Carlier 2008). In the lamellipodium, numerous Arp2/3 molecules are activated behind the leading edge membrane, producing a dendritic array of actin filaments, with polymerization occurring towards the direction of migration (Le Clainche and Carlier 2008). Typically, this is mediated downstream of Rac and WAVE activation (Padrick and Rosen 2010). This process of branching and polymerization helps drive the protrusive actin dynamics required for membrane protrusion (Le Clainche and Carlier 2008). Also during cell migration and at the leading edge, thin filamentous protrusions consisting of bundled actin filaments are also produced, and these are called filopodia (Le Clainche and Carlier 2008). These structures may be generated downstream of a *cdc42*-N-WASP pathway (Yang and Svitkina 2011). Although dendritic branching may be structurally inconsistent with the bundles of actin filaments seen in filopodia, it is believed that

Arp2/3-generated filaments converge to produce these structures, recruiting fascin, ENA/VASP, and formins as structural and actin-polymerization driving factors, respectively (Yang and Svitkina 2011). Both structures are often observable during cellular migration, a process that is critical to normal development and immunological function.

Additionally, Arp2/3 plays a critical role during phagocytosis and endocytosis. As above, Arp2/3-mediated nucleation and polymerization drives protrusive actin dynamics that shape the nascent endocytic structures and facilitate membrane scission along with a host of other factors (Takenawa and Suetsugu 2007). During endocytosis, WASP-family NPFs engage membrane-binding and membrane-deforming proteins via its PRD (Takenawa and Suetsugu 2007). Subsequently, Arp2/3 activation results in membrane scission and drives vesicle movement away from the plasma membrane (Takenawa and Suetsugu 2007). A similar, WASP-family NPF-driven mechanism is thought to be involved in phagocytosis, in which Arp2/3 promotes phagocytic cup closure and scission.

Arp2/3 is also indispensable in cell-cell and cell-matrix adhesion, wherein the actin cytoskeleton is attached directly to extracellular contacts (Ren et al. 2009). Cortactin is one of the pivotal regulators at these cellular adhesions, coordinating cellular signals from integrins, cadherins, Src-family kinases, and NPFs (Ren et al. 2009). Cortactin also has an N-terminal acidic (NTA) domain that acts as a weak activator of Arp2/3 (Higgs and Pollard 2001; Ren et al. 2009).

Role of Arp2/3 in HIV Infection

Arp2/3 has been implicated in HIV infection, though the exact mechanism remains unclear. In one study, HIV and SIV infection was inhibited by expression of the N-WASP WCA domain, expressed as GFP-WCA, which dysregulates and dislocates Arp2/3 from physiologically relevant conditions (Komano et al. 2004). This inhibition was not related to fusion, as determined by a cell-to-cell fusion assay in which the target cell

expressed CD4 and a T7 RNA polymerase-dependent reporter vector, and the donor cell expressed HIV Env and T7 RNA polymerase (Komano et al. 2004). Additionally, VSV-G pseudotyping of HIV-1 particles mitigated inhibition, suggesting that the route of entry confers dependency on Arp2/3 (Komano et al. 2004). Furthermore, HIV-1 inhibition could be mediated by the CA or acidic domain alone. Though no mechanism was elucidated in this study specifically, constitutive expression of GFP-VCA significantly delayed the kinetics of HIV-1 replication in H9 cell clones.

Another study corroborated that Arp2/3 is important in HIV infection; however, this study indicated that inhibition occurred during a post-hemifusion step, such as pore formation or expansion (Harmon et al. 2010). Additionally, siRNA knockdown of the upstream regulators of Arp2/3, WAVE2, IRSp53, Rac, Tiam-1, and Abl generates similar fusion defects, indicating a potential pathway of activation necessary for HIV entry and infection (Harmon et al. 2010). In addition, the Abl inhibitors imatinib, nilotinib, and dasatinib also blocked HIV entry as determined by fusion assay (Harmon et al. 2010). Molecules that induced positive membrane curvature, overcoming blocks to hemifusion, diminished the effects of siRNA knockdown of Tiam-1, Abl, Rac, IRSp53, WAVE2, and Arp3 (Harmon et al. 2010).

As the findings of these two studies are somewhat incompatible, perhaps due to differing methodologies and cell systems, the exact mechanism of how Arp2/3 is involved in HIV entry remains uncertain. Recently, the Arp2/3 complex and WAVE2 have been implicated in the nuclear migration of the viral core following entry (Spear et al. 2014). Stable shRNA knockdown of Arp3 inhibited viral infection of CD4 T cells without blocking viral entry and early DNA synthesis (Spear et al. 2014). However, the accumulation of 2-LTR circles, a correlative of viral nuclear migration, was inhibited (Spear et al. 2014). A small molecule inhibitor of Arp2/3, CK-548 (Nolen et al. 2009), was also found to inhibit viral nuclear migration: viral DNA synthesis was not inhibited by CK-548, while the 2-LTR circles were reduced (Spear et al. 2014). CK-548 was also found to

block HIV latent infection of resting CD4 T cells at dosages that did not inhibit T cell activation (Spear et al. 2014). It was demonstrated that during HIV infection of resting CD4 T cells, the virus actively promotes Arp2/3 activity through triggering WAVE2 phosphorylation on serine 351. This HIV-mediated WAVE2 activation was observed in X4 (CXCR4) virus infection of resting CD4 T cells and in R5 (CCR5) virus infection of primary macrophages (Spear et al. 2014). In the X4 virus infection of resting CD4 T cells, WAVE2 phosphorylation could be blocked by AMD3100, a CXCR4 antagonist, suggesting that the signal was transduced from HIV gp120 interaction with CXCR4 (Spear et al. 2014). However, treatment with pertussis toxin, which inhibits Gai signaling, only partially blocked WAVE2 phosphorylation at later time points (Spear et al. 2014), indicating that the WAVE2 phosphorylation induced by HIV gp120 is likely dependent on both Gai and Gaq (Spear et al. 2014). It was postulated that Arp2/3 could be anchored onto the viral pre-integration complex (PIC) through the viral core binding to actin filaments. This Arp2/3-mediated actin polymerization may drive the PIC towards the nucleus (Spear et al. 2014).

The HIV pathogenicity factor and accessory protein Nef has also been linked to Arp2/3. Expression of Nef in peripheral blood mononuclear cells and Jurkat T cells inhibited immunological synapse maturation and cell spreading induced by anti-CD3/CD28 antibody-coated cover slips, a model system that mimics T-cell activation (Haller et al. 2006). This effect was dependent on the Nef SH3-binding domain, as a well-characterized Nef mutant lacking this motif ameliorated defects in T-cell spreading and contact maturation (Haller et al. 2006). This effect was further linked to an overall reduction in active, phosphorylated N-WASP, including at TCR-stimulatory contacts (Haller et al. 2006). Direct inhibition of N-WASP utilizing wiskostatin mimicked these Nef-mediated effects, corroborating evidence that Nef-mediated defects in immunological synapse maturation and cell spreading are mediated by N-WASP dysregulation (Haller et al. 2006). PAK2, a serine/threonine kinase and a Nef interactor, was necessary for these

Nef-mediated effects, as observed in siRNA knockdown experiments (Haller et al. 2006).

Conclusion

The Arp2/3 complex is a critical regulator of actin dynamics that mediates F-actin nucleation and branching. This process is critical for lamellipodium formation, T-cell activation, certain types of endocytosis, and metastasis. Arp2/3 is dynamically regulated by nucleation-promoting factors (NPFs), including WASP/N-WASP, WAVE family proteins, WASH, WHAMM, and JMY. Known NPF activation schemes require signal convergence from phospholipids, GTPases, adaptor proteins, and kinases, which induce the exposure of the Arp2/3-activating WCA domain found at the C-terminus of the NPF. HIV-1 infection has recently been shown to require Arp2/3 and the upstream regulators such as WAVE2, for nuclear migration. HIV-1 Nef also interferes with N-WASP signaling, which may affect CD4 T-cell activation at the immunological synapse.

Definition

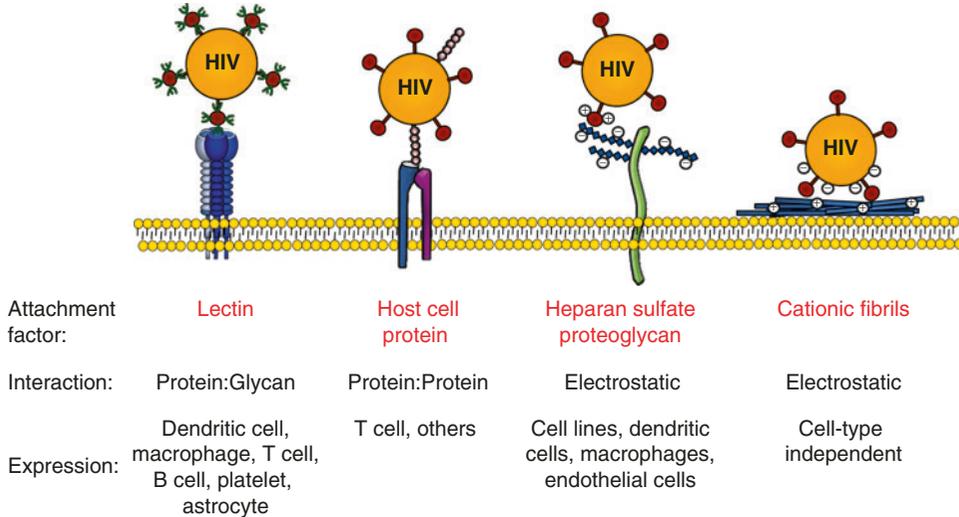

The envelope glycoprotein (Env) of the human immunodeficiency virus (HIV) mediates entry into target cells. Binding of Env to cellular attachment-promoting factors (attachment factors) is frequently unspecific and generally dispensable for entry. However, engagement of attachment factors can profoundly augment HIV infectivity and might impact viral tropism and spread. The lectin DC-SIGN is an archetypic attachment factor, which can facilitate capture of infectious HIV by dendritic cells and might impact HIV transmission and dissemination.

Introduction

The human immunodeficiency virus (HIV) uses its envelope protein (Env) as a key for entry into target cells, mainly CD4⁺ T cells and macrophages. Env is synthesized as a polyprotein in the constitutive secretory pathway of infected cells. An N-terminal signal sequence mediates import of the nascent protein into the endoplasmic reticulum where Env is extensively modified by high-mannose glycans (Scanlan et al. 2007). Upon transport of Env trimers into the Golgi apparatus, the high-mannose glycans are processed into complex glycans. However, processing is incomplete, in part due to the dense packaging of glycans, and about half of the glycans remain in the high-mannose or hybrid form (Scanlan et al. 2007). Env proteins traversing the *trans*-Golgi network are cleaved into the surface unit, gp120, and the transmembrane unit, gp41, by the proprotein convertase furin, and cleavage is essential for infectivity. The two subunits of Env remain non-covalently associated, and trimers of gp120:gp41 heterodimers are incorporated in the plasma membrane, the site of HIV ► budding, and ultimately in the viral envelope.

The physical separation of Env into a surface and a transmembrane unit mirrors the separate functions of these subunits: The surface unit gp120 binds to the receptor and coreceptor, while the transmembrane subunit drives ► fusion of the viral and the cellular membrane, which allows delivery of the viral genetic information into the host cell cytoplasm. Specifically, binding of gp120 to CD4 creates or exposes a coreceptor binding site, and coreceptor binding then activates gp41 for membrane fusion (“► Fusion” and “► CXCR4, Co-Receptors”). The multiple subsequent interactions between Env, CD4, and coreceptor are highly specific and attractive targets for antiviral intervention.

Attachment of HIV to the cell surface can be mediated by factors other than CD4. For instance, binding of Env glycans to cellular lectins or the interaction of charged surfaces on Env with host cell proteoglycans can facilitate attachment (Fig. 1). In addition, the cognate recognition of ligands on the cell surface by cellular receptors

Attachment/Binding, Fig. 1 HIV attachment factors discussed in the present review. DC-SIGN and other cellular lectins can bind glycans on the viral envelope protein (*Env*) and transmit infectious virus to target cells in *cis* (i.e., infection of the lectin-expressing cell) and in *trans* (i.e., infection of an adjacent cell). Several host cell proteins are incorporated into the viral envelope during budding of progeny virions from infected cells. The interaction of host cell-derived proteins with binding partners expressed on the

surface of viral target cells can augment HIV infection in *cis*. Electrostatic interactions between the positively charged V3 loop of *Env* and negatively charged heparan sulfates facilitate binding of HIV to heparan sulfate proteoglycans. Bound viruses are infectious for target cells in *cis* and in *trans*. SEVI and other cationic fibrils bind to negative charges presented on the HIV surface and concentrate virions onto target cells, thereby augmenting infection efficiency

incorporated into the viral envelope can promote attachment. Since attachment of HIV to the cell surface is a rate-limiting step in the entry cascade, engagement of attachment factors can increase infection in *cis* (infection of the attachment factor expressing cell) and might expand viral tropism. Moreover, binding of HIV to attachment factors on cells negative for CD4 and coreceptor can promote infection of adjacent susceptible cells (a process termed *trans*-infection), which might facilitate HIV dissemination (Fig. 2). Here, we will introduce selected HIV attachment factors, and we will discuss how binding to these factors might impact HIV spread and pathogenesis.

HIV Attachment Factors

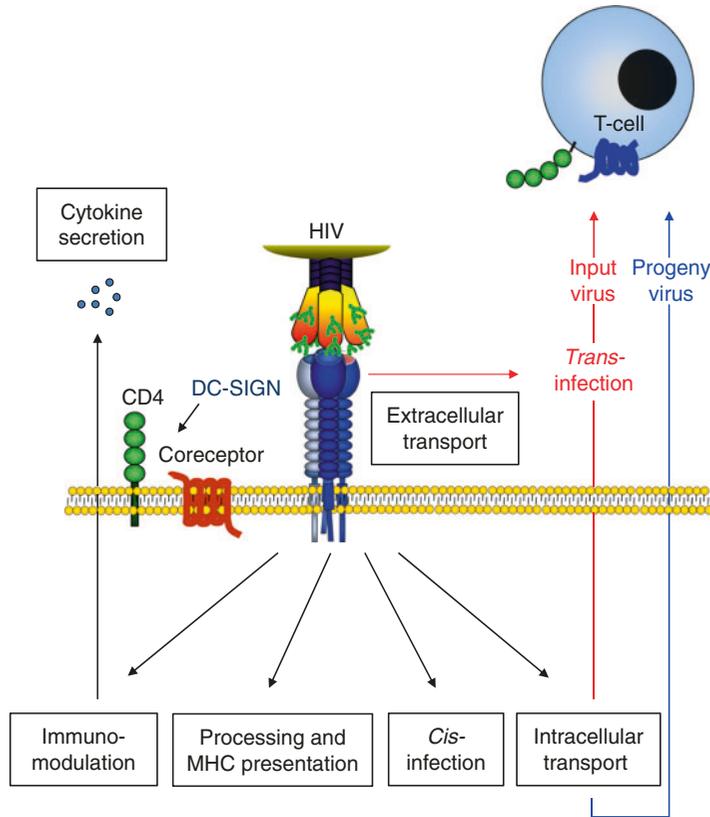

Lectins

DC-SIGN

The lectin *dendritic cell-specific intercellular adhesion molecule-3-grabbing non-integrin*

(DC-SIGN, CD209) is a type II transmembrane protein consisting of an N-terminal cytoplasmic domain, a transmembrane domain, a stalk domain, and a calcium-dependent (C-type) lectin domain (Geijtenbeek et al. 2000; Fig. 2). The cytoplasmic tail contains LL and EEE motifs which mediate receptor internalization upon ligand binding and appropriate intracellular trafficking, respectively. The stalk and lectin domains are located on the cell surface and are intimately involved in ligand binding: The stalk region, which consists of 7.5 blocks of a 23-amino acid-comprising sequence, mediates DC-SIGN tetramerization which is essential for efficient recognition of multivalent ligands. In addition, the stalk region is responsible for adequate spatial orientation of the lectin domain, which binds to mannose- and fucose-containing glycans displayed on the surface of HIV and other viral and nonviral pathogens (Tsegaye and Pöhlmann 2010).

DC-SIGN is mainly expressed on dendritic cells (“► [Role of Dendritic Cells in HIV-2](#)

Attachment/Binding, Fig. 2 Multiple consequences of HIV binding to DC-SIGN. DC-SIGN on dendritic cells binds to glycans on the viral Env protein and modulates HIV infection via different mechanisms: capture of HIV by DC-SIGN can increase infection of the DC-SIGN-expressing cell (*cis*-infection), resulting in constant release of infectious particles. Alternatively, bound viruses can be

transmitted via the cell surface or upon intracellular trafficking to adjacent T cells (*trans*-infection). A substantial portion of the DC-SIGN-bound virions is endocytosed and processed for MHC presentation. Finally, binding of HIV glycans to DC-SIGN can induce intracellular signaling which modulates cytokine expression upon TLR stimulation (Figure adapted from (Tsegaye and Pöhlmann 2010))

Pathogenesis”) which are among the first cells exposed to sexually transmitted HIV and are believed to play an important role in HIV dissemination (“Modeling Early HIV-1 Infection and Dissemination” and “► HIV-1 Transmission; Cell-Types Associated with”). Specifically, DC-SIGN was detected on dendritic cells located in the submucosa of the vagina, rectum, and foreskin (Geijtenbeek et al. 2000). In addition, DC-SIGN is expressed by certain tissue macrophages, including placental Hofbauer cells, which might play a role in vertical HIV transmission (Tsegaye and Pöhlmann 2010; “► HIV-1 Transmission; Cell Types Associated with”). Finally, subsets of B cells and platelets express

DC-SIGN and were shown to capture infectious HIV via this lectin.

Dendritic cells are largely resistant to HIV infection but catalyze infection of adjacent T cells. This process involves the formation of so-called infectious synapses between virus-loaded dendritic cells and uninfected T cells, which provide ideal microenvironments for HIV transmission. The discoveries that (i) placental DC-SIGN binds to the HIV Env protein, (ii) DC-SIGN expression endows certain cell lines with the capacity to transmit HIV (Geijtenbeek et al. 2000), (iii) DC-SIGN can facilitate HIV uptake into dendritic cells and promotes the formation of infectious synapses (Blanchet

et al. 2011), and (iv) DC-SIGN contributes to the HIV transmission from dendritic cells to T cells (Geijtenbeek et al. 2000) suggest that DC-SIGN on dendritic cells might play a key role intra- and interindividual spread of HIV (Fig. 2). Thus, it was proposed that dendritic cells might take up sexually transmitted HIV at peripheral sites via DC-SIGN, migrate into lymphoid tissues, and transfer the virus to adjacent T cells, thereby facilitating viral dissemination (Trojan horse model; Geijtenbeek et al. 2000).

Important features of the Trojan horse model were challenged by subsequent studies (Tsegaye and Pöhlmann 2010): It was shown that dendritic cells can capture HIV in a lectin-independent fashion and that lectins other than DC-SIGN (e.g., mannose receptor and DCIR) can contribute to HIV interactions with these cells. In addition, capture of HIV by dendritic cells was shown to result either in productive infection, HIV transmission to T cells, or degradation of the virus for antigen presentation. Which pathway prevails seems to be determined, at least in part, by the nature of the glycans present on the HIV Env protein.

An additional layer of complexity in the HIV interactions with DC-SIGN and dendritic cells results from the ability of DC-SIGN to elicit intracellular signals, which promote HIV spread in several ways (Fig. 2). Thus, ligation of DC-SIGN on dendritic cells by an antibody or by HIV can trigger signaling via the nucleotide exchange factor LARG, Rho GTPases, and Raf-1. The DC-SIGN-dependent signaling can have multiple consequences: It forces the cells to maintain an immature state and reduces their ability to induce T cell proliferation upon treatment with LPS, a TLR4 ligand. In addition, signaling is required for the DC-SIGN-driven formation of infectious synapses and can trigger an increase in the production of IL-6, IL10, IL-12p35 and IL12p40 upon exposure of dendritic cells to TLR4 ligands. Finally, stimulation of DC-SIGN by binding to the viral Env protein and simultaneous activation of TLR8 by the HIV mRNA is required for the production of full-length HIV transcripts, due to Raf-1-dependent phosphorylation of NF κ B and recruitment of the

transcription factor pTEF-b (Gringhuis 2010). Thus, glycan-dependent binding of HIV to DC-SIGN modulates dendritic cell function and thereby facilitates viral spread. The HIV glycosylation is cell type dependent, and viruses produced in macrophages and T cells, the major viral target cells, exhibit a markedly different glycosylation pattern. Whether these differences impact the interaction with dendritic cells remains to be investigated.

Langerin

The C-type lectin langerin is expressed on Langerhans dendritic cells and, like DC-SIGN, binds to the HIV envelope protein. However, HIV capture by DC-SIGN and langerin may have differential consequences for infectivity: While HIV binding to DC-SIGN can increase viral infectivity, at least under some conditions, langerin was reported to endocytose bound virions into Birbeck granules, unique structures within Langerhans cells, where HIV is degraded. These observations were made with Langerhans cells isolated from human skin, underlining that langerin-dependent HIV degradation might be operative in vivo. Thus, Langerhans cells in the top layer of the anogenital mucosa were proposed to constitute a powerful defense against sexually transmitted HIV (de Jong and Geijtenbeek 2010). However, relatively high doses of HIV can override the antiviral effect of langerin, which can also be compromised by herpes simplex virus type 2 (“► Risk of HIV-1 Transmission; Coinfections Associated with Risk”) which downregulates langerin expression and competes with HIV for langerin binding. In addition, langerin expression does not inhibit HIV infection of Langerhans cells generated from CD34⁺ dendritic cells, and these cells can facilitate *trans*-infection of T cells upon activation. Within skin explants Langerhans cells are preferentially and productively infected by HIV and promote viral spread by catalyzing infection of adjacent T cells. Finally, HIV capture, migration, and *trans*-infection of T cells were shown for Langerhans cells within the foreskin and vaginal mucosa. While high viral inoculum and differential expression of langerin on Langerhans cells in different tissues might

account for some of these pro-viral effects, the role of langerin in HIV infection warrants further analysis.

DCIR

The finding that HIV transmission by dendritic cells can proceed in a DC-SIGN-independent fashion spurred efforts to identify the responsible factors. One such study showed that the C-type lectin DCIR (*dendritic cell immunoreceptor*), which is expressed on dendritic cells and many other antigen-presenting cells, contributes to dendritic cell-mediated HIV *trans*-infection of primary T cells and also augments *cis*-infection of dendritic cells (Lambert et al. 2008). However, a direct interaction between the Env protein of HIV and DCIR remains to be demonstrated.

The cytoplasmic tail of DCIR contains an immunoreceptor tyrosine-based inhibitory motif, which can repress cell activation, and mutation of this motif reduces the capacity of DCIR to augment *cis*-infection by HIV. In accord, inhibition of protein tyrosine phosphatases (SHP-1, SHP-2), tyrosine kinases (Src and Syk family members), serine and threonine kinases (PKC), and mitogen-activated protein kinases (ERK1/2 and p38) inhibits DCIR-mediated HIV *cis*-infection. Thus, as for DC-SIGN, HIV might signal via DCIR to generate an environment suitable for efficient viral replication. Interestingly, soluble factors released in the context of HIV infection induce DCIR expression on both infected and uninfected bystander T cells, and upregulation is associated with increased HIV *cis*- and *trans*-infection. Therefore, several cell types might augment HIV spread in a DCIR-dependent fashion in HIV-infected individuals.

Mannose Receptor

The mannose receptor (MR) contains a large extracellular domain consisting of a membrane-proximal cysteine-rich domain, a fibronectin type II domain, and eight carbohydrate recognition domains (CRD). The cysteine-rich domain can bind to sulfated glycans, while the CRDs 4–8 facilitate calcium-dependent binding to mannose-, fucose-, or *N*-acetylglucosamine-containing ligands, including HIV gp120.

The HIV capture activity of MR might play a role in vaginal transmission. Thus, MR⁺, DC-SIGN⁺ dendritic cells, and MR⁺ macrophages are located in the submucosa of the endocervix, while CD68⁺, DC-SIGN⁺, and MR⁺ cells are present in the lamina propria of the ectocervix. Expression of MR on vaginal epithelial cells was shown to facilitate gp120 binding to these cells, and a link between MR expression on vaginal epithelium and sexual acquisition of HIV infection was suggested. Binding of gp120 to MR on the vaginal epithelium induces expression of matrix metalloproteinases (MMP), and MR-induced expression of MMPs might increase susceptibility of vaginal cells to HIV infection due to degradation of components of the extracellular matrix. MR and heparan sulfate proteoglycans might also promote capture of infectious HIV by spermatozoa, and these cells can present infectious virus to target cells.

Interactions of HIV with MR might also impact viral spread after the establishment of primary infection. For instance, binding of HIV to MR on astrocytes facilitates infection of these cells, which are CD4 negative, and triggers signals which induce expression of MMPs. Moreover, MR on macrophages and dendritic cells can promote attachment of HIV to these cells and the bound viruses are infectious for adjacent T cells. However, presentation of infectious, MR-bound virus is transient since HIV is taken up into macrophages in an MR-dependent manner and uptake does not lead to establishment of productive infection (Trujillo et al. 2007). Thus, HIV binding to MR could augment and repress HIV spread, as reported for DC-SIGN. Which effect prevails might depend on complex parameters, including cell type, coexpression of CD4 and coreceptor, and HIV glycosylation. Finally, it is noteworthy that MR expression is downregulated in HIV-infected cells in a partially Nef-dependent fashion, which might compromise innate defenses and HIV capture by infected cells.

Galectin-1

Attachment of HIV to target cells can be modulated by both membrane-associated and soluble lectins. The dimeric lectin galectin-1, which is

secreted by activated T cells, macrophages, and several other cell types, binds to beta-galactoside-containing glycans present on gp120 and on the surface of HIV-infected cells (Sato et al. 2012). Binding of galectin-1 to the surface of cells can induce apoptosis and is increased in the context of HIV infection, which alters the glycosylation status of host cell factors (“► [Lymphocyte Apoptosis](#)”). In addition, binding of galectin-1 to gp120 can augment viral infectivity. This effect is due to simultaneous binding of galectin-1 to CD4, which cross-links virus and receptor and thereby boosts infectious entry (Sato et al. 2012). Morphine increases galectin-1 expression and macrophage infection, suggesting that this lectin might augment viral spread particularly in drug users.

Proteoglycans

Proteoglycans are proteins covalently linked to one or more glycosaminoglycans (GAG), unbranched polysaccharide chains built from disaccharide units. Five classes of GAGs are known: hyaluronan, chondroitin, dermatan, heparin/heparan, and keratan. Apart from hyaluronan, GAGs are sulfated and thus contain a negative charge, which is important for ligand binding. Proteoglycans are integral parts of the extracellular matrix but are also found within cells and at the cell surface. The electrostatic interactions between sulfated proteoglycans presented at the plasma membrane and positively charged structures on the virion surface can promote cellular attachment of non-enveloped and enveloped viruses. HIV engages heparan sulfate but not chondroitin sulfate for attachment to T cell lines and HeLa cells, which express high levels of proteoglycans. In contrast, expression of heparan sulfate proteoglycans (HSPG) on primary T cells is low, and HSPGs have little impact on HIV attachment to these cells, which is largely mediated by Env binding to CD4.

The role of HSPGs in HIV attachment is mainly determined by the net charge of the V3-loop. Thus, viruses with a high net charge of V3 due to the presence of basic amino acids will bind robustly to negatively charged sulfates within HSPGs, resulting in efficient attachment and entry via CD4 and coreceptor. In particular, Arg-298 in the V3 loop determines the interaction

with HSPGs by binding to 6-O sulfates, and this amino acid also governs Env engagement of CCR5 via recognition of sulfated tyrosines at the receptor N-terminus. In contrast, viruses with a low net charge in V3 seem to be repulsed by HSPGs resulting in decreased attachment and infectious entry. Indeed, the analysis of a larger panel of Env sequences revealed that the infectivity of most HIV isolates might be reduced by HSPGs (Zhang et al. 2002). The coreceptor binding site, which is only exposed/created upon gp120 binding to CD4, is a second determinant of HSPG interactions, although its physiologic importance is less clear. Finally, it is noteworthy that GAGs can also modulate HIV infectivity in an indirect fashion by interacting with the CCR5 ligand CCL5 (RANTES). Within a certain concentration range, CCL5 blocks HIV infection by binding to CCR5. However, at higher concentrations CCL5 can form oligomers which cross-link enveloped virions to cells by binding to GAGs present on the surfaces of virions and cells. In addition, CCL5 can bind to GAGs attached to CD44, which activates MAPK, and both the cross-linking of virions and the activation of the MAPK pathway augment HIV infection. In sum, HSPGs bind to HIV Env in a charge-dependent fashion and can modulate viral infectivity for cell lines but might have little impact on viral infection of T cells in patients (Fig. 1).

Macrophages can sustain high viral loads upon depletion of T cells and constitute important viral reservoirs. These cells express high levels of proteoglycans, which facilitate HIV attachment to the cell surface. Specifically, expression of betaglycans and syndecans was detected on macrophages and the latter were shown to capture infectious HIV and to augment viral replication in a syndecan transfected cell line expressing low amounts of CD4. Syndecan-1, syndecan-2, syndecan-3, and syndecan-4 capture HIV upon directed expression in cell lines in a heparan sulfate-dependent manner and capture activity extends to SIV (Gallay 2004). More importantly, endogenous expression of syndecan-2 and syndecan-4 endows human endothelial cells with the ability to capture and transmit HIV to T cells. The infectivity of bound virus is conserved over

days, and a comparison between syndecans and DC-SIGN, for which conservation of infectivity was initially reported, showed that the proteoglycans are slightly more adept than the lectin in maintaining HIV in an infectious form. Syndecan-3 is also expressed by dendritic cells, and inhibition analysis revealed that C-type lectins and syndecan-3 contribute to HIV capture by these cells, with blockade of both factors diminishing HIV attachment to background levels (Gallay 2004). Binding of HIV to syndecan-3 on dendritic cells is heparan sulfate-dependent, promotes infection in *cis* and in *trans*, and conserves viral infectivity, indicating that syndecan-3 plays an important role in HIV interactions with dendritic cells. In sum, syndecans might aid HIV transmission and spread by promoting viral attachment to macrophages, dendritic cells, and endothelial cells. Whether HIV binding to syndecans induces signaling events which increase the susceptibility of cells to *cis*-infection or augment their capacity to transmit the virus to adjacent cells remains to be established.

Host Cell Factors Incorporated into the Viral Envelope

The envelope of HIV is derived from the host cell and is acquired during budding of progeny particles from the plasma membrane. Approximately 8–10 Env trimers and a substantial number of membrane-associated host cell factors are incorporated into the envelope of budding particles, including HLA-DR, CD40, CD40L, and CD86. Some of the cellular factors inserted into the viral membrane serve as receptors or ligands for structures presented on the surface of HIV target cells. As a consequence, cellular factors inserted into the viral envelope can bind to their partner molecules on the cellular membrane, and these cognate interactions can promote attachment of HIV to host cells (Fig. 1). One of the best studied examples is the incorporation of cellular ICAM-1 into the HIV envelope and its interaction with LFA-1 on the surface of target cells (Pöhlmann and Tremblay 2007), which is in the focus of the present discussion.

The interaction of ICAM-1 and LFA-1 promotes cell-cell interactions, for instance, during

the formation of immunological synapses. HIV infection upregulates ICAM-1 expression, and ICAM-1 and LFA-1 produced in T cells are incorporated into budding particles. The incorporation of ICAM-1 does not depend on the presence of the viral envelope protein but is promoted by interactions between the cytoplasmic tail of ICAM-1 and the p55 Gag protein. Virion-associated ICAM-1 interacts with LFA-1 on target cells, and this interaction can increase HIV infectivity for peripheral blood mononuclear cells (PBMCs) and *ex vivo*-cultured lymphoid tissue. Cross-linking of the T cell receptor (TCR) transiently increases the affinity of LFA-1 for ICAM-1, resulting in augmented infectivity of ICAM-1-bearing HIV. In addition, TCR cross-linking induces the formation of LFA-1 clusters, which contain CD4 and CXCR4 and are bound by HIV particles. The formation of these clusters and augmentation of infectivity require the activities of ZAP-70, phospholipase C γ 1, and calpain. Calpain abrogates the association of LFA-1 with the actin cytoskeleton and thereby increases its lateral motility and thus its ability to form clusters within the plasma membrane.

The presence of ICAM-1 in the viral envelope and LFA-1 on target cells could impact control of viral spread by the humoral immune response and by therapeutic agents. Thus, virion-associated ICAM-1 increased the neutralization resistance of CCR5- and CXCR4-tropic viruses and reduced sensitivity towards the membrane fusion inhibitor T-20. It has been proposed that the resistance to T-20 might be due to accelerated membrane fusion which shortens the time during which the T-20 target structure is exposed. However, a recent study indicates that ICAM-1 binding to LFA-1 promotes viral attachment but not membrane fusion, and the mechanism underlying relative resistance against membrane fusion inhibitors and neutralizing antibodies merits further analysis.

The association between ICAM-1 on the viral surface and LFA-1 on the target cell surface might also account for important features of the viral cell tropism: HIV-1 is known to preferentially target the memory subset within the CD4⁺ T cell compartment, and virion incorporation of ICAM-1

notably augments HIV-1 infection of these cells (Tardif and Tremblay 2005). In contrast, the presence of ICAM-1 on the virion surface has relatively little effect on infection of naïve T cells. Finally, it is noteworthy that ICAM-1/LFA-1-mediated binding of HIV to receptor-negative cells can promote *trans*-infection of adjacent susceptible cells, although this process does not seem to contribute to HIV transmission by macrophage and dendritic cells.

Cellular attachment of HIV facilitated by ICAM-1/LFA-1 interactions is a potential target for therapeutic inhibition. Thus, the inhibitory effect of cholesterol depletion on HIV infection might in part be due to abrogated ICAM-1/LFA-1 interactions. More specifically, statins and the small molecule integrin inhibitor XVA143, which are known to block binding of LFA-1 to ICAM-1, were shown to inhibit HIV replication in T cells by inhibiting ICAM-1/LFA-1-dependent viral attachment to target cells. Blockade of the ICAM-1/LFA-1 interaction increased inhibition of HIV by T-20, indicating that combinatorial approaches targeting attachment and entry in parallel might be promising.

SEVI and Other Cationic Fibrils

The most frequent mode of HIV transmission is sexual intercourse, and the identification of cellular and viral factors which determine transmission efficiency is of high interest to the development of preventive strategies (Doncel et al. 2011). Screening of a semen-derived peptide library resulted in the identification of a fraction containing fragments of prostatic acidic phosphatase (PAP), which potently enhanced HIV and SIV infection (Münch et al. 2007; “► HIV-1 Transmission; Influence of Bodily Secretions”). The predominant peptide, PAP248-286, assembles into amyloid fibrils termed semen-derived enhancer of viral infection (SEVI), which bind to HIV and the cell and augment viral infectivity by facilitating viral attachment (Fig. 1). Augmentation of infectivity is independent of viral coreceptor tropism and virus-producer/target cell type and has also been observed for other retroviruses. Enveloped viruses outside the retrovirus family have not been examined so far. Mutagenic

analysis and zeta potential measurements revealed that the interaction of SEVI with HIV depends on the positive surface charges of the fibrils. Thus, the infection-enhancing activity of SEVI but not its capacity to form fibrils is abrogated upon substitution of lysines and arginines by alanines.

The formation of SEVI fibrils is promoted by anionic constituents of seminal plasma and the SEVI levels correlate with the ability of semen to augment HIV infectivity in cell culture. Thus, SEVI and semen components which facilitate formation of SEVI fibrils are potential targets for microbicides (“► HIV-1 Transmission Blocking Microbicides”). Initial studies showed that epigallocatechin-3-gallate, present within green tea, and theaflavin derivatives promote SEVI degradation and polyanionic compounds, including self-assembling peptides, interfere with SEVI's infection-enhancing capacity. However, antiviral approaches targeting SEVI need to take into account that semenogelin fragments present with semen can also assemble into fibrils and augment HIV infectivity, suggesting that HIV might hijack several fibril-forming peptides to ascertain infection of cells within the anogenital mucosa.

Conclusion

Several secreted and membrane-associated cellular proteins can bind HIV and promote viral attachment to target cells. The interaction of HIV with these attachment factors is dispensable for infectious entry but can profoundly augment viral infectivity. Engagement of attachment factors frequently depends on the charge and glycan composition of the viral Env protein. Alternatively, the interaction of host cell factors inserted into the viral envelope with their binding partners on the surface of target cells can promote HIV attachment. Attachment factors can augment viral infectivity by concentrating viral particles on the cell surface, thereby increasing the chance that Env proteins interact with CD4 and coreceptor. In addition, binding of Env to attachment factors can elicit intracellular signals which render cells more susceptible to infection or to transmission of the virus to adjacent cells. However, attachment

factor binding can also promote HIV degradation and parameters like target cell type and HIV glycosylation control whether infection is augmented or repressed. Inhibition of attachment factors in cell culture can markedly decrease viral infectivity, and expression of several attachment factors on important viral target cells suggests a role in viral spread in patients. The potential of attachment factor inhibitors to prevent viral transmission and dissemination therefore merits further analysis.

Definition

Autophagy is a fundamental and highly regulated lysosomal degradation mechanism, dependent on specialized autophagy-related proteins (Atgs) (Mizushima et al. 2011). It can be classified into macroautophagy, microautophagy, and chaperone-mediated autophagy, but only

^SAuthor contributed equally with all other contributors

macroautophagy will be described and hereafter referred to as autophagy since it is the major lysosomal route for the turnover of cytoplasmic constituents. It is characterized by the formation of membranes that engulf cytoplasmic material through the formation of autophagic vacuoles, called autophagosomes. These structures fuse with lysosomes to form autolysosomes where the sequestered material is digested by lysosomal hydrolases. Before this degradative step, autophagosomes can also fuse with endosomes to form amphisomes, making a direct connection between the endo-lysosomal and autophagic pathways. This process is highly dynamic, and constituents are continuously recycled through lysosomal transporters toward the cytosol. Autophagy plays essential physiological roles in survival, homeostasis, and development and is closely linked to several mechanisms of cell death such as apoptosis, pyroptosis, and necroptosis. It is also involved in the defense against invading intracellular pathogens and acts in both innate and adaptive immunities.

Introduction

Autophagy has an essential role in cell homeostasis and has been implicated in several pathologies including cancer, neurodegeneration, and

myopathies. It is a constitutive mechanism further induced by different stresses or stimuli that are dangerous for the cell. For example, autophagy is essential to provide energy and amino acids during starvation. It also prevents cell death or senescence due to accumulation of defective organelles, in particular damaged mitochondria, and large macromolecular aggregates.

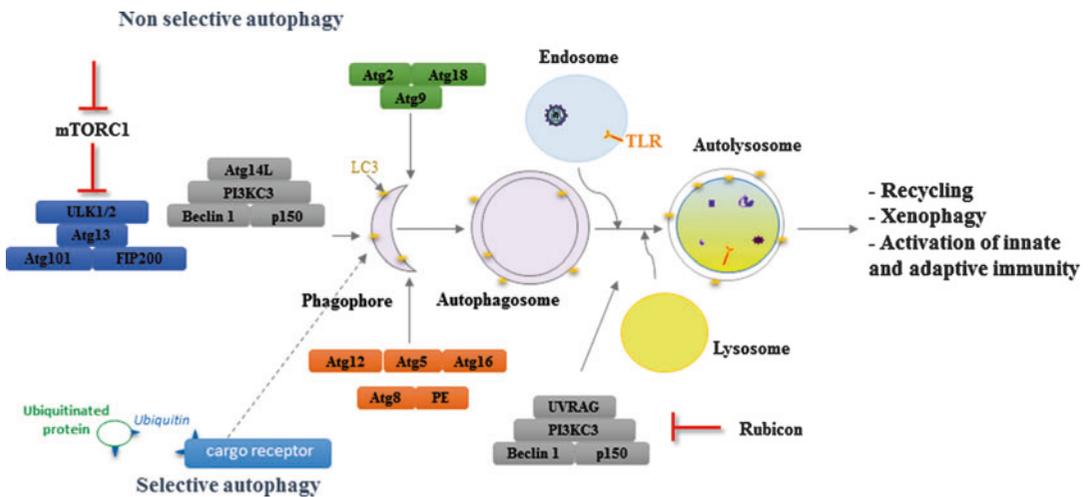

The global autophagy process is presented in Fig. 1.

It requires several specific protein complexes regulating different steps of the autophagy flux (for review (Ravikumar et al. 2010)).

The ULK1/ULK2 complex is involved in the initiation step of autophagy. The function of this multi-protein complex, composed of ULK1/ULK2, Atg13, Atg101, and FIP200, is tightly controlled by the mammalian target of rapamycin (mTOR) complex 1 (MTORC1), which represses autophagy flux initiation under nutrient-rich conditions.

The second complex is composed of class III phosphatidylinositol 3-kinase (PI3KC3), Beclin 1, p150, and Atg14L, which produces an autophagy-specific pool of phosphatidylinositol 3-phosphate (PI3P). Several additional proteins interacting with Beclin 1 ensure a timely and spatial regulation of PI3P formation during the autophagy process.

Then, two unique ubiquitin (Ub)-like conjugation systems drive the elongation and closure of

Autophagy and HIV Infection, Fig. 1 Autophagy pathway

the autophagic membrane. In the first conjugation system, Atg12 is conjugated to Atg5, in a reaction mediated by the Ub-activating enzyme (E1)-like Atg7 and the Ub-conjugating enzyme (E2)-like Atg10. No specific and exclusive Ub ligase (E3)-like has been discovered so far. Atg16L1 interacts with the Atg12–Atg5 conjugate to form a scaffold necessary for LC3 lipidation. The second conjugation system leads to the conjugation of proteins of the Atg8 family to the lipid phosphatidylethanolamine (PE) through a mechanism controlled by Atg7 and Atg3, another E2-like enzyme. The Atg12–Atg5 conjugate is an E3-like for the Atg8–PE conjugation reaction. In humans, the Atg8 family comprises three microtubule-associated protein 1 light chain 3 (LC3A, LC3B, and LC3C), one gamma-aminobutyrate receptor-associated protein (GABARAP), and three GABARAP-like proteins (GABARAPL1–3). However, only LC3B has been extensively studied and will be hereafter referred to as LC3. LC3 is synthesized as pro-LC3 and is very rapidly processed by the protease Atg4 to expose its C-terminal glycine. During autophagosome formation, a fraction of this cytosolic, soluble form of LC3, also called LC3-I, can be conjugated to PE to generate the lipid-conjugated form of LC3, or LC3-II, which becomes tightly associated with the autophagosomal membrane while the Atg5–Atg12 conjugate is removed from the neo-formed vesicles. Interestingly, LC3-II can also return to an unlipidated state via the proteolytic activity of Atg4, indicating, therefore, that this process could be reversible, although its functionality is not yet understood.

In turn, Beclin 1 recruits several proteins such as UVRAG and PI3KC3 to form a complex that plays a major role in the maturation step of autophagy. This complex is negatively controlled by the RUN domain-containing protein Rubicon. It is worth noting that Beclin 1 interacts with the anti-apoptotic protein Bcl2, as well as Bcl-XL, Bcl-w, and Mcl-1. Beclin 1 binding to Bcl2 represses autophagy when Bcl2 is localized in the endoplasmic reticulum. Upon stress, Beclin 1 dissociates from Bcl-2, allowing the activation of PI3KC3 and the subsequent stimulation of autophagy. This is one of the multiple links that exist between

autophagy and apoptosis. Although not yet fully investigated, other cross talks also exist between autophagy and other programmed cell death pathways (necroptosis, pyroptosis) and the Ub–proteasome system, the other main degradative pathway.

Autophagy was first described as a non-selective bulk degradation pathway. However, specific forms of autophagy can also selectively degrade cytoplasmic components such as organelles (e.g., mitochondria, peroxisomes, lipid droplets, ribosomes) and proteins that can also be under aggregate forms.

This function is supported by cargo receptors (e.g., p62/SQSTM1, NBR1, and NDP52), which bind to both “eat-me” signals, mainly molecules of Ub, and Atg8 family members present on the autophagosomal membrane. Binding to Atg8 family engages a specific motif, called an LC3-interacting region (LIR), with the general sequence W/F/YxxI/L/V preceded by acidic residues.

There is now a growing line of evidence that autophagy is also an essential pathway for host defense against viral infection. Autophagy acts at different stages of antiviral immunity, including the degradation of entire viruses or specific viral proteins by a process termed xenophagy, the activation of innate immune signaling by delivery of viral nucleic acids to endosomal Toll-like receptors (TLRs), and the activation of adaptive immunity by presentation of viral antigens to major histocompatibility complex (MHC) class I and MHC class II molecules. As a consequence, the viruses have evolved strategies to counteract or to exploit autophagy for their own profit.

HIV-1, as many other viruses, manipulates autophagy for its own replication. Its regulation depends on the cell type (CD4⁺ T cells, macrophages, or dendritic cells) and the status of the cells (i.e., infected or uninfected cells). This process is also at the center of the innate and adaptive immune responses against HIV-1.

Autophagy is mainly an anti-HIV mechanism, although several Atgs, including Atg7, Atg12, Atg16L, and GABARAPL2, are seemingly required for HIV-1 infection, as demonstrated through a functional genomic screen using

HeLa-derived TZM-bl cells (Brass et al. 2008). Several Atgs, in particular Atg5 and Atg16, are also needed for HIV-1 replication in CD4⁺ T cells (Eekels et al. 2012), suggesting that either HIV-1 needs the initiation step of autophagy or at least some of its components. It is worth noting that autophagy-related proteins can also function independently of the autophagic process, and this aspect has to be taken into consideration when trying to decipher the link between autophagy, autophagic proteins, and HIV-1 infection.

Strikingly, autophagy is also responsible for the apoptosis of bystander CD4⁺ T cells triggered by HIV-1 envelope.

Autophagy in CD4⁺ T Cells During HIV-1 Infection

CD4⁺ T lymphocytes represent the main target cell population for HIV-1 infection, and their progressive destruction is the hallmark of AIDS (Barré-Sinoussi et al. 1983). Depletion of this cell population is mainly due to apoptosis of bystander uninfected CD4⁺ T cells (“► [Lymphocyte Apoptosis](#)” and Finkel et al. (1995)) for which the viral envelope, composed of gp120 and gp41, plays an important role since it constitutes the primary interface between viruses and target cells. In particular, the gp41-mediated fusion process occurring during HIV-1 entry triggers activation of the intrinsic pathway of apoptosis, with activation of the caspases 9 and 3 (Roggero et al. 2001; Blanco et al. 2003; Garg and Blumenthal 2008). Recently, abortive HIV-1 infection, occurring in the vast majority of bystander quiescent CD4⁺ T cells, was shown to be responsible for an inflammatory form of cell death, called pyroptosis (“► [Pyroptosis and HIV Replication](#)”), characterized by the activation of caspase 1 and the release of inflammatory cytokines upon viral DNA sensing by the interferon- γ -inducible protein 16 (IFI16) (Doitsh et al. 2014; Monroe et al. 2014).

Importantly, autophagy is also activated in bystander CD4⁺ T cells after their contact with infected cells, through the gp41-dependent fusion of both membranes, and leads to their apoptosis (Espert et al. 2006; Denizot et al. 2008).

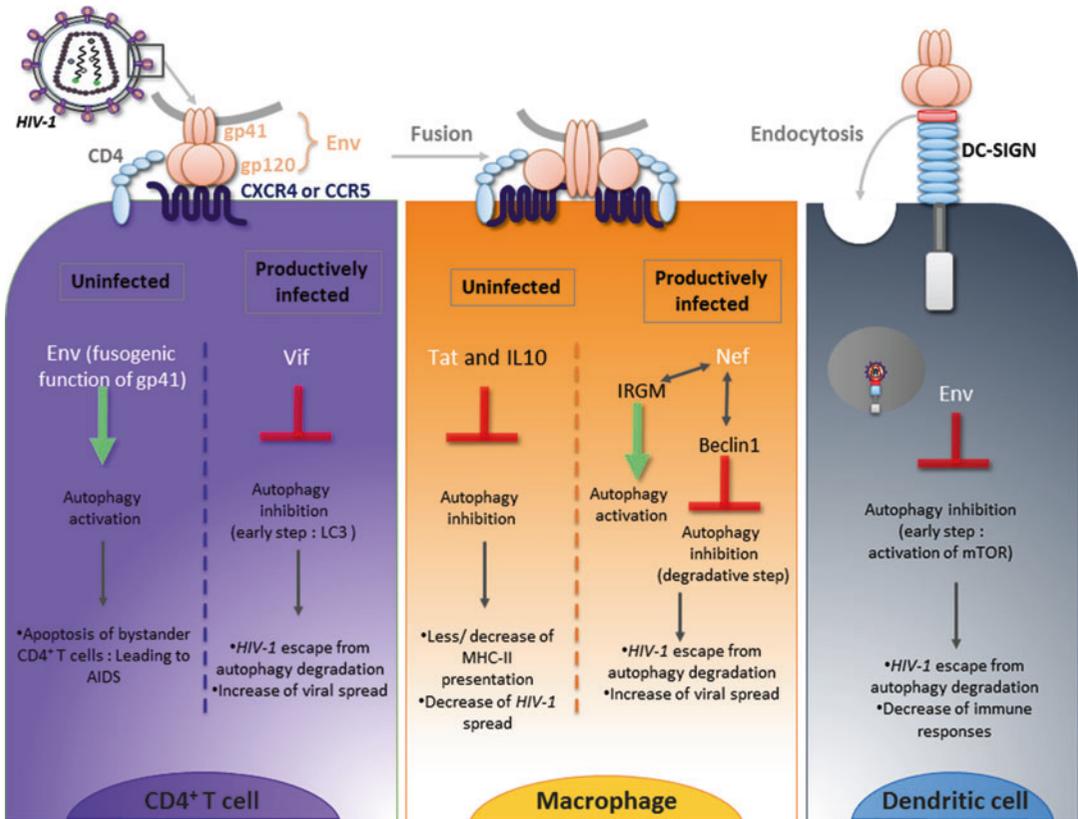

Autophagy contributes, therefore, to the depletion of CD4⁺ T cells during HIV-1 infection.

Autophagy is an anti-HIV-1 process by specifically degrading Tat, a viral protein essential for viral replication (Sagnier et al. 2015). As a consequence, autophagy is repressed in productively infected cells. Very recent data indicate that autophagy in CD4⁺ T cells could be indeed targeted by the viral protein Vif upon specific binding to the autophagy-related protein LC3 (Borel et al. 2015) (Fig. 2, left part).

Autophagy in Macrophages During HIV-1 Infection

In contrast to CD4⁺ T cells, bystander macrophages do not undergo autophagy after contact with HIV-1 envelope (Espert et al. 2009). This blockade is dependent on the activation of Src–Akt and Stat 3 by HIV-1 Tat and IL-10, both previously reported to inhibit autophagy (Van Grol et al. 2010). HIV-1 Tat was also shown to suppress IFN- γ -induced autophagy in primary macrophages (Li et al. 2011), suggesting that inhibition of autophagy could negatively impact on innate immune defenses of myeloid cells devoted in the killing of intracellular pathogens. Overall, this result correlated well with the physiopathology reported from HIV-1-infected patients. Indeed, macrophages do not undergo Env-mediated apoptosis and are seemingly not subjected to depletion during HIV-1 infection, at least compared to the level of CD4⁺ T cell depletion. These observations raise many relevant but still unsolved questions, including why the fusogenic function of gp41 induces autophagy only in CD4⁺ T cells and why Tat and IL-10 would not inhibit autophagy in bystander CD4⁺ T cells.

Conversely, in cells from the monocyte/macrophage lineage, autophagy is induced following a productive infection (Espert et al. 2009) and acts as an antiviral mechanism (Espert et al. 2009; Kyei et al. 2009). Surprisingly, two populations of autophagic cells are present, one highly autophagic and the other weakly autophagic, and viruses could be detected in the weakly

Autophagy and HIV Infection, Fig. 2 Relationship between autophagy and HIV-1 infection of its main target cells, namely, CD4⁺ T cells, macrophages, and dendritic cells

autophagic cells but not in the highly autophagic cells, suggesting that autophagy might still be controlled by HIV-1 in these cells to avoid degradation (Espert et al. 2009). Indeed, Nef regulates autophagy in these cells by two ways. First, Nef binds to the immunity-associated GTPase family M (IRGM), inducing autophagy (Gregoire et al. 2011), and second, Nef binds to Beclin 1, blocking the degradative step of autophagy (Kyei et al. 2009).

The dual interaction of HIV-1 with autophagy thus enhances viral yields by using the early stages while inhibiting the late stages of autophagy (Fig. 2, central part).

Apart from Nef, the antisense protein ASP, produced from antisense transcription of the HIV-1 genome, partially co-localizes with LC3. Preliminary data suggest that expression of ASP induces autophagy and increases viral replication

in the promonocytic U937 cell line (Torresilla et al. 2013).

Autophagy in Dendritic Cells During HIV-1 Infection

Although some dendritic cell (DC) subsets could differ in phenotype and functions, one of their hallmarks is their propensity to regulate innate and adaptive immunity.

DC (DCs) are known to regulate innate and adaptive immunity, and most of the subsets express a plethora of pathogen recognition receptors (PRR) (“Pathogen Recognition Receptors (General)”) facilitating their antigen sampling activity and contributing to their quickness in efficiently igniting adapted immune responses. Some DC subsets were also reported to be

involved in the early events of HIV transmission. Even if they are mostly refractory to productive HIV infection, these cells can readily internalize virions via different receptors expressed at the surface, like C-type (CD209/DC-SIGN) or I-type (CD169/SIGLEC-1) lectins, and transmit them toward CD4⁺ T cells.

Upon viral challenge, autophagy is rapidly inhibited in DCs through the activation of mTOR by HIV-1 envelope. This autophagy blockade impairs Toll-like receptor-mediated innate immune response while also strongly affecting antigen processing and MHC-II-mediated antigen presentation to CD4⁺ T cells (Blanchet et al. 2010) (Fig. 2, right part) potentially limiting anti-HIV immune responses.

Conclusion

Taken together, these results suggest a complex, cell-type-specific relationship between HIV-1 and the autophagic response and highlight the complexity of HIV-1 pathogenesis. Autophagy appears to play different roles in controlling HIV-1 replication, depending on the cell type. In turn, HIV-1 has evolved individualized strategies to manipulate autophagy in each cell type. Whatever the cells involved, autophagy is unambiguously involved in HIV-1 pathogenesis, and more investigation on its antiviral role should strengthen our understanding of the interplay between the virus and the host.

Further studies are needed to (i) decipher the mechanisms that are activated after gp41-dependent membrane fusion during the entry of the virus leading to autophagy, (ii) understand the link between autophagy and apoptosis or other cell death mechanisms in the bystander CD4⁺ T cells, (iii) determine the viral proteins responsible for the control of autophagy in the infected cells, and (iv) understand the connections between autophagy and viral trafficking through endocytic compartments linked to immune responses in DC.

Modulation of the autophagy flux might thus be a promising approach to improve immunomodulatory approaches to treat HIV-1 infection aimed

to increase immune responses in complementation to HAART.

usual pathogens, and in AIDS patients with neutropenia, infection with *Pseudomonas aeruginosa* can occur. In severely immunosuppressed patients, additional opportunistic infections (OI) with *Rhodococcus equi* and *Nocardia* spp. (both CDC category B OI diagnoses) occur (Feldman and Anderson 2013).

This entry will discuss factors predisposing HIV-infected patients to bacterial lower respiratory infections, the epidemiology of such infections, the major bacterial pathogens involved, and their pathogenesis, diagnosis, management, and prevention. *Streptococcus pneumoniae*, the most important pathogen in this group, for which a specific prevention strategy in the form of vaccination is available, will be discussed in depth.

Definition of the Problem

HIV-infected patients have a high risk of bacterial lower respiratory tract infections, even in the era of highly active antiretroviral therapy (HAART). Recurrent pneumonia (≥ 2 episodes/year) is both an indication for HIV testing and an acquired immunodeficiency (AIDS)-defining event. The clinical presentation of community-acquired pneumonia (CAP) is usually similar to that in HIV-uninfected patients, although the prognosis can be worse in the severely immunosuppressed. *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Staphylococcus aureus* are the

Introduction

Since the beginning of the HIV epidemic, the vulnerability of the respiratory system of HIV-infected patients to the development of severe infections caused by opportunistic pathogens has been clearly evident. Lower airway infections, specifically those caused by *Pneumocystis jirovecii*, *Mycobacterium tuberculosis*, and the pneumococcus, are the leading causes of death resulting from the severe immunosuppression, which accompanies advanced HIV infection. In the western world, CAP is now the most common pulmonary infection, while

tuberculosis is the most common infection in Africa. The CD4 cell count is inversely correlated with pneumonia risk and recurrent pneumonia (two or more episodes within a 1-year period) is an AIDS-defining CDC stage C condition. However, even in the HAART era and in patients with relatively normal CD4 cell counts, the CAP incidence remains elevated. Not only does the mortality remain high in HIV-infected persons with CAP, but the occurrence of CAP is also associated with a permanent decline in lung function and an increase in long-term mortality in these patients (Feldman and Anderson 2013).

Bacterial Pathogens Causing CAP

Excluding tuberculosis, the most common bacterial pathogens are *Streptococcus pneumoniae*, which will be discussed in detail separately, and *Haemophilus influenzae*, which accounts for 10–15% of bacterial pneumonias with known pathogens in HIV-infected patients. *H. influenzae* is more frequent in advanced immunosuppression and tends to present subacutely, with diffuse pulmonary infiltrates. *Staphylococcus aureus* ranks third in frequency (around 5% of CAP in HIV-infected persons). Pathogenesis includes either septic pulmonary embolization from central venous catheters or injection drug use-related right-sided endocarditis or superinfection after viral respiratory infection such as influenza. Colonization and/or infection with highly virulent Panton-Valentine leukocidin-producing community-acquired methicillin-resistant *S. aureus* (PVL-CA-MRSA) is a third possibility. The most frequent gram-negative pathogens are *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, and *Moraxella catarrhalis* (the latter mostly in patients with chronic obstructive pulmonary disease). The atypical pathogens, *Mycoplasma pneumoniae* and *Chlamydomphila pneumoniae*, appear to be much less common in HIV-infected patients, as do infections with *Legionella* spp., although these occur slightly more frequently than in the general population (Feldman and Anderson 2013).

Epidemiology of CAP and Pneumococcal Disease in the HIV-Infected Persons

As indicated above, *S. pneumoniae* is the most common bacterial cause of CAP in HIV-infected persons, being implicated in 20% of cases overall, in 40% of cases in which a microbiological diagnosis is confirmed, and in 70% of cases that are associated with the occurrence of bacteremia (Feldman and Anderson 2013). Several studies have documented a substantially increased risk of bacteremia in HIV-infected patients with CAP, with rates of invasive pneumococcal disease (IPD) of up to 100-fold higher than among HIV-uninfected patients (Raju et al. 2012; Feldman and Anderson 2013, 2014a). In addition recurrent infections have been commonly noted. There has been some conflicting data as to whether the rates of CAP, and in particular invasive pneumococcal CAP, in HIV-infected persons have decreased considerably with the use of HAART and/or pneumococcal vaccination; nevertheless even if the rates of invasive pneumococcal disease (IPD) have decreased with the use of these measures, they still remain very high, being approximately 35-fold higher than in HIV-uninfected persons (Siemieniuk et al. 2011; Feldman and Anderson 2013). While rates of IPD declined within 3 years following vaccine with the 23-valent polysaccharide vaccine, 74% of IPD that occurred was due to serotypes contained in that vaccine (Siemieniuk et al. 2011). Part of this ongoing and increased risk appears to relate to the negative impact of cigarette smoking and injection drug use, with several studies showing the positive benefit of smoking cessation on rates of CAP (Siemieniuk et al. 2011; Feldman and Anderson 2013).

In the UK, the overall rates of IPD in HIV-infected persons have been documented to be 245/100 000 persons, which was 50 times higher than that of the general population; rates were 281/100 000 persons in patients not on HAART and 563/100 000 persons in cases with advanced immunosuppression (Raju et al. 2012). Since HIV infection is one of the most important risk factors for IPD, it is recommended that

patients presenting with pneumococcal bacteremia should be tested for HIV infection, if they have not been previously tested, irrespective of the presence or absence of other IPD risk factors (Feldman and Anderson 2014a). In the study from the UK described above, 2.4% of adults aged 15–44 years with IPD had undiagnosed HIV infection (Raju et al. 2012).

It is well recognized that in addition to smoking and alcohol use, various underlying medical conditions are associated with an increased risk of IPD (Kyaw et al. 2005). Investigations have been undertaken documenting the incidence rates of IPD in adult patients with specific medical conditions, comparing the rates of IPD in those adults with and without those medical conditions in the USA (Kyaw et al. 2005). In one study the overall incidence rates in healthy adults were found to be 8.8/100 000 persons, with rates, for example, in diabetes mellitus of 51.4/100 000 persons and in chronic lung disease of 62.9/100 000 persons. However, incidence rates in those with HIV/AIDS were 422.9/100 000. Overall, in patients with diabetes mellitus, chronic heart, and lung disease, there was a three- to sevenfold increased risk of IPD compared with healthy controls, whereas adults with immunocompromising conditions, including HIV/AIDS, had a 23–48-fold higher risk of IPD than healthy adults (Kyaw et al. 2005). Risk factors for IPD in HIV-infected persons in the HAART era are said to be similar to that of HIV-uninfected persons and include current smoking, alcoholism, underlying comorbid conditions, and prior hospitalization, as well as low CD4 cell counts in the former patients (Feldman and Anderson 2015).

HIV Infection and Increased Vulnerability to Pulmonary Infection

Suppression of Pulmonary Host Defenses

The major protective airway host defenses which are progressively and significantly compromised by HIV-mediated depletion of the CD4⁺ T lymphocyte population are as follows:

- Infection of a subtype of CD4⁺ T helper cell known as follicular cells (Tfh) (Ueno et al. 2015). These cells which abound in secondary lymphoid tissues, such as the highly organized network of mediastinal lymph nodes in the lungs, provide essential help to antibody-producing B lymphocytes. However, infection and functional dysregulation of Tfh cells by HIV result in defective production of mucosal IgA and IgG antibodies, severely compromising mucosal antibacterial host defenses.
- Infection and depletion of the CD4⁺ Th1 and Th17 T cell subsets resulting in decreased production of the monocyte/macrophage/neutrophil recruiting and activating cytokines IFN- γ and IL-17A, also contributing significantly to predisposition for the development of severe mucosal bacterial infection.

In addition, neutropenia is also a common manifestation of advanced HIV infection and a probable contributor to susceptibility for IPD, as well as for pneumonia due to *Pseudomonas aeruginosa*.

Pathogenesis of Pneumococcal Disease: From Colonization To Invasive Disease

Pneumococcal infections are broadly grouped into either invasive or noninvasive (mucosal) infections (Ludwig et al. 2012; Drijkoningen and Rohde 2014). The term invasive infections refers to infections in which the microorganism is found in normally sterile body sites, such as the blood, the cerebrospinal fluid (CSF), pleural and joint fluid, etc. Noninvasive infections, which can become invasive, include otitis media, sinusitis, and some patients with pneumonia.

As with the development of severe pneumococcal disease in the general population, nasopharyngeal colonization of the upper respiratory tract in HIV-infected subjects is a prerequisite for subsequent translocation of the pathogen to the lower respiratory tract and development of invasive disease (Steel et al. 2013; Huson et al. 2015).

Colonization necessitates evasion of the expulsive actions of the mucociliary escalator and is achieved via the complementary interactions of several pneumococcal virulence factors. These are (i) the highly electrostatically charged, anti-phagocytic, polysaccharide capsule, the primary virulence factor of the pneumococcus, which also prevents attachment of the pathogen to respiratory mucus and (ii) the pneumococcal cytotoxins, hydrogen peroxide, and pneumolysin, which damage the ciliated respiratory epithelium, interfering with ciliary beat frequency (Steel et al. 2013; Huson et al. 2015). Pneumolysin is the major protein virulence factor of the pneumococcus.

Evasion of the mucociliary escalator, in turn, facilitates interaction of the pathogen with the respiratory epithelium, a process which is dependent on a transient decrease in the thickness of the capsule, enabling exposure of an array of underlying cell wall-associated protein adhesins. Like pneumolysin, many of these are immunogenic and have been identified as being priority candidates for development of novel protein-based vaccines (Feldman and Anderson 2014b). These include pneumococcal surface adhesin A (PspA) and pneumococcal surface protein C (also known as CbpA and SpsA) which mediate binding of the pathogen to epithelial E-cadherin and the polymeric immunoglobulin (Ig) receptor, respectively. In addition, cell surface phosphorylcholine promotes attachment of the pneumococcus to the platelet-activating factor (PAF) receptor, which is also expressed on epithelial cells (Steel et al. 2013; Huson et al. 2015; Feldman and Anderson 2014b).

At this point, containment of the pathogen is dependent on the efficacy of innate airway host defenses. Notwithstanding the mucociliary escalator and various antimicrobial peptides/proteins present in epithelial lining fluid, the major cellular effectors include resident macrophages, dendritic cells, mast cells, and groups 1 and 3 innate lymphoid cells, as well as epithelial cells. Pattern recognition receptors (PRRs) expressed on/in these cells interact with various pathogen-associated molecular patterns (PAMPs), triggering a protective inflammatory response. Foremost

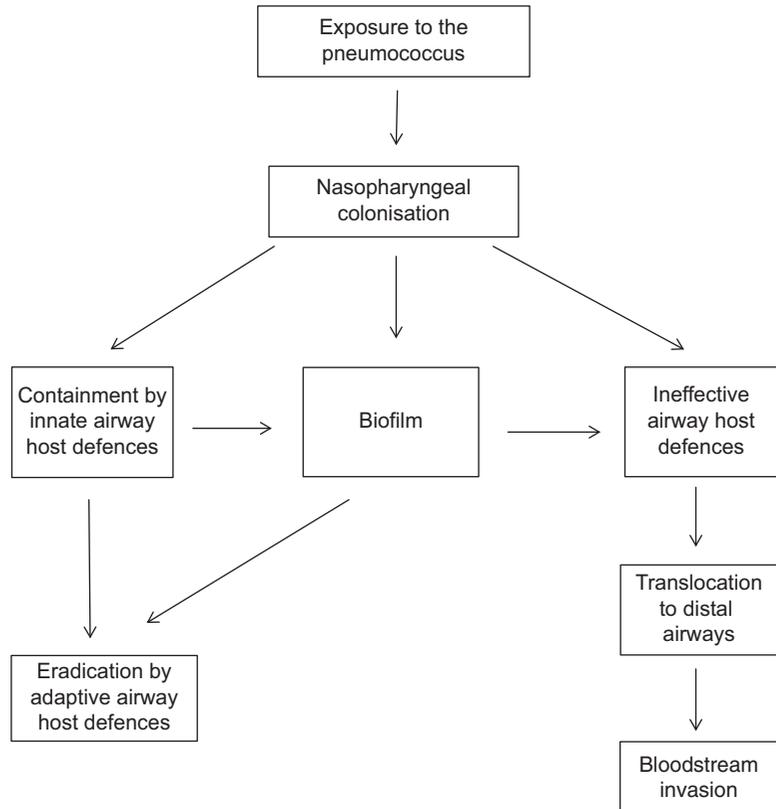

among the various families of PRRs are (i) the Toll-like receptors (TLRs); (ii) nucleotide-binding oligomerization domain (NOD) receptors, including the subfamily of inflammasomes; and (iii) various cytosolic microbial nucleic acid sensors. Activation of these various PRRs by pneumococcal constituents such as cell wall teichoic acid/peptidoglycan, pneumolysin, and DNA results in the generation of a series of pro-inflammatory cytokines/chemokines which act in concert to promote mobilization and recruitment of monocytes/macrophages and neutrophils. These include the cytokines interleukin (IL)-1 β , IL-6, IL-12, IL-17A, IL-18, interferon-gamma (IFN- γ), and tumor necrosis factor (TNF), as well as the monocyte/neutrophil chemokine, IL-8 (Huson et al. 2015). In addition, these innate immune mechanisms are also essential in shaping the more slowly occurring adaptive immune response to pneumococcal antigens.

Onset of the adaptive immune response is characterized by the production of specific IgA and IgG antibodies which target cell wall adhesins and the polysaccharide capsule, preventing adhesion to respiratory epithelium and promoting phagocytosis of the pathogen. In addition, pneumococcal protein antigens also activate cell-mediated responses involving CD4⁺ helper T lymphocytes, specifically those of the Th1 and Th17 subtypes, which as mentioned above, produce the cytokines IFN- γ and IL-17A, respectively. These cytokines enhance the antimicrobial activities of monocytes/macrophages and neutrophils (IFN- γ), while promoting the recruitment of these cells to sites of pneumococcal colonization (Huson et al. 2015). Eradication of the pneumococcus is dependent on these antibody- and cell-mediated adaptive immune mechanisms operating effectively and in unison.

Two scenarios now exist: these are either eradication of the pneumococcus or its coexistence as a seemingly passive, but nevertheless menacing, colonist. In the latter scenario, the pneumococcus, present in and/or on respiratory epithelial cells, may protect itself against airway host defenses by concealment in an extracellular matrix of polymeric materials, known as biofilm. The biofilm matrix consists predominantly of

Bacterial Respiratory and Invasive Pneumococcal Infections and HIV, Fig. 1

The events involved in the transition of the pneumococcus from nasopharyngeal colonization to lower airway and bloodstream invasion

polysaccharides, proteins, and nucleic acids. Encased in biofilm, which has been proposed to play a role in the pathogenesis of up to 80% of all microbial infections, the pneumococcus is relatively inaccessible to both antibiotics and host defenses. In this relatively dormant state, the pneumococcus can survive and reemerge as a dangerous invasive pathogen when airway host defenses are subdued either transiently or on a protracted basis. In this setting translocation of the pneumococcus to the distal airways causes pneumonia, as well as possible bloodstream invasion due to the cytotoxic effects of pneumolysin on the alveolar epithelial barrier (Huson et al. 2015).

The events involved in the transition of the pneumococcus from nasopharyngeal colonization to lower airway and bloodstream invasion are summarized in Fig. 1.

Taking into account the suppression of pulmonary host defenses described above, namely, the accumulation of dysfunctional T cells and

depletion of CD4 Th17 cells, it is easy to imagine how in HIV-infected patients the balance can be tipped from pneumococcal colonization toward pneumococcal disease and invasion. The fact that the extremes of age and a multitude of comorbidities predispose patients to pneumococcal disease regardless of their HIV status illustrates the paradigm of pneumococcal pathogenesis. The pneumococcus mostly behaves as a commensal in the nasopharynx. However, already weakened mucosal host defense mechanisms can allow it to become a pathogen causing both mucosal and invasive disease.

Pulmonary Microbiota in HIV-Infected Patients

The few studies performed in HIV-infected individuals have identified unique microbiota in the lower airway compared with HIV-negative people, such as an increase in *Tropheryma whipplei*

lung colonization (Gingo et al. 2013). However, a causal link between altered pulmonary microbiota and pulmonary function or susceptibility to infection cannot yet be made. Changes in oral, upper airway, and gut microbiota due to HIV infection per se or due to antibiotic prophylaxis (azithromycin, co-trimoxazole) may well turn out to affect pulmonary infection rates in HIV patients in the future (Clarke et al. 2010; Vujkovic-Cvijin et al. 2013; Brown et al. 2015).

Bacterial Lower Respiratory Tract Infections: Clinical Syndromes and Course

Community-Acquired Pneumonia

There has been conflicting data on whether HIV infection has any impact on the clinical presentation and outcome of CAP, and in particular pneumococcal CAP, with earlier studies suggesting that the mortality was no different when comparing HIV-infected and HIV-uninfected patients (Feldman and Anderson 2013). However, in one multicenter, international, prospective observational study of bacteremic pneumococcal pneumonia, HIV-infected cases were more likely to be of younger age, to be IV drug users, and to have a higher frequency of respiratory and systemic symptoms (rigors, pleuritic chest pain, cough, sputum production, hemoptysis, diarrhea, vomiting, and headache) than HIV-uninfected cases (Feldman et al. 2007). Furthermore, when cases were stratified according to age and severity of infection, the mortality in patients with severe CAP was higher in HIV-infected cases compared with HIV-uninfected cases, with a significant trend for increasing mortality associated with lower CD4 cell counts (Feldman et al. 2007; Feldman and Anderson 2013). Therefore some experts have suggested that both a low CD4 count (<200 cells/ μ L) and a high severity of illness score (PSI score IV and V) should be considered as potential reasons for admitting an HIV-infected patient with bacterial CAP to hospital (Feldman and Anderson 2013). Other investigators have documented that the overall mortality rate for hospitalized patients with IPD has hardly

changed between the years 1952 and 2001 and still remains in the region of approximately 12% (Ludwig et al. 2012).

Pathogens Causing Cavitating Bacterial Pneumonia

In addition to mycobacterial and fungal infections, cavitating lung disease may also be caused by a range of other bacteria, often presenting in the form of subacute or acute pneumonia. Among the abovementioned CAP etiologies, *S. pneumoniae* can cause lung abscesses, mostly with contiguous empyema, while *S. aureus*, either in the form of bloodstream infection with septic pulmonary infarctions or in the case of PVL-CAMRSA, can cause multiple lung cavities. Anaerobic lung abscesses occur more frequently in persons who use drugs as well as in patients with gingivitis/periodontitis. Rare reports have described cavitating pneumonia due to *Legionella* spp. or *Salmonella typhimurium* infection in HIV-infected patients.

Pseudomonas aeruginosa can present both as CAP or hospital-acquired pneumonia, and there are several case series describing subacute presentation with cavitating disease which tends to have a milder course than non-cavitating disease. Severely immunosuppressed patients with CD4 counts <50 cells/uL and accompanying neutropenia have the highest risk of such disease.

The gram-positive aerobic actinomycete *Nocardia* has a predilection for patients with defective cellular immunity and characteristically causes cavitating pneumonia. In HIV-infected patients, susceptibility is highest in those with CD4 counts below 200 cells/uL. Most likely as a result of co-trimoxazole prophylaxis in these patients, nocardiosis (traditionally susceptible to co-trimoxazole therapy) remains somewhat rare.

Rhodococcus equi, an aerobic, weakly acid-fast gram-positive rod, is another infrequent cause of subacute cavitating pneumonia in severely immunosuppressed HIV patients. Presentation typically includes fever, cough, pleuritic chest pain, and weight loss. Patients are often bacteremic and prognosis in the pre-HAART era was dismal (Shepp et al. 1994; Gallant and Ko 1996; Feldman and Anderson 2013).

Diagnostic Evaluation of Patients with Suspected Bacterial Pneumonia in HIV-Infected Patients

In HIV-infected patients with clinical suspicion of a bacterial lower respiratory tract infection and consistent findings on pulmonary imaging, the following diagnostic studies should be performed.

A sputum of good quality should be obtained, before initiation of antibiotic therapy, in those patients able to comply. When using sputum analysis, one has to bear in mind that only isolation of an obligate pathogen, such as *Legionella* spp. or *M. tuberculosis*, for example, can firmly establish an etiology. Isolation of organisms that can be both colonizing and pathogenic makes establishing an etiology much more difficult.

Since many pathogens causing bacterial pneumonia in HIV-infected persons can be associated with bacteremia, obtaining two sets of blood cultures is usually recommended, particularly in hospitalized patients (Feldman and Anderson 2013). Establishing a firm diagnosis using blood cultures is not only of importance to individual patient management but also for surveillance of pneumococcal disease. Many countries base their surveillance of antibiotic resistance and serotype distribution of *S. pneumoniae* exclusively on invasive pneumococcal isolates. In the face of the continuously evolving serotype distribution under vaccine pressure such serotype surveillance is crucial. If unusual pathogens are suspected, such as *Nocardia* spp., one can consider holding blood cultures for 2 weeks in order to try and detect this pathogen.

If resources permit, urinary antigen tests for *Legionella pneumophila* serotype 1 should be obtained, and despite some debate in the literature, the use of the BinaxNOW[®] pneumococcal urinary antigen test in patients who have not had potential pneumococcal disease in the previous 3 months is recommended. In adult patients with a compatible clinical picture, the test has sufficient specificity to allow for narrowing of the antibiotic spectrum to *S. pneumoniae* (Sordé et al. 2011). In the future more sensitive and serotype-specific pneumococcal urinary antigen tests may become routinely available, such as illustrated by a urine

antigen detection test specifically designed for vaccine efficacy studies (Bonten et al. 2015).

Clinicians often adhere to the principle of Occam's razor that advocates the least possible number of diagnoses for a given combination of symptoms. In HIV patients with advanced immunosuppression, the counterargument of Hickam's dictum "Patients can have as many diagnoses as they please" is often more appropriate. Therefore the question remains as to how much further routine diagnostic workup needs to be done in patients with suspected bacterial pneumonia. In certain clinical situations, the possibility of infection with pathogens other than bacteria may be suspected; in addition, patients with suspected CAP may not respond adequately to initial treatment, either clinically or radiologically. In both these situations, additional investigations need to be performed.

In areas with high rates of tuberculosis, any patient with a history of preceding constitutional symptoms (weight loss, night sweats), cavitating disease, hemoptysis, or failure to respond to CAP therapy should be suspected of having tuberculosis and investigated routinely using sputum examination by smear and culture and/or, if available, GeneXpert TB testing.

Isolator blood cultures can be performed for detection of dimorphic fungi, as well as sodium citrate blood cultures if atypical mycobacteria are suspected. Depending on local epidemiology, other fungal, urinary antigen tests may be indicated (e.g., *Cryptococcus* spp., *Histoplasma* spp.). In hospitalized patients clinicians may also recommend PCR-based testing (nasopharyngeal secretion or bronchoalveolar lavage (BAL)) for respiratory viruses to assist with clinical management, including initiation and/or stopping of appropriate isolation precautions.

If TB or other cavitating, nodular, tree-in-bud pattern causing pathogens, as well as *Pneumocystis jiroveci* pneumonia (PCP), cytomegalovirus (CMV), cryptococcosis, or other interstitial pattern pathogens, are a possibility, or in the seriously ill, and severely immunocompromised, or in patients with undiagnosed, unclear, or protracted disease, a BAL with or without biopsy and full pulmonary opportunistic workup are

recommended (infections with PCP, CMV, respiratory viruses, atypical bacteria including *Legionella* spp., *Nocardia* spp., mycobacterial infections, and infections with molds and dimorphic fungi need to be sought, and cytology/histology specimens need to be obtained to investigate for noninfective conditions). Pleural effusions not responding to therapy may necessitate diagnostic and therapeutic thoracentesis to exclude empyema, tuberculosis, or neoplastic disease.

Obtaining a CD4 cell count in patients with acute CAP may not be helpful since CD4 cell counts may be transiently depressed during acute illness without any prognostic value. However, in HIV patients admitted with known recent CD4 counts, the test may be of use in choosing the appropriate diagnostic approach as well as for prognosis (Feldman and Anderson 2013).

Approach to Therapy of Bacterial Pneumonia

The treatment of CAP in HIV-infected patients is considered to be very similar to that of HIV-uninfected patients. It should be directed at the most commonly expected bacterial pathogens and their local antibiotic susceptibility patterns and modified according to microbiological findings. Usual recommended empirical treatment is the use of either a beta-lactam/macrolide combination or fluoroquinolone monotherapy. If there is concern that the macrolide may be interacting with the patient's antiretroviral therapy, the use of newer fluoroquinolone monotherapy or beta-lactam plus doxycycline can be considered, or alternatively azithromycin could be used instead of clarithromycin [hiv-druginteractions.org]. If the patient has a prolonged QTc interval, doxycycline can replace both macrolide and fluoroquinolone for coverage of suspected *Legionella* spp., infection, pending urinary antigen testing.

After numerous meta-analyses and randomized trials, the matter of the best empirical CAP treatment, i.e., a beta-lactam/macrolide combination versus beta-lactam monotherapy versus fluoroquinolone monotherapy, is still not completely settled. However, a recent meta-analysis of

critically ill patients with CAP clearly showed benefit of macrolide containing regimens, such that the authors concluded that combination antibiotics with macrolides should be considered as first line therapy in severely ill cases with CAP (Sligl et al. 2014). In less severely ill cases, beta-lactam monotherapy seems to be non-inferior to the other approaches (Garin et al. 2014; Postma et al. 2015). There are, however, no randomized controlled trials on this issue specifically targeting HIV-infected patients.

However, since HIV patients are at risk of severe disease, we would recommend the use of combination therapy (such as beta-lactam/azithromycin and occasionally beta-lactam/doxycycline) or fluoroquinolone monotherapy for the treatment of most cases. Fluoroquinolones should not, however, be used routinely as empirical therapy in areas in which tuberculosis is a highly probable differential diagnosis for fear of masking the disease and/or for selecting quinolone resistance in tuberculosis.

For patients not responding to empiric therapy, targeting routine bacterial pathogens; implementation of additional investigations, such as those described above; and appropriate escalation of empirical therapy may need to be considered (Feldman and Anderson 2013).

Prevention

There is no antimicrobial prophylaxis directed specifically at classical bacterial respiratory infections. Co-trimoxazole prophylaxis, irrespective of CD4 cell count, may have some protective effects against common bacterial pathogens causing CAP (Church et al. 2015). Whereas prescribing co-trimoxazole prophylaxis to patients not in need of prophylaxis against *Pneumocystis jirovecii* (e.g., CD4 counts above 200 cells/ μ L) may be considered in developing countries, especially in sub-Saharan Africa, this strategy is not recommended in resource-rich western countries. In the HAART era, azithromycin prophylaxis against *Mycobacterium avium/intracellulare* has become less common, but if used it may have protected patients from CAP in the past.

Annual influenza vaccination is recommended in HIV-infected persons since respiratory viral infections are common and may be associated with more severe infection, as well as increasing the risk of bacterial superinfection. Pneumococcal vaccination is a complex issue and is dealt with below. Other important issues that need to be considered are the need for strategies related to smoking cessation and the management of alcohol and drug abuse (Feldman and Anderson 2013).

Immunization Strategies Against *Streptococcus pneumoniae*

As mentioned above, even in the face of virologically suppressive HAART and associated immune reconstitution, HIV-infected patients remain at considerably higher risk than their HIV-uninfected counterparts for the development of IPD, underscoring the necessity for effective immunization strategies in this setting (Feldman and Anderson 2014a). Two types of pneumococcal vaccine are currently available. These are (i) the pneumococcal polysaccharide vaccine 23 (PPV23) containing a mixture of capsular polysaccharides derived from 23 common serotypes which induce T cell-independent antibody responses and (ii) several pneumococcal conjugate vaccines (PCVs) with improved immunogenicity in which capsular polysaccharides representative of the most common disease-causing serotypes are coupled to a nontoxic protein carrier, usually the modified diphtheria toxoid, CRM197. These vaccines evoke T cell-dependent antibody responses and PCV13 is the current front-runner in this category (Feldman and Anderson 2014b).

Although effective against invasive pneumococcal disease in immunocompetent, healthy young, and older adults, the evidence in support of a protective effect of PPV23 in high-risk HIV-infected patients remains contentious (Feldman and Anderson 2014a).

In the case of PCVs, PCV7, and PCV9, fore-runners of PCV13 have demonstrated efficacy in protecting against recurrent pneumococcal infection in HIV-infected adults and against development of a first episode of invasive disease in

HIV-infected children, respectively (Feldman and Anderson 2014a). Emerging evidence from several countries such as England, France, Mexico, South Africa, and the USA has also documented the efficacy of PCV13 introduced into routine national immunization programs. Like its predecessors, PVC13 is significantly impacting on the rates of invasive pneumococcal disease caused by vaccine serotypes, not only in vaccinated children but also indirectly in adults, a phenomenon known as herd protection.

However, the efficacy of PCV13 in the context of protection against IPD in HIV-infected subjects remains to be established. Nonetheless, in 2012 the United States Advisory Committee on Immunization Practices recommended a routine immunization strategy for immunocompromised adults aged ≥ 19 years which is based on sequential administration of PCV13 and PPV23 (Feldman and Anderson 2014a). This “prime-boost” strategy involves primary immunization with PCV13 followed 8 weeks later by a single dose of PPV23 and is recommended for all vaccine-naive HIV-infected subjects, with the possible exception of those with circulating CD4⁺ T cell counts of $< 200/\mu\text{L}$. With respect to patients who fall into this latter category, it has been proposed that administration of PPV23 be delayed until the numbers of circulating CD4⁺ T cells recover to levels above the threshold of 200 cells/ μL following implementation of HAART (Feldman and Anderson 2014a). The future development of protein vaccines based on either unencapsulated intact cells or recombinant proteins holds promise (Feldman and Anderson 2014b).

Conclusion

Despite all the advances that have been made in the management of HIV-infected patients since the introduction of HAART, CAP, and in particular pneumococcal infections continue to be a major challenge, being associated with significant morbidity and mortality. Lifestyle factors, especially cigarette smoking, contribute substantially to the ongoing risk of CAP, and smoking cessation strategies should be incorporated into the overall

management of HIV-infected patients. It has been recommended that the antibiotic treatment of HIV-infected patients with CAP should be similar to that of HIV-uninfected cases, but no specific studies of antibiotic strategies have been undertaken in HIV-infected patients. The pneumococcal conjugate vaccines offer the potential for safe and effective prevention of the most common pneumococcal infections in HIV-infected persons.

Definition

Barrier-to-autointegration factor (BAF or BANF1) is a highly conserved 10-KDa protein in multicellular eukaryotes. It was identified as a factor that blocks ► [integration](#) of Moloney murine leukemia virus DNA into itself (autointegration) *in vitro*. BAF binds DNA non-specifically and, because it is a dimer, bridges together DNA molecules. BAF also binds the LEM domain, a domain that is shared among lamina-associated polypeptide 2, emerin, and MAN1. BAF is an essential cellular protein, and knockdown or knockout results in a defect in chromosome segregation during mitosis.

Introduction

A role for barrier-to-autointegration factor (BAF or BANF1) in retroviral DNA ► [integration](#) was first inferred from *in vitro* experiments with Moloney murine leukemia virus. After entry of a virion into the cytoplasm of a newly infected cell, ► [reverse transcription](#) occurs within the reverse transcription complex, a nucleoprotein complex

derived from the core of the infecting virion. The resulting linear double-stranded viral DNA forms part of a large nucleoprotein complex called the preintegration complex (PIC). PICs contain a number of viral proteins, including integrase which is the viral enzyme that carries out the key DNA cutting and joining steps of DNA integration. Cytoplasmic extracts of virus-infected cells contain PICs, and the viral DNA within PICs efficiently integrates into an exogenously added target DNA *in vitro* in the presence of a divalent metal ion (Brown et al. 1987). This reaction system provided the foundation for early biochemical studies of retroviral DNA integration.

The products of integration of viral DNA within PICs into a plasmid DNA target *in vitro* can be readily monitored by digesting the integration product with appropriate restriction enzymes, followed by gel electrophoresis and southern blotting. The major reaction products result from intermolecular integration of the viral DNA into the plasmid target DNA. However, a minor fraction of integration products result from intramolecular integration of the viral DNA into itself. Such autointegration products had previously been detected *in vivo*. Autointegration is a dead end on the reaction pathway and the locally high concentration of viral DNA necessitates mechanisms that prevent this fate. It was found that when PICs are treated with high-ionic strength and then separated from smaller macromolecules by gel filtration or sedimentation, the preference for intermolecular integration is abolished, and autointegration products predominate (Lee and Craigie 1994). The preference for intermolecular integration could be restored by incubation with an extract of uninfected cells suggesting that a cellular factor was responsible for blocking autointegration and promoting intermolecular integration. Fractionation of cellular extracts, using blocking of autointegration as a functional assay, resulted in the identification of a single polypeptide barrier-to-autointegration factor (BAF) (Lee and Craigie 1998). BAF is a previously unidentified 89 amino acid cellular protein that at about the same time was also identified as an interacting partner of the LEM domain (Furukawa 1999), a domain that is conserved among a

family of proteins associated with the nuclear lamina including lamina-associated polypeptide 2, emerin, and MAN1.

BAF Structure and DNA Binding

BAF is a dimer in solution, and the structure has been determined by both NMR and X-ray crystallography. A helix-hairpin-helix motif was proposed to bind DNA (Umland et al. 2000). Consistent with the sequence-independent binding of BAF to DNA, the helix-hairpin-helix motif binds DNA through contacts between DNA phosphates and amide groups in the protein backbone. This mechanism of DNA binding was confirmed by solving the crystal structure of the BAF dimer in complex with DNA (Fig. 1; Bradley et al. 2005). In addition to the helix-hairpin-helix motif, DNA binding is aided by the first alpha helix which forms hydrogen bonds with phosphates. There are no contacts involving bases, and the BAF dimer does not undergo any conformational change upon DNA binding; the RMS deviation between the free and DNA-bound dimer is 3.5 Å for all atoms.

Mechanism of DNA Compaction by BAF

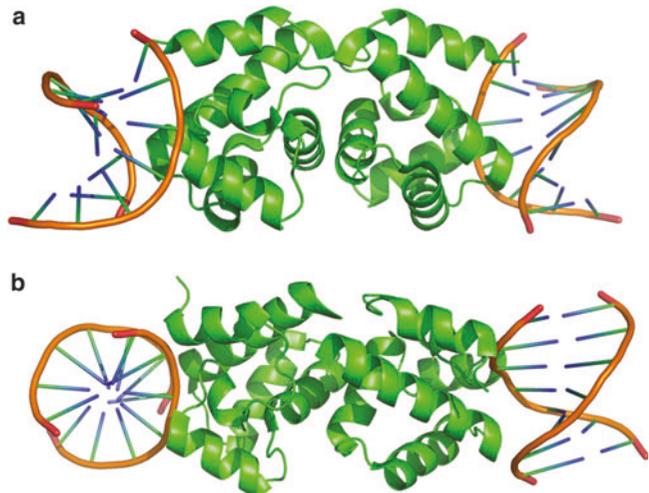

One DNA duplex binds to each monomer of the BAF dimer with the two DNAs forming an angle

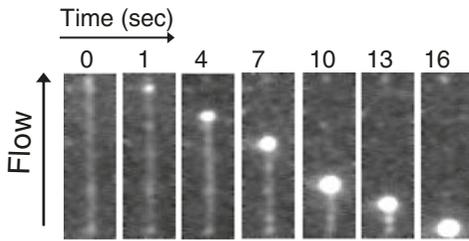

of close to 90 °C with one another (Fig. 1). Wrapping of a single DNA molecule around the BAF dimer to occupy both DNA-binding sites would be energetically unfavorable because of the required bending and the preponderance of negative charge on the surface of the BAF dimer between the two DNA-binding sites. The DNA-binding sites are therefore likely occupied by two difference of DNA molecules or sites on the same DNA molecule that are separated by a large enough distance that the DNA can form a loop between the two binding sites. At high DNA concentration intermolecular bridging will aggregate DNA. At a low DNA concentration, such as retroviral DNA within the cytoplasm of an infected cell, intramolecular bridging will result in compaction of the DNA molecule. It has been proposed that such compaction of retroviral DNA by BAF within the PIC makes it inaccessible as a target for integration and therefore blocks auto-integration (Lee and Craigie 1998).

The degree of compaction of viral DNA within the PIC correlates with protection against auto-integration. Salt-stripped PICs sediment more slowly in sucrose gradients. Treatment with purified BAF restores the protection against auto-integration and the faster sedimentation behavior in parallel. Other protein factors appear to not be required to compact the viral DNA within the PIC because incubation of BAF with plasmid DNA at DNA low concentration results in similar

BAF (BANF1),

Fig. 1 Ribbon representation of the BAF dimer in complex with DNA. BAF is shown *green* and the DNA helices in *orange*. The views in (a) and (b) are rotated about the horizontal axis (Note that the relative orientation of the two DNA molecules is close to orthogonal)

BAF (BANF1), Fig. 2 Compaction of DNA by BAF. A single 50-Kb DNA molecule was attached a flow cell and extended by buffer flow in the direction show. The DNA was labeled with the fluorescent dye YoYo1 and visualized by total internal reflection fluorescence microscopy. At time 0, the buffer was switched to buffer containing BAF. The DNA progressively condenses into a tight ball from the free end (*top*) toward the point of attachment (*bottom*) (Reproduced from Skoko et al. (2009))

compaction as judged by sucrose gradient sedimentation (Skoko et al. 2009).

DNA compaction by BAF can be directly visualized by total internal reflection fluorescence microscopy (TIRFM) (Skoko et al. 2009). Figure 2 depicts compaction of a 50-kb DNA molecule by BAF. The DNA is labeled with the fluorescent dye YOYO-1 and extended by buffer flow. At time zero BAF is introduced into the flow cell. The initially extended linear DNA rapidly condenses toward its attached point on the flow cell, and by about 15 s the DNA is condensed into a tight ball. The dissociation of BAF from DNA is surprisingly slow even in the presence of 1-M NaCl, with some BAF remaining bound even after 1 h of washing. The compacted structure likely presents a kinetic barrier to dissociation of BAF. Release of DNA from one of the two binding sites within the dimer does not result in immediate release of BAF because it remains anchored by the second binding site. Furthermore, the locally high DNA concentration favors rebinding at the first site before the second site dissociates. Thus the DNA-binding properties of BAF alone can account for its tight association with the PIC and the requirement for very high-ionic strength to release BAF and decondense the DNA. Autointegration may not require complete dissociation of all BAF from the PIC but rather sufficient dissociation to cause the viral DNA to adopt a more open structure.

Phosphorylation of BAF Abrogates DNA Binding and Protection from Autointegration

BAF exists in both unphosphorylated and phosphorylated forms. The major site of phosphorylation is Ser4 with a minor population phosphorylated at Thr2 and/or Thr3 (Bengtsson and Wilson 2006; Nichols et al. 2006). Phosphorylation of BAF abrogates DNA binding. The major kinase responsible for phosphorylation of BAF is vaccinia-related kinase 1 (VRK1) (Nichols et al. 2006). Treatment of MoMLV PICs with VRK1 and ATP abolishes intermolecular integration and promotes autointegration, consistent with a dominant role of BAF in blocking autointegration (Suzuki et al. 2010). The VRK1-treated PICs migrate more slowly in sucrose gradients consistent with a reduction in compaction resulting from a loss of BAF after phosphorylation. This change in sedimentation behavior resembles that resulting from treatment of PICs with high salt, which also causes a loss of BAF (Suzuki and Craigie 2002). It is noteworthy that treatment of HIV PICs with ATP promotes autointegration (Farnet and Haseltine 1991); this phenomenon may have resulted from phosphorylation of BAF by endogenous kinases present in the cell extract.

Role of BAF in POX Virus Replication

BAF has been implicated in host cell defense during poxviral infection (Wiebe and Traktman 2007; Ibrahim et al. 2011). Poxviruses, such as vaccinia, are DNA viruses that replicate exclusively in the cytoplasm. Vaccinia B1 kinase is an essential viral enzyme that is encapsidated within the virion. Mutations in B1 kinase cause a DNA replication defect that can be rescued by the cellular vaccinia-related kinase 1 (VRK1). The absence of known viral targets for the B1 kinase, and the fact that BAF is the major substrate for VRK1, led Traktman and colleagues to investigate whether the role of B1 kinase in poxvirus replication might involve phosphorylation of cytoplasmic BAF (Wiebe and Traktman 2007).

Several lines of evidence support this hypothesis. Firstly, phosphorylation of BAF increases with vaccinia virus infection. Secondly, in the absence of B1 kinase, BAF localizes to the sites of vaccinia virus DNA replication. Thirdly, increased BAF levels correlate with decreased vaccinia DNA synthesis. Finally, expression of a non-phosphorylatable mutant of BAF from the viral genome is lethal for vaccinia replication. The data support a model in which in the absence of phosphorylation cytoplasmic BAF compacts and sequesters the vaccinia DNA thereby blocking DNA replication. Thus the same mechanism that blocks autointegration of retroviral DNA can inhibit replication of poxviral DNA.

Function of BAF for the Host Cell

In this brief overview we focus what is known about the function of BAF for viral replication. However, BAF is an essential protein for the host cell, and this complicates *in vivo* functional studies because cells in which BAF is severely knocked down or knocked out are not viable. BAF plays a crucial role in chromatin segregation during mitosis and nuclear envelope assembly. Knockdown of BAF by RNAi in *C. elegans* results in a defect in chromatin segregation during mitosis (Zheng et al. 2000). In *Drosophila*, homozygous *BAF* mutants are lethal at the larval-pupal transition (Furukawa et al. 2003). Abnormalities in interphase nuclear structure were also observed, including clumping of chromatin and abnormal nuclear morphology. The molecular basis of these changes in chromatin organization is unclear, but studies with a temperature-sensitive BAF mutant in *C. elegans* show nuclear envelope defects are apparently independent of and before the defect in chromatin phenotype (Gorjanac et al. 2007).

BAF plays an important role in nuclear envelope formation. BAF interacts with the LEM domain of the nuclear envelope-associated proteins LAP2, emerin, and MAN1 (Furukawa 1999; Lee et al. 2001; Shumaker et al. 2001; Mansharamani and Wilson 2005). The structure of the BAF/LEM complex has been determined

by NMR (Cai et al. 2007). BAF has also been reported to interact with other cellular proteins including cone-rod homeobox (Crx) (Wang et al. 2002) and the C-terminal domain of MAN1 (Mansharamani and Wilson 2005), but a direct physical interaction is not supported by biophysical measurements (Huang et al. 2011).

Conclusion

The primary role of BAF for the host cell is in the assembly of the nuclear envelope and chromatin organization. Why is BAF also present in the cytoplasm where it serves no obvious cellular function? It has been proposed that cells employ the DNA compacting properties of BAF as a defense against DNA viruses and foreign DNA in general (Ibrahim et al. 2011). The same mechanism that blocks replication of DNA viruses can also compact the viral DNA within retroviral PICs making it inaccessible as a target for autointegration.

Behavioral Aspects of HIV Mother-to-Child Transmission

Robert Malow and Consuelo M. Beck-Sagué
Department of Health Promotion and Disease Prevention, Robert Stempel College of Public Health and Social Work, Florida International University, Miami, FL, USA

Definition

HIV mother-to-child transmission (MTCT) is defined as infection acquired by an infant from an HIV-positive mother during pregnancy, labor, delivery, or breastfeeding.

Introduction

Worldwide, an estimated 3.4 million children under the age of 15 years were living with HIV in 2011, of whom 330,000 acquired HIV that year; over 95% are believed to have acquired HIV by MTCT (UNAIDS 2012) (374, 359). Without intervention, 28–40% of infants born to HIV-positive mothers will acquire HIV, most during delivery; less frequently, intrauterine MTCT can occur. MTCT can also occur during breastfeeding, and over 10% of MTCT cases in breastfeeding populations may be due to this mode of transmission (Horvath et al. 2009). Prenatal interventions for prevention of MTCT (pMTCT) can decrease risk considerably. Multi-dose zidovudine and single-dose nevirapine regimens during pregnancy have been shown to decrease the risk of HIV

Robert Malow: deceased.

transmission to rates of 8–15% (384,414,381). Elective cesarean delivery can also reduce the risk of MTCT. The most effective method of reducing MTCT has been prenatal highly active antiretroviral therapy (ART), which has been able to reduce rates of HIV transmission to <1–2%, especially if administered for at least 3–6 months (Sturt et al. 2010). Exclusive artificial infant feeding eliminates postnatal MTCT due to breastfeeding. Cesarean delivery offers no additional protection if prenatal ART suppresses maternal viral loads to undetectable levels. Prenatal ART use has led to virtual elimination of MTCT in high-income countries and is currently the standard of care, making MTCT elimination theoretically achievable worldwide (US PEPFAR 2010).

Because ART provides health benefits to both the mother and the child, in 2010, the World Health Organization (WHO) introduced guidelines for moving beyond single-dose nevirapine for pMTCT, which offered no benefits to mothers, to lifelong ART for HIV-positive pregnant women if they needed it for their own health (381,414). Other options also recommended short-term ART to prevent MTCT if mothers did not need it, based on CD4 counts (WHO 2012). These recommendations were:

Option A: Initiating lifelong treatment as soon as possible after diagnosis if the CD4+ T-lymphocyte/mL³ (CD4) count is <350. If the CD4 count is ≥350, prenatal multi-dose zidovudine starting as early as 14 weeks' gestation, single-dose nevirapine and a dose of zidovudine and lamivudine during labor, and 7 days of zidovudine-lamivudine postpartum, with infant multi-dose nevirapine regimens of variable durations based on breastfeeding duration and maternal postpartum ART regimen.

Option B: Initiating lifelong ART including nevirapine or efavirenz as soon as possible after diagnosis if the CD4 count is <350; if the CD4 count is ≥350, starting ART containing efavirenz as early as 14 weeks' gestation, continuing through childbirth if not breastfeeding or until 1 week after breastfeeding cessation, with daily infant nevirapine or zidovudine regardless of feeding strategy (WHO 2012).

More recently, a third option (**Option B+**) was introduced which provides the same ART regimen (generally tenofovir-lamivudine or tenofovir-emtricitabine and efavirenz) to HIV-positive pregnant women beginning in prenatal care regardless of CD4 count and continues this therapy for life (WHO 2012). A single universal ART regimen has clinical and programmatic advantages: it treats HIV-positive women for their own health, prevents MTCT and streamlines, and strengthens pMTCT program performance through harmonization and linkages with ART standard programming for adults and adolescents, as seen in Option B (371).

Worldwide, the use of Option B+ is the most promising strategy for MTCT elimination (CDC 2013; Haas et al. 2016). However, because every HIV-positive pregnancy carries some MTCT risk, prevention measures have to be both accessible and sustainable. MTCT elimination is considered to depend on four key fundamentals or “prongs” (US PEPFAR 2010): (1) primary prevention of HIV infection in fertile women, including during pregnancy (Johnson et al. 2012) (312); (2) prevention of unwanted pregnancy in HIV-positive women (Reynolds et al. 2006); (3) prenatal and post-delivery maternal ART use for the mother's health and for MTCT prevention (WHO 2012) (373); and (4) effective integration of care, treatment, and support for HIV-positive women and their families (35) (Ackerman Gulaid and Kiragu 2012). The fulfillment of these key fundamentals requires the accessibility of and adherence to highly effective biomedical strategies, particularly ART regimens. Interpersonal and structural factors may influence the ability of HIV-positive women to initiate and adhere to ART during their pregnancy. Inequities and barriers to access, along with a lack of basic knowledge and information, may impede the uptake and sustainability of interventions to reduce MTCT in the most HIV-affected communities. Against this challenging backdrop, a “cascade” of prevention measures may identify HIV-positive women and their families at critical crossroads while providing strategies to negotiate these fragile prongs (Marcos et al. 2012), including prenatal counseling and education, specialized HIV care and ART,

perinatal testing and management, and infant feeding practices and family planning. The effectiveness of this cascade relies on a considerable degree on the robustness of the relationship between pregnant women and their providers (Barry et al. 2012). This section focuses on behavioral aspects of MTCT, including diagnosis and treatment of HIV infection in pregnant women, prevention or timely detection of maternal HIV infection acquired during pregnancy (Moodley et al. 2009), perinatal behaviors, and postpartum, post-delivery, and inter-pregnancy issues, including infant feeding, maternal contraception, and ART continuation.

pMTCT During Pregnancy and Delivery

Worldwide, HIV in women is most often acquired through unprotected sex with HIV-positive men, and many women are diagnosed with HIV during prenatal testing (UNAIDS 2011). Contact with providers who are able to administer or link women to HIV testing is thus a critical first step to diagnosing HIV infection and providing ART (WHO 2012). Evidence suggests that the vast majority of pregnant women accept universal HIV testing if it is routinely offered, either through opt-out or opt-in testing policies (Creek et al. 2009). Integration of HIV testing in prenatal and other maternal and child health programs has been particularly successful in enhancing acceptance of testing, if consent procedures are streamlined. The relatively high acceptability of routine, universal prenatal HIV testing to pregnant women and healthcare providers contrasts starkly with the low rates of acceptability for focused testing among women who considered “high risk” based on behavioral or other demographic characteristics that may stigmatize women, place providers in an uncomfortable position of explaining why a woman is considered “high risk,” lead to resistance to both offering and accepting testing, and therefore may miss the opportunity to test many women.

A significant barrier to women’s acceptance of prenatal testing, even when universally available and offered in a sensitive and respectful manner, is

the fear of loss of confidentiality, particularly the unauthorized disclosure of results to partners, in-laws, and employers. Fear that a positive test may result in loss of support or respect from acquaintances and friends and even violence, abandonment, and unemployment is an especially daunting barrier to the acceptance of testing, particularly in countries without robust, explicit legal protections for HIV-positive persons. For pregnant women, acceptability of universal HIV testing is greatest among women who are well informed regarding the preventability of MTCT and the availability at no cost of ART for both pMTCT and their own health, whose partners accept testing for themselves, and who know other women receiving ART for pMTCT (Creek et al. 2009). As such, the integration of “expert” mothers living with HIV in prenatal HIV testing programs (367), who can provide information regarding MTCT and offer support for ART initiation and continuation for those who test positive, is a promising strategy for pMTCT support and scale-up (Kim et al. 2012; Marcos et al. 2012)

In all settings, rapid tests are more acceptable than tests requiring the client to return days after for testing results (321). While drop-off and attrition are present at all levels of the cascade, the highest risk of loss to follow-up is arguably before an HIV-positive client receives her results. HIV-positive women are often overrepresented in the lowest income brackets; therefore, barriers to return for test results may include factors such as lack of transportation and/or child care, inability to take time off from work, and other obligations. For these reasons, rapid testing with results given within the same visit is the recommended standard. Currently available third- and fourth-generation rapid tests have extremely high specificity; the likelihood that a positive rapid test represents a false positive is extremely low, especially when the client can be retested with another rapid test using a different principle. As such, the HIV rapid test should be considered the highest priority, along with syphilis and anemia screening, in the first prenatal healthcare encounter.

The nature of the relationships between pregnant women and providers and women’s

satisfaction with their care are among the most significant predictors of maternal adherence to prenatal ART and, consequently, pMTCT effectiveness (Barry et al. 2012) (367). Strengthening the relationship between women and providers (Marcos et al. 2012) and addressing structural barriers faced by particularly marginalized and vulnerable populations are vital strategies to increasing prenatal ART adherence. The relationship between pregnant women and their providers depends upon the feeling that providers can be trusted, and women must feel that their disclosure decisions are respected. Additionally, women's disclosure of their HIV status to partners tends to be associated with increased ART and prenatal care attendance. However, immediately after HIV-positive pregnant women learn of their diagnosis, there are many priorities, such as ensuring housing stability and food and transportation access, which take priority over disclosure to the partner.

Many HIV-affected populations may have limited access to prenatal and delivery care (35, 325). In sub-Saharan Africa, while 71% of women have ≥ 1 prenatal care visit, only 44% have >4 visits; for delivery care, just 46% women deliver with assistance of a skilled attendant and 42% deliver in a hospital (UNICEF 2010). In other populations where prenatal care utilization for women may be higher, HIV-positive women may face significant barriers to prenatal care access, including lack of health insurance, lack of citizenship and/or documentation, or other marginalized statuses. In these circumstances, innovative strategies to offer prenatal testing outside of conventional prenatal care include mobile clinics, health fairs, and other approaches. Unconventional settings present challenges to effective linkage to care but may be an alternative strategy to at least provide HIV testing. Community engagement and support at multiple levels, such as assuring that the rights of HIV-positive persons are secured, have proven effective in ensuring the critical first steps: accepting testing and receiving results and accessing and adhering to ART (Ackerman Gulaid and Kiragu 2012) (321).

Special Circumstances

Acute HIV Infection During Pregnancy

An important but often overlooked component of pMTCT is the prevention of HIV infection during the time of pregnancy for HIV-negative women (Johnson et al. 2012). Because condom use tends to be higher among persons who desire contraception, pregnancy may be a particularly high-risk period for unprotected sex (312). Traditional taboos in some societies against sex during pregnancy, during the immediate postpartum period, and during lactation are rarely observed, especially if vulnerable women who depend for their livelihood on their partners feel that they may be replaced if they observe such abstinence periods. Acute HIV infection (AHI) during pregnancy, which is undetectable in early prenatal HIV testing, is extremely risky for MTCT, as AHI is generally asymptomatic or characterized by nonspecific symptoms, while viral loads reach extremely high levels during AHI. Encouraging pregnant women's partners to accept testing can help identify women at highest risk of AHI (those who are in stable discordant relationships with HIV-positive men [315,377]); partner testing also may increase women's acceptance of testing (Creek et al. 2009). Other strategies include encouraging providers to screen and treat genital conditions that may promote HIV transmission and encouraging pregnant women and their partners to adopt universal prenatal condom use. However, the most important behavioral measure to address acute HIV infection in pregnancy is motivating providers to facilitate third trimester or delivery retesting or rapid tests for newborns of women who test negative early in their pregnancy, regardless of maternal risk (Moodley et al. 2009). Women should be informed of the routine retesting policy during their initial prenatal test, as this may increase acceptability. Furthermore, both clients and providers need to understand that initiation of infant antiretroviral post-exposure prophylaxis (PEP) is very effective and of low risk for the newborn if started before 72 h postpartum. Infant PEP should be continued

according to Option B+ for 4–6 weeks or until after breastfeeding is discontinued, as in other perinatally exposed infants (WHO 2012) (384).

Serodiscordant Couples

Serodiscordant couples are couples in which one partner is HIV-positive and the other is HIV-negative; these couples are a small but critically important population in MTCT, particularly when the HIV-positive partner is the male (315). Artificial insemination with sperm separated from seminal fluids which could contain HIV (“sperm washing”) appears to be a safe and effective strategy (Semprini et al. 2013; Royal College of Obstetricians and Gynaecologists 2013). However, it requires considerable technological expertise and is financially unavailable to most couples worldwide who needed it. ART use by HIV-positive men in serodiscordant couples has emerged as an important alternative, offering health benefits to the HIV-positive partner even if they do not meet CD4 count criteria for ART initiation and reducing the risk of HIV transmission by over 95% to the HIV-negative partner and, thus, to a potential infant (Cohen et al. 2011; Royal College of Obstetrics and Gynaecologists 2013) (377). No assessment has been performed of the safety and effectiveness of “treatment as prevention” during the periconceptional period for prevention of HIV transmission to the female partner in serodiscordant couples desiring conception. However, it appears to be the most promising alternative and is tentatively being considered for couples where the HIV-positive male partner is adherent to ART, has an undetectable viral load and no sexually transmitted infections, and confines unprotected intercourse to HIV-negative female partner’s most fertile period (ideally at ovulation, confirmed by point-of-care testing). The use by the HIV-negative female partner of pre- and/or post-exposure prophylaxis (PrEP, PEP) with antiretrovirals to which the male patient’s strain is not resistant may be an additional protection (296,378,329,411). In these cases, both commonly used non-nucleoside reverse transcriptase inhibitors (NN-RTIs) are

relatively contraindicated, efavirenz (because of modest teratogenic potential) and nevirapine (because of the high risk of adverse reactions in multi-dose regimens for HIV-negative women). Therefore, PrEP and/or PEP regimens including only two N-RTIs or two N-RTIs with a boosted protease inhibitor are preferable. For cases in which the female partner is HIV-positive, conventional artificial insemination is safe and effective in protecting the male partner from HIV transmission during attempts to conceive, and pMTCT Option B+ is the most appropriate for the mother.

Single-dose nevirapine use should be confined to women whose HIV infection is diagnosed at onset of labor or at delivery, because it does offer a substantial decrease in MTCT risk (US PEPFAR 2010; WHO 2012), (414,381). Despite its apparent simplicity, adherence to this method can be quite low (in some settings, less than 70%) (Kuonza et al. 2010). In routine situations, the length of time between the HIV diagnosis (typically early in pregnancy) and the moment when a healthcare provider and the mother will be expected to act on the positive result can be over 6 months. During the critical time window (2–8 h pre-delivery for the maternal dose and less than 72 h postpartum for the infant dose) in which single-dose nevirapine doses must be administered, the mother may be the only person aware of her HIV status and may be overwhelmed requesting a single dose of an unfamiliar medication for pMTCT. Higher risk of non-adherence is associated with fewer prenatal visits, home deliveries, and multiparity, the latter, because of the higher likelihood of precipitous labor. Single-dose nevirapine use for pMTCT of maternal infections diagnosed before or during early pregnancy is clearly suboptimal, not only because of its inferior performance for pMCT but also because it makes other essential elements, including support for disclosure to partners and education to increase adherence to maternal treatment and infant nutrition and follow-up recommendations, very challenging. Conducting testing, receipt, and explanation of test results, safety and effectiveness of nevirapine, and subsequent steps in

pMTCT during a woman's labor in an open ward is also challenging (46). For these reasons, single-dose nevirapine should be considered a pMTCT strategy of last resort.

Post-Delivery and Infant Care

Infant Nutrition

Postnatal MTCT is generally related to breastfeeding. Exclusive artificial feeding can eliminate the risk of MTCT; however, the risks of malnutrition, diarrhea, respiratory infections, and other serious and often fatal complications of exclusive artificial and mixed feeding, along with infant formula's high cost, make this choice controversial (Creek et al. 2010; WHO 2012). In virtually all industrialized countries and in some low- and middle-income countries, provision of formula at no cost to mothers and capacity building for safe formula preparation have resulted in HIV-free infant survival with exclusive artificial feeding, often with lower infant mortality than in non-perinatally exposed breastfed infants (Ivers et al. 2011). However, the complexities implicit in exclusive artificial feeding, its stigmatization in some populations, and the lowered risk of breastfeeding-related MTCT and maternal and infant mortality when mothers adhere to post-delivery ART and administer PEP to their infants have made breastfeeding an appealing alternative (White et al. 2014).

Maternal adherence to postnatal MTCT prevention options may depend on the mother's receipt of accurate information regarding her options in a non-coercive and respectful way that supports her autonomy (WHO 2012). In the rushed, public setting of maternity wards, standard referral strategies to specialized services for perinatally exposed infants may fail to adequately inform the mother of the need for and location of these services, expose the mothers to stigmatization, and make reestablishing contact difficult—particularly if the infant's medical record is only initiated at the time of the initial infant visit at specialized services (Ciampa et al. 2012). Methods that have increased adherence rates by

over 50% include accompaniment of mothers by staff to visit the specialized infant services before their discharge from maternity wards; counseling in that private setting by maternity staff on infant care, feeding, PEP, and need for return; and infant medical record generation before discharge. Before discharge of perinatally exposed infants, maternity staff should identify and address concerns regarding housing, food insecurity, and transportation availability and ensure support in the mother's community, ideally by other mothers of perinatally exposed uninfected infants (367).

Family Planning

The roles of contraception and sterilization in pMTCT are extremely controversial. Coerced sterilization, often as a condition to providing prenatal or delivery services, such as cesarean delivery, has been documented worldwide and contributes to women's fears of HIV testing. Conversely, desired sterilization, as well as other elective surgical procedures, is often denied to women by healthcare providers worried about the risk of occupational HIV infection (360). Contraception is extremely cost-effective for pMTCT and has additional health benefits for women and children through spacing of pregnancies (Reynolds et al. 2006). Knowing one's positive HIV status is strongly associated with desire to limit childbearing through contraception and with increased condom use (Johnson et al. 2009). Fertility preferences are complicated in the diverse population of HIV-positive women, including mothers of HIV-positive children and those at highest risk (seronegative partners of HIV-positive men). Many women often desire to defer but not completely eliminate future childbearing options and prefer reversible rather than permanent contraception.

Despite its promise, reversible contraception use by HIV-positive women is extremely complicated. There are numerous interactions between the most widely used antiretrovirals, including efavirenz and nevirapine, and oral-combined hormonal contraceptives that considerably limit the use of oral contraceptives (US DHHS 2011). These interactions include lowering of blood

levels of estrogen components of combined hormonal contraceptives causing contraceptive failure when used concurrently with efavirenz; lowering of antiretroviral levels to subtherapeutic concentrations if used concurrently with various contraceptives; and elevations of antiretrovirals to toxic levels. These interactions may be inconsistent and difficult to control with dosing changes. Contraceptives that have virtually no interactions with antiretrovirals are less acceptable due to some of their other side effects; for example, long-acting progesterone-only injection contraceptives that need dosing only once every 3 months are especially attractive because of their limited adherence issues, high contraceptive effectiveness, non-interaction with antiretrovirals, absence of the cardiovascular risks, and non-contraceptive benefits, such as reduction or elimination of menstruation, with consequently lowered risk of anemia, a common problem in HIV-positive women (US DHHS 2011). However, many women do not understand that the irregular bleeding and spotting with injection contraceptives is short-lived and that long-term absence of menstruation related to prolonged use is not harmful and, in fact, is beneficial. Unfortunately, providers who could reassure potential users sometimes have misconceptions about the safety of amenorrhea similar to those of patients. Alternatively, the option of male sterilization among HIV-positive men is rarely discussed in the context of pMTCT, and male condom use is the only contraceptive option where the male partner's involvement is seriously considered.

Healthcare Providers

The knowledge, attitudes, and behaviors of healthcare providers are critical to successful pMTCT (360). They can provide information, counseling, testing, linkage to care, and treatment – factors which are critical to every level of the pMTCT cascade, including prevention of infection among female partners of HIV-positive men and unintended pregnancies in HIV-positive women. The strength and quality

of provider relationships with HIV-positive women are strongly associated with effective pMTCT (Barry et al. 2012). However, healthcare providers are often uninformed and lack confidence about best practices at critical decision points. Stressors such as exaggerated fears of occupationally acquiring HIV, misinformation about the risk of pMTCT (frequently including that all infants whose mothers have not received pMTCT interventions will acquire HIV, that pMTCT is only marginally effective, and that HIV infection is uniformly fatal in infants and their mothers), and overwhelming workloads and lack of psychological support serve to greatly reduce the potential for meaningful provider contributions. The inclusion of HIV-positive mothers as treatment partners for pregnant women in multidisciplinary teams can greatly improve quality of care for the patient as well as the experience of the provider (Ackerman Gulaid and Kiragu 2012) (367). Moreover, provider-created quality improvement strategies have been shown to be highly effective and among the most effective for promoting adherence and preventing loss to follow-up (Ciampa et al. 2012). Although less studied, the provision of support services, specifically for providers in pMTCT, may greatly increase their willingness to competently serve the women and infants in their care. These services include information regarding the low risk of occupationally acquired HIV from HIV-positive pregnant women, especially when they are receiving ART; on-site PEP for occupational exposure at no cost to the provider, provided confidentially and competently (329); and consistent access to the most important tools for pMTCT (384), including rapid tests, easily dispensed ART, and protective devices for procedures associated with occupational risk, particularly phlebotomy.

Conclusions

The elimination of HIV MTCT is potentially one of the most achievable HIV prevention goals; however, targeted strategies at all levels of the

prevention cascade must be introduced and maintained in diverse and challenging populations, including sexually active fertile women, their sex partners, and healthcare providers.

Definitions

- **Combination prevention:** A term for an approach in HIV prevention that includes an array of behavioral, biomedical, and structural interventions, selected to best address the specific HIV prevention needs of a population.
- **Substitution prevention:** A term for an approach in HIV prevention that utilizes a singular ideal intervention, often pitting behavioral, biomedical, and structural interventions against one another.
- **Complementary prevention:** Similar to *combination prevention*; a term for an approach that appreciates the diverse context for HIV prevention efforts and synergistically involves prevention interventions from all domains to address clients' specific service needs.

Background

Certain behaviors and conditions such as unprotected anal or vaginal sex, having other sexually transmitted infections, sharing of contaminated needles or syringes, or receiving unsafe injections or blood transfusions put individuals at greater risk of contracting HIV (WHO 2012). Beyond these *proximal* risk factors, there are *distal* and *structural* factors such as homelessness or stigma,

which shape the general socio-environmental context that also drives HIV transmission. Additionally, policies and resources that influence the availability of HIV care and treatment are important factors in HIV transmission and risk. These structural, epidemiological, biological, and behavioral risk factors overlap and interact with one another, increasing risk for not only HIV and other sexually transmitted infections but also other conditions (e.g., mental illness, substance abuse) and social problems (e.g., homicide, violence, and crime) (Rotheram-Borus et al. 2009).

Due to the multilevel factors involved in HIV risk and transmission, optimally effective HIV prevention efforts will require a combination of behavioral, biomedical, and structural intervention strategies. The 2010 United States National HIV/AIDS Strategy endorses this “combination prevention” approach, emphasizing the need for clients to receive the best array of interventions to address their specific HIV prevention needs (The White House Office of National AIDS Policy 2010).

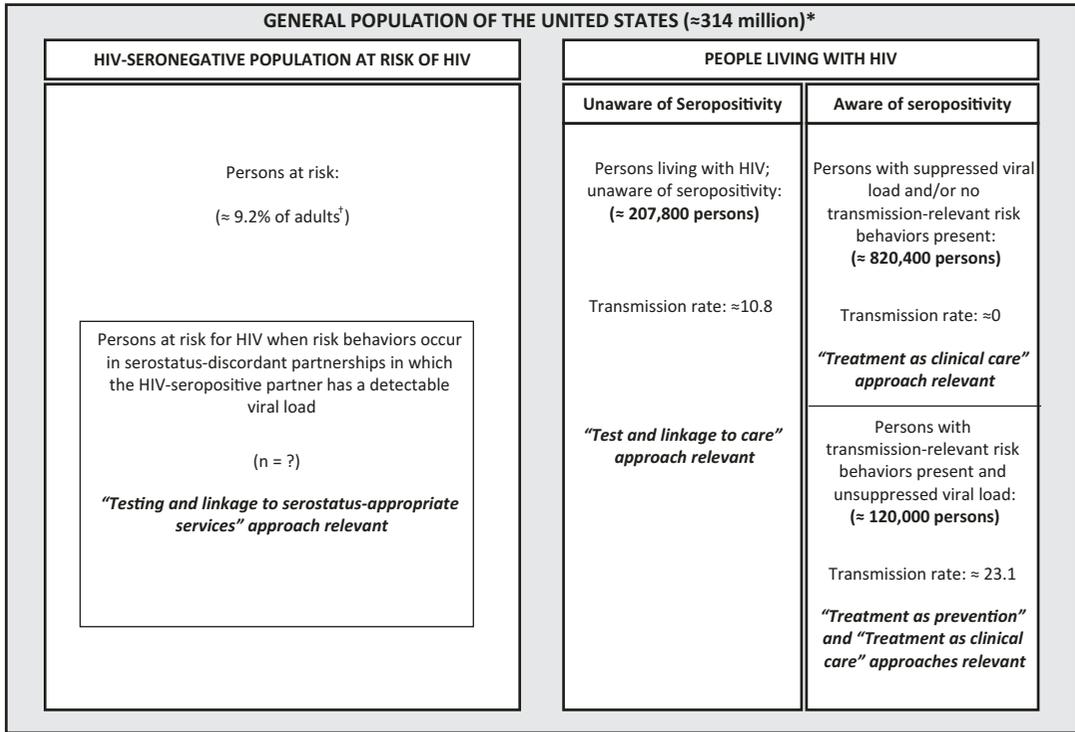

In addition to the established body of research on behavioral and structural interventions, emerging work in the field of biomedical HIV prevention strategies has received much attention in recent years. A recent NIH study, entitled HIV Prevention Trials Network (HPTN) 052, was touted as the “scientific breakthrough of the year 2011” by *Science* and showed that antiretroviral therapy for persons living with HIV (PLWH) can effectively reduce transmission in HIV serostatus discordant heterosexual partnerships (Cohen et al. 2011). The implications of this trial and of the growing body of work on Treatment as Prevention (TasP) on the broader landscape of HIV prevention have been profound and have led many to proclaim it as “The Beginning of the End of AIDS.” In a fact sheet addressing the state of the epidemic on World AIDS Day 2011, the Obama administration emphasized the significance of the recent breakthrough, but also highlighted the need for “combination prevention” efforts, acknowledging that not all types of intervention are appropriate for all populations and that it is important to consider strategic investment of funding in order to support the

interventions with the largest impact (White House Office of the Press Secretary 2011). In other words, though the recent biomedical breakthroughs provide a new class of prevention interventions, they should be considered in combination with existing intervention strategies rather than a direct substitution. Indeed, in subsequent discussions on the topic of TasP, the issue of HIV-related risk behavior has been nearly absent (Holtgrave et al. 2012; Small and Kerr 2011). The “combination prevention” discussion sometimes lapses into “substitution prevention” debates where one approach is pitted against the other (Holtgrave et al. 2012; Small and Kerr 2011).

While TasP is highly relevant for some subpopulations, the larger population of PLWH is far from homogenous in its risk of transmission and therefore in the optimal prevention intervention approach. Indeed as the scientific community and general public celebrate the NIH HPTN 052 study results and its potential impact on the fight against the epidemic, there is a need to emphasize a “complementary prevention” approach, choosing the best prevention interventions from all domains to address clients’ specific service needs (Holtgrave et al. 2012).

HIV Serostatus and Key Populations in the USA

Using a serostatus approach to consider the HIV epidemic in the USA (and as illustrated in Fig. 1), three key populations have been identified: (1) the general population, (2) HIV-seronegative persons at risk of infection, and (3) persons living with HIV (PLWH), which includes three subpopulations (persons unaware of seropositivity, persons aware and with suppressed viral load and/or engaged in no risk behavior that could result in transmission, and persons aware and engaged in unprotected serodiscordant risk behavior with unsuppressed viral load that could result in transmission) (Holtgrave et al. 2007, 2012). Due to the differences in serostatus, risk behavior, and transmission rates between these populations, interventions should be tailored to meet the unique needs of each group.

* Note: Figures are based on most recently available statistics described in the text.
[†] Percentage reflects federal estimates of risk behaviors among 15-44 year olds (Chandra et al., 2012).

Behavioral Aspects of HIV Treatment as Prevention, Fig. 1 Key U.S. populations defined by HIV serostatus and relevance of various treatment-related prevention approaches

The General Population

As of 2012, the US Census Bureau estimates that the US general population was nearly 314 million (US Census Bureau 2012). Although widespread education and awareness efforts are both necessary and valuable for the general population as a whole, specific behavioral and biomedical interventions, including TasP, are most relevant and cost-effective when directed at and custom-tailored for the specific subpopulations listed just above. The rationale for intervention tailoring is presented below for each of these groups, in turn.

HIV-Seronegative Persons at Risk of Infection

Federal estimates indicate that roughly 9.2% of seronegative adults between 15 and 44 years of age currently engage in some form of HIV-related risk behavior (Chandra et al. 2012). Within this group, there are an unspecified number of individuals who engage in unprotected transmission-

relevant risk behavior within a serodiscordant partnership where the HIV-positive partner has an unsuppressed viral load. This subpopulation represents the seronegative persons most at risk for acquiring the virus (this point is discussed further below).

People Living with HIV

The estimated number of PLWH in the USA as of 2009 includes both people aware of their serostatus (approximately 940,400 PLWH) and those unaware of their serostatus (approximately 207,800 PLWH) (CDC 2011; Hall et al. 2013). Among these subpopulations, there is a large discrepancy in the estimated transmission rates. While the estimated HIV transmission rate among PLWH who are aware of their serostatus is 3.0%, the transmission rate among PLWH who are unaware of their serostatus is an estimated 10.8% (due to the impact of behavioral changes upon learning one is

living with HIV and due to the impact of treatment on transmissibility). (Of course, the HIV transmission rate is the number of HIV transmissions to HIV-seronegative partners of 100 PLWH per year.) Due to this disparity, it is imperative that PLWH who are unaware of their serostatus should receive testing in order to improve linkage to HIV care for its clinical benefits and to limit the chance of HIV transmission. Although there are programmatic challenges in identifying undiagnosed PLWH (such as systematizing HIV testing in clinic settings and reaching PLWH who are entirely out of the healthcare system), awareness of serostatus is a major predictor of risk behavior and viral suppression and therefore of the potential risk of transmission (Hall et al. 2012, 2013).

The subpopulation of PLWH who are aware of their serostatus includes individuals who engage in unprotected risk behavior in serodiscordant partnerships with unsuppressed viral load (approximately 120,000 out of 940,400 persons) (CDC 2011; Holtgrave et al. 2012; Hall et al. 2013). Of the two subpopulations of PLWH who are aware of their serostatus, the vast majority (approximately 820,400 out of 940,400 persons) are not engaged in any risk behavior that may lead to transmission and/or has suppressed viral load, making the transmission rate for this subpopulation effectively 0% (Holtgrave et al. 2012; Hall et al. 2013). It has been estimated recently that approximately 120,000 diagnosed PLWH who are aware of their serostatus and who do engage in unprotected serodiscordant risk behavior in which the index partner has unsuppressed viral load account for about 27,800 HIV infections in the USA (the other roughly 22,400 HIV infections per year in the USA are transmitted from the approximately 207,800 undiagnosed PLWH) (Hall et al. 2013; Holtgrave et al. 2014). These key estimates are summarized in Figs. 1 and 2.

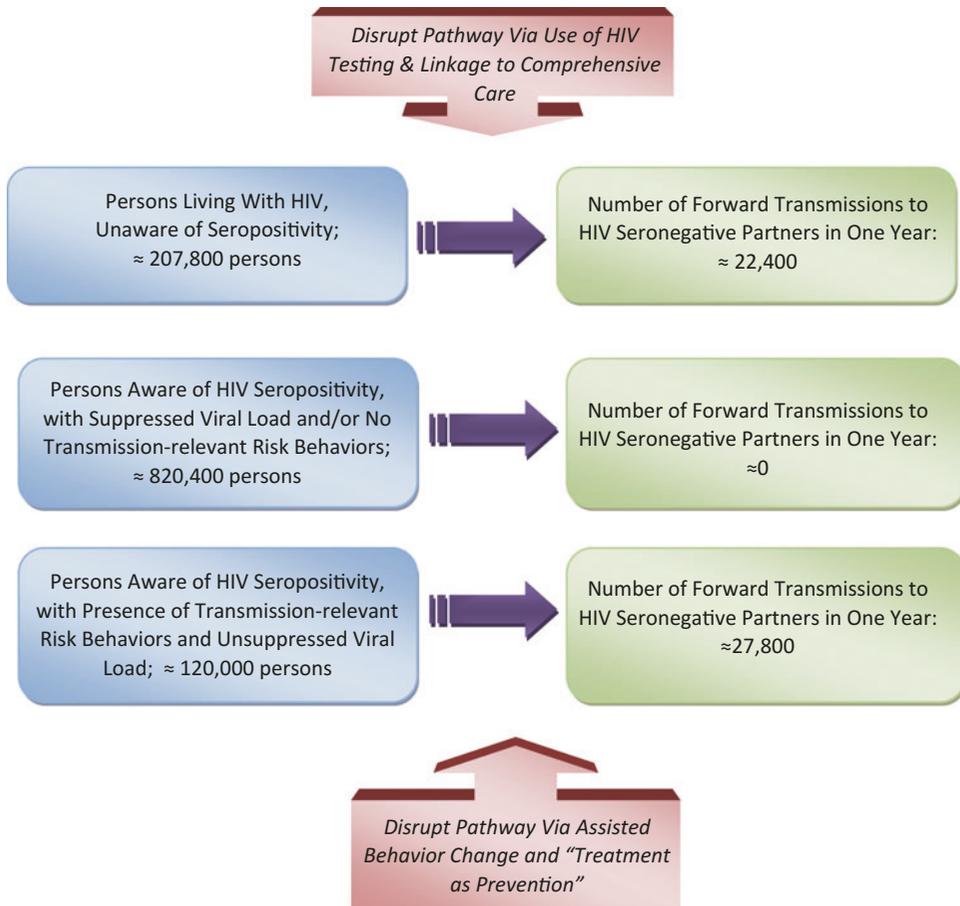

Further, as noted above, HIV-seronegative persons most at risk of infection are those who engage in unprotected risk behaviors with PLWH with unsuppressed viral load. Although this number of HIV-seronegative persons has not yet been specified in the literature, it could be approximated by (a) taking the number of

PLWH unaware of HIV seropositivity multiplied by the number of unprotected partnerships per unit time and then (b) adding to that product the number of PLWH who are diagnosed and engaged in unprotected risk behavior in serostatus discordant partnerships multiplied by the number of such partnerships per the same unit time.

Intervention Approaches by Subpopulation of PLWH

Table 1 displays the connection between key subpopulations of PLWH and the necessary array of client-centered HIV services. In summary (and also shown in Fig. 1), for PLWH, a “treatment as clinical care” strategy is always relevant as every PLWH should have unfettered access to high-quality, client-centered care (The White House Office of National AIDS Policy 2010).

For undiagnosed PLWH, a “treatment and linkage to care” strategy of HIV prevention is relevant since testing is the first step on a pathway to diagnoses, linkage to care, and ultimately suppression of viral load. For PLWH who are diagnosed and engaged in unprotected, serodiscordant risk behavior with unsuppressed virus present, there are two important pathways to avoid the transmission of the virus to seronegative partners: one pathway is behavioral risk reduction and the other is via TasP. (Of course, both HIV-related risk behavior and care access are influenced by broader social determinants as well.) Understanding the size of this particular subpopulation of PLWH provides insight into the impact that TasP strategies might have in the USA. For example, the impact of TasP on HIV incidence will be minimal if the next 10,000 persons entering care include very few PLWH who are engaged in transmission-relevant risk behavior. Conversely, the impact of TasP on incidence is potentially much greater if the next 10,000 persons entering care include many persons from this subpopulation. Again, this points to the need for truly synergistic combination HIV prevention approaches that meld together the best of behavioral and biomedical strategies (CDC 2009).

Behavioral Aspects of HIV Treatment as Prevention, Fig. 2 Number of forward HIV transmissions from subgroups of persons living with HIV, and potential points of prevention intervention

Further Key Behavioral Issues in HIV Care

Key steps in the continuum of care required for successful implementation TasP include HIV diagnosis, linkage and retention in care, prescription of antiretroviral therapy (ART), and ART adherence (CDC 2011). Persons retained in care can also benefit from counseling to reduce risk behaviors associated with HIV transmission. However, about one in five persons with HIV is unaware of their infection, less than half of persons with HIV are in regular care, and less than half of persons with HIV in care report receiving risk counseling in the past year (CDC 2011). Socioeconomic factors such as lack of health insurance, lower education, poverty,

unemployment, homelessness, lack transportation, feeling healthy, health literacy, and stigma are associated with lower retention in HIV care (Horstmann et al. 2010).

Mental health or substance abuse problems among PLWH also contribute to missed care visits and indicate greater need for health services. Structural factors that can enhance provider and patient participation and reduce stigma associated with HIV disease include policies for opt-out testing, HIV testing with routine blood draw from each patient entering the emergency department and inpatient facility, and reminders for appointments for care visits and risk counseling. A major factor in adherence to HIV care is a good provider-patient relationship, including effective communication, time to address individual needs, prompt

Behavioral Aspects of HIV Treatment as Prevention, Table 1 Key services needs of three subpopulations of persons living with HIV (PLWH)

Population	Testing	Linkage to care ^a	Care and treatment ^a	Behavioral prevention services	Mental health, reproductive health, housing, substance abuse treatment, sterile syringe and condom access, and other related services
PLWH, unaware	✓	✓	✓	✓	As client relevant
PLWH, aware; no risk behaviors	N/A	✓	✓	Support already existing behavior change	As client relevant
PLWH, aware; risk behaviors present	N/A	✓	✓	✓	As client relevant

“✓” indicates service is relevant for that subpopulation

“N/A” means not applicable

^a“Care” includes HIV specialty care and treatment, as well as comprehensive primary care, retention services, adherence support services, and ancillary support services such as transportation; linkage to care may include both initial and subsequent reengagement to care services

scheduling of appointments, and support through case managers (Aberg et al. 2009). In addition, care should be linguistically and culturally appropriate and address depression and substance abuse (Aberg et al. 2009). Effective interventions for linkage and retention in care must address barriers to accessing care. Some promising approaches using outreach to improve retention in care have been implemented (Bradford 2007; Horstmann et al. 2010); more research, however, is needed to develop optimal strategies and proven interventions for retention in care.

Conclusion

Scientific breakthroughs have clearly shown the importance of HIV treatment in terms of improving the morbidity and mortality of PLWH as well as on the disruption of HIV transmission. As a result, it is sometimes erroneously inferred that *only* HIV treatment is needed in HIV prevention. This is not the case, however, as an optimal combination of behavioral, social, and biomedical interventions creates a much stronger prevention package. It is only such complementary approach that has the potential to urgently and effectively address the HIV epidemic in the USA.

Behavioral Interventions for Adherence

Brooke G. Rogers, Jasper S. Lee and Steven A. Safren

Department of Psychology, University of Miami, Coral Gables, FL, USA

Definition

Management of HIV infection requires consistent medication use to keep viral load undetectable and prevent transmissions to sexual partners. While newer agents have made this process easier by creating simplified dosing, adherence still requires careful planning and behavioral management to ensure medications are taken correctly. To address this, psychosocial interventions have been developed to enhance adherence behaviors. Behavioral interventions for adherence have generally shown moderate success.

Behavioral Interventions for Adherence: Overview

Treating HIV to attain virological suppression is important both for long-term care of those living with HIV as well as minimizing the spread of HIV to others. Accordingly, interventions are needed for some individuals living with HIV/AIDS to maintain long-term adherence to antiretroviral therapy (ART). As a result, starting in the late 1990s when HIV went from a fatal diagnosis to a manageable chronic condition due to ART, medication regimens were quite complicated which spurred the creation of interventions with the goal of increasing or sustaining adherence to ART. These interventions have social-psychological health behavior models at their base and utilize various behavioral approaches such as problem-solving, cognitive behavioral therapy, or motivational interviewing to address barriers to adherence. The first set of meta-analyses suggest that the first major set of

adherence interventions were moderately successful in increasing or sustaining adherence (Amico et al. 2006; Simoni et al. 2006).

A central feature of most behavioral interventions for HIV medication adherence is that they have various skills-building techniques to address potential barriers to taking medication on time and as prescribed. Typical psychosocial theories for health behavior change are at the root of these interventions; strategies include attempting to change person-specific attitudes, norms, behavioral intentions, cognitions, and readiness to change. Other interventions have utilized therapy-based techniques including supportive psychotherapy, motivational interviewing, cognitive behavioral therapy, and problem-solving. Of the extant behavioral interventions for HIV medication adherence to date, most have fallen under one of the following three intervention categories: (1) individual education and behavioral skills building, (2) electronic reminder interventions, and (3) social support interventions. Each category is discussed briefly below with overviews of key trials and interventions.

Individual Education and Behavioral Skills Building

Education and behavioral skills building interventions are typically short term and performed in-person. These interventions emphasize basic medication management skills and problem-solving techniques that specifically address adherence barriers as opposed to problem-solving therapy, which teaches the general problem-solving skills. Consistent with the spirit of motivational interviewing, most of these effective interventions are conducted through a collaborative lens with both patient and counselor working together to achieve adherence goals. Interventions range in intensity from low to high (Amico et al. 2006) and from single-session to weekly sessions delivered intermittently over 12 months (Simoni et al. 2006). Approaches to treatment include psychoeducation about HIV and the importance of adherence to prevent viral mutation. However, for health behavior change interventions and

adherence to HIV medication interventions, education alone is necessary but not sufficient. As such, the inclusion of cognitive behavioral therapy and problem solving to address barriers to medication adherence is an important part of these interventions. These interventions often incorporate reminder systems or schedule planning to complement education and problem solving. In addition, the inclusion of cognitive-behavioral principles helps patients focus on changing thoughts and behaviors around taking medication. Most interventions also emphasize patient-centered care and utilize the therapeutic alliance to increase likelihood of adherence (Simoni et al. 2008). As an example, the LifeSteps intervention (Safren et al. 1999), one of the first published intervention trials of adherence counseling (Safren et al. 2001), coaches patients through a series of “steps” that address various barriers to adherence including attending medical visits, storing medication, and remembering to take medication. Another example of a similar approach utilizes “managed problem solving” that follows a 5-step process to identify barriers to adherence, brainstorm solutions, select the best strategy, monitor implementation of that solution, and evaluate whether that strategy was helpful for overcoming the barrier (Gross et al. 2013). These interventions specifically target psychosocial barriers to adherence compared to memory alone.

Electronic Reminder Interventions

One set of interventions has focused on enhancing adherence by utilizing technology, such as pagers or text messages, to set reminders to take medication. Electronic reminders through pagers or text messages are one intervention option that is both low-cost and feasible for large numbers of patients. These interventions may also be particularly useful, potentially as a complement to other interventions, for individuals with impaired memory possibly due to HIV associated neurocognitive disorders (HAND) or comorbidities including depression, dementia, and substance use (Andrade et al. 2005). In electronic reminder studies, patients typically receive automated alerts on

a personal pager or cell phone (e.g., “Take the 2 blue pills now” or “Eat lunch now before your 2 p.m. pill”) (Safren et al. 2003; Simoni et al. 2006). Interventions have also used pagers to deliver other forms of messages and encouragement including education about HIV and medication assessments to keep participants engaged (Simoni et al. 2009). More recently, two-way text messaging has been employed to try to increase adherence (Harris et al. 2010; Lewis et al. 2013) requiring a reply to the text to confirm that the medication has been taken. Despite directly addressing the most frequently given reason for lapses in adherence such as forgetting to take the medicine, studies employing electronic reminders have shown moderate change during the intervention period with mixed outcomes in long-term maintenance (Simoni et al. 2006, 2008).

Social Support Interventions

Social support consistently predicts positive health outcomes in a variety of illnesses. As a result, some HIV medication adherence interventions are largely based on social support and supportive therapies. These interventions utilize principles from the theory of reasoned action and planned behavior (Fishbein and Ajzen 1975) by emphasizing the role of social norms and principles of social learning theory (Bandura 1986), which posits that watching an individual perform a behavior can increase one’s own self-efficacy and likelihood of compliance with the desired behavior. Peer-led groups also offer an opportunity for observational learning and modeling, thus incorporating principles from social learning theory. In peer-led groups, HIV+ group facilitators can share their own experiences with participants, thereby modeling medication adherence strategies. Couples counseling for medication adherence have also shown to be effective (Remien et al. 2005) as support from a significant other may create an environment in which an individual can begin to value themselves enough to change. Overall, social support interventions have utilized a combination of informational and affirmational therapy (Simoni et al. 2006) as well as

emphasized the role that both functional and emotional support can provide in helping adherence. Topics covered include addressing barriers to adherence as well as how to engage and accept support from others. These interventions have been conducted face-to-face over a series of weeks and sometimes included additional support provided in the form of follow-up phone calls (Simoni et al. 2008, 2009). It is unclear, however, as to whether all forms of social support confer better adherence.

Limitations of Adherence Only Interventions

Overall, interventions that generally address the basic social-psychological barriers to adherence have had moderate results. While they improve adherence, additional interventions may be needed for individuals with the more severe adherence problems. Psychosocial comorbidities have been found as moderators of intervention effectiveness. Mental health and substance use can interfere with traditional, basic, short-term counseling approaches to increase adherence; these comorbidities or life conditions might diminish the benefit from brief or basic adherence interventions. As such, researchers started to address comorbidities within adherence treatments to try to further improve on already existing adherence therapy. The remaining portion of the chapter is dedicated to exploring interventions that have addressed comorbidities as a means of improving medication adherence in people living with HIV/AIDS (PLWHA).

Syndemics

From a theoretical perspective, one could see how mental health, substance use, and associated psychosocial problems could interfere with the ability of adherence counseling to make behavior changes. For example, with clinical depression, symptoms such as sadness, lack of interest, and loss of sleep can affect basic social-cognitive variables related to behavior change such as one’s

self-efficacy, one's ability to acquire new information, one's motivation for change, the ability to engage in new behavioral skills, as well as one's attitudes, norms, or beliefs. In meta-analyses, depression is associated with worse adherence in HIV (Gonzalez et al. 2011; Uthman et al. 2014). Additionally, traumatic stress, as in the case of posttraumatic stress disorder (PTSD), may make it difficult to benefit from adherence counseling via symptoms such as disassociation, sleep problems, concentration problems, or others due to a past or ongoing traumatic event. Symptoms of PTSD can also decrease medication adherence (Vranceanu et al. 2008). Similarly, substance use can interfere with normal decision-making processes. Acute intoxication can certainly affect the ability to carry out intended behavioral changes, and processes such as cravings or activities to obtain substances may interfere with problem-solving to keep medical appointments, refill prescriptions, or take medicines as prescribed. While acute substance use is associated with poor adherence, individuals with a substance use history appear to benefit from ART as much as others, and substance use disorders should not be a reason to withhold ART medications (Binford et al. 2012).

Furthermore, many of the psychosocial problems that occur in the context of HIV are interrelated; these problems are referred to as syndemics. A syndemic is defined as two or more conditions that interact synergistically to increase the burden of disease in a given population (Singer 1994, 1996). Some examples of these conditions are: alcohol or substance use/abuse, posttraumatic stress disorder, mood disorders, childhood sexual abuse, intimate partner violence, psychotic disorders, anxiety spectrum disorders, etc. One study has found additive effects of syndemics on ART adherence in individuals living with HIV (Blashill et al. 2015).

Depression

Despite the prevalence of syndemics and their adverse impact on medication adherence, there are few interventions that address both adherence

and a mental health or substance use comorbidity. One such intervention that addresses adherence and depression, which is prevalent in PLWHA, is cognitive-behavioral therapy for adherence and depression (CBT-AD). CBT-AD has emerging support among different populations, including HIV-seropositive men and women with depression receiving treatment for HIV in New England (Safren et al. 2009), PLWHA with depression and a history of injection drug use (Safren et al. 2012), HIV-seropositive Latinos on the US-Mexico border (Simoni et al. 2013), and a pilot study in South Africa with nurse interventionists (Andersen et al. 2015).

CBT-AD is a manualized, modular intervention (Safren et al. 2008a, b) and integrates psychosocial adherence counseling and treatment of depression in each session. CBT-AD consists of traditional CBT skills along with other skills to treat depression and improve adherence. In the context of HIV, the first module, Life-Steps, is a single session designed to increase motivation, improve adherence-related behavior, identify barriers, and solve problems related to ART adherence. Additional modules build off of this by reviewing barriers and developing techniques to overcome those barriers that emerge or are not resolved in the first session. The second module is psychoeducational and aims to introduce the patient to CBT for depression and how depression can affect adherence and self-care. The next modules consist of skills trainings for depression integrated with additional adherence counseling and include behavioral activation (examining and increasing activities that involve pleasure or mastery), cognitive restructuring (learning how to think more adaptively in difficult situations or situations that lead to depressed mood), problem solving, relaxation training, and relapse prevention. Throughout all sessions, CBT-AD simultaneously addresses depression and ART adherence as they relate to each other. Prospective trials in HIV that address depression alone but not adherence (e.g., psychopharmacological interventions, collaborative care) seem to result in improved depressive symptoms but have not improved HIV medication adherence (Tsai et al. 2013;

Pence et al. 2015). Therefore, when working with patients who have mental health comorbidities such as depression, it is important to evaluate and treat the mental health problem while concurrently addressing adherence in the context of the comorbidity.

Substance Use

Similarly, in the case of substance use, effective interventions address both adherence and the substance use comorbidity; the intervention combines motivational interviewing (MI) and cognitive-behavioral skills training (Parsons et al. 2007). This intervention, called Project PLUS, has been studied among HIV-seropositive adult men and women in New York City who met criteria for hazardous drinking. This intervention decreased the number of drinks per drinking day and improved adherence; these effects were sustained at the 6-month follow-up. Participants who received this intervention also had improved biologic outcomes (i.e., increased CD4 cell count; decreased viral load) at the 3-month follow-up compared to participants in the control condition, but not at the 6-month follow-up.

Project Plus consists of eight sessions and allows counselors to deliver information and skills training tailored to each individual's needs and motivation to change. The first two sessions are psychoeducational and motivational and are designed to increase motivation to change, encourage greater responsibility for one's adherence and alcohol use, and create behavior change plans. In the third session, a functional analysis of the patient's drinking and nonadherence behaviors is performed, which allows the counselor to select four skills-based modules, two to improve adherence, and two to decrease alcohol use. These modules are then covered in sessions four through seven, each of which include information/didactics from the counselor, self-assessment, skills-building activities, practice, and home-assignments (Parsons et al. 2007). The last session consists of relapse prevention.

Conclusions

General behavioral interventions for adherence demonstrate moderate effects that may be further enhanced by addressing co-occurring psychosocial problems, such as depression, trauma, and substance use, which might hinder the benefits of adherence interventions. Emerging studies that address both adherence and co-occurring comorbidities or problems have positive adherence outcomes for specific high-risk groups. Delivery of these interventions has varied greatly; however, most combine some form of either individual or group in-person sessions as well as an instrumental reminder (e.g., worksheets, pill diary, pager, cell phone) of adherence. In addition to needing more interventions that address adherence in patients with the greatest need and psychosocial comorbidities, a relatively unstudied area is how to best implement these interventions and disseminate them into settings where they would have a larger impact on long-term medication adherence behaviors.

societal challenges often faced in low-resource settings. Contextual factors influence human behavior and must therefore be addressed when fighting the disease (Myer et al. 2004). This includes addressing the micro- (individual), mesa (familial/social, community), macro- (government policy), and global (broad environment) levels.

Social Determinants of Population Health

The social determinants of health are the circumstances in which people are born, grow up, live, work, and age, as well as the systems put in place to deal with illness (WHO website 2014). These circumstances are in turn shaped by a wider set of forces: economic stability, education, politics, social and community context, health and healthcare, and neighborhood environment. Among these lie contributing factors that affect the reality of HIV/AIDS prevention, care, and treatment and overall health behaviors:

- Economic stability:
 - Poverty
 - Employment status/ income
 - Access to employment and migration
 - Housing stability/ access
- Education:
 - Lack of money for secondary school fees
 - High school graduation rates
 - School policies supporting public health
 - School environment
 - Enrollment in higher education
- Social and community context:
 - Family structure
 - Social cohesion
 - Religion
 - Stigma, discrimination, and equity
 - Civic participation
 - Incarceration/ institutionalization
- Health and healthcare:
 - Access to primary and HIV/AIDS health services
 - Access to preventive care and community-based health promotion

Behavioral Science Highlights of Evidence and Research

Ann F. Green

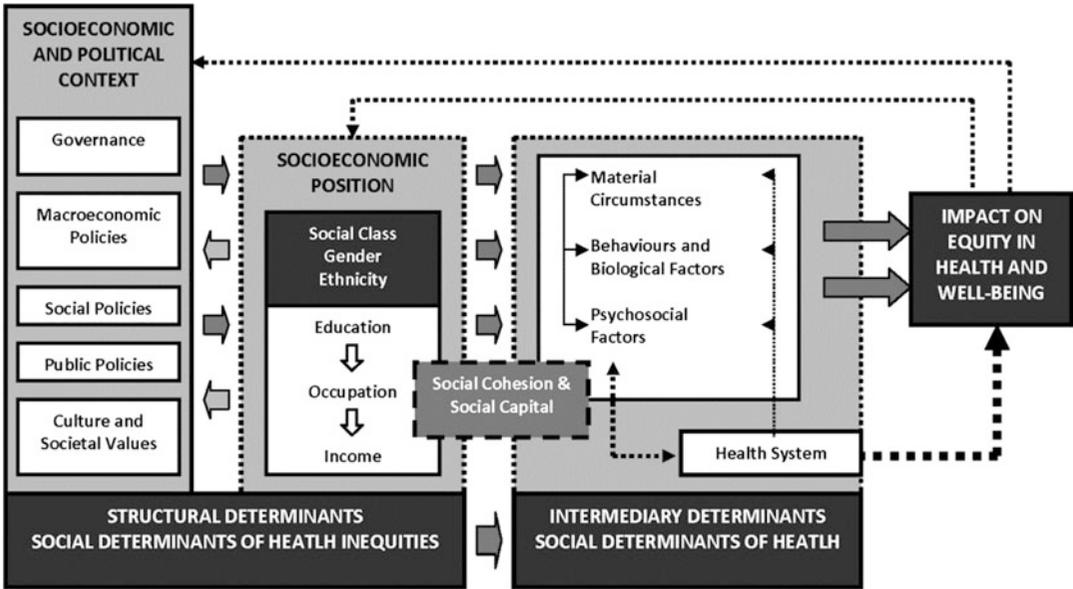

Vanderbilt Institute for Global Health, Vanderbilt University Medical Center, Nashville, TN, USA

Definition

Human behavior relates to HIV/AIDS risk as a sexually, pre-/postnatally, and blood-acquired virus that has been investigated since the recognition of the disease in 1981. The facets of sexual risk factors, mother-to-child transmission, drug injection and blood-borne risk, challenges in HIV prevention, medication adherence, and overall societal impact of HIV/AIDS have been characterized through thousands of observational and experimental studies. Existing scientific evidence details how aspects of poverty, political unrest, social exclusion, gender inequality, human rights violations, stigma, and other societal challenges influence human behavior.

Characteristics

The presence of HIV/AIDS in a community further exacerbates the effects of existing

Behavioral Science Highlights of Evidence and Research, Fig. 1 Conceptual framework for social determinants of health (developed by Solar and Irwin 2010 of WHO Commission on Social Determinants of Health)

- Health technology/equipment
- Neighborhood and built environment:
 - Housing quality
 - Violence and crime
 - Environmental conditions
 - Access to healthy foods

(Adapted from the HealthyPeople.gov website 2014).

The WHO has developed a conceptual framework for considering the interdigitation of social determinants of health (Fig. 1).

Sociodemographic Factors

Health inequities involve a lack of equality in health between groups of people within and between countries. Depending on the circumstances of economic and political stability in a region, these inequalities can arise at varying rates within and between societies. Social and economic conditions and their effects on a person's lives determine individual risk of illness and the actions required to prevent someone from becoming ill or treat illness when it occurs.

The following are examples of health inequities between countries:

- The infant mortality rate (the risk of a baby dying between birth and 1 year of age) is 2 per 1000 live births in Iceland and over 120 per 1000 live births in Mozambique.
- The lifetime risk of maternal death during or shortly after pregnancy is only 1 in 17,400 in Sweden, but it is 1 in 8 in Afghanistan.

The following are examples of health inequities within countries:

- In Bolivia, babies born to women with no education have infant mortality >100 per 1000 live births, while the infant mortality rate of babies born to mothers with at least secondary education is <40 per 1000.
- Life expectancy at birth among Indigenous Australians is substantially lower (59.4 for males and 64.8 for females) than that of non-Indigenous Australians (76.6 and 82.0, respectively).

(Adapted from the WHO website 2014).

Social Gradient

A correlation known as the social gradient exists globally whereby the world's poorest of the poor are believed to experience the worst health outcomes. A statistical measurement known as the Gini coefficient configures an inequality score ranging from zero (0), reflecting highest economic parity/equality in a region, to one (1), representing extreme inequality. From an HIV/AIDS perspective, many countries with the highest Gini coefficients are among those with the highest prevalence rates for HIV/AIDS. Efforts have been made to create a multi-dimensional poverty index that factors in a variety of indicators in an effort to measure the nuances of relative poverty and agency (Victor et al. 2014).

Women

Females comprise just over half of the estimated 36.7 million adults living with HIV in 2015. Evidence shows that the position of women and their role in a society is directly related to the health outcomes of children in that society (WHO Progress Report, 2016). Inequalities that may exist between men and women include access to education, income level, individual agency, and respect or hierarchy, which can manifest as gender-based violence and/or stigma. Despite these potential inequalities within a society, women tend to outweigh men in terms of health clinic attendance and have been proven to make more effective use of financial benefits or other patient rewards. Considering these factors, interventions often place emphasis on the female audience.

Many women bear the burden of juggling the role of both patient and caregiver for family members. Pregnancy and motherhood in women living with HIV has concentrated primarily on fetus health and the prevention of mother-to-child transmission. Currently, access to appropriate reproductive health services is less than optimal in most developing countries (Loutfy et al. 2013).

Youth

Roughly half of new HIV infections worldwide occur among young people aged 15–24 years; thus, behavior change effort geared toward this population group will be essential in fighting the pandemic. Research evidence illustrates how social and cultural factors influence the sexual behavior of youth. Seven key concepts or themes have emerged from the literature: young people assess potential sexual partners as either “clean” or “unclean”; sexual partners have an important influence on overall behavior; condoms can be stigmatizing and associated with lack of trust; gender stereotypes are a critical piece in determining social expectations and behavior; there are penalties and rewards for sex from a societal perspective; there is importance in reputations and social displays of sexual activity or inactivity; and social expectations can hamper communication about sex (Marston and King 2006). In addition, as HIV-positive adolescents mature into this age group, issues surrounding the disclosure of disease status become a critical area to navigate and address.

Male Engagement

One emerging area of focus for HIV-related interventions is the engagement of males. This includes advocacy for increased involvement in their partner's healthcare as well as education and awareness related to gender-based violence. Along these lines, evidence suggests that incorporation of male partners into prenatal care with expectant mothers improves health outcomes related to the prevention of mother-to-child transmission of HIV (Dunlap et al. 2014).

HIV Testing Coverage

In areas of highest HIV prevalence, such as sub-Saharan Africa, provision of healthcare and, specifically, HIV testing coverage and subsequent enrollment into care and treatment can be a challenge due to the rural areas of incidence. To help alleviate some of the barriers faced in resource-

limited settings, a multipronged approach is often taken toward HIV counseling and testing, incorporating voluntary counseling and testing centers and mobile campaigns in rural communities as well as provider-initiated HIV testing within health centers. Innovative strategies continue to be explored that make access to testing easier, including home visits for testing, kits for individuals to test themselves at home and education of traditional healers (Audet et al. 2014). Regardless of testing method, evidence has shown a need to tailor the testing approach/campaign toward the local cultural context.

HIV Knowledge

HIV knowledge within a population can have a strong impact on health outcomes related to HIV/AIDS. In addition to clinical outcomes, HIV knowledge and awareness can improve community support and reduce AIDS-related stigma. An HIV knowledge scale assessing a variety of key topics, such as modes and methods of transmission, has been validated in resource-limited settings and proven that low literacy and numeracy scores are related to low HIV knowledge scores (Ciampa et al. 2012). The validated scale is used to measure program and intervention effectiveness by taking pre- and post-measurements.

Clinics: Their Availability, Policies, and Effectiveness

Universal Antiretroviral Therapy (ART) Access The Alma Ata Declaration of 1978 declared the importance of primary healthcare for all citizens and set a goal of “health for all.” Decades later, in 2000, the United Nations issued a set of Millennium Development Goals (MDG), which included universal access to antiretroviral therapy for patients living with HIV by 2010 (Maddison and Schlech 2010). While this particular MDG was not met due to barriers in available

workforce, medication supply, and overall lack of resources, the push to make ART universally accessible continues. Research and interventions explore clinic capacity and accessibility as well as the politics and logistics surrounding HIV/AIDS prevention and support.

ART Expansion In many rural areas of resource-limited regions around the globe, expansion of ART services has been prioritized. Logistics of such expansion include human resource availability and capacity, drug supply chain structure, and capabilities to monitor and evaluate operations.

Task Shifting Due to the limited number of human resources for health in some areas, task shifting of responsibilities to a lower level cadre of health personnel has been incorporated into the care model for HIV/AIDS. This involves shared or trained responsibility for certain tasks related to HIV/AIDS care and treatment, such as the initiation of patients onto antiretroviral therapy being transferred from doctors to nurses. Evidence shows that under such circumstances, nurse provision of care and treatment is non-inferior to that of physicians (Fairall et al. 2012).

Option B+ A strategy referred to as option B+ offers lifelong antiretroviral treatment for all HIV-positive pregnant women and has been adopted by regions around the globe. Benefits of option B+ implementation include operational simplification, maternal health benefits, protection in future pregnancies, and reduction of sexual transmission. Implementation efforts report that the approach comes with challenges related to human and infrastructural resource availability, necessary training, strength in supply chain, monitoring, and evaluation. Behavioral issues loom large as women of childbearing age have no tradition of lifelong chemotherapy for a hidden disease that may not have even made them ill yet.

Mobile Clinics Mobile units outfitted for clinic purposes have been utilized in a variety of ways to offset challenges in HIV/AIDS care and treatment. These mobile clinics have been

incorporated for HIV counseling and testing and ART distribution as well as for provision of other health services such as family planning and cervical cancer screening. Models for operation include mobile clinics that constantly rotate among rural communities as well as those that compliment a resource-constrained facility, working alongside the existing structure to serve as mentors to the team while present.

Stigma and Discrimination

Research has shown that HIV/AIDS-related stigma can present itself in various forms such as community/familial ostracism, violence, loss of civil rights, and humiliation. Often this stigma is manifested in conjunction with other forms of stigma related to other at-risk populations (commercial sex workers, men who have sex with men (MSM), intravenous drug users (IDU), etc.). Evidence has revealed that perceived stigma can result in delayed initiation to HIV testing and/or care and treatment (Mukolo et al. 2013).

To combat such stigma, interventions have centered on community awareness and understanding of the modes of HIV transmission, treatment options, and dispelling existing myths about HIV/AIDS. While it is widely accepted that stigma is an integral factor that must be addressed in the fight against the disease, measuring the effectiveness of stigma-related interventions has proven challenging. Literature emphasizes the importance of incorporating a validated stigma scale when evaluating stigma-related interventions (Sengupta et al. 2011).

Discrimination against marginalized populations includes human rights violations such as homicide; physical and sexual violence from law enforcement, clients, and intimate partners; unlawful arrest and detention; discrimination when accessing health services; and forced HIV testing. Research stresses the importance of rights-based initiatives in the HIV response, which can prove challenging in low-resource settings rife with inequalities (Decker et al. 2015).

Health Communication

An increased awareness of the need for strong health communication strategies has influenced the engagement of communication experts to assist in program design for HIV/AIDS interventions. When biomedical and health communication approaches are strategically combined in evidence-based methods, interventions can have a stronger impact. Examples of the biomedical approaches to HIV control include treatment as prevention, voluntary medical male circumcision, preexposure prophylaxis, sterile needle exchange, opiate substitution therapy, and prevention of mother-to-child transmission (Vermund et al. 2014).

Outreach Programs for Enrollment and Retention

Without effective health communication, the success of biomedical interventions is limited. Often in the context of HIV/AIDS, it becomes difficult to retain all patients in care and/or treatment, and community level outreach is necessary. Evidence shows that barriers for patients include lack of transport, competing priorities such as employment, stigma, fear, and related costs of care and treatment. In an effort to combat these challenges, governments and nongovernmental and community-based organizations have identified various outreach interventions such as behavior change communication, community adherence groups, patient case finding, home visits, companion programs, patient reminders, and numerous other models being piloted.

Behavior Change Communication Mass media interventions are often incorporated into HIV/AIDS prevention to promote awareness or behavior change among an intended population through channels that reach a broad audience. These channels include radio, television, video, print, internet websites, and online social media, often taking the form of event announcements, dramas or plays, songs, interviews, music videos, instructional

films, brochures, billboards, posters, interactive websites, emails, text messages, or mobile phone applications. Research continues to explore audience response to such forms of communication as it relates to HIV/AIDS health behavior.

Community Adherence Groups Due to the strain of patient transport to health facilities on a monthly basis, it became necessary to explore options to limit the required visits related to HIV/AIDS treatment. A study led by *Médicins sans Frontières* in Tete Province of Mozambique explored a new model for distribution of antiretroviral treatment through self-forming groups of patients. Under this Community ART Group, patients who were stable on ART for 6 months were invited to form groups whereby members had four key responsibilities: facilitate monthly ART distribution to other group members, provide adherence and social support, monitor outcomes, and ensure that through the rotating clinic visits each group member undergoes a clinical consultation at least once every 6 months. Mortality and retention in care outcomes through this intervention were highly satisfactory, and Mozambique, as well as several other countries, has subsequently rolled out this mutual community support model nationally (Decroo et al. 2011).

Patient Case Finding/Home Visits Health facility monitoring and evaluation systems can produce lists of patients not attending scheduled visits or medication pickup, otherwise known as defaulting on treatment. Research continues to explore the range in time period for defining a patient as “lost to follow-up” from the health facility perspective, as this varies across countries and regions, and the optimal point in this range for seeking out these individuals (Shepherd et al. 2013). Teams of volunteers and/or health facility staff are frequently recruited to conduct community searches for patients lost to follow-up and encourage individuals to return to care. Often these cadres of community health workers conduct visits to patient homes to monitor status and offer support. In some regions, this community level access is utilized to provide health services at home such as testing, counseling, or medication provision.

Patient Reminders In some regions of the world, healthcare providers have explored the use of mobile phone technology and emails to remind patients of upcoming visits, missed appointments, schedule for taking medications, and messages for overall healthy living.

Microfinance/Conditional Cash Transfers In resource-limited settings, a lack of consistent income is often seen to be a primary limiting factor affecting patient health outcomes. For this reason, some community outreach efforts include the establishment of microfinance opportunities, income-generation projects among community groups, or conditional cash transfers, all in an attempt to alleviate the constraints of poverty on health. Evidence has shown that a comprehensive, tailored adherence intervention coupled with economic support is both feasible and effective among certain patients in some low-resource settings (Muñoz et al. 2011).

Conclusion

Behavioral risk is at the heart of the HIV/AIDS epidemic but is nested within gender-power imbalance, socioeconomic and cultural contexts, and stigma and discrimination. The powerful matrix complicates HIV prevention, diagnosis, care, and treatment.

Risk of HIV in Blood Recipients, and Rarely, in Blood Donors

While recipients of HIV-contaminated blood or blood products are well known to be at risk of HIV acquisition, China experienced an unexpected epidemic of HIV in blood/plasma donors in the early 1990s. To describe this event, we first present two definitions.

- Blood and blood products include (1) fresh whole blood or blood components, such as red blood cells (RBC), platelets, clinical fresh frozen plasma, cryoprecipitate, and cryodepleted plasma and (2) plasma-derivatives and recombinant products, such as albumin, immunoglobulins, and clotting factors.
- Blood transfusion is the process of receiving blood or blood products into one's circulation intravenously and is used for various medical

conditions to replace blood loss or deficiencies in certain blood components.

The use of blood and blood products can be lifesaving. Hence, blood and blood products are a vital resource derived from voluntary or paid donors, followed by processing and/or manufacture by public sector or commercial laboratories. The primary risk to blood recipients is the transmission of blood-borne diseases, including HIV and other viruses, bacteria, prions, and parasites. On rare occasions, donors may also have the risk of contracting these diseases through unsterile blood or plasma-collecting equipment or improper procedures such as the return of RBC to donors in ways that can mix them between patients or otherwise handle reinfusion in an unsterile fashion.

We review the practices and policy of blood donation and collection and the risk of HIV transmission to blood donors and recipients in China, including the historical event of HIV spread among paid plasma donors in rural provinces in central China during the early 1990s.

Blood Transfusion and Donation in China

Blood Shortages

Shortages of blood and blood products for medical use have been a chronic problem worldwide, particularly in low- and middle-income countries. Statistics from the World Health Organization (WHO) in 2010 showed that 50% of the all blood donations are collected in low- and middle-income countries, which are the home to 84% of the world's population. In the world's most populous country, China, blood and blood product shortages have become even more severe since its economy started to grow in the early 1980s and the demand for blood outstripped supply due to increased job- and transportation-related injuries, an aging population, and a rapidly rising epidemic of chronic diseases.

In general, people in China are reluctant to donate blood, as it is believed that losing blood is equivalent to losing one's bodily vigor or "Yuan

Qi," and therefore, the loss of blood is harmful to health. Only about 0.9% of the Chinese population donates blood in a given year. However, according to the WHO estimate, at least 1–3% of the population should donate blood to meet a nation's basic demand for clinical blood. In addition, more than 90% of whole blood donations collected in China are only 200 ml in volume, in contrast with the Western tradition of 400–500 ml per donation (Shan et al. 2002). Endemic hepatitis also limits voluntary blood donation from a large proportion of the general population, as blood is discarded when screened if found to be positive for hepatitis B surface antigen (HBsAg) or hepatitis C antibody (anti-HCV) (Qian et al. 2005).

Blood Collection and Donation

The policies and system for blood collection and donation in China have evolved through three major phases since China adopted a market economy in the early 1980s (Shi et al. 2014).

The first phase (Phase I) was from the early 1980s to the middle 1990s. The supply of blood and blood products relied primarily on paid or commercial donation, and the recruitment efforts for voluntary blood donation were minimal. For example, only 11% of blood for clinical use nationwide was collected from volunteer donors in 1996. Poorer residents, especially from rural areas, were motivated by monetary reimbursement in exchange for the donation. Most hospitals had a relatively stable team of donors who could sell blood to the hospitals when blood was needed for a surgery or other types of medical care. From 1991–1995, a large-scale collection of plasma using unsafe practices caused the spread of HIV, hepatitis, and other blood-borne diseases among many farmers who were blood donors in the rural areas of Henan Province and surrounding provinces in Central China (Shan et al. 2002; Qian et al. 2005, 2006).

The second phase (Phase II) began in 1998 when China enacted the "Law of Blood Donation." Large-scale HIV and hepatitis outbreaks among paid blood and plasma donors in the early 1990s (discussed below) led the central government of China to increase regulations on the safety of blood and blood products. The new

blood donation law became effective nationwide, banning commercial blood collection, encouraging voluntary donation, and requiring HIV screening for all blood donations. The commercial blood stations were closed, and the screening of blood collection was more strictly enforced. However, voluntary donation was still insufficient to meet national needs during this phase. In order to fill the gap of blood supply from the commercial sources in Phase I, blood collection relied on near-compulsory, employer-organized donation. State-run work units were assigned donation quotas, and employees were required to donate with minimal compensation (Shi et al. 2014). Recruitment efforts for blood donors were mainly targeted at public sector employees, college students, and military personnel. Although routine serologic screening of donors was implemented in employer-organized donation, employer-organized donors are not considered as the safest source of blood due to the wide use of employer incentives and coercion in some cases (Shi et al. 2014).

The third phase (Phase III) started in 2004 when the Chinese Ministry of Health mandated employer-organized donations to be discontinued within 3–5 years. Since then, China's blood donation system has transitioned to voluntary, non-remunerated donation. During this phase, blood centers have been actively engaged in donor mobilization and recruitment targeted to the general population. By 2008, most cities had already achieved the goal of meeting their regional blood needs with volunteer donations.

HIV Outbreak Among Paid Plasma Donors in the Early 1990s

From the early 1980s to the middle 1990s, China's blood donation system was largely driven by commercial interests, coinciding with the profound social and economic transition from a planned economy to a market economy. Though attempts were made in the 1980s to move to a voluntary system, these efforts were mostly unsuccessful due to reluctance in giving blood among Chinese people. In the early 1990s, China restricted the import of blood products due to concern about bringing in HIV from foreign countries, while

the demand for blood and blood products for advanced medical treatments had become ever bigger due to the rapid economic expansion and a growing population in China. Collection of blood, and especially blood plasma, became a lucrative business for blood traders or "bloodheads," who were businessmen or local government employees. These blood traders set up thousands of official and unofficial plasmapheresis stations in counties, townships, and villages in Henan Province and its neighboring provinces in Central China. In Henan Province, even local health officials promoted plasma collection activities through the "Plasma Economy" campaign, as selling blood and plasma was an easy way for poor farmers to augment their income (Shan et al. 2002; Wu et al. 2001). The average monthly income from farming was \$9–12 (USD) at that time, while a donor would receive 50 Chinese yuan (approximate \$6 (USD)) for each donation of 400 mL plasma and 200 yuan (approximate \$25 (USD)) for each donation of whole blood (Wu et al. 2001). Plasma donation was much more popular than whole blood donation because of commercial demand for plasma and a greater willingness of donors. A donor might make more money from selling plasma than selling whole blood, as a donor could sell plasma more frequently when anemia was reduced with re-infusion of pooled, same blood type RBC. According to the national regulation for plasma and blood donations, the shortest interval allowed between each donation was 15 days for plasma and 3 months for whole blood. However, this regulation was not adhered to by many stations. In addition, donors might use fake identification to sell plasma more frequently in different stations.

The blood/plasma collection practices in these commercial plasmapheresis stations generally had low health and safety standards and lacked proper sterilization procedures. Needles, blood bags, and other equipment in contact with blood were often recycled and reused. A physical examination and testing for HBsAg and anti-HCV were required for each donation according to national guidelines, but they were often omitted. HIV screening had also been required by law in large cities since

1993, but it was not performed at any of the local plasma collection stations, both for the purpose of reducing operational costs and because they believed they did not have an HIV problem.

The typical plasma collection procedures were: peripheral blood was drawn from several donors at the same time; donations with the same blood type were mixed together in the same centrifuge and the plasma was extracted; and the remaining blood constituents, such as RBC, were re-infused with normal saline solution to the donors in order to reduce anemia. In this fashion, even a single HIV-infected person who donated blood plasma could result in the infection of dozens of others, either through direct infection by mixed RBC that were reinfused to many or via contamination of equipment. Such RBC reinfusion procedures without screening tests, along with the reuse of needles and unsterilized equipment, became a very efficient way to spread HIV and other blood-borne diseases among local donors.

HIV infections among plasma donors were initially reported by local physicians, and the central government then sent a team to investigate and recognize the severity of HIV epidemic. The estimated number of total HIV infections among paid plasma donors from the government source was around 55,000 (Lu et al. 2006), while some AIDS activists estimate the number to be much higher.

From about 1995, the spread of HIV among commercial plasma donors began to be widely recognized. The central Chinese government took strong legal and police action to prevent further spread of HIV infection by closing commercial plasma collection stations and issuing new regulations for blood/plasma donation. By 1996, it was believed that all of the illegal, unregulated stations were closed.

Several lessons are learned from this public health tragedy. Failure to follow the regulations on blood and plasma donation was the major reason for the outbreak of HIV and other blood-borne diseases among donors. Pooling blood and reinfusing RBC to multiple donors is a prohibited plasma collection practice that can pass on any number of dangerous pathogens, yet this was common in these commercial stations. Equipment

was not sterilized. Testing for hepatitis B and C was not performed to save time and cost or donors avoided screening by bribing blood station staff. Donors had no knowledge of safe blood donation practices and had a low awareness of HIV risk. A decade prior to this HIV outbreak, the spread of hepatitis through unscreened blood collection had been reported as early as 1985 (Meng 1990). Unfortunately, this evidence did not become an alert among local health officials and bloodheads for avoiding unhygienic plasma collection and HIV outbreak in the early 1990s.

HIV Prevalence Among Donors and Secondary Transmission in Former Donating Communities

Since the Chinese government banned all commercial blood/plasma collection practices, HIV transmission through plasma collection has been under control in rural regions. However, secondary transmission from infected former donors to their spouses and children continued to be a public health concern. HIV cases among spouses and children had been reported by the mass media and were confirmed by the national HIV reporting and surveillance data. Until the early 2000s, very few community-based studies in the former plasma collection villages were conducted to evaluate HIV prevalence among former donors and the residents in these villages and assess the risk of secondary transmission.

A retrospective study was conducted during 2005–2009 among 420 HIV-infected former commercial plasma donors or recipients of contaminated blood, whose spouses denied any high-risk behaviors. The median time of potential HIV transmission between these spouses was 11.2 years, the spousal transmission rate of HIV was two per 100 person-years (2%), and rates were slightly higher for female-to-male (1.8%) than for male-to-female (2.1%) (Yang et al. 2010).

A census was conducted in 2004 among all villagers aged 18 to 64 years in four former plasma-donating villages in Shanxi Province that bordered Henan Province. Of 3,062 participants, 29.5% ($n = 904$) had a history of selling plasma or blood, 12.9% reported more than one lifetime sexual partner, and 6.4% had ever had

extramarital sex. HIV infection was detected in 1.3% ($n = 40$) villagers, including 4.1% ($n = 37$) detections among former plasma/blood donors and 0.1% ($n = 3$) detections among non-donors (Qian et al. 2006). Illicit drug use was rare in this rural population of farm families. The three infections detected in non-plasma donors were likely due to sexual transmission, though other routes such as blood transfusion or other blood contacts could not be excluded. Another census conducted in 2005 among villagers aged 25–55 years in 40 villages in Anhui Province, bordered with Henan Province, suggested a higher likelihood of sexual transmission; HIV prevalence was 10.8% among all villagers and 4.8% among non-donors (Ji et al. 2006).

A survey conducted in 2005 among villagers aged 2–79 years in Henan Province found that 36.3% (466/1285) villagers ever sold plasma/blood, and 15.3% (197/1285) were infected with HIV. In 197 HIV cases, 2.0% ($n = 4$) were regarded as sexual transmission from an infected plasma donor, 3.6% ($n = 7$) through mother-to-child transmission (MTCT) with the mothers having been former plasma donors, 0.5% ($n = 1$) through receipt of an unscreened transfusion, and 0.5% ($n = 1$) through nosocomial infection (Zhang et al. 2006).

HIV prevalence among donors and community members might be underestimated, as these surveys were conducted about a decade after the outbreak of the disease in the early 1990s. Some HIV-infected former donors may have died. In these censuses, all villagers' names were obtained from household registration and missing villagers could be identified; thus the likelihood of choosing not to participate due to stigma and concern about discrimination was small. The risk of secondary sexual transmission between discordant couples seemed to be at a low or moderate level. One possible reason is that it was common that both couples sold plasma or blood and as a result might both be infected via the unsafe donation procedures.

Current Blood Donation and HIV Risk

Following a few years of transition from employer-organized donation, China's blood

donation system changed to voluntary donation in the early 2010s. In 2011, the country's total whole blood collection volume was 4,164 tons (or 12.3 million whole blood donations), and 99% was from voluntary non-remunerated donors (Li et al. 2012). There were 452 blood establishments nationwide, including 32 provincial blood centers, 321 regional blood centers/stations, and 99 county blood stations. Blood centers/stations are the only authorized establishments to collect blood from voluntary donors, supply blood to hospitals for civilian clinical use, and charge fees from hospitals for covering the costs of blood screening and storage. However, some hospitals are still short of blood supply, particularly those in rural areas. A significant proportion of the blood supply is still dependent on family/replacement donors.

Although the safety of blood sources has been greatly improved in China, blood transfusion remains an ongoing risk factor for the spread of blood-borne infections. A survey among 4,366,283 donations collected from 2000 to 2010 in four Chinese regional blood centers in Guangzhou, Nanjing, Shenyang, and Yancheng found that the overall prevalence of HIV was 0.08%, HBsAg 0.86%, anti-HCV 0.51%, and syphilis (two rounds of enzyme immunoassay) 0.47% (Li et al. 2012). A meta-analytic review of 87 studies that reported HIV infection rates in voluntary blood donors from 2000–2009 showed that the pooled prevalence was 13.2/100,000 (range 0.74–126/100,000) and increased from 5.62/100,000 in 2000 to 28.9/100,000 in 2009 (Hong et al. 2012), which coincided with the rising HIV epidemics in both the general population and high-risk groups in China. HIV infections from blood transfusions were also reported by mass media. In comparison, global data in 2014 from the WHO showed the median prevalence of HIV infection in blood donations of only 0.002% (interquartile range: 0.0004–0.02%) in high-income countries, 0.12% (0.03–0.2%) in middle-income countries, and 0.85% (0.48–2.0%) in low-income countries (WHO 2014).

There are several major challenges for achieving a safe and adequate blood supply in China, including cultural and social barriers to blood

donation, lack of high-quality donor service and care, conservative selection criteria which eliminates many otherwise eligible donors, lack of a national/regional blood distribution mechanism for coordinating cross-region blood sharing, and lack of a national/regional blood donation information system for following up with blood donors to encourage repeat donation. According to the Law of Blood Donation, the central health department of China is responsible for enacting national standards and policies, while the public health bureaus at provincial, city, and county levels manage the day-to-day operations and planning for blood donation and mobilize and recruit blood donors by partnership with local blood centers/stations.

To mitigate the chronic blood shortage and reduce the risk of blood-transmissible diseases, both national policies and local operations may need to be modified. The following four strategies may be taken:

- (1) Reducing demand for blood and blood products that is not indicated clinically. Unnecessary blood transfusions and injections are too common in many low- and middle-income countries. Blood demand can be curbed through application of newer surgical methods, such as laparoscopic techniques that involve tiny incisions and little blood loss. Additionally, hospitals may implement more sophisticated blood management programs to reduce blood demand, such as using medications to reduce bleeding during surgery.
- (2) Increasing blood collection. Current donors are predominantly soldiers and college students who are living in urban areas. The voluntary blood drive campaigns should reach rural residents, as well as a larger proportion of urban residents. These campaigns may use psychological theory and evidence-based approaches to utilize positive factors such as altruism, support from family members, and role modeling by government leaders or movie stars. They may also minimize the influence of negative factors such as fear of losing blood, suspicion about blood centers' profiting from selling blood from volunteers to hospitals, and short-term donor deferral (e.g., sore throat). Lack of mobile vans limits blood drive campaigns, particularly for rural regions where blood shortage is more severe. The criteria for voluntary donation could also be changed. The upper limit of eligible age increased from 55 to 60 years in 2012, which is still lower than the limit of 65 or 69 years in other Eastern Asian countries or regions such as Japan, South Korea, and Taiwan. Currently, about 70% of donors are young adults aged 18–35 years, and older adults should be encouraged to donate blood. There is also a need to implement strategies to retain donors and increase collection from repeat donors who regularly donate blood.
- (3) Improving blood use. A national/regional coordinating mechanism should be established to improve distribution and sharing of blood and blood products across regions. A real-time communication for blood collection and supplies across blood centers/stations should be available so that surplus blood can be redistributed to the needy places in a timely manner.
- (4) Ensuring blood safety. All blood donations should be screened following the national guidelines. Health care providers should also ensure a safe transfusion practice and have a quality systems check throughout the blood transfusion process.

Conclusions

The unhygienic plasma collection practices in the early 1990s caused hundreds of thousands of HIV infections among rural residents in the poorer regions of Henan and its surrounding provinces in Central China. This led to the transition of a Chinese blood donation system from commercial donation from the 1980s to the middle 1990s, to employer-organized donation during 1998 and 2004, and to voluntary donation since 2004. Now, almost all blood supply comes from voluntary donors. However, more efforts are needed to

increase voluntary donation, to meet blood demand and to ensure the safety of blood transfusion. Furthermore, the Chinese experience provides cautionary guidance to other nations that struggle to implement universally safe blood donation and blood banking programs.

Budding

Vincent Dussupt, Paola Sette and Fadila Bouamr
Laboratory of Molecular Microbiology, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, MD, USA

B

Definition

Budding is the process of lipid envelopment of viral particles by the cell membrane during exit from infected cells, a strategy that allows the virus to bypass the need for cell lysis to release newly formed virions and spread infection. As HIV-1 assembly progresses at the plasma membrane, viral capsids form on the inner leaflet of the cell surface and become gradually surrounded by the plasma membrane. In late steps of budding, the fully assembled immature capsids are completely surrounded by the membrane but remain connected to the cell by a membranous stalk. The ultimate separation of nascent virions from their progenitor cells involves host proteins of the endosomal sorting complex required for transport (ESCRT) pathway, a cell membrane fission machinery that will place the final cut and release the newly made virions.

Introduction

HIV-1 budding requires nascent virions to traverse the plasma membrane and acquire their envelope, a process that begins with the enfoldment of virus particles with the cell membrane and ends with the separation of progeny virions from cells to spread infection. Budding was originally thought to occur spontaneously driven by the outward egress of an “assembling” viral particle at the plasma membrane. In 1991, the removal of a short domain at the end of Gag, the viral structural protein responsible for virus particle formation, brought virus production to a halt and led to a remarkable accumulation of fully formed virus particles at the plasma membrane

(Gottlinger et al. 1991). These particles' failure to sever away from the cell surface revealed that specific regions in the Gag protein mediate virus release from the cell and identified budding as a distinct step in HIV-1 production. Further experiments led to the identification of short motifs responsible for mediating virus budding from the cell. Owing to their role in post-assembly events, these sequences were named late or L domains. Newly identified L domains became the focus of intense efforts to identify cellular factors involved and decipher mechanisms of function. A decade ago, members of the endosomal sorting complex required for transport (ESCRT) pathway, the host cell machinery required for membrane fission, were found to bind HIV-1 L domain sequences (Verplank et al. 2001; Garrus et al. 2001). These seminal findings provided key information on HIV-1 biology and signaled that release of an enveloped virus may require extensive assistance from the cell. Identification of these proteins was just the "tip of the iceberg" and subsequent work revealed that the cell membrane fission machinery is constituted of a network of multiprotein complexes that is evolutionarily conserved from Archaea to humans. An overview of HIV-1 budding mechanisms, host factors involved, and standing questions in the field are outlined below.

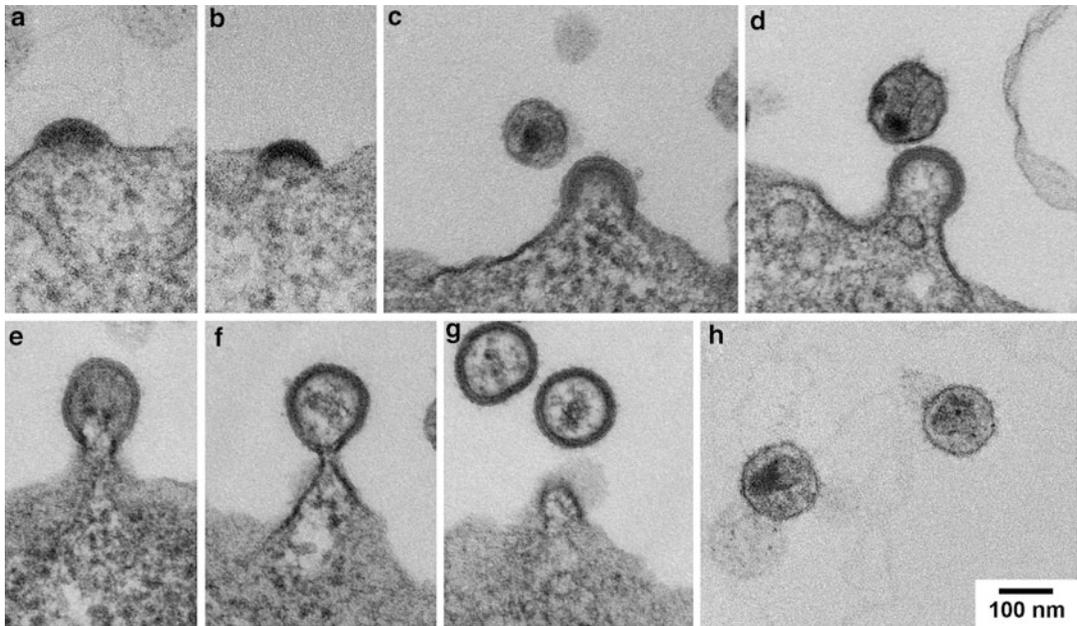

HIV-1 Particle Morphogenesis

HIV-1 must cross the plasma membrane in late steps of virus egress from cells to acquire its envelope. The major component that orchestrates virus particle assembly (► [Virus Assembly](#)), budding, and exit is the structural polyprotein Gag (Sundquist and Krausslich 2012). Gag is sufficient for the formation of noninfectious virus-like particles (VLPs).

Gag carries three domains: matrix (MA), capsid (CA), and the nucleocapsid (NC). The N-terminal end carries the MA domain, which anchors Gag molecules at the plasma membrane. Such interactions require a bipartite signal composed of a co-translationally acquired myristic

acid and a cluster of positively charged residues believed to engage in interactions with the negatively charged phospholipids at the membrane. MA is also responsible for the incorporation of the viral envelope glycoprotein in nascent virions. CA is endowed with Gag-Gag multimerization function responsible for the formation of large Gag complexes and assembly of nascent virus particles. NC serves primarily as a platform for the incorporation of HIV-1 genomic RNA to the assembling viral particle. HIV-1 harbors a fourth domain called p6, which is located in the C-terminal end of Gag. Not required for assembly, p6 mediates virus separation from infected cells, since its disruption leads to the accumulation of virus budding arrest on the cell surface. This domain is found in other primate lentiviruses where it appears to play similar roles.

Upon synthesis of Gag and Gag-Pol – a product of infrequent frameshifts that generate a Gag polyprotein in fusion to the *pol* gene, which encodes for the viral enzymes protease, reverse transcriptase (► [Reverse Transcription](#)), and integrase (► [Integration](#)) – viral assembly is believed to begin in the cytoplasm. These small assemblages are however invisible by electron microscopy and can only be isolated from cellular extracts using biochemical assays. Further multimerization of Gag on the inner leaflet of the plasma membrane leads to the appearance of a crescent shape electron-dense structure (Fig. 1a, b). Upon recruitment of additional Gag molecules, the latter evolves into a sphere-shaped particle, which becomes enveloped by the cellular membrane by budding outward away from the cytoplasm (Fig. 1c, d). Budding particles remain attached to the surface with elongated membranous stalks until complete viral release (Fig. 1e–g). Soon after or during separation from the cell, the Gag proteins that are part of the spherical particles are cleaved by the viral protease, inducing them to collapse into a central conical core (Virus Structure) in the newly released virions (Fig. 1h). This process is called maturation (► [Maturation](#)) and is central to the production of infectious virions.

Budding, Fig. 1 Steps of HIV-1 budding. Electron micrographs showing HIV-1 budding from human T cells in a chronological order. (a, b) The first visible budding structures are characterized by an electron-dense layer of Gag proteins that start to accumulate beneath the plasma membrane. (c, d) Upon addition and extensive multimerization of new Gag molecules, HIV-1 assembles its immature spherical shell that induces membrane curvature

and becomes surrounded by the plasma membrane. (e, f, g) In late stages of budding, thinning of the membrane connection between the nascent virion and the cell will ultimately lead to membrane fission that releases the new particle. (h) Soon after release, Gag is processed by the viral protease during a maturation step that leads to the formation of a central conical core, a hallmark of infectious HIV-1 virions

Late Domains and Their Interacting Host Cell Proteins

Soon after the identification of p6 as the region of HIV-1 Gag that drives virus separation from cells, virus exit determinants were further mapped to short motifs in p6 that are conserved among divergent retroviruses. As they function in late steps of particle morphogenesis, these sequences were named late or L domain (Wills et al. 1994). In HIV-1 Gag, a proline-rich motif carrying the PTAP or PSAP sequence (named PTAP hereafter) was the first to be described and mutational analysis revealed its important role in virus separation from cells (Huang et al. 1995). The PTAP motif is highly conserved in primate lentiviruses and is also found in viral proteins of other non-related enveloped viruses such as Ebola. Interestingly, the

equine infectious anemia virus (EIAV) lentivirus harbors a p9 domain in the same location as p6 but does not contain a PTAP motif. Instead, virus budding is supported by a LYPXnL-type L domain. Further mutational analysis in the p6 domain unveiled the existence of an equivalent L domain (LYPXnL) in this region of HIV-1 Gag, which functions alongside the PTAP motif to drive a secondary budding pathway (Strack et al. 2003). It became apparent that, in contrast to PTAP, the LYPXnL consensus motif exhibits greater sequence divergence that made its identification difficult. Three different types have been characterized: the type 1 LYPDL in EIAV, the type 2 LYPLASL in HIV-1, and a more divergent type 3 PYKEVTEDLLHLNSLF only found in some simian immunodeficiency viruses. Nearly all primate lentiviruses carry at least one of the LYPXnL

motifs, suggesting that its presence confers an advantage to the virus. A third type of L domain, not found in HIV-1 Gag, has been identified in the Rous sarcoma virus (RSV). Its core sequence was subsequently mapped using mutational studies to the proline-rich minimal motif PPXY (Wills et al. 1994). Regardless of their sequence, disruption of L domain integrity halted virus release and led to the accumulation of budding particles, emphasizing their important role in mediating virus detachment from cells.

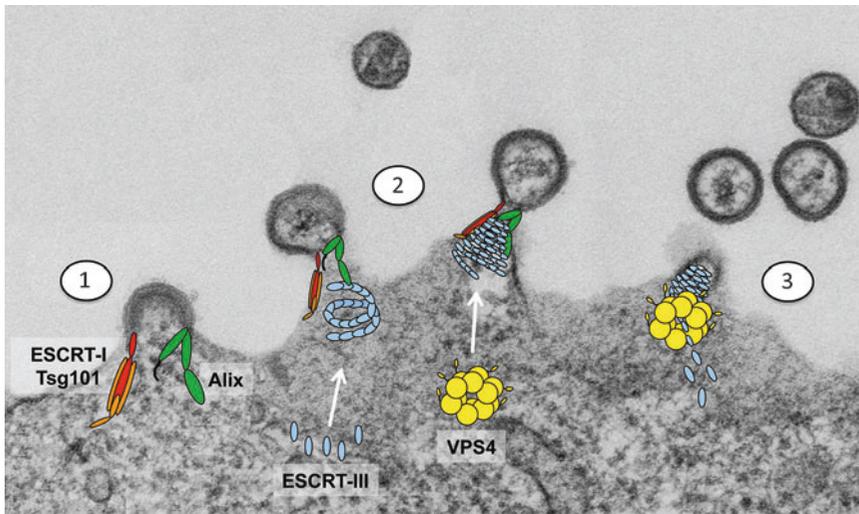

Virion release can also be restricted in certain cell types for HIV-1 mutants lacking the accessory gene *vpu*. This is due to the activity of tetherin/BST-2, a host cell factor believed to inhibit virus release by physically tethering virions to producer cells (Neil et al. 2008). Tetherin-mediated block of virus production is distinct from that resulting from interference with L domains. Whereas in the latter case, particles remain attached to the cell surface with elongated membranous stalks (indicating failure to detach) and appear immature, virions trapped by Tetherin/BST-2 exhibit a mature phenotype indistinguishable from released virions and remain tied to the cell surface and to each other with a thin proteinous tether further distinguishing this phenotype from deletion or disruption of L domain activity.

Clues that L domain motifs are docking site for host cell factors came from the observation that they can functionally replace one another in heterologous contexts. Indeed, RSV PPXY and HIV PTAP L domain motifs were shown to be functionally interchangeable (Parent et al. 1995). Groundbreaking studies led to the identification of the PTAP interacting factor as the tumor suppressor gene 101 or Tsg101 (Carter 2002). The LYPXnL L domain was found to bind Alix (Strack et al. 2003), whereas the RSV PPPY L domain interacts with members of the cell Nedd4 ubiquitin ligase family (Kikonyogo et al. 2001). Further seminal studies linked L domain-binding proteins to the ESCRT pathway, a set of cellular protein complexes involved in membrane fission. Tsg101 was later identified as an integral component of the ESCRT pathway, whereas Alix and Nedd4 are ESCRT-associated proteins that provide two additional entry points in the

pathway. Efforts to understand the role of these cellular factors in facilitating virus exit produced one of the best studied examples of how human viruses hijack host proteins to produce progeny virus and spread infection.

The ESCRT Pathway

The discovery of the interaction between the PTAP L domain and Tsg101 revealed that HIV-1 utilizes host cell proteins from the ESCRT pathway to catalyze scission of the newly made virions from the plasma membrane of the producer cell. The ESCRT pathway comprises four sets of multi-protein complexes (called ESCRT-0, ESCRT-I, ESCRT-II, and ESCRT-III) in addition to the VPS4 complex and associated proteins, like Alix. ESCRT proteins were first identified in yeast where they are involved in the formation of late endosomal structures called the multivesicular bodies (MVBs), an organelle that sorts protein cargoes into the vacuole or lysosome for degradation (Henne et al. 2011). Cargoes destined for degradation are tagged with ubiquitin (see below) and as such recognized by the ESCRT-0 complex that initiates the sequential recruitment of the other ESCRT complexes on the endosomal membrane. Assembly of ESCRT-I and ESCRT-II complexes leads to the invagination of the cargoes into a vesicle that buds inside the endosome or vacuole following the action of the ESCRT-III complex. The latter catalyzes the membrane fission reaction required to release the vesicle into the endosome lumen (Hurley and Hanson 2010). The VPS4 ATPase complex comes last to disassemble the polymerized ESCRT-III proteins and recycle them for the next round of cargo sorting. Budding of HIV-1 at the plasma membrane of human cells is topologically equivalent to the biogenesis of intraluminal vesicles in MVBs as both exhibit invagination of a cellular membrane away from the cytoplasm and require the participation of a membrane fission machinery (ESCRT) acting from the cytoplasmic face of the budding neck to drive the membrane fission that frees vesicle (or the HIV-1 particle) in the luminal (or extracellular) compartment. In mammalian

Budding, Fig. 2 Schematic model of how proteins of the ESCRT pathway might drive HIV-1 budding. (1) The L domain-interacting Tsg101/ESCRT-I (in red and orange) and Alix (in green) factors are recruited in early stages of budding during the assembly of the immature viral particle. (2) When assembly is complete, ESCRT-I and Alix are believed to serve as a platform for the recruitment and the formation of the ESCRT-III filaments (in light blue). The

ESCRT-III CHMP2 and CHMP4 proteins assemble in a membrane-bound helical structure within the budding neck, driving its constriction. (3) The combined action of the ESCRT-III and VPS4 complexes (in yellow) triggers membrane fission and release of the nascent virion. VPS4 recycles the ESCRT-III proteins back as monomers that can be used in the next budding event

cells, proteins of the ESCRT pathway have an expanded repertoire of functions: they catalyze membrane fission in vesicle formation, abscission step that separates two daughter cells at the end of mitosis (Caballe and Martin-Serrano 2011), sealing of the nuclear envelope (Olmos et al. 2015; Vietri et al. 2015); assembly of nuclear pore complex (Webster et al. 2014) Viral budding from nuclear envelope (Lee et al. 2012); wound repair (Jimenez et al. 2014) exosome secretion (Baietti et al. 2012), and autophagy, a conserved mechanism for degradation of cytoplasmic components (Rusten and Stenmark 2009).

ESCRT-I

HIV-1 Gag recruits components of the ESCRT pathway primarily via the PTAP L domain, a binding site for the ESCRT-I subunit Tsg101 (Fig. 2). Interestingly, the ESCRT-0 component HRS also uses a PTAP (or PSAP) motif to recruit ESCRT-I during MVB biogenesis. HIV-1 Gag protein has evolved to mimic this cellular

interaction to hijack ESCRT-I from its normal cellular function in the ESCRT pathway. Consequently, the ESCRT-0 complex is not required for HIV-1 budding. Mammalian ESCRT-I is a heterotetrameric complex composed of a single copy of Tsg101, VPS28, VPS37, and MVB12 proteins assembled in a 1:1:1:1 stoichiometry. There is only one version of Tsg101 and VPS28 proteins in humans, but four isoforms of VPS37 (VPS37A–D) and three MVB12-like subunits (MVB12A–B and UBAP1) are present, giving rise to 12 possible ESCRT-I complexes. It is likely that the VPS37 and MVB12 isoforms confer specificities to ESCRT-I complexes in both interaction and function. HIV-1 has been shown to utilize VPS37B or C and any of the MVB12 isoforms. Structural studies have revealed that the ESCRT-I complex adopts an asymmetric conformation made of a headpiece attached to an extended rigid stalk with two flexible tethers on each side of the stalk. These two flexible regions are, on one side, the N-terminal UEV domain of Tsg101 that binds the PTAP L domain and, on the other, the C-terminal domain of VPS28 that interacts with

the downstream ESCRT-II, in MVB biogenesis, and possibly ESCRT-III complexes, at least in yeast (Votteler and Sundquist 2013). The requirement for ESCRT-I in HIV-1 budding first became apparent following the identification of Tsg101 as a binding partner of the PTAP L domain. Subsequent studies using RNAi knockdown experiments confirmed that depletion of cellular Tsg101 was highly detrimental to HIV-1 budding, leading to an accumulation of budding particles unable to detach from the cell plasma membrane. The same budding defects were observed upon mutation of the PTAP L domain in Gag or overexpression of the PTAP-binding N-terminal domain of Tsg101 that competes out the recruitment of the whole ESCRT-I complex (Carter 2002; Freed 2015).

ESCRT-II

The human ESCRT-II complex is a Y-shaped heterotetramer that consists of EAP30, EAP45, and two copies of EAP20. In yeast, where it has been extensively characterized, ESCRT-II is essential in linking ESCRT-I to ESCRT-III and nucleates the polymerization of the membrane-severing ESCRT-III proteins during multivesicular bodies biogenesis. In mammalian cells, knockdown studies revealed that ESCRT-II might not bear the same pivotal role than its yeast counterpart since it was shown that sorting of some endosomal cargoes could proceed independently of ESCRT-II. Similarly, HIV-1 budding was found to be insensitive to ESCRT-II depletion, raising the possibility that ESCRT-III recruitment could occur independently of ESCRT-II in humans, at least in some cases. The latter is also true in cytokinesis where a role for ESCRT-II in the separation of the two daughter cells has not been reported. Instead, the ESCRT-associated protein Alix (see below) is believed to recruit and nucleate the ESCRT-III complex through a direct interaction with CHMP4, a component of ESCRT-III. Interestingly, Alix is also recruited by HIV-1 Gag to sites of viral budding by interacting with the LYPXnL L domain. However, mutating this L domain or depleting Alix has only a mild effect

on HIV-1 budding in model cells, suggesting that HIV-1 Gag possesses yet another way (or multiple redundant ways) of recruiting ESCRT-III in the absence of ESCRT-II or Alix.

ESCRT-III

Unlike the other ESCRT complexes, ESCRT-III is not present as a stable complex in the cell but, rather, is recruited by the upstream complexes late in the pathway and assembles at sites where its membrane fission activity is required (Fig. 2). Humans encode 12 different ESCRT-III proteins, also known as the charged multivesicular proteins (CHMP), which are CHMP1A–B, CHMP2A–B, CHMP3, CHMP4A–C, CHMP5, CHMP6, CHMP7, and IST1. Among them, CHMP2A–B, CHMP3, CHMP4A–C, and CHMP6 form the core component of the membrane fission machinery. ESCRT-III core proteins are very similar in size and structure with an N-terminal basic and a C-terminal acidic domain. In the cytoplasm, CHMP proteins adopt an inhibited monomeric soluble form where the N-terminal domain folds over the C-terminal end. Upon activation following recruitment to budding sites, ESCRT-III proteins associate with membrane and polymerize extensively into helical filaments (Cashikar et al. 2014). In MVB biogenesis, CHMP6 is believed to act as a “nucleator” of ESCRT-III assembly owing to its membrane-binding ability. In turn, it recruits CHMP4B, the main component of the ESCRT-III filament. CHMP4 filaments are controlled by CHMP3 and capped by one of the CHMP2 isoforms that contained a binding site for the VPS4 ATPase that comes at the end of the pathway to disassemble the ESCRT-III polymers. Based on a study where depletion of individual ESCRT-III subunits was systematically analyzed, this model does not seem to hold true for HIV-1 budding. Instead, HIV-1 was found to rely on a surprisingly small subset of ESCRT-III proteins, with only CHMP2 and CHMP4 isoforms playing key functional roles in viral release. This could be explained by a direct interaction between CHMP2A and CHMP4B that is unique to humans. Although probably not essential,

CHMP3 was shown *in vitro* to synergize the assembly of CHMP2A on helical CHMP4 filaments. One of the major unanswered questions remains how CHMP4 is recruited to sites of viral budding, given that its known binding partners, CHMP6 and Alix, are not essential for HIV release. How ESCRT-III drives constriction of membrane at the budding neck is not fully understood either but an attractive computational model was put forward based on electron tomography imaging of *in vitro* assembly of ESCRT-III polymers. This model proposed that ESCRT-III proteins would assemble as a hemispherical dome-like structure within the neck of the membrane bud (Fabrikant et al. 2009). The dome formation, accompanied by the membrane attachment to the dome surface, would generate sufficient energy to drive the narrowing of the membrane neck up to the point where the two membranes are close enough for spontaneous fission to occur. This model is in agreement with the large body of evidence gathered from both *in vitro* and *in vivo* studies and is likely to be conserved in all ESCRT-mediated membrane fission events such as MVB biogenesis and the abscission step that separates two daughter cells at the end of mitosis (Guizetti and Gerlich 2012).

VPS4

The first evidence for a role of ESCRT-III in HIV-1 release originated from the finding that a dominant-negative VPS4 mutant, lacking ATPase activity, could block HIV-1 budding by preventing the nascent viral particle to pinch off. The VPS4 complex is the last component in the ESCRT pathway and is endowed of enzymatic activity required for the disassembly of the ESCRT-III lattice (Fig. 2). It consists of the VPS4 AAA-type ATPase and its activator LIP5. VPS4 exists as an inactive dimer in the cytoplasm and assembles into a high-molecular-weight complex upon activation and recruitment by ESCRT-III complexes on cellular membranes. Two isoforms, VPS4A and VPS4B, exist in humans and, according to knockdown studies, are believed to perform essential but redundant functions in

MVBs and HIV-1 budding. VPS4 proteins have a modular structure with a single ATPase cassette and an N-terminal substrate recognition region known as microtubule-interacting and trafficking (MIT) domain. The MIT domain of VPS4 proteins has been found to engage ESCRT-III proteins such as CHMP2 and CHMP6 in direct protein-protein interaction by recognizing a MIT-interacting motif (MIM) at the C-terminal of the CHMP protein. Structural studies and homology with other AAA-type ATPases suggest that the activated VPS4 is a mechanoenzyme complex made of the a double ring of hexamers with the flexible MIT domains projecting away to pull out ESCRT-III subunits from assembled lattice and release monomers of CHMP proteins through the central pore of the complex upon hydrolysis of ATP. This model suggests that removal of individual CHMP proteins could potentially constrict the ESCRT-III helical filaments and participates in generating the energy required for membrane fission. Whether VPS4 has an active role in membrane fission or is strictly limited to recycling remains an open question. Recent live imaging studies looking at HIV-1 assembly sites by TIRF microscopy indicate that VPS4 is recruited prior to particle release, therefore supporting a more active role for VPS4 in membrane fission events (Baumgartel et al. 2011; Jouvenet et al. 2011).

Alix

Alix is an ESCRT-associated protein that binds the LYPXnL L domain motif in the HIV-1 Gag p6 region and drives an auxiliary pathway of viral release (Fig. 2). In EIAV, a lentivirus that contains the type 1 LYPDL motif, Alix is sufficient to drive viral release in the absence of any other L domain. This can be explained by the fact that the EIAV L domain exhibits much higher affinity for Alix than the LYPXnL motif of HIV-1. HIV-1 release depends primarily on the PTAP L domain and its ability to recruit the cellular protein Tsg101. Mutations in the PTAP motif, which prevent Tsg101 recruitment to Gag, profoundly inhibit virus budding. In this context, however, increased

levels of cellular Alix can efficiently restore HIV-1 release and infectivity, revealing that Alix also functions in HIV-1 budding and can drive virus release independently of the PTAP L domain, provided Gag harbors an intact LYPXnL L domain motif.

Structural studies revealed that Alix comprises three distinct domains: an N-terminal Bro1 domain, a LYPXnL-binding coiled-coil V domain, and a C-terminal proline-rich domain (PRD). The Bro1 domain has a boomerang/banana-shaped structure and contains two main hydrophobic patches relevant for Alix function in HIV-1 release. The first patch or hydrophobic interface is localized in the concave face of the Bro1 domain and binds CHMP4 isoforms, connecting Gag directly to ESCRT-III isoforms (Zhai et al. 2007, *Nature Structural and Molecular Biology*). Mutations of residues involved in the Bro1-CHMP4 interaction prevent Alix to function in viral release, indicating that Alix is able to link Gag to the ESCRT-III complex and promote HIV-1 budding. A second hydrophobic surface is centered at the phenylalanine residue 105 (Phe105) at the tip of a long flexible loop protruding from the convex side of the Bro1 domain. Disruption of residues within this loop severely inhibited the ability of Alix to stimulate HIV-1 release, without affecting its ability to interact with Gag or its natural partner CHMP4 (Sette et al. 2011). The exposed nature of the Phe105 loop suggests that it could function as an acceptor site for a cellular cofactor of Alix that remains to be identified and characterized.

The central domain of Alix folds into a V-shaped structure that binds the LYPXnL L domain in HIV-1 p6 and other viral Gag proteins through a hydrophobic pocket located on one of its arms. Recently, the same V domain pocket was shown to interact with a cellular LYPXnL motif belonging to syntenin, a protein involved in exosome biogenesis (Baietti et al. 2012). In addition, the V domain is involved in Alix-Alix homodimerization, a property that appears to be required for Alix activation and function in virus release. Indeed, in its active dimeric form, Alix is believed to recruit and nucleate CHMP4 polymers during membrane budding processes. Recently, the Alix

V domain was also found to interact with K63-linked poly-ubiquitin chains. Mutation of the ubiquitin-binding motifs in the V domain impaired Alix ability to function in retroviral release, suggesting that Alix interaction with ubiquitinated proteins is critical for function. The nature of these ubiquitinated proteins and how they function with Alix remain to be elucidated, however.

The unstructured C-terminal PRD domain is essential for Alix activity in virus release. The current model suggests that Alix is present in the cytoplasm in an autoinhibited monomeric form with the PRD region folding back toward the upstream domains. In this closed conformation, the PRD prevents Alix interaction with the LYPXnL L domain. At the budding neck, the displacement of PRD is believed to trigger the activation and dimerization of Alix and subsequent binding to the L domain and possibly CHMP4. In addition to the LYPXnL-V domain interaction, a second point of contact between Alix and Gag was recently characterized involving the p6-adjacent nucleocapsid (NC) region of Gag and the Bro1 domain of Alix. Interestingly, Alix Bro1 domain alone was found to rescue budding defects of HIV-1 mutant lacking L domains, suggesting that Bro1 can act as a minimal functional unit of Alix that links Gag to the ESCRT pathway via interactions with NC (Dussupt et al. 2009). Findings that residues on both sides of the Alix Bro1-NC interface are positively charged, suggested that RNA is involved in this interaction, although molecular mechanisms involved are yet to be elucidated. Mutations that prevent Bro1-NC binding affect Alix ability to promote viral release, revealing its functional relevance. These studies suggested a model in which Alix engages in dual interactions with Gag via both NC and the adjacent p6 domain. Further studies are warranted to decipher the functional significance of the newly identified interactions.

Nedd4-Like Ubiquitin Ligase

Some retroviruses, including RSV, Moloney murine leukemia virus (MoMLV), and the human T-cell leukemia virus, utilize the PPXY-

type L domain to acquire an envelope and leave the cell. PPXY functions by recruiting members of the Nedd4-like ubiquitin ligase family and linking Gag proteins to the host cell ESCRT pathway. Nedd4-like family of ubiquitin ligases has a common structural organization with an N-terminal C2 domain involved in membrane binding, multiple WW domains for substrate recognition, and a C-terminal HECT domain with an intrinsic catalytic activity. The catalytic activity of the HECT domain is essential for their functions in the sorting of cargo proteins in endosomal/lysosomal compartments as well as in virus budding, suggesting that ubiquitin conjugation is central for function in these processes. Despite the absence of a PPXY L domain in its Gag protein, HIV-1 appears to be sensitive to the effect of Nedd4-like ubiquitin ligases. One of its members, Nedd4-2s, a natural isoform of Nedd4L/Nedd4-2 – which lacks most of the N-terminal C2 domain – was found to potently stimulate HIV-1 release. Remarkably, Nedd4-2s corrected the budding defects of HIV-1 mutants lacking all L domains and thus appeared to provide an additional access to the host cell ESCRT pathway. Nedd4-2s rescue of HIV production required both cellular Tsg101 and intact C2 and HECT domains, and further data supported the idea that Nedd4-2s is recruited to sites of virus assembly through specific interaction between its residual C2 domain and Gag. Nedd4-2-mediated ubiquitination of either the ESCRT-I complex or Gag itself was suggested to facilitate the recruitment of the ESCRT pathway and promote viral budding in absence of L domains. Further studies are needed to better understand how this ubiquitin ligase (and possibly other Nedd4-like members) stimulates HIV-1 release and decipher the molecular mechanisms involved.

Role of Ubiquitin in HIV-1 Budding

Ubiquitin plays a central role in cellular processes involving ESCRT proteins including virus budding and sorting of cargo proteins at the MVBs. Attachment of ubiquitin molecules to cargoes signals their entry into endosomal compartments

(Shields and Piper 2011). Therefore, it is not surprising that ubiquitin was found to play a role in ESCRT-mediated retroviral budding. Ubiquitin is a highly conserved protein composed of 76 amino acids, which can be covalently linked post-translationally to a lysine residue of a target protein. Ubiquitin itself has seven lysines (K6, K11, K27, K29, K33, K48, and K63) that all have the potential to engage in interaction with other ubiquitin molecules (poly-ubiquitination) allowing the formation of different types of chains. The biological role of poly-ubiquitination depends on the type of linkage and the length of the chain. For example, proteasomal degradation is signaled by poly-ubiquitin conjugation through lysine residues at position 48 (Lys-48-linked), whereas single or multiple mono-ubiquitination and Lys-63-linked poly-ubiquitination mediate protein entry in the ESCRT pathway. To enter the pathway, cargos are ubiquitinated by specific E3 ubiquitin ligases and as such recognized by members of the ESCRT-0, ESCRT-I, and ESCRT-II complexes that contain ubiquitin-binding domains (UBDs). The first evidence that ubiquitin plays a role in retrovirus release came from the finding that free ubiquitin is selectively incorporated into avian sarcoma leukosis virus particles. Subsequently a small subset of Gag molecules within HIV-1, simian immunodeficiency virus (SIV), and MoMLV viral particles were found to be mono-ubiquitinated, and the level of Gag ubiquitination appeared to be L domain dependent. In addition, depletion of soluble ubiquitin by treating cells with proteasome inhibitors induced a late budding defect. Whereas a role for ubiquitin in virus budding is accepted, the identity of the ubiquitinated protein(s) and the functional significance of ubiquitination at HIV-1 budding sites was (Vogt 2000) and still is a subject of debate. One possibility is that the relevant targets for ubiquitination are cellular Gag binding proteins involved in viral budding. In fact, Tsg101 and Alix are both ubiquitinated, a modification that might play a role in their facilitation of viral budding. Along this thought, an artificial lysine-free Gag protein from foamy virus that cannot be ubiquitinated was still able to promote viral budding and release. Aside from the importance of

ubiquitin conjugation to cellular factors in the vicinity of Gag, an alternative model is that Gag itself is the relevant target for ubiquitination, and several findings supported such a model. Indeed, cumulative mutations of lysine residues in the p6 region of HIV-1 Gag-arrested viral budding, although milder, were reminiscent of L domain disruption. Such defects however were alleviated by the physical fusion of ubiquitin to Gag including in the absence of L domains, suggesting that the mere presence of ubiquitin molecule near Gag (or onto Gag) is sufficient for the recruitment or utilization of the ESCRT machinery for virus release. In agreement with this notion, Gag ubiquitination appears to be highly dependent on its association with the plasma membrane, the site of virus budding, and deposition K63-linked ubiquitin chains to Gag by the ubiquitin ligase Nedd4.2s correlated with the stimulation of HIV-1 release. Although these observations and others support the notion that conjugation of ubiquitin chains to Gag is involved in ESCRT-mediated virus scission from producer cells (Sette et al. 2013), further studies are warranted to elucidate mechanisms of ubiquitin involvement in HIV-1 budding.

Conclusion

The last decade has brought a wealth of information on how HIV-1 assembles nascent virus and exit cells. Notably, the major finding was the discovery that budding is a tightly regulated step of the HIV-1 life cycle that requires the participation of a complex cellular membrane fission machinery, the ESCRT pathway. A significant progress has been made in understanding how HIV-1 hijacks a select number of ESCRT proteins to separate from cells. However, the possible involvement of additional host factors and mechanistic details in the sequence of events leading to the membrane fission step that ultimately releases

the newly formed HIV-1 virions are yet to be uncovered. More efforts are needed to gain a better understanding of the budding process at the molecular level, a prerequisite for the development of novel antiretroviral therapies (ART) (► [Antiretroviral Therapy and Cellular Cofactors as Drug Targets](#)) such as small-molecule inhibitors of HIV-1 production and spread.

Burkitt and Burkitt-Like Lymphoma

Kishor Bhatia¹ and Sam Mbulaiteye²
¹AIDS Malignancy Program, Office of HIV and AIDS Malignancy and Infections and Immunoepidemiology Branch, National Cancer Institute, Bethesda, MD, USA
²Infections and Immunoepidemiology Branch, National Cancer Institute, Bethesda, MD, USA

Definition

Burkitt lymphoma (BL) is a rare tumor of mature B lymphocytes. Clinically, it develops rapidly and runs an aggressive course. Tumor can develop in

any body organ, but most often involves sites other than lymph nodes, especially in the abdomen, pharynx, or the jaw. BL is relatively more common in sub-Saharan Africa, where it is endemic. Patients with HIV infection are also at increased risk of BL, and in this setting it is called epidemic BL. Endemic and epidemic BL are both associated with Epstein-Barr virus, a common virus that infects 90% of the global population. Although the tumor is highly aggressive, being the most rapidly growing cancer known and doubling every 24 h, it is also very responsive to modern chemotherapy. With currently available regimens, 90% of patients can expect to be cured when properly treated.

Introduction

In 1982, reports of Kaposi sarcoma and *Pneumocystis carinii* infections in ► **men who have sex with men (MSM)** heralded the advent of the AIDS epidemic in the USA. Soon afterward, a cluster of cases of aggressive B-cell non-Hodgkin lymphoma (NHL) was noted in the same population. As the epidemic unfolded, it was noted that these AIDS-associated lymphomas included cases of Burkitt lymphoma (BL) or Burkitt-like lymphomas (BLL). Burkitt lymphoma (BL), a rapidly growing B-cell non-Hodgkin lymphoma (NHL), was known prior to the HIV epidemic. The pathology of BL was described as small non-cleaved cell lymphoma in the Lukes and Collin's classification system of lymphomas, and prior to the AIDS epidemic, it was relatively rare outside sub-Saharan Africa, where it was known to be endemic. First described by Denis Burkitt in 1958, the tumor was known to affect mostly children who developed tumors in the jaw or in the abdomen. Shortly after, the pathology of the tumors was described, allowing sporadic cases to be described worldwide and leading to the disease to be named after Burkitt as a specific clinical and pathologic entity.

Three epidemiological variants of BL are now recognized: endemic, sporadic, and immunodeficiency related (or epidemic). These variants differ

with respect to their incidence, geographic areas, and associated factors, but they are currently not distinguishable by routine histopathological, immunohistochemical, or molecular criteria. All three variants of BL share the starry-sky pattern under the microscope and a morphology of uniform medium-sized cells with cytoplasmic vacuoles, small nucleoli, and a non-cleaved nucleus. The immunophenotype typically shows positivity for monotypic surface IgM, B-cell antigens (CD20, CD10, CD79a), and a high proliferation index. Cytogenetic studies show the presence of a rearranged *c-myc* gene. The rearrangement is often the result of translocation of *c-myc* on chromosome 8 into the vicinity of heavy chain immunoglobulin (IgH) sequences on chromosome 14, or light-chain immunoglobulin genes on chromosomes 2 and 22 as well. The cell of origin for BL is a germinal center B cell, and BL thus expresses *bcl-6* but not *bcl-2*, CD-138, or TdT (Swerdlow et al. 2008).

Epidemiology

The two major variants of BL described prior to the HIV epidemic mainly differ by geography and incidence rates. Endemic BL occurs in sub-Saharan Africa and Papua New Guinea, in regions that are also holoendemic for *Plasmodium falciparum* malaria. In sub-Saharan Africa, patients with endemic BL frequently present with a rapidly growing tumor involving the jaw or abdomen. The peak age is 5–9 years, in part because of early acquisition of ► [Epstein-Barr virus \(EBV\)](#) infection in sub-Saharan Africa coupled with repeated infection with *Plasmodium falciparum*, the two generally accepted key risk factors. EBV is detected in more than 95% of endemic BL cases. In regions of sub-Saharan Africa that have holoendemic malaria, BL constitutes the majority of pediatric lymphomas and accounts for as many as half of all childhood cancers. Accurate estimates of the incidence of endemic BL are lacking, but the annual incidence is between 40 and 50 cases per million children (Molyneux et al. 2012). Boys are affected more than girls, particularly for tumors involving the

jaw where the male-to-female ratio may be higher than 10:1. BL occurring outside the malarial regions of Africa and Papua New Guinea and outside the setting of HIV infection is referred to as sporadic BL.

The clinical presentation of sporadic BL differs from that of endemic BL by more frequently involving the lymph nodes, the abdomen, and the bone marrow. In addition, sporadic cases generally occur later during adolescence and young adult age, although cases have been reported in the elderly. The incidence of sporadic BL is at least ten times lower than endemic BL – about two per million in the USA, Europe, and some parts of Asia. Unlike endemic BL, no specific risk factors have been identified for sporadic BL. The association of EBV in sporadic BL varies considerably from country to country. In the USA and Western Europe, only about 20–30% of BL are EBV positive. However, in Brazil, Argentina, Turkey, and Egypt, where the cases are considered to be sporadic, EBV positivity ranges from 50% to 70% (Magrath et al. 1992). It is not clear whether EBV-positive BL in the USA differs by race.

Risk for BL is very high in individuals with immunodeficiency, either as a result of infection with human immunodeficiency virus (HIV) or following solid-organ transplantation. Patients with AIDS have about a 50- to 60-fold greater risk of developing BL than people without AIDS of a similar age and sex. The burden of AIDS-associated BL in the USA from 1980 to 2007 has been estimated to be about 3,452 cases (Shiels et al. 2011b), and these cases account for one-fifth of all BL cases diagnosed in the USA during the same period. A distinct age-associated peak of BL at age 40 has been identified in persons with HIV infection, perhaps influenced by the fact that most HIV-infected individuals are less than 50 years of age. More recent analyses of cancer registry datasets now suggest that the age-specific pattern of BL in most countries (except Africa, for which data are sparse and/or incomplete) is trimodal. Separate incidence peaks near ages 10, 40, and 70 are clearly apparent. While the middle peak overlaps with cases of AIDS-BL, this trimodal age-specific incidence of BL is also apparent in the general population. The multiple

incidence peaks of BL raise the possibility that conditions currently diagnosed and classified as BL comprise a mixture of entities with distinct biology or etiology and distinct age peaks. It remains to be seen if variation in BL immunophenotype, molecular, and viral profiles corresponds with the distinct age peaks identified and/or with the immune status of tumors.

How immunodeficiency increases the risk for BL is not entirely clear. It is likely that immunocompromised patients are unable to control EBV infection, which might increase the risk of EBV-associated BL. EBV is indeed found in 40–60% of HIV-associated BL from the USA and Western Europe, but changes in control of EBV alone may not explain all of the observed increase in HIV-associated BL because a substantial proportion of cases are not EBV positive. Although HIV has been associated with dramatically increased BL incidence in the USA and Western Europe, data are conflicting about the impact of HIV on BL in sub-Saharan Africa, where the HIV epidemic is substantial and BL was previously endemic. For example, comparison of rates of incidence of BL in Uganda, between pre-HIV (1960–1971) and HIV era (1991–1997), suggests only slight increase in BL incidence, and while some of the increase might be attributable to HIV, it is not possible to be certain because cancer registry studies do not collect HIV status on their patients. Two case-control studies conducted in Uganda showed a modest but statistically significant increase in BL risk with HIV (with the odds ratio in one study of 7.5 and the other 2.2), raising doubt about the significance of the overall association. Similarly conflicting results were reported in two analyses from a study conducted in Malawi, with significant results reported in one analysis (OR = 12.4) and a non-significant result in the other (OR = 2.2). There are sparse data on the association between HIV and BL in adults in Africa. A study from Kenya (Otieno et al. 2001) showed the median age of BL was 35 years, suggesting an impact HIV on the age of BL diagnosis, but this study was small, and it did not estimate the fold increase. Therefore, it is quite unlikely that a substantial effect of HIV on AIDS-associated BL

in sub-Saharan African BL belt has been missed. Why this difference? One reason is that competing mortality – death from other, more common conditions – contributes. This may be supported by one study that has reported a stronger impact in South Africa, where survival rates for children with HIV may be better than in Uganda and Malawi, although this has not been shown. In that study, the BL risk in children with HIV was increased nearly 46-fold. However, since BL in South Africa is more likely the sporadic type, i.e., not associated with holoendemic malaria, the substantially higher risk of BL with HIV infection may simply indicate that the impact of HIV on BL is greater for sporadic than endemic BL. Following the widespread availability of ► [combination antiretroviral therapy \(cART\)](#), the overall incidence of AIDS-related NHLs has significantly decreased with the largest decrease seen for primary central nervous system (CNS) lymphomas (Shiels et al. 2011). There are conflicting data on the incidence of BL in particular during the cART era. A large meta-analysis of 23 cohort studies did not support a decline in BL (International Collaboration on HIV and Cancer 2000).

BL accounts for a substantial proportion of AIDS-associated NHL in the cART era. The relationship between degree of immunosuppression and risk to BL contrasts with that of the correlation between degree of immunosuppression and risk for primary CNS lymphoma. While the latter occurs at very low CD4 counts, there is a clear deficit of BL cases in people with very low CD4, suggesting a requirement of a threshold of CD4 for BL pathogenesis (Guech-Ongey et al. 2010). Although access to antiretroviral therapy has expanded significantly in recent periods in sub-Saharan Africa, there are sparse data to understand whether cART has impacted incidence of BL in these regions.

Molecular Features of BL

Irrespective of the epidemiological variant, almost all BL are characterized by a signature translocation that juxtaposes and thereby deregulates the

c-myc gene, bringing it under the regulatory control of the B-cell-specific immunoglobulin locus. Most frequently this translocation is between c-myc on chromosome 8 and the IgH gene on chromosome 14 [t (8:14)]. Variant translocations involving c-myc and antibody light-chain genes, either Immunoglobulin Kappa (IgK) [t (2:8)] or Immunoglobulin Lambda (IgL) [t (8:22)], occur in about one-fifth of BL cases. Some reports of lymphomas that otherwise are immunophenotypically identical to BL but do not carry these translocations have also been described. Such myc-negative cases occur both in adults and children. It is likely that alternate pathways with the end result similar to a deregulated myc might be in play in these lymphomas. The proportion of AIDS-related BL that similarly shows absence of a c-myc translocation is not known. Molecular translocations of chromosome 8 and 14 differ with respect to their breakpoints between sporadic and endemic BL and also differ between sporadic BL from different regions. In endemic BL the breakpoint often leaves the transcriptional unit of c-myc intact and occurs several hundred kilobases upstream or downstream of the c-myc gene. On the other hand, in sporadic BL cases in the USA, the translocation often involves breaks between exons 1 and 2 of the c-myc gene. Sporadic BL and AIDS-associated BL from the USA do not appear to be different at the molecular level of the translocations. The breakpoints in sporadic BL cases from other world regions such as Argentina and Brazil differ and often cluster immediately upstream of c-myc gene (Magrath et al. 1992). There is insufficient data on breakpoints from AIDS-associated BL from countries outside the USA. The significance of these regional differences in breakpoints is unclear. However with the exception of BL from Algeria (where the breakpoints are often within the c-myc transcriptional unit), there appears to be a gradient of association between the proportion of EBV positivity and breakpoint location among BL from other regions. Patients with EBV-negative BL are relatively more likely to have breaks occurring within the transcriptional structure of c-myc gene, suggesting the possibility that EBV may contribute to deregulation of translocated

c-myc with breakpoints far upstream or far downstream of c-myc.

There is considerable evidence that the Ig-myc translocations lead functionally to myc deregulation, although this in itself is insufficient to trigger onset of clinical BL. Some data suggest that proliferation in normal germinal center cells is not myc driven and thus a forced expression of c-myc in germinal center B cells is the most likely central component of the pathway to B-cell lymphomagenesis in BL. In addition to the translocation, a contribution to the deregulation of c-myc is also provided in AIDS-associated BL by mutations that are present in a small 500 base pair regulatory region in the junction of the first exon and first intron of the c-myc gene. Most BL, including AIDS-associated BL, carry no or only a few other cytogenetic abnormalities. Abnormalities involving chromosomes 1q, 7q21, and 12p13 have been reported in sporadic BL.

However, like other cancers, additional genetic alterations are required to circumvent the homeostatic feedback loops triggered by deregulated c-myc to prevent progression to malignancy. Among the additional molecular lesions described in BL, those that incapacitate apoptotic pathways are prominent. Inactivation of p53 is frequently found in BL including AIDS-associated BL. Other molecular abnormalities include mutations in proapoptotic proteins such as Bak and diminished expression of proteins that inhibit apoptosis such as cIAP-1 and cIAP-2. The presence of inactivating mutations of RBL2 has been reported in endemic and some sporadic BL, while HIV-positive BL cases have been found to demonstrate an overexpression of wild-type RBL2. The tumor suppressor functions of RBL2 have been shown to be neutralized by physical interactions with HIV-1 Tat protein suggesting that HIV-1 may directly interact in the pathogenesis of BL. In addition to mediating proliferation, constitutional expression of c-myc also blocks cell differentiation and induces apoptosis. The oncogenic conversion of c-myc in HIV-associated BL often incorporates mutations within the c-myc coding regions (Bhatia et al. 1993). Mutations affecting c-myc are most

likely a result of abnormal somatic hypermutations. Aberrant somatic hypermutation also results in a wide range of mutations in other oncogenes including BCL6. Epigenetic alterations are also frequently associated with both HIV and non-HIV BL and target expression of MGMT, DAPK, and P73.

Phosphoinositide-3-kinase (PI3K) signaling plays a critical role downstream of B-cell receptor signaling in B cells. More recent data implicate activation of PI3K pathway as an important pathogenic event in BL that might synergize with deregulated c-myc (Schmitz et al. 2012). Aberrations in this pathway result from somatic mutations that deregulate the activity of E2A or inactivate its negative regulator ID3 and also from mutations in cyclin D3, a gene that is the direct target of E2A and is intricately involved in the control of germinal center B-cell proliferation. It is not yet clear whether there are differences in the proportion of HIV and non-HIV BL with respect to the synergistic involvement of the PI3K pathway in conjunction with a deregulated c-myc.

Role of EBV

Most of the cancers associated with HIV infection have a viral etiology. ► [Hodgkin lymphoma](#) and primary CNS lymphomas arising in the context of immunodeficiency are almost always associated with EBV, and approximately 30–50% of ► [diffuse large B-cell lymphomas \(DLBCL\)](#) in people with HIV are EBV positive compared to less than 5% of EBV-positive DLBCL in the HIV-negative setting. Also, approximately 30–60% of cases of HIV-associated Burkitt lymphoma are EBV associated. This is more than what is observed in sporadic BL but less than what is found in endemic BL, in which 95% or so of cases are EBV associated.

As in other lymphomas, EBV is generally latent in BL tumor cells. In latent EBV infection, a very restricted pattern of gene expression is observed. There are three programs of EBV latency, ranging from latency I, in which only EBV nuclear antigen 1 (EBNA-1) and EBV-encoded RNAs (EBERs) are expressed, to

latency III in which all the latent genes are expressed. Many latently expressed EBV proteins are immunogenic. Latency III is only found in tumors in immunodeficient hosts such as in HIV-associated DLBCL and the polymorphic posttransplant lymphoproliferations. Interestingly, in BL that occurs in the context of immunodeficiency, the pattern of latency expression is latency I, in which only EBNA-1 and EBERs are expressed. This is similar to the latency pattern in non-HIV BL. Also similar to the non-HIV BL, EBV is monoclonal in BL that arises in AIDS patients. Both these observations are consistent with the hypothesis that EBV is not merely an opportunistic passenger as a result of diminished immunosurveillance but plays a pathogenic role in HIV-associated BL.

Several possible roles for EBV in the pathogenesis of BL have been suggested. The expression of EBERs might support survival by inducing the expression of IL-10. Both EBNA-1 and EBERs also confer antiapoptotic activity and thereby promote survival of clones with a deregulated c-myc. The restriction of expression of latency genes to latency pattern I in immunodeficiency-associated BL is nonetheless intriguing and suggests that even in the context of reduced immune pressures, there is a need for downregulating the expression of the majority of EBV latent genes. It is possible that the expressions of certain latent EBV genes, such as EBNA-2, are incompatible with pathways that support BL lymphomagenesis. A scenario that emerges therefore is that HIV-positive BL cells are derived from an amplified pool of EBV-transformed B cells that initially expressed the full repertoire of latent genes. It might be that some of these genes such as latent membrane protein-1 (LMP-1) helped orchestrate immunoglobulin class switching and somatic hypermutation through the induction of activation-induced deaminase (AID) pathways, as will be discussed below.

The contribution of EBV to antiapoptotic mechanisms in BL along with the incompatibility of EBNA-2 with BL lymphomagenesis is also supported by recent observations of a variant latency pattern in a small proportion of BL. This

latency pattern, called Wp-restricted latency, results from the use of the Wp promoter in mutant EBV genomes and is associated with about 15% of BL. The mutant EBV genomes carry a deletion of the EBNA-2 region and allow expression of EBNA 3A, 3B, and 3C and the EBV antiapoptotic gene BHRF1 (Bornkamm 2009). It is yet not known how often mutated EBV genomes are associated with HIV-positive BL in comparison to non-HIV BLs. There is a greater genomic diversity associated with EBV in HIV-infected individuals, and HIV-positive BL are more often associated with type B EBV. The theoretical possibility therefore exists that a wider genomic diversity of EBV strains and subtypes prevalent in the context of a reduced EBV immunosurveillance in people with HIV infection allows for more “oncogenic” variants of EBV to enhance the likelihood of lymphomagenesis including the development of Burkitt lymphomas.

Role of HIV

HIV does not directly infect BL clones, and thus its influence in enhancing risk for BL in people with HIV infection is mediated indirectly. T-cell immunodeficiency resulting from HIV infection plays a central role in increasing the risk of certain cancers, particularly those caused by oncogenic viruses. Thus both the degree and the duration of immunosuppression measured by deficit in CD4 T cells correlate with the risk of lymphomas. A decrease in incidence of some lymphomas such as primary CNS lymphomas in the cART era supports the importance of such immune surveillance, directed against the virus and/or viral antigens expressed on the tumor cells. By contrast with primary CNS lymphoma, the correlation between the degree of immunosuppression and the risk for BL is more complex. The incidence of BL is only modestly affected in the cART era, and BL arises even in the context of a relatively recovered immune status in patients receiving cART therapy. A deficit of BL has been documented in patients with extremely low CD4, such as those with CD4 counts between 100 and 50/ul, suggesting a

threshold requirement of T cells in BL lymphomagenesis. In addition to decrease and dysfunction of T lymphocyte as a result of HIV infection, there is a parallel increase in B-cell activation and an overproduction of B-cell stimulatory cytokines combining to allow chronic B-cell hyperactivation, contributing indirectly to risk for lymphomas. As noted above, one postulated mechanism of HIV-driven lymphomagenesis is the activation and expression of the DNA-editing enzyme-induced cytidine deaminase (AID). AID expression has been shown to be elevated in B cells of HIV-positive individuals prior to the diagnosis of NHL. It is possible thus that this overexpression of AID, which is known to promote *c-MYC/IgH* translocations, induces aberrant (*Ig*) class-switch recombination (CSR) and somatic hypermutation (SHM) contributing to increased frequency of B cells with lymphoma-specific translocations (Epeldegui et al. 2006).

Other mechanisms whereby HIV-related proteins may directly influence BL development also need to be considered. HIV-infected cells secrete ► *tat* protein which is present in sera and thus is capable of exerting biological effects when taken up by other cells including B cells. *Tat* has potential oncogenic activity and can inactivate tumor suppressor genes including RB2, which has been shown to play a contributory role in development of some BL.

Presentation and Pathology

Endemic BL often presents with localized disease, frequently affecting the jaw or the abdomen. In some cases, other extranodal sites including breasts, ovaries, and kidneys may be involved. Bone marrow involvement and nodal involvement are rare in endemic BL. Sporadic BL particularly in children also frequently involves the abdomen, while facial involvement is rare. A greater proportion of sporadic BL than endemic BL involves the bone marrow. By contrast to endemic BL, AIDS-BL often presents with lymphadenopathy. CNS involvement and advanced stage at presentation are also seen

more frequently with AIDS-BL than in other types of BL, both in children and adults.

Most cases of endemic and pediatric BL present a classical cytologic appearance. The tumor is comprised of monomorphic, uniform cells of medium size with round nuclei, moderately clumped chromatin, and multiple basophilic nucleoli. The cytoplasm is abundant and basophilic and contains many lipid vacuoles. The characteristic “starry-sky” pattern of BL results from multiple infiltrating macrophages that ingested apoptotic tumor cells. Compared to classic BL, AIDS-associated BL and a proportion of adult BL have a variant appearance and depict less uniformity. In AIDS-associated BL there is a tendency for plasmacytoid differentiation. Irrespective of the type of BL, several important immunophenotypic characteristics are common. These include positivity for surface IgM, CD10, and CD79a, a high score of proliferation identified by Ki67 staining of all or nearly all (>95%) of tumor cells, and an absence of BCL-2 and TdT staining.

In patients with HIV and particularly in adults, distinguishing between cases that are true BL from morphologically similar other aggressive B-cell lymphomas such as those that are diffuse large B-cell lymphomas (DLBCL) is prognostically important. A fraction of BL cases remain difficult to classify because they have features intermediate between diffuse large B-cell lymphomas and BL. Recent data using molecular gene expression profiles have provided a characteristic molecular signature of BL. Therefore application of such molecular diagnostics might provide added diagnostic tools in the future. In the more recent WHO classification of lymphomas, a category of B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and BL (B-UNC/BL/DLBCL) has been introduced to characterize the lymphomas that are difficult to distinguish between BL and DLBCL (Jaffe and Pittaluga 2011).

Treatment

Endemic BL was one of the first malignancies that was shown to respond to chemotherapy. Since

then, chemotherapy has remained the mainstay for therapeutic management of all forms of BL. Surgery and radiotherapy have little to offer to BL treatment. Early studies demonstrated a high degree of chemosensitivity of endemic BL, which responds particularly well to cyclophosphamide, methotrexate, and vincristine. Long durations of remissions were noted with these drugs, and late relapsing tumors were found to retain chemosensitivity to the initial treatment and to respond fully to second-line treatment. The use of simultaneous and upfront combination chemotherapy, particularly using drugs that were not cross-reactive, along with intrathecal chemotherapy, improved long-term outcomes and reduced relapse of BL in the central nervous system. The experience gained from these early treatment protocols continues to influence the management of BL in Africa.

The recommended first-line treatment of BL is intravenous treatment with cyclophosphamide, vincristine, and methotrexate (COM) and intrathecal methotrexate and cytarabine. At least three cycles, given every 2–3 weeks, are recommended for early stage disease and 6 cycles for late-stage disease. The second-line regimen, for patients who fail the first line, is a four-drug intravenous regimen including etoposide, ifosfamide, mesna, and cytarabine, along with intrathecal methotrexate and cytarabine. While these treatments are likely very efficacious (80% response in African settings), many patients with endemic BL die soon after diagnosis from tumor lysis syndrome, late presentation, and the patients choosing to stop receiving treatment.

Treatment of sporadic BL in the USA and other western countries was informed by the experience in treating endemic BL. Cyclophosphamide, vincristine, and methotrexate formed the backbone of initial treatment regimens, which over time became increasingly intensive. An important step to optimal treatment of both adult and pediatric BL was the design of the CODOX-M/IVAC regimen, sometimes called the Magrath regimen, which achieves remission rates of up to 100% and 92% event-free survival at 5 years in children and adolescents (relapses in BL are very rare after 1 year). Subsequent

clinical studies have evaluated this protocol in multi-institutional settings, and some modifications of the protocol have been introduced to preserve efficacy while decreasing neurotoxicity. These modifications include a reduction in the dose of methotrexate, limiting the dose vincristine, and increasing the dose of doxorubicin. Utilizing data from preclinical studies that suggested diminished tumor resistance when sustained concentrations of doxorubicin, vincristine, and etoposide are used, Wyndham Wilson and colleagues in the National Cancer Institute intramural program introduced infusion dose-adjusted etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin (DA-EPOCH) for the treatment of adult lymphomas, and this regimen was found to have utility in the treatment of sporadic BL.

Early in the AIDS epidemic, most AIDS-associated lymphomas, irrespective of histological subtype and stage, were treated with less aggressive therapy as compared to standard regimens, and the general outcome of these initial approaches in HIV-associated BL was inferior compared to non-HIV BL. With the introduction of combination antiretroviral therapy (cART), there was an appreciation that HIV patients were better able to tolerate standard chemotherapeutic regimens, generally along with cART. The AIDS Malignancy Consortium has studied modified CODOX/IMVAC regimen for AIDS-related BL. DA-EPOCH is another option that has been shown to be effective for treating AIDS-BL and AIDS-BL-like lymphomas. Because BL and BL-like lymphomas, both in HIV-positive and HIV-negative patients, frequently express CD20, the use of rituximab, a monoclonal anti-CD20 antibody, has also been tested and found to have activity. Rituximab has been incorporated into a modified Magrath regimen as well as with the infusion dose-adjusted EPOCH regimens (Mwamba and Remick 2012).

The treatment of HIV-related BL in sub-Saharan Africa poses special challenges. In general, the use of highly intensive therapy is difficult in Africa because of limited drug supply, as well as a lack of high-quality supportive care. Modified regimens that are practical in the

locoregional setting, including oral-based regimens and modified CHOP-like regimens, are being studied in Africa; similarly incorporating cART to standard regimens used to treat BL in sub-Saharan Africa such as the COM regimen is a possible alternative for use in sub-Saharan HIV-related BL (Magrath 2012).

Conclusion

The discovery of the entity now known as Burkitt lymphoma was first made by Dr Dennis Burkitt in equatorial Africa. The study of what is now called endemic BL proved to be immensely important and established several landmarks in biology and treatment of cancers worldwide. These included the discovery of the first human virus associated with cancers – EBV – and the first demonstration of the use of chemotherapy in the treatment of solid tumors. The risk for BL is increased about 50- to 60-fold in people with AIDS in the USA; however, the magnitude of increase of BL is only about tenfold in HIV-infected children and adults in areas where BL is endemic. BL is a lymphoma derived from germinal center B cell and is variably associated with EBV. A defining feature of BL is the presence of a simple translocation involving the c-myc locus with an IgH, IgK, or IgL locus. It is a highly proliferating tumor with more than 95% of tumor cells staining for Ki67. Molecular analysis of gene expression studies has defined a BL signature, which distinguishes it from other aggressive B-cell lymphomas such as DLBCLs. However, some tumors are intermediate between BL and DLBCL and are now considered a separate category of tumor. A diagnosis of BL is clinically relevant since BL-specific therapy is essential for optimal outcome. The treatment of HIV-associated BL now yields a comparable response rate and outcome as compared to BL in the HIV-negative setting. Recent laboratory-based studies have identified new genetic lesions in BL which may provide novel targets for the development of small molecules capable of interfering with genetic circuits that sustain proliferation of BL cells.

Medicine, Massachusetts General Hospital,
Boston, MA, USA

Definition

With the advent of widespread use of ART and associated immunologic recovery and viral suppression, there has been a concomitant reduction in AIDS-related mortality across multiple patient populations worldwide. This phenomenon has led to the emergence of noncommunicable diseases, such as non-AIDS malignancies, hepatic disease, and cardiovascular disease as major sources of morbidity and mortality in the HIV-infected population. Included among these complications are cardiovascular diseases that affect the heart and peripheral vasculature. During the early course of the HIV epidemic, the major cardiovascular complications included dilated cardiomyopathy and pericarditis. While these are present in the current era of HIV treatment, the successes of antiretroviral therapy (ART) and the aging of the HIV-infected population combined with unique predisposing factors have led to the emergence of coronary heart disease (CHD) as a major source of morbidity and mortality. Management

strategies for CHD in HIV-infected patients require attention to traditional coronary risk factors and novel, HIV-specific factors (Deeks et al. 2013).

Early Cardiovascular Complications

From the initial stages of the HIV epidemic even prior to the introduction of widespread ART, cardiomyopathy was recognized as an important comorbidity. HIV-infected patients were noted to have disproportionate rates of left ventricular dysfunction and dilated cardiomyopathy. Autopsy studies suggested myocarditis as the major cause of cardiac dysfunction, though the etiologic agent remained unknown in the vast majority of cases. Chronic viral infections including cytomegalovirus (CMV) or herpes simplex virus (HSV) in addition to bacterial infections such as *Mycobacterium tuberculosis* and *Toxoplasma gondii* and HIV itself were also implicated. Rates of dilated cardiomyopathy fell after the introduction of ART, likely in the setting of better virologic control and reduced rates of infections related to immunosuppression.

Pericarditis has also been identified as a cardiovascular complication of HIV infection since the early days of the epidemic, with patients presenting with pericardial effusions and cardiac tamponade. The underlying etiology, when able

to be identified, often related to opportunistic infections such as *Mycobacterium tuberculosis* or *Cryptococcus neoformans* or AIDS-associated malignancies such as lymphoma or Kaposi's sarcoma.

Endocarditis has remained a notable complication of HIV infection given the shared mode of transmission of intravenous drug use. Early autopsy reports frequently found nonbacterial thrombotic (marantic) endocarditis in HIV patients, but this association has not been seen in the ART era. Among cases of bacterial endocarditis, *Staphylococcus aureus* occurred most frequently, with other significant pathogens including *Streptococcus pneumoniae*, *Candida albicans*, *Haemophilus influenzae*, and *Cryptococcus neoformans*.

HIV and Coronary Heart Disease

As ART became more widely available in resource-rich settings, case reports emerged of myocardial infarction in HIV-infected patients, particularly those on protease inhibitor (PI)-based therapies. These events occurred with the recognition that patients on ART had increased rates of metabolic disorders such as diabetes mellitus, insulin resistance, and dyslipidemia. Initial reports subsequently led to larger, more systemic examination of rates of cardiovascular disease among HIV-infected patients compared to control patients. The result has been consistent evidence showing a 1.5- to 2-fold higher relative risk of myocardial infarction (MI) or coronary heart disease among HIV-infected patients across various time periods and a variety of clinical settings. Accumulated data indicates that the increased risk of CHD is independent of demographic factors or traditional cardiovascular risk factors. Specific subpopulations of HIV-infected patients bear a disproportionate amount of CHD risk. HIV-infected women appear to be at greater relative risk than men, and hepatitis C virus (HCV) coinfection also may increase CHD risk (Boccarda et al. 2013; Freiberg et al. 2013; Grinspoon et al. 2008; Triant et al. 2007).

Cardiovascular Risk Factors in HIV

The underlying reason behind the heightened risk of CHD in HIV infection likely reflects a complex array of factors including traditional cardiovascular risk factors, medication effects, and immunologic and inflammatory changes.

Traditional Cardiovascular Risk Factors

HIV-infected patients exhibit higher rates of traditional cardiovascular risk factors, including hypertension, smoking, diabetes, and dyslipidemia. These trends may explain a component of elevated CHD risk. Rates of smoking among HIV-infected patients have been reported to be double that of non-HIV-infected patients. Quitting smoking has been shown to decrease cardiovascular risk for HIV-infected patients, with greater risk reduction with longer times since quitting. Elevated rates of diabetes and dyslipidemia in HIV-infected patients highlight the interplay between ART and traditional risk factors. Some selected antiretroviral medications have been implicated in higher incidence rates of insulin resistance and diabetes among HIV-infected patients, although these metabolic effects were most widely seen with medications such as stavudine and indinavir, which are currently less commonly used. Prior to the ART era, patients with advanced AIDS were noted to have lower levels of favorable high-density lipoprotein (HDL) cholesterol and elevated levels of triglycerides. Treatment with antiretroviral therapy tends to raise all lipid indices, although the net result is an unfavorable lipid profile given lower increases in HDL relative to other lipid indices. In the current treatment era among the different classes of ART, PIs in particular have been associated with dyslipidemia. Ritonavir, even when used at lower doses for pharmacokinetic boosting, is associated with hypertriglyceridemia. Newer PIs, such as atazanavir and darunavir, demonstrate lower but still persistent levels of lipid abnormalities. Antiretroviral therapy, particularly medications used in the earlier stages of the epidemic, can cause fat redistribution with lipoatrophy in the limbs and face and lipohypertrophy of existing fat deposits.

The clinical features of this syndrome are similar to those of the metabolic syndrome of obese, non-HIV-infected patients (Grinspoon et al. 2008; Grunfeld et al. 2008; Grinspoon and Carr 2005).

The Role of Antiretroviral Therapy in Cardiovascular Risk

Several antiretroviral medications have been directly implicated in the development of cardiovascular events. Initial evidence indicated that the PI class of medications had a direct association with MI not entirely explained by changes in dyslipidemia. Further studies indicated that this finding may be driven by the particular effects of lopinavir/ritonavir, amprenavir/ritonavir, fosamprenavir/ritonavir, and indinavir, medications that are used with decreasing frequency. The nucleoside reverse transcriptase inhibitor (NRTI) abacavir has also been investigated regarding its possible association with MI. There is no consensus as to whether abacavir is associated with MI, although meta-analyses do not support an association (Ding et al. 2012; Friis-Moller et al. 2007).

Inflammation and Immune Dysfunction

While traditional cardiovascular risk factors are more prevalent in HIV and specific antiretroviral medications may contribute to risk, these factors do not fully account for the increased risk seen by HIV-infected patients. Subsequent efforts in outlining the relationship between HIV and CHD therefore focused on inflammatory and immunologic changes in HIV. Both advanced and moderate immunosuppression, with CD4+ T-cell counts less than 200/ μ L or less than 500/ μ L, have been associated with MI, with risk on the same order of magnitude as traditional CHD risk factors. These findings may be related to the importance of chronic inflammation and immune activation in HIV-associated CHD pathogenesis.

Chronic inflammation has been associated with CHD outcomes in HIV. Multiple inflammatory indices, including interleukin 6 (IL-6), D-dimer, and C-reactive protein (CRP), are elevated in HIV-infected patients. Initial interest in

the role of chronic inflammation stemmed from investigation showing that an interrupted ART strategy, when compared with one of continuous ART use, was associated with both increased cardiovascular event rates and with increased markers of chronic inflammation, including IL-6 and D-dimer. These markers were notably found to be elevated after treatment interruption, coincident with cardiovascular events. In addition to elevated levels in HIV infection, CRP has also been shown to be associated with MI among HIV patients. Activation markers also shed light into the immune-mediated pathogenesis of CHD. T-cell activation markers, which decrease with ART, are connected to cardiovascular disease progression as measured by surrogate markers of atherosclerosis including carotid intima-medial thickness (cIMT). Macrophage and monocyte activation markers, notably soluble CD163 and soluble CD14, have also been linked to CVD disease progression among HIV populations (Deeks 2011; El-Sadr et al. 2006).

While virologic suppression with ART reduces inflammatory and immune activation markers, it does not completely normalize them. Even elite controllers, HIV-infected patients who maintain viral suppression without ART, demonstrate evidence of an activated immune response, suggesting that patients with controlled HIV disease in the long term will still confront an elevated risk of cardiovascular disease. Other sources of chronic inflammation which disproportionately affect HIV-infected patients and may heighten cardiovascular risk include chronic infections such as CMV, HSV, or HCV (Hsue et al. 2009).

Acute Coronary Syndrome Characteristics

In addition to increased disease incidence, HIV-infected patients have altered presentation, management, and subsequent outcomes of cardiovascular events. HIV-infected patients are more likely to present with an ST-elevation MI (STEMI) as opposed to a non-ST-elevation MI (NSTEMI) or unstable angina. There also may

be altered angiographic presentation with HIV-infected patients more likely to have single-vessel disease or less complex lesions. The management of acute events also differs with HIV-infected patients receiving lower rates of anticoagulation, cardiac catheterization, and coronary artery bypass graft (CABG) surgery. Regarding outcomes, HIV-infected patients have higher rates of in-hospital cardiovascular mortality and recurrent MI. They also have higher rates of subsequent hospitalization for heart failure. It remains unclear whether outcome differences are driven by differing underlying pathophysiology or by differing rates of interventions.

Cardiovascular Outcomes and Surrogate Markers of Cardiovascular Disease

HIV infection may predispose to other cardiovascular complications beyond coronary heart disease. Stroke and peripheral arterial disease rates appear to be higher among HIV-infected patients compared with control populations, with similar underlying mechanism as ischemic coronary heart disease. Additionally, congestive heart failure, atrial fibrillation, and sudden cardiac death disproportionately affect HIV-infected patients. Whether ischemia-related cardiomyopathy and arrhythmias account for these findings remains unclear.

HIV-associated cardiovascular disease can also be demonstrated using surrogate markers of atherosclerosis including imaging studies. Carotid intima-medial thickness (cIMT) is a marker of subclinical atherosclerosis measured by ultrasound that is associated with cardiovascular events. HIV-infected patients generally have higher cIMT than non-HIV-infected patients. Additionally, cIMT progresses more rapidly among HIV-infected patients, notably at the carotid bifurcation. Coronary artery plaque burden, measured by computed tomography (CT), is greater among HIV-infected patients. This increased plaque burden is also more likely to be noncalcified, a characteristic associated with a higher likelihood of rupture. Imaging studies also show the heightened inflammation associated

with HIV. Positron emission tomography (PET) imaging shows that arterial, and in particular aortic, inflammation is elevated in HIV infection and associated with markers of monocyte and macrophage activation. Apart from imaging studies, HIV-infected patients demonstrate the downstream effects of cardiovascular risk factors through measurements of worsened flow-mediated dilation of the brachial artery, which is a proxy for endothelial function, and poorer measures of arterial elasticity.

Cardiovascular Risk Reduction in HIV

Optimal cardiovascular risk reduction in HIV infection involves aggressive management of traditional CHD risk factors as well as consideration of novel, HIV-specific risk reduction strategies. However, a major current challenge is the difficulty in accurate cardiovascular risk prediction. Current risk prediction models for the general population employ demographic and traditional CHD risk factors. These models designed for the general population have yet to be validated for use among HIV-infected patients. Additionally, methods of risk prediction which incorporate novel HIV-related risk factors such as ART use and markers of inflammation or immune activation have not been widely validated and have not been incorporated into clinical practice (Schambelan et al. 2008).

Regarding management of traditional CHD risk factors, smoking cessation may be one of the most important interventions given the disproportionate impact of smoking on the HIV-infected population. Recommended interventions include screening, counseling, participation in cessation groups, and adjunctive pharmacologic therapies and are based on recommendations for the general population. The cornerstone of dyslipidemia therapy is pharmacologic management with agents such as HMG co-A reductase inhibitors (statins) and fibrates. Statins may be less effective at LDL cholesterol reduction in the setting of HIV compared with the general population, but their anti-inflammatory properties may mitigate the effects of HIV-specific chronic inflammation. The indications for statin treatment in HIV have not been

established but are under active investigation. Vigilance is required given the interactions between selected statins and PIs through the cytochrome P450 pathway. New cholesterol guidelines released for the general population by the American College of Cardiology (ACC)/American Heart Association (AHA) in 2013 can be used to inform HIV practice until further HIV-specific recommendations become available. Blood pressure should be measured regularly and managed according to Joint National Committee (JNC 8) guidelines. Whether aspirin has a differing role for the primary and secondary prevention of CHD in HIV infection has yet to be elucidated; accordingly, its use should mirror that for the general population.

Apart from management of traditional risk factors, modification of chronic inflammation and immune activation is likely to be important as a preventive strategy. Initiation of antiretroviral therapy resulting in virologic suppression and immune reconstitution is a critical first step toward achieving these goals. Importantly, the net beneficial effects of antiretroviral therapy with concomitant virologic suppression are thought to outweigh any proatherogenic effects of individual antiretroviral medications. This shift in thinking has resulted in acceptance of the use of ART as a cardioprotective strategy, an approach reflected in the most recent HIV treatment guidelines. Given that inflammation and immune activation persist even after viral suppression, the role of additional immunomodulatory interventions will likely become important in minimizing CHD risk for HIV-infected patients even further (Aberg 2009).

Conclusion

HIV infection is associated with a wide range of cardiovascular complications. The early years of the HIV epidemic were characterized primarily by complications related to opportunistic infections and advanced immunosuppression. With the advent of ART and the prolonged life span of HIV-infected patients, CHD has emerged as the major cardiovascular complication, with presentation and sequelae that differ from those of the

general population. The pathogenesis of cardiovascular disease in HIV infection is distinct from that of the general population because of the unique contributions of ART, chronic inflammation, and immune activation. Treating HIV to achieve virologic suppression and aggressively controlling traditional risk factors should be employed to decrease cardiovascular risk among HIV populations. HIV-specific tailored prevention measures will likely help further diminish CHD risk among HIV-infected patients in the future.

cART and Supportive Care for HIV-Associated Malignancies

Ronald T. Mitsuyasu

UCLA Center for Clinical AIDS Research and Education (CARE Center), University of California, Los Angeles, Los Angeles, CA, USA

Definition

cART is an abbreviation for combined antiretroviral therapy and generally refers to a three- or four-drug combination regimen of antiretroviral medications, which is considered standard treatment for human immunodeficiency virus-1 (HIV-1) infection. Another name for cART is highly active antiretroviral therapy (HAART). This treatment is important for suppressing HIV-1 replication and has greatly increased the longevity of individuals with this infection. As part of the treatment of malignancies in HIV-infected patients, cART and other supportive measures such as antiemetics, hematopoietic growth factors, blood transfusions, prophylactic and therapeutic antibiotics, antidiarrheal medications, and psychosocial support for each individual undergoing the stressful therapy for these often life-threatening cancers have greatly enhanced both the efficacy and tolerability of these treatments and allowed patients to achieve remissions and/or cure of their cancers.

cART as Treatment for HIV and Cancer

Cancers have been a recognized as part of the acquired immune deficiency syndrome (AIDS)

since the initial recognition of this disease in 1981 (Hymes et al. 1981; Ziegler et al. 1982, 1984a). Initially reported mortality from Kaposi's sarcoma (KS) and non-Hodgkin's lymphoma (NHL), the two most common of these AIDS-associated malignancies (► [Cancers Related to HIV](#)), was extremely high, in the range of 40% at 2 years for KS and 80% at 1 year for NHL with what then was considered standard chemotherapy (Longo et al. 1984; Moss et al. 1984; Ziegler et al. 1984b). With the advent of combination antiretroviral therapy (cART), not only have HIV treatment outcomes improved but the ability to dose-intensify cancer treatment regimens has increased, allowing better control of cancer, fewer treatment-related serious adverse effects and complications, higher remission rates, more durable remissions, and longer survival. It has been reported that HIV-associated diffuse large B-cell lymphoma can be successfully treated with a regimen that involves HAART being temporarily stopped during therapy. However, there is a general consensus among most clinicians with expertise in this area that when possible, HIV should be controlled with HAART if possible during the treatment of HIV-related malignancies and other diagnosed cancers in patients with HIV/AIDS (Lim et al. 2005; Thiessard et al. 2000; Little et al. 2000). Single and multi-institutional studies have shown that HAART can be administered along with anticancer therapy as long as attention is paid to pharmacokinetic interactions and overlapping toxicities. The increasing occurrence of cancer as a major part of the HIV/AIDS epidemic and the recognition of cancer as a leading cause of death in HIV have led to a greater emphasis on initiating treatment with cART earlier and to continue its use when possible during management of patients who develop cancers during the course of their disease.

Drug Interactions Between cART and Chemotherapy

Of concern has been the potential for significant drug interactions between some of the currently used antiretroviral drugs (ARVs) and some

chemotherapeutic and other treatments for malignancies. Given the relatively small number of these patients and the need to get lifesaving ARVs out to the HIV-infected community as quickly as possible, with a few exceptions, little attention was focused on the interactions of cancer therapies with ARV, and few pharmacokinetic studies were undertaken early on in the AIDS epidemic to assess the degree and influence of these drug interactions on the outcome of patients with AIDS and cancers (Ratner et al. 2001). Some of these adverse drug interactions have been found empirically in the course of treating HIV-infected individuals with specific malignancies, such as the well-known enhanced myelosuppressive effects of many cytotoxic chemotherapy drugs with zidovudine and the serious increase in irinotecan gastrointestinal toxicities with certain protease inhibitors for HIV (Kaplan et al. 1997; Corona et al. 2005; Makinson et al. 2001). With the growing realization that cancer is now a growing problem in HIV, especially as the population of HIV-infected individuals ages and because of increased longevity in the setting of continued immunodeficiency, and with the ever-growing list of available new cancer treatment agents, it has become increasingly important that HIV-treating physicians and oncologists know and are able to make appropriate dosage adjustments for possible cancer therapy-ARV interactions and to avoid certain combinations of drugs which may lead to severely enhanced toxicities. Most clinical trial protocols for treatment with cytotoxic chemotherapies now require that patients not receive zidovudine when receiving myelosuppressive chemotherapy or will restrict the use of dideoxynucleosides or other drugs that may significantly induce peripheral neuropathy (PN) when using cancer therapies with high potential for PN. More recently the National Cancer Institute's (NCI) Clinical Therapy Evaluation Program (CTEP) has embarked on formally assessing the pharmacokinetic/pharmacodynamic (PK/PD) interactions of antiretroviral drugs with new investigational cancer agents in conjunction with the NCI-supported AIDS Malignancy Consortium (AMC). These phase I PK/PD studies will hopefully enable greater participation of

HIV-infected patients with cancers in general oncology clinical trials for various cancers, thus making the results of these phase II and III trials more widely applicable and avoiding the previous situation where HIV patients would be excluded from studies of new investigational cancer drugs, because of concerns about unknown and potentially harmful drug interactions with antiretroviral treatments.

Supportive Care for HIV Patients Receiving Cancer Treatments

Another important principle in the management of individuals with cancer and HIV is the need to provide adequate medical and logistical support for patients needing to receive therapy for their cancers. It is well known that patients with HIV, especially those with advanced HIV disease, e.g., those with lower CD4 counts or a history of prior opportunistic or other infectious diseases, generally have poorer marrow tolerance to the myelosuppressive effects of chemotherapy and, in some cases, radiotherapy as well. High rates of infections have been reported in trials of chemotherapy for HIV-associated lymphoma with regimens such as R-CHOP and R-EPOCH (Kaplan et al. 1997, 2005), which may be avoided to a large degree with the use of hematopoietic growth factors, such as granulocyte colony-stimulating factor (G-CSF) or granulocyte-macrophage colony-stimulating factor (GM-CSF), blood transfusions, and prophylactic antibiotics (Kaplan et al. 1994; Scadden et al. 1991; Barta et al. 2012; Sparano et al. 2010). In a lymphoma trial conducted by the AMC, the routine use of prophylactic antibiotics dramatically reduced the incidence of severe infections in patients receiving intensive chemotherapy (Sparano et al. 2010).

Neurologic complications of HIV also may confound the management of patients with HIV and cancers, as peripheral neuropathy is a common complication of HIV and a not infrequent side effect of some ARVs and several anticancer drugs (e.g., vinca alkaloids, cis-platinum, oxaliplatin, bortezomib, etc.). In addition,

progressive cognitive impairment due to progressive and long-term effects of HIV or to central nervous system (CNS) involvement with malignancy may impact the patient's ability to adhere to HIV, cancer treatments, and associated therapies for complications or side effects of these treatments.

The management of nausea, vomiting, pain, diarrhea, rashes, headaches, and other side effects of cancer and HIV therapies is critical and can be very effectively controlled with prophylactic treatments or mitigated post hoc with standard antiemetics, antidiarrheals, analgesics, etc. to allow patients to better tolerate and continue to receive important drug treatments.

As with anyone diagnosed with a life-threatening disease such as cancer, psychological support and the ability to listen to the patient's and their caregiver's concern are critical for the successful outcome of treatment. With the added burden of having HIV and the many financial, social, and logistical issues for providing the care that this engenders, it is particularly important to assure that a working support system is in place to assist the patient in maneuvering the healthcare system and getting the help they need to receive optimal care. In this regard, the concept of patient navigators (PNs) has received considerable attention as a means of facilitating patient access and their ability to navigate the complex medical and social-financial situation caused by diseases such as cancer and HIV. With the assistance of the Center to Reduce Cancer Health Disparities (CRCHD) within the NCI, the AMC has piloted and is investigating the usefulness of PNs as a means of improving access of HIV cancer patients to AMC clinical trials and for increasing the ability of individuals from racial/ethnic minorities and other underrepresented groups (such as women) to take part in these clinical trials and to maneuver the complexities of obtaining required diagnostic and therapeutic procedures and services for their malignancies. Understanding the special burdens faced by cancer patients with HIV, especially as it relates to obtaining needed social and psychiatric services to help deal with social ostracism and

isolation, lack of transportation, loss of insurance, unemployment, poverty, homelessness, drug use, under or poor nutritional state, and multiple comorbid diseases, is critical in allowing patients to fully benefit from the many recent advances in cancer diagnostics and therapy which have occurred in the past few decades. Unfortunately, faced with severe budget deficits, many state- and locally funded organizations and programs set up to provide social services, case managements, and other support services have had their funding dramatically reduced, making it more difficult for individuals to adhere to the strict treatment schedules required for some of the more complicated treatment regimens.

Cancer Screening in HIV

Early diagnosis and established prevention strategies for many cancers should also be considered in the routine management and follow-up of the HIV-infected individual. Age-appropriate American Cancer Society (ACS), NCI, and US Preventive Services Task Force (USPSTF) cancer screening guidelines should, as a minimum, be followed for screening HIV-infected individuals for cancer and/or precancerous lesions, as they would be for non-HIV-infected adults. In addition, routine monitoring for cervical and anal dysplasia and intervention for high-grade squamous intraepithelial lesions (SIL) have been recommended or are under evaluation to determine the best frequency for monitoring in HIV-infected patients, where the relative risk of cervical (► [Cervical Cancer](#)) and/or invasive anal cancer (► [Anal Cancer](#)) is higher than in the general population. Whether HIV patients would benefit or should be checked and monitored more closely or more frequently for certain AIDS-related cancers (ADC) or non-AIDS-related cancer (NADC) because of their higher risk of developing these malignancies remains to be determined. Future prospective studies will be needed to assess the efficacy and cost effectiveness of some of these routine screening procedures in HIV.

Conclusion

Significant advances in understanding and treating cancers have occurred in the past several years. Similarly, the ability to treat HIV and to provide a normal life expectancy to individuals with HIV infection has improved dramatically. Subsequently, malignancies in HIV are now emerging as a growing problem and will require greater vigilance on the part of the primary care providers to identify these cancers and a heightened awareness on the part of HIV physicians and oncologists about the many complications and special needs of individuals who have these diseases concurrently.

Case Management for Linkage

Christa L. Cook
University of Florida, College of Nursing,
Gainesville, FL, USA

Definition

Case Management

Case management is a collaborative process that includes client identification, outreach, engagement, assessment, planning, coordination,

linkage, monitoring, reassessment, and discharge planning to meet the health and social service needs of clients.

Linkage to HIV Care

Conceptually, HIV care is challenging to define and can best be illustrated along a continuum that ranges from people not aware of their status to people who are fully engaged in care and have achieved viral suppression (Gardner et al. 2011). Linkage to HIV care represents a point along this continuum after a person is diagnosed with HIV and initially seeks care from an HIV provider (Mugavero et al. 2013).

Main Text

Background

In the United States, over 1.2 million people currently live with human immunodeficiency virus (HIV), and approximately 1 in 6 of those infected is not aware they have the virus (Centers for Disease Control 2016). While the incidence of infection has remained relatively stable, disparities exist among racial, ethnic, and sexual minorities, and some regions, such as the Southeast, have been disproportionately impacted (Centers for Disease Control 2016).

Treatment advances with antiretroviral therapy (ART) have contributed to both population and individual benefits. At the individual level, those who are in care and receiving ART are more likely to experience decreased mortality, decreased viral load, and decreased morbidity and have life expectancies now equal to that of the general population (Quinn et al. 2000; Anglemyer et al. 2013; Loutfy et al. 2013; Samji et al. 2013). At the population level, people with HIV who take therapeutic levels of ART are less likely to transmit the virus compared with those who delay ART (Anglemyer et al. 2013). They are also more likely to abstain from having unprotected sex with someone who is HIV negative or status in unknown (Metsch et al. 2008); thus, getting people into HIV care is a public health priority for preventing transmission of the virus.

With research supporting the individual and population benefits of being in HIV care, there has been increased focus on helping people become aware of their HIV status through expanded testing efforts and getting them into treatment as soon as possible (test and treat). However, just because someone knows their HIV status does not mean they will seek care, and approximately 25–31% of persons with HIV/AIDS fail to seek treatment after initial diagnosis (Gardner et al. 2011).

There are numerous barriers to linkage to HIV care, and these can be organized by social ecological levels and may include individual (mental health, substance use, stigma, housing, transportation, and access to care), relationships (partner, family, friends, providers), community (poverty, social norms, stigma), healthcare system (appointment and service availability), and policy (funding, quality, service coordination, workforce) (Mugavero et al. 2013). Many people with HIV each face multiple and unique combinations of barriers necessitating a patient-centered approach to linkage to care.

Linkage to care has been identified as a priority by the Presidential National HIV/AIDS Strategy (NHAS), the Centers for Disease Control (CDC), and the Health Resources and Services Administration (HRSA). Several interventions exist that help facilitate linkage to HIV care after someone receives an HIV diagnosis.

Case Management Interventions

Case management can be an integral component for the treatment and management of acute and chronic disease, and, according to the International Advisory Panel on AIDS Care guidelines, it is a recommended intervention to increase linkage to HIV care (IAPAC Guidelines 2015). There are many models of case management (i.e., broker, strengths, assertive community treatment, clinical/rehabilitative), and it is practiced among a variety of disciplines (nursing, social work, rehabilitation) and in a variety of settings (hospital, community, insurance, and private industry). The Health Resources and Services Administration HIV/AIDS Bureau (HAB) outlines the concepts of HIV medical case

management as being client centered, focused on linkages, coordination, and continuity of care and services (Health Resources and Services Administration 2008). Six core functions serve as the foundation for HIV case management practice in federally funded programs including client identification, outreach and engagement, assessment, planning, coordination and linkage, monitoring and reassessment, and discharge.

The most well-known case management intervention for linking newly diagnosed people to HIV care is Antiretroviral Treatment and Access to Services (ARTAS). The ARTAS intervention is one of the few interventions that has been shown effective in a randomized controlled trial to increase the percentage of people newly diagnosed with HIV linked to care (Gardner et al. 2005) and further tested for effectiveness in community settings (Craw et al. 2010). ARTAS is grounded in a strength-based case management approach and typically consists of a limited number of sessions with a linkage coordinator. During the sessions, the linkage coordinator assesses the client's strengths and, with input from the client, identifies goals and develops a structured plan to meet those goals. Often linkage coordinators are partners with community-based organizations, support groups, and other providers to aid in referrals to formal and informal services that may be needed by the client to promote a successful transition into care. Once the client engages in HIV care or the limited number of sessions have been used, the linkage coordinator's relationship with the client is terminated. Implementing this intervention in sites with co-located care yielded the best success in linking to HIV care (Craw et al. 2010).

Navigation and Outreach Models

Other models of care utilizing case management approaches have been evaluated in the Special Projects of National Significance (SPNS). System navigation, an intervention modality that is based on a social work model, assists patients to overcome barriers (structural, financial, and personal), improve mediators (efficacy of treatment, quality of treatment, adherence), and improve outcomes (morbidity, mortality, well-being, and functioning)

(Bradford et al. 2007). If delivered by peers with HIV, this type of model requires assistance from trained personnel to help patients navigate through the system and treatment, but peers are not always adequately trained for the challenging process (Bradford et al. 2007) and the efficacy of navigation programs is not well known (Koester et al. 2014).

Recommendations for Successful Linkage to Care Programs

There are several characteristics, core components, and operational strategies for successful linkage to HIV care. Successful linkage programs are low cost, intensive, time limited, and flexible; however, the interventions specifically focus on linkage to care instead of multiple points in the HIV care continuum (Liau et al. 2013; Gilman et al. 2012). They will utilize dedicated linkage staff, employ active referral strategies, maintain a patient-centered approach, and strive for cultural concordance between staff and the population served (Gilman et al. 2012). From the systems perspective, these programs will develop and adhere to protocols for the linkage process, select staff that are appropriately trained and effective in working with the population, seek to coordinate and integrate services, and strive to maintain consistent funding for sustainability.

Limitations of Current Intervention Strategies

Geographic area of residence, funding, and effectiveness with certain populations present limitations to current case management intervention strategies. While the interventions enhancing linkage to care have shown promise in large metropolitan areas, implementation in smaller targeted metropolitan/rural areas has met with challenges in funding and feasibility. National funding shortages for HIV care challenge implementation of linkage to care strategies that require additional personnel support (Mugavero et al. 2011). Finally, several population subgroups have not responded as well to case management interventions. In the ARTAS studies, people with mental illness or substance use problems did not respond as well to the intervention (Gardner et al. 2009) although referring to a case manager soon

after diagnosis is associated with improved health outcomes (Kenya et al. 2014). In the prison population, an intensive, strength-based case management intervention designed to help the transition into HIV care was no more effective than the standard of care, which consisted of intensive dedicated pre-discharge planning by a prison nurse (Wohl et al. 2011). However, patient navigation could be a potential approach to improve linkage in this population (Koester et al. 2014). To optimally engage people in care, further research is needed in these hard to engage populations.

Conclusion

It is essential that we develop strategies to prioritize and target interventions to promote linking to HIV care in a timely manner that are effective, feasible, and efficiently use available resources. Developing strong partnerships within communities may help with implementation of case management interventions such as ARTAS. The successful linkage to care case management interventions presented in this section all include assessment, referral, navigation, and the provision of social support. Linkage to HIV care remains an important concern among healthcare providers and public health officials in both prevention and care goals. In the design of interventions for linkage to HIV care, it is important that the intervention include (1) coordination between public health agency and medical providers, (2) continuity of care from the time of diagnosis until the person is situated in HIV care, and (3) advocacy for the client to ensure appropriate services are obtained.

Cell-Intrinsic Immunity

Hila Elinav¹ and Richard E. Sutton²

¹Department of Clinical Microbiology and Infectious Diseases, Hadassah Hebrew University Medical Center, Jerusalem, Israel

²Section of Infectious Diseases, Yale University, New-Haven, CT, USA

Definition

Eukaryotes have been under attack of retroviruses for millions of years; thus different mechanisms evolved to protect cells immediately after infection from dissemination. These mechanisms include a diverse array of proteins that are constitutively expressed in cells, but the expression of many can be augmented at the first signs of evasion. The potent enzymatic activities that can abort or inhibit to some extent viral replication are the component of the cellular intrinsic immunity. This system confers the first defense line of the organism and also signals for the innate and adaptive immune system to mobilize their effectors.

Introduction

Human immunodeficiency type 1 (HIV) is a lentivirus that infects and replicates in immune cells that express the CD4 cell surface receptor and a chemokine coreceptor, namely, CD4⁺ T helper, macrophages, and likely dendritic cell subsets. Although the host employs multiple cell-intrinsic restriction mechanisms against HIV, none is effective enough to completely block viral replication,

whereas the virus has evolved a number of strategies to effectively circumvent most if not all of these mechanisms. Thus, despite the activation of cell-intrinsic immunity and its numerous effectors, HIV continues to replicate in these cells, resulting in high-level viremia in most infected individuals and eventual exhaustion and depletion of the CD4⁺ T-cell population. In the absence of antiretroviral medications, over time HIV⁺ individuals will invariably progress to AIDS and death.

Antiretroviral therapy (ART) includes a combination of medications that typically target different steps in HIV life cycle: virus binding to host cells, cell fusion, reverse transcription, genomic integration, and viral particle maturation. Unfortunately, although ART can halt and often reverse the immunological failure induced by HIV, it does not result in cure or virus eradication and necessitates lifelong treatment. Understanding the host restriction factors and the counteracting viral evasion mechanisms may provide insight into novel approaches to manipulating the immune system in controlling viral replication and combating this devastating disease.

The expression of many, if not most, of the recently identified intracellular restriction factors, including IFITMs, Trim5 α , APOBEC3G, SAMHD1, MX2, Schlafen-11, KAP1, HERC5, and Tetherin, is induced by type I interferons. We will first focus on the interferon response induced by HIV and subsequently we will review the scientific data that have been accumulated for a subset of the restriction factors. It should be emphasized that thus far there is no convincing data *in vivo* in humans that any of these restriction factors plays a critical role in controlling the replication of HIV.

The Type I Interferon Response Suppresses HIV Replication

As the role of interferons in the antiviral response was known since the early 1960s, the effect of interferon upon HIV replication was investigated soon after the virus was identified as the causative agent of AIDS. The suppression of HIV

replication in human PBMCs (peripheral blood mononuclear cells), measured by a reduction in reverse transcriptase activity of 50–75%, was demonstrated to be due to interferon- α and interferon- β , but not interferon- γ , by Yamamoto et al. in 1986. Subsequent work by Wong showed that pretreatment of cells with either interferon- γ or TNF- β reduced susceptibility to HIV infection and inhibited the production of HIV mRNA, CA protein, Capsid, and infectious virions (Wong et al. 1988). The observed effects of both host factors were synergistic, suggesting independent mechanisms were at play.

Evidence of HIV suppression by interferon in the clinic accumulated slowly, originating from observations made during treatment of HIV/HBV co infected patients and also from treatment of patients with advanced HIV and Kaposi's sarcoma (KS), in which circulating levels of CA were reduced by interferon. These encouraging results led to the combined use of interferon and zidovudine for the treatment of AIDS patients suffering from KS (Kovacs et al. 1989).

The effectiveness of interferon- α therapy for asymptomatic HIV⁺ adults was tested in a 12-week randomized, placebo-controlled clinical trial. Significant differences were found between the interferon- α -treated and control group with respect to positivity of HIV cultures obtained from peripheral blood (59% vs. 87%), respectively stabilization of peripheral CD4⁺ T-cell counts, and slowing the progression to AIDS. These promising effects, however, were accompanied by a high dropout rate of 35% in the interferon-treated arm, due to toxicity and adverse events (Lane et al. 1990). Other early studies evaluated the effects of interferon- α , β , and γ upon HIV in man, most commonly combining the interferon with early antiretroviral medications that were in different stages of development. The necessity of parenteral administration, the high incidence of adverse events, the questionable additive effects in comparison to antiretroviral drugs alone, and the high efficacy of combination antiretroviral medications left interferon out of the armamentarium and off the shelves, excluding it as a major treatment option by the late 1990s. Some insight into dual effects of IFN in humans

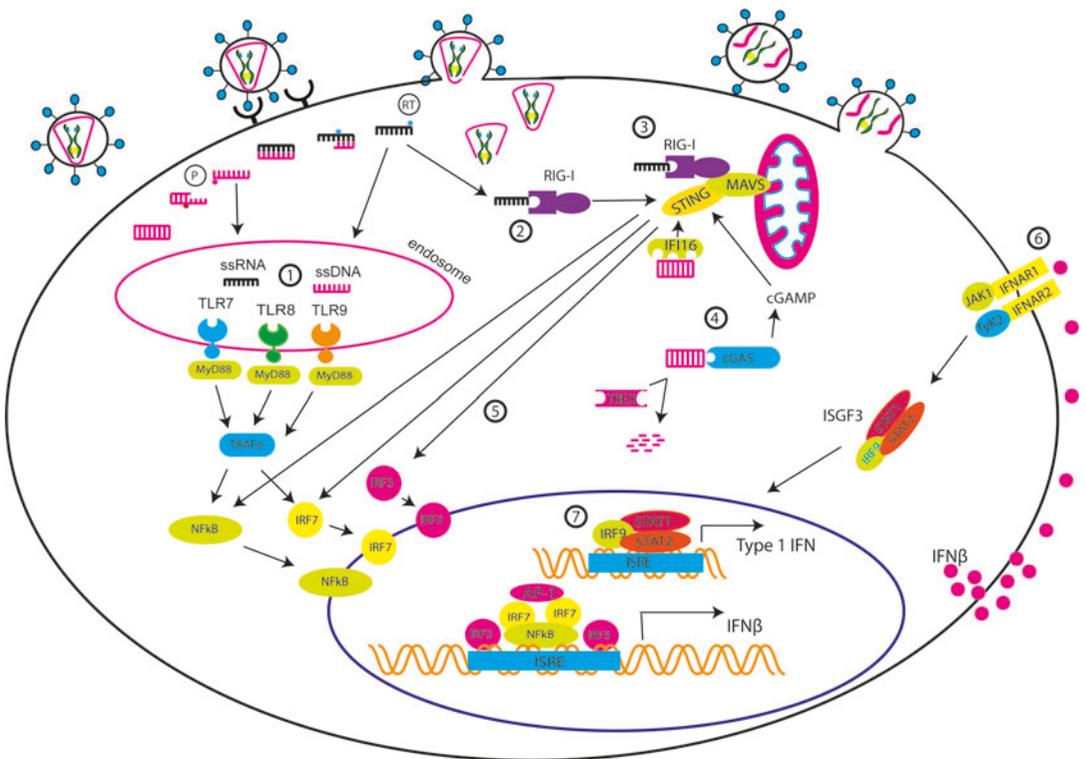

can be gleaned from recent experiments in rhesus macaques that demonstrated the effects of IFN upon resistance to SIV infection and also disease progression. Blockade of the IFN-I receptor reduced antiviral gene expression and accelerated CD4 T-cell depletion, resulting in rapid progression to simian AIDS. Although IFN- α 2a administration induced transient resistance to SIV infection, surprisingly it also led to the same unfortunate accelerated disease progression as a result of induction of a negative feedback mechanism mediated by FOXO3a (Sandler et al. 2014). The hope of identifying antiviral host factors and how the virus counteracts each one was the driving force for further exploring the interferon-

induced anti-HIV response. If precise mechanisms could be uncovered as to how the interferon-induced host response is evaded, that could be the impetus driving the development of novel antiviral therapeutics.

Detection of HIV Infection by the Host

See (Fig. 1)

The cascade of events that results in IFN production is complex and is highly regulated by both positive and negative feedback mechanisms. Many of the components and regulators of the cascade are currently known, but it is likely that many others will be identified in the future. The initiation and activation of this signaling pathway

Cell-Intrinsic Immunity, Fig. 1 Virus detection by intracellular receptors and induction of type 1 IFN. (1) Viral ssRNA and ssDNA are detected in the endosome by TLRs and induce IRF3, IRF7, and NFkB activation via MyD88 and TRAF6. (2) After RIG-I detects ssRNA, it relocates to the mitochondrion where it interacts with MAVS (3). (4) dsDNA is detected by cGAS and IFI16, activating STING. TREX1 degrades cytosolic DNA, inhibiting STING activation. (5) Activation of MAVS and STING results in NFkB signaling and formation of the enhanceosome

(composed of NFkB, IRF3, IRF7, and AP-1), which induces transcription of IFN- β . (6) IFN- β is secreted from the cell and binds to the IFN receptor in both a paracrine and autocrine manner, thus activating the IFN pathway. JAK/STAT activation by receptor binding results in the formation of ISGF3 (composed of phosphorylated STAT1 and IRF9), which binds to ISRE (IFN-stimulated responsive element), and stimulates transcription of type 1 IFN and hundreds of ISGs (including those shown in Fig. 1). RT reverse transcriptase, P DNA polymerase

first requires identifying and discriminating viral components called PAMPs (pathogen-associated molecular patterns) as nonself by PRRs (pattern recognition receptors). When they accumulate in the cytoplasm, single- and double-stranded RNA, uncapped RNA, and various forms of DNA are all PAMPs that induce immune signaling. The major classes of cellular molecules relevant to HIV that serve as PRRs include TLRs (toll-like receptors), RLRs (RIG-I-like receptors), or retinoic acid inducible gene I-like receptor NLRs (NOD-like receptors), or nucleotide binding oligomerization domain receptor and DNA sensors. Each of these PRR classes activates different adaptor proteins and pathways to induce the production and release of interferon, which in turn acts in a paracrine and autocrine manner to induce the expression of hundreds of interferon-stimulated genes or ISGs. These ISGs then act by various mechanisms to limit or curtail viral replication, including that of HIV (Blanco-Melo et al. 2012; Malim and Bieniasz 2012).

The TLRs, or toll-like receptors, are transmembrane proteins located at the plasma or endosomal membrane and play a major role in pathogen sensing and signal transduction. The TLRs that act as sensors for the presence of HIV in the cell are TLR7 sensing (ssRNA), TLR9 recognizing (ssDNA), and to lesser extent TLR8 identifying (ssRNA) (Buitendijk et al. 2014). In the case of HIV, these various forms of nucleic acids may be released from dead or dying cells. The role of TLR3 in HIV recognition, which is a major intracellular viral sensor that recognizes dsRNA and possibly short loop hairpin RNAs, is not established. All these three TLRs are expressed at the endosomal membrane, and they utilize TIRAP/MyD88 to activate the NF κ B pathway (Chakrabarti and Simon 2010; Rustagi and Gale 2014).

The RLRs, RIG-I-like receptors, are a family of cytosolic PRRs that include RIG-I, MDA5, and LGP2 which are DexD/H box RNA helicases that bind RNA, hydrolyze ATP, and scan RNA substrates for recognition motifs. RIG-I and MDA5 both contain a caspase activation and recruitment domain (CARD) that is essential for their antiviral activity. LGP2, which lacks this domain, is a

negative regulator of RIG-I and MDA5. RIG-I and MDA5 bind to different PAMPs, but after binding RNA, RIG-I and MDA5 relocate to the mitochondrial-associated endoplasmic reticulum membrane. There they interact with MAVS (mitochondrial antiviral signaling protein) and assemble into a protein complex together with STING (stimulator of interferon genes) to activate NF κ B, IRF3, and IRF7. Despite numerous reports describing the inhibitory effects of type I IFN (including subtypes of IFN- α , IFN- β , and IFN- ω) on retroviral replication, there is little evidence that HIV RNA triggers RLR signaling. RIG-I, but not MDA5, may detect incoming HIV RNA after particle uncoating in the cytosol, which results in the activation of the RIG-I pathway and possibly the suppression HIV replication (Berg 2012).

The NLR proteins (NOD-like receptors) are another diverse group of cytosolic PRRs, the prototypes of which are NOD1 and NOD2. These PRRs can identify both bacterial products and viral ssRNA and activate NF κ B and IRF3. Although the NLRs could potentially play a role in the anti-HIV cellular response, this has yet to be shown.

The DNA sensors are a very heterogeneous group; two of the members are TLR-9 and RIG-I, mentioned above. Other DNA sensors include IFI16, DNA-dependent activator of IRFs (DAI), DDX41, LRRFIP1, Ku70, and cGAS. Due to the diversity of this group of sensors, there is no characteristic mechanism and no common pathway that is triggered upon the activation of these proteins. Thus, while DAI activates IRF3, RIG-I signals through MAVS, DDX41, and IFI16 stimulate STING for the activation of IRF3 and NF κ B. LRRFIP1 binds to and activates β -catenin, which then binds to the C-terminus of IRF3, and Ku70 signals by activating the promoter of IFN- λ 1 after binding to cytosolic DNA. The ability of IFI16 to restrict HIV replication, in addition to its role as a DNA sensor, was shown recently in macrophages but not in T cells, and there is limited evidence that it is counteracted by Vpr (Jakobsen et al. 2013). cGAS was demonstrated to sense HIV DNA after reverse transcription and then synthesize cGAMP (cyclic guanosine

monophosphate-adenosine monophosphate) in order to activate STING and cause IFN- β production (Gao et al. 2013). Surprisingly, Ku70 was shown to enhance HIV replication, due to the protection of HIV integrase from proteasomal degradation (Rustagi and Gale 2014; Zheng et al. 2011).

Recent work has shown that HIV not only uses viral proteins to circumvent or inactivate the IFN-induced restriction factors but also cellular proteins. For example, HIV recruits cyclophilin A and possibly CPSF6 to camouflage and escape detection by PRRs (viz., TRIM5 α) (Rasaiyaah et al. 2013).

Transcription of Type I IFN and Subsequent Genes

As described above, sensing and identifying the various components of HIV by multiple PRRs results in elevated levels of phosphorylated IRF3, IRF7, and NF κ B, all of which are transcriptional activators of IFN- β . The assembled complex of proteins, which includes NF κ B (composed of subunits p50 and p65/RelA), an IRF3 dimer, an IRF7 dimer, and AP-1 (composed of subunits ATF-2 and c-Jun), is termed an enhanceosome. This complex binds to DNA promoters and other sequences that contain an ISRE (IFN-stimulated responsive element) to facilitate the transcription of IFN- β . IFN- β augments the transcription of IRF7 and thus further boosts its own transcription in a feed-forward manner. Although even a partial complex can enhance transcription, the fully assembled enhanceosome induces robust and rapid transcription of IFN- β and different isoforms of IFN- α that establish intrinsic cellular anti-HIV resistance. The main effect of IFN- γ upon HIV infection, on the other hand, is mediating NK and CD8 $^+$ T-cell activity against HIV-infected CD4 $^+$ T cells and macrophages, and it does not play a role in the intracellular restriction of HIV.

Type I IFN induces expression of multiple genes at the transcriptional level, some of which are specialized components of the conventional innate immune system that inhibits HIV replication at different levels of the HIV life cycle. To achieve this, the IFN signal transduction pathway

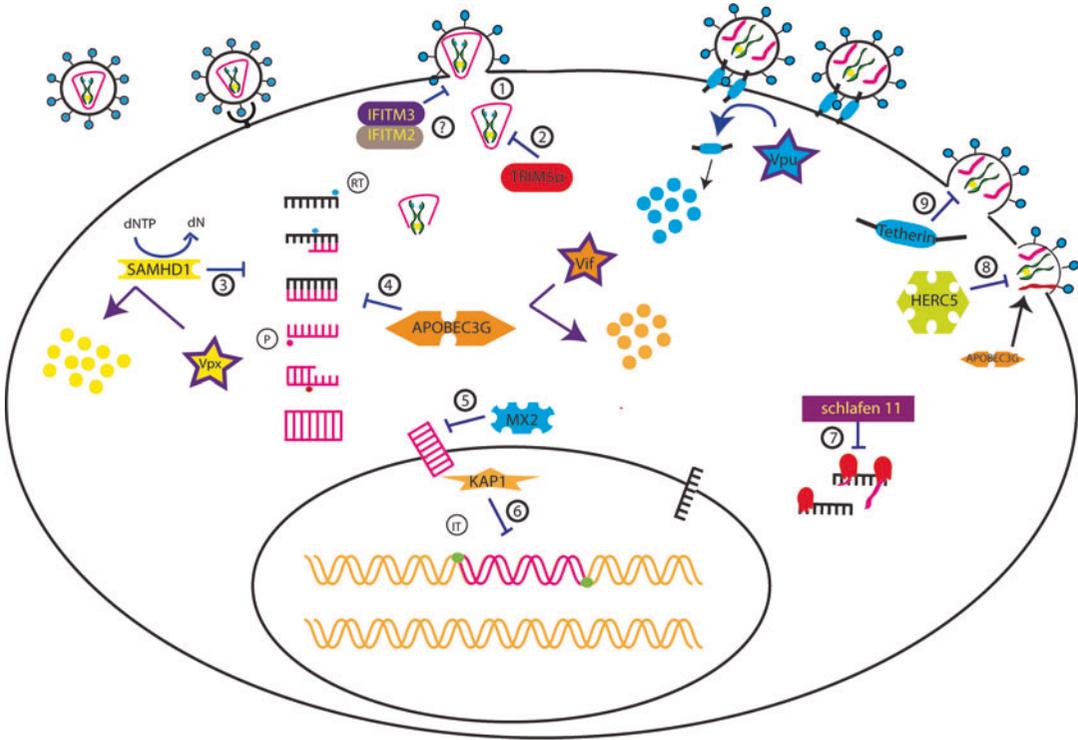

must be activated. IFN- α /IFN- β binding to IFNAR, composed of the two subunits IFNAR1 and IFNAR2, stimulates the JAK1-STAT pathway. This leads to the assembly of the ISGF3 complex (IFN-stimulated gene factor 3), which is composed of STAT1-STAT2 dimers and IRF9. ISGF3 binds to the ISREs located in the promoters of hundreds of ISGs in order to positively regulate their expression. Numerous ISGs have already been thoroughly investigated, and as might be expected, a substantial number of them can inhibit HIV replication, although most of them do not exclusively block HIV. As additional inhibitory factors become uncovered, it appears that almost every discrete step in the viral life cycle is targeted, with some of these factors counteracted by the various accessory proteins encoded by the virus. In the next section, some of these restriction factors that are induced by IFN and how they inhibit each step of HIV replication will be reviewed.

Intracellular Anti-HIV restriction factors

See (Fig. 2)

Virus-Cellular Fusion: IFITM1, IFITM2, and IFITM3

The interferon-inducible transmembrane proteins have been shown to restrict the replication of multiple viruses. This family of approximately 15 kd proteins was reidentified using a genome-wide RNA interference (RNAi) screen of influenza A (IAV) replication. This family of proteins was found to block very early stages of IAV and JSRV (Jaagsiekte sheep retrovirus) replication by somehow inhibiting virus-cell fusion (Lu et al. 2011). IFITM2 and IFITM3 were identified as HIV restriction factors in a large-scale antiviral ISG screen, but the inhibitory effect was fairly minimal (Schoggings et al. 2011). Although the precise resistance mechanism is not known, it has been suggested that the IFITMs bind to double-stranded viral RNAs such as RRE and TAR and interfere with viral protein expression (Chutiwitoonchai et al. 2013).

Cell-Intrinsic Immunity, Fig. 2 Inhibition of HIV replication by intracellular factors. (1) IFITM2 and IFITM3 inhibit virus particle-cell membrane fusion; ? indicates this is controversial. (2) TRIM5 α accelerates uncoating and likely signals as well. (3) SAMHD1 enzymatically depletes dNTPs, thus blocking reverse transcription. SAMHD1 is targeted by SIV/HIV-2 Vpx for ubiquitination and proteasome-mediated degradation. (4) APOBEC3G (and others) inhibit reverse transcription by deaminating single-stranded DNA, causing mutations and virus catastrophe. APOBEC3s are degraded by Vif, also via the proteasome. In general, APOBECs are incorporated into virus particles in the producer cell (shown) but act in the

target cell (also shown). (5) Perinuclear MX2 interferes with viral pre-integration complex transport into the nucleus in an unknown manner. (6) KAP1 induces integrase deacetylation and reduces integration efficiency. (7) Schlafen 11 specifically inhibits viral mRNA translation. (8) HERC5 affects Gag assembly. (9) Tetherin blocks fully mature virus from detaching from the cell. Tetherin is removed from the cell surface by Vpu in order to enhance viral replication. Tetherin also signals, similar to TRIM5 α . Here, viral RNA is indicated in black, DNA pink, ribosomes red, cellular DNA orange. RT reverse transcriptase, P DNA polymerase, IT integrase

Capsid Dissociation: TRIM5 α

A decade ago, TRIM5 α , a member of the TRIM family that contains a carboxy-terminal B30.2 (SPRY) domain, was shown to restrict HIV replication in old-world monkey cells (rhesus macaques and owl monkeys). While rhesus macaque TRIM5 α markedly inhibited HIV replication, the effect upon SIV was less pronounced. Human TRIM5 α has minimal activity against HIV due to an amino acid change in the SPRY domain. Although TRIM5 α is thought to directly interact with CA to induce premature disruption of the CA multimeric structure and block reverse

transcription and at the same time induce intracellular signaling, its exact mechanism of action is not yet known. Certainly, a major role of TRIM5 α , like other restriction factors, is to prevent cross-species retroviral transmission.

Reverse Transcription: APOBEC3G

The first HIV restriction factor identified (Sheehy et al. 2002) is a cellular protein that is incorporated into virions and deaminates cDNA after first-strand reverse transcription, causing G to A mutations in the sense HIV genome and viral catastrophe (Harris et al. 2003). Its activity is

inhibited by the viral protein Vif. This restriction factor is reviewed elsewhere and will not be covered further here.

Reverse Transcription: SAMHD1

SAMHD1 was first identified as a protein induced by IFN- γ in dendritic cells. Its role in cellular immunity was further investigated as it was found that specific, loss-of-function mutations in SAMHD1 can result in Aicardi-Goutières syndrome (AGS). The phenotype of AGS is congenital chronic encephalopathy and lupus-like phenomena, accompanied by high levels of IFN- α . In some ways AGS resembles a congenital viral infection. AGS can result from mutations in TREX1, RNASEH2A, RNASEH2B, RNASE2C, ADAR1, or SAMHD1: the consequences of these mutations are high levels of cytosolic DNA. Thus, it was postulated that SAMHD1, along with the other proteins, are negative regulators of the innate immune system, offering some protection against autoimmunity.

The SAMHD1 gene is located on chromosome 20 and encodes a 626 amino acid protein that is composed of two main motifs – the SAM (sterile alpha motif) and the HD domain (an amino acid doublet of divalent cation-coordinating histidine and aspartic acid residues). SAM likely functions as a protein-protein interacting domain, whereas the HD domain is a potent dGTP-stimulated triphosphohydrolase, which converts deoxynucleoside triphosphates to the constituent deoxynucleoside and inorganic triphosphate. Data to suggest that SAMHD1 is also a nuclease are not yet convincing and have been refuted.

SAMHD1 is highly expressed in dendritic cells, moderately in MDM (monocyte-derived macrophages) and resting T cells, and at low levels in activated T cells. Because of its enzymatic activity, there is an inverse correlation between the amount of SAMHD1 and the level of dNTPs. In terminally differentiated MDM, dNTP levels are 20–40 nM, 1% of the levels in activated CD4⁺ T cells (2–4 μ M). These low levels of dNTPs impede reverse transcription.

Lahouassa et al. demonstrated using knock-down assays and overexpression studies in MDM that SAMHD1 regulates the intracellular dNTP pool and that the reduction of the dNTPs

below the K_m (Michaelis coefficient) of HIV RT (reverse transcriptase) inhibits viral replication in these nonpermissive cells (Lahouassa et al. 2012). In permissive cells, such as activated T cells, despite the expression of SAMHD1, high levels of dNTPs allow reverse transcription to progress. This may be due to posttranslational regulation of SAMHD1's enzymatic activity. Both the teams of Lahouassa and Hrecka (Hrecka et al. 2011) showed that Vpx, an accessory protein encoded by HIV-2 and some SIVs (simian immunodeficiency viruses), counteracts SAMHD1. Vpx targets SAMHD1 for proteasome-mediated degradation via CRL4^{DCAF11} E3 ubiquitin ligase, thus increasing dNTP pools and enabling these viruses to replicate in monocytic and dendritic cells. Why doesn't HIV-1 encode a homologue of Vpx? Perhaps it is because infecting dendritic cells would stimulate the PRRs described above, thus initiating an antiviral response. Since dendritic cells express high levels of SAMHD1 and are largely resistant to HIV infection, the triggering of an antiviral innate immune response is largely avoided. Evidence supporting this hypothesis is the milder clinical course of individuals infected with HIV-2, in comparison to those infected with HIV-1. Of course that begs the question as to why Vpx evolved in the SIV lineage in the first place, a conundrum still under active investigation. TREX, another host protein that when mutated clinically manifests as AGS similarly to SAMHD1, is an example of a host protein that facilitates HIV replication indirectly by degrading cytosolic HIV cDNA (which of course should be inhibitory to the virus). The nuclease activity of TREX prevents the stimulation and the production of INF- β since the cytosolic DNA sensors are not activated. Thus, knockdown of TREX mRNA results in cytosolic DNA sensing, high levels of IFN- β , and eventual suppression of viral replication. The physiological role of TREX in the HIV replicative cycle is still an area of active investigation. TREX, in contrast to SAMHD1 and others, is not considered a restriction factor since it does not directly inhibit HIV replication, there is no evidence of positive selection of the gene, and no HIV accessory gene counteracts TREX.

Nuclear Transport: MX2

MX2 is a recently discovered intracellular HIV restriction factor. It is closely related to human MX1 (63% amino acid sequence identity), which inhibits a variety of RNA and DNA viruses, including IAV, La Crosse encephalitis virus, and hepatitis B virus. MX2 does not inhibit influenza virus, and MX1 has no effect upon HIV. The role of MX2 in HIV restriction was first identified by Kane et al. and Goujon et al. simultaneously in 2013 (Goujon et al. 2013; Kane et al. 2013).

Both groups used high-throughput screening to identify factors whose levels of induction by IFN correlated closely to the levels of inhibition of HIV infection observed in monocytoid cell lines. Kane et al. used microarrays to quantify mRNA transcripts, whereas Goujon et al. performed transcriptional profiling of RNA isolated from 15 different cell lines. MX2 was the only factor with validated inhibitory effect upon HIV titers. Although the mechanism of inhibition is not yet established, both groups showed that viral cDNA levels were not reduced in the presence of MX2, whereas levels of 2-LTR circles were decreased. This suggests that MX2 blocks nuclear import of the pre-integration complex (PIC) or causes a decrease in PIC stability. This is consistent with the perinuclear localization of MX2. Mutation of CA amino residues that are important for interaction with host proteins such as cyclophilin A, CPFS6, NUP358, or NUP153 abrogated or reduced the effects of MX2. The observation that modifying CA can modulate MX2 susceptibility or escape suggests that the CA is a specific target of MX2, which remains to be fully explored. Given the inner nuclear envelope localization of Vpr in infected cells and its potential role in HIV nuclear entry in macrophages, it is intriguing to speculate that Vpr could counteract this host gene.

Integration: KAP1

KAP1 was previously known as a transcription corepressor which interacts with HDAC, SETDB1, or HP-1. As a TRIM protein family member, it was also known to restrict murine

leukemia virus. KAP1 was identified by using the yeast two-hybrid assay system as an integrase (IN)-interacting protein (Allouch et al. 2011). KAP1 overexpression and knockdown experiments were consistent with the role of KAP1 as a restriction factor and mechanistic investigations revealed that by binding to acetylated integrase, KAP1 induces HDAC1 complex formation, leading to integrase deacetylation and reduced integration efficiency.

Translation: Schlafen 11

The SLFN family includes six human proteins that are induced by IFN- β , and SLFN5 and SLFN11 are the most prominent family members.

Li et al. investigated the effect of knockdown and overexpression of SLFN11 and demonstrated that this protein blocked HIV replication (Li et al. 2012). SLFN selectively decreased viral protein production without any reduction in viral RNA levels, consistent with inhibition of mRNA translation. Plasmid reporter constructs, encoding HIV Gag open reading frame using the virally preferred codons (Gag^{vir}, which has low guanine and cytosine content, and in which adenine/uracil are preferred in third position) or human-preferred codons (Gag^{opt}), were used to investigate the role of codon usage in the inhibition induced by SLFN11. SLFN11 strongly affected expression of Gag^{vir} but had little effect on Gag^{opt} expression. Using a tRNA array, the investigators demonstrated that HIV triggered substantial changes in tRNA concentrations in SLFN11-knockdown cells, and this effect was abrogated by SLFN11. Further work will help clarify how SLFN11 counteracts alterations in tRNA levels induced by HIV.

Gag Assembly: HERC5

The HERC5 gene is located on chromosome 4 and encodes a 1,024 amino acid protein. HERC5 is ubiquitously expressed, with highest levels of expression within the testis. HERC5 is a ligase that targets newly synthesized proteins for ISG15 conjugation and facilitates many cellular pathways. Woods et al. showed that overexpression

of HERC5 induced a fourfold decrease in HIV production in 293T cells and HERC5 knockdown doubled viral production (Woods et al. 2011). By transmission electron microscopy, it was shown that HERC5 blocks an early step of HIV-1 particle assembly at the plasma membrane. HERC5 and Gag proteins were found to associate with each other in vitro and to co-localize within cells. These interactions correlated with ISG15 modification of Gag. As expression of HERC5 is induced by IFN, HERC5 and ISG15 levels are increased in viremic patients, both in lymphatic tissue and in monocytes. Further work should help elucidate whether HERC5 plays a critical restrictive role in HIV replication.

Budding: Tetherin

This protein was identified as a result of a long search for the target of viral accessory protein Vpu (Neil et al. 2008). As its name implies, this IFN-induced transmembrane host protein anchors and traps virions extracellularly, thus blocking the release of nascent, fully mature viral particles from the cell membrane. Tetherin is also known to signal through the NFkB pathway. This restriction factor is discussed at length elsewhere in this series.

Conclusions

Taken together, the multifaceted innate immune response to HIV infection of cells may be well orchestrated but certainly appears somewhat chaotic, with numerous contributing host factors and multiple feedback mechanisms, with intersecting and overlapping pathways. The primary role of this system is to rapidly respond to exogenous pathogens, as the adaptive immune system begins to react, thus limiting microbial and viral dissemination and preventing catastrophic consequences to the infected organism. The innate immune system thus acts as a gatekeeper mechanism that controls the damage inflicted by pathogen invasion at its earliest stages. As an integral part of the innate immune response, PRRs identify microbial and viral

PAMPs and elicit a robust cellular response, as well as instruct the more specific yet slower adaptive cellular and humoral immune response against the invading pathogen (Chakrabarti and Simon 2010). HIV elicits a potent innate immune response, including the activation of multiple signaling pathways, including the type I IFNs. Elevated IFN levels induce the expression of numerous downstream effectors, some of which are quite well characterized, whereas others remain elusive. Many of these proteins can inhibit HIV replication at multiple stages of the viral life cycle. At the same time, HIV expresses accessory proteins that can block or render ineffective at least some, if not most, of these intracellular protective mechanisms, while circumventing the natural innate immune “cocktail” of antiretroviral proteins. Targeting or disrupting these viral counterstrategies, perhaps as an adjunct to cART, may augment the immune response and provide an additional level of virologic control and improve patient outcomes.

Cellular and Soluble Immune Activation Markers in HIV-Infected Subjects

Basile Siewe and Alan Landay
Affymetrix, San Diego, CA, USA

Introduction

Chronic and generalized immune activation characterized by an elevated frequency of immune cells with an activated phenotype, increased lymphocyte turnover, and high serum levels of pro-inflammatory cytokines has been established as a key feature and a main driver of HIV disease progression. Indeed, the increased frequency of T cells expressing the T-cell activation markers, CD38 and HLA-DR, is an independent and better predictor of HIV disease progression than CD4 T-cell count or viral load (Liu et al. 1997, 1998) in untreated HIV-infected subjects, and in patients on antiretroviral therapy (ART), persistent immune activation (predominantly inflammation) is a significant driver of non-AIDS comorbidities. Further, in primate HIV infection models, elevated levels of immune activation/inflammation are detectable only in pathogenic SIV infections (rhesus and pigtail macaques) while absent in nonpathogenic SIV infection of natural hosts (sooty mangabeys and African green monkeys) (Silvestri et al. 2003). Finally, data suggest that the potential of ART to effectively reconstitute the immune system is dependent on how efficient ART reduces immune activation. Though ART is effective in suppressing viral replication to levels below detection, restoring the functionality of the immune system and reducing immune activation, abnormally high levels of inflammation and immune activation persist in comparison to uninfected individuals (Deeks and Phillips 2009). This residual immune activation may importantly contribute to non-AIDS comorbidities including cardiovascular diseases, metabolic disorders, neurocognitive decline, increased risk of malignancies, and loss of bone density. Considering that immune activation is a highly pertinent predictor of disease progression, evaluation of cellular and

soluble markers of immune activation is essential for the clinical management of infected ART-naïve subjects and in subjects on ART.

What Is the Mechanism Underlying Immune Activation?

The specific mechanisms underlying the generation of HIV-associated immune activation are still largely unclear, but data from a large body of work suggest the mechanisms entail multifactorial, complex, molecular, and cellular factors. The fact that the introduction of ART leads to a reduction in immune activation provides significant evidence that the virus itself is a driver of immune activation. The presence of the virus invariably elicits host antiviral innate and adaptive responses; further, HIV viral proteins such as gp120, Tat, and Nef directly activate immune cells (Juno and Fowke 2010). Additionally, immune cells expressing the appropriate pattern recognition receptors (PRR) including Toll-like receptors (TLR) are likely activated by the recognition of pathogen-associated molecular patterns (PAMPS) within the HIV proteome. HIV encodes TLR7 and TLR9 ligands that can directly activate plasmacytoid dendritic cells (pDCs) and B cells expressing TLR7 and TLR9. However, viral load alone cannot account for HIV pathogenesis considering that in nonpathogenic SIV infection in natural hosts, high viral loads are not coincident with high levels of immune activation (Silvestri et al. 2003). Another likely key driver of immune activation is the dramatic depletion of CD4+ T cells in gut-associated lymphoid tissue (GALT) and the resulting loss of epithelial barrier (due to depletion of a subset of T cells; Th17 + CD4+ T cells) (Dandekar et al. 2010). Loss of the epithelial barrier contributes to the translocation of microbial products including TLR ligands from the lumen into the circulation, and results from multiple studies indicate that the presence of these microbial products in the systemic circulation triggers broad and persistent activation of immune cells, especially innate cells and B lymphocytes expressing a range of TLRs (Brenchley et al. 2006). In addition to loss of epithelial barrier, other causes of microbial translocation include impaired clearance of bacterial products by

Kupffer cells in the liver. Kupffer cells are monocyte-derived macrophages, whose function is to phagocytose bacteria and microbial products. HIV infection is associated with a decreased density of Kupffer cells possibly leading to impaired clearance of bacteria and microbial products. Further evidence for the role of systemic translocated microbial products in triggering immune activation is provided by data from studies, in which lipopolysaccharide (LPS) administration led to increased immune activation in SIV natural hosts. HIV infection-associated CD4⁺ T-cell depletion can also indirectly lead to immune activation. In healthy individuals, the detection of cytomegalovirus (CMV)-specific T cells is an indication of persistent CMV reactivation. In HIV-infected individuals, CD4⁺ T-cell loss results in the inability to mount a competent immune response against reactivated CMV, which contributes to immune activation.

Finally, disruptions in the immunoregulatory machinery likely contribute to immune activation in chronic HIV infection. The most studied regulatory cell subset remains regulatory T cells (Tregs) that dampen excessive T-cell activation; however, during HIV pathogenesis, studies show conflicting data regarding the role of Tregs in dampening HIV-associated immune activation. Another regulatory subset is the myeloid-derived suppressor cells (MDSC, CD11b⁺CD14⁺CD33⁺CD15⁺) that suppress T-cell functions and have elevated frequencies in untreated HIV infection (Vollbrecht et al. 2012). Finally, the frequency of IL-10-secreting regulatory B cells (Bregs, CD19⁺CD24^{hi}CD38^{hi}) has been shown to correlate with immune activation in HIV-infected subjects (Siewe et al. 2013). Bregs inhibit anti-HIV cytotoxic T-lymphocyte activity, leading to viral persistence and likely contributing to immune activation.

Cellular Markers of Immune Activation

Markers of Dendritic Cell Activation

Dendritic cells (DCs) are innate cells, patrolling mucosal, lymphoid tissue, and blood, acting as the first line of host defense by recognizing PAMPs

on invading pathogens. Further, DCs create a link between the innate and adaptive immunity by processing and presenting microbial antigens to T and B cells thus exerting a critical host immune function against invading pathogens. There are two major DC subsets – myeloid DCs (mDCs) and plasmacytoid DCs (pDCs) – differing in morphology, phenotype, and function. mDCs are largely responsible for antigen presentation, and although they express the HIV coreceptors CD4, CCR5, and CXCR5 (mDCs can also bind and endocytose HIV via c-type lectins), mDCs are largely resistant to productive HIV infection. mDCs from HIV-infected individuals express increased levels of the activation marker and T-cell cognate ligand, CD40, but expression normalizes during ART to some extent. pDCs specifically recognize pathogens expressing TLR7 and TLR9 ligands, producing copious amounts of interferon-alpha (IFN- α) (McKenna et al. 2005). Because of the potent response (IFN- α production) to TLR stimulation, pDCs have been intensely studied in HIV infection (the role of IFN- α in driving HIV disease progression is discussed below in detail). In vitro studies have determined that exposure of HIV to pDCs leads to upregulation of co-stimulatory molecules HLA-DR, CD80, CD86, and CD83, though pDCs from HIV-infected individuals exhibit marginally elevated expression of co-stimulatory molecules. Finally, TLR7-stimulated pDCs express the tumor necrosis factor (TNF)-related apoptosis-inducing ligand (TRAIL). Activated TRAIL-expressing pDCs can bind the receptors TRAIL R1 or R2 on to CD4⁺ T cells, leading to CD4⁺ T-cell apoptosis via the caspase pathway.

Markers of Monocyte Activation

As discussed above, drivers of HIV infection-associated immune activation including viral replication and translocated microbial products directly activate innate cells. Monocytes express multiple TLRs including TLR4, the ligand for LPS, which is widely used as the marker of microbial translocation in HIV-infected subjects (Brenchley et al. 2006). During HIV infection, dysregulated TLR expression has been reported as a marker of monocyte activation. Monocytes

from HIV-infected individuals exhibit upregulated TLR2 and TLR4 expression, correlating with viral load in patients without ART. However, upon ART initiation, TLR2 expression remained elevated, while TLR4 expression returned to normal levels. A critical marker of monocyte activation in HIV-infected subjects is elevated expression of the procoagulant tissue factor (TF, also known as thromboplastin). In vitro studies have shown that LPS-stimulated monocytes upregulate TF expression, and monocytes from HIV-infected subjects exhibit higher expression of TF, which was reduced after ART initiation but remained higher than in uninfected individuals. Further, there was a positive correlation between the frequency of TF-expressing monocytes and immune activation (as determined by HLA-DR+ CD38+ expression on CD4+ T cells). Additional results suggest that compared to monocytes from uninfected individuals, monocytes from HIV-infected counterparts exhibit an increase in the expression of the inflammatory marker CD16+, which normalized after initiation of ART. Further, monocytes from HIV-infected subjects exhibit elevated CD11b expression (a component of the β 2-integrin macrophage-1 antigen). This marker is involved in recruitment of monocytes to atherosclerotic plaques and correlates with atherosclerosis in experimental animal models. Expression of CD11b is reduced during ART but still remains higher compared to age-matched HIV-uninfected controls. Further, monocytes from HIV-infected individuals exhibit reduced expression of the adhesion molecule CD62L as well as CD115 (a macrophage colony-stimulating factor, M-CSF receptor). Initiation of ART did not lead to restoration of CD62L or CD115 expression.

Markers of Natural Killer (NK) Cell Activation

Natural killer (NK) cells are innate lymphoid cells first identified by their potential to kill infected cells by releasing cytotoxic granules containing perforin and granzymes. However, this cytotoxic function has been attributed to the major CD56dimCD16+ subset. A minor CD56brightCD16- subset has been identified that in response to IL-12 stimulation secretes

cytokines including IFN- γ . Activation of NK cells, as identified by the co-expression of HLA-DR and CD38, is associated with impaired NK cell function. Elevated frequencies of activated NK cells occur frequently in untreated HIV-1 infection and persist even during ART.

Markers of B-Cell Activation

Though there is limited evidence that HIV replicates in B cells, data from multiple studies indicate that in vivo B cells interact with HIV via the complement receptor CD21 and complement proteins on HIV (Moir et al. 2000). Some studies suggest that B cells also interact with HIV virions expressing CD40 ligand. Further, B cells likely interact with HIV viral proteins. Finally, as discussed above, TLR stimulation plays a critical role in driving immune activation during HIV infection; B cells express a range of TLRs suggesting that B cells can be directly activated via TLR signaling. The result of these diverse B-cell interactions during HIV infection is B-cell hyperactivation, characterized by the heightened expression of activation markers including CD70 and CD71 and the co-stimulatory molecules CD40, CD80, and CD86. Although most B-cell defects are readily reversed with ART (Moir and Fauci 2009), recent findings suggest that the elevated expression of activation markers persists during ART; this may have implications for the development of B-cell malignancies during HIV-1 infection (Guo et al. 2013).

Markers of T-Cell Activation

Depletion of CD4 T cells is a hallmark of HIV infection with memory CCR5 + CD4+-activated T cells being the prime targets of the virus. Further, up to 80% of gut lymphoid tissue-associated (GALT) CD4+ T cells are activated and express CCR5 and are likely depleted in the first 3 weeks of HIV infection. The mechanisms underlying CD4+ T-cell depletion have been intensely investigated, and the data strongly indicate that during HIV infection, disease progression is largely a result of persistent chronic T-cell activation and increased T-cell turnover, ultimately resulting in CD4+ T-cell loss. Accordingly, T-cell activation markers predict the rate of disease progression,

and after initiation of ART, the reduction in T-cell activation indicates a critical role for virus in causing T-cell activation. Further, some data suggest that the efficacy of ART in restoring the damage to the immune system is dependent on its ability to dampen immune activation. T-cell activation markers including CD38, HLA-DR, CD25, CD69, and CD70 have been extensively studied in HIV-infected subjects; however, CD38 remains the most thoroughly characterized marker of immune activation. CD38 is a transmembrane protein upregulated early in T-cell activation, coincident with cell-to-cell adhesion, increased cytokine expression, and rapid cell turnover. During HIV infection, T-cell CD38 expression positively correlates with other T-cell activation markers, and accordingly, the frequency of T cells coexpressing HLA-DR and CD38 is the most validated marker of immune activation during HIV infection (Liu et al. 1997, 1998).

Soluble Markers of Immune Activation

Markers of Microbial Translocation

As discussed above, microbial translocation is a critical driver of immune activation, and biomarkers of microbial translocation often correlate with disease progression. Since breach of the intestinal epithelial barrier leads to microbial translocation, assessing damage to epithelial cells (enterocytes) is an indicator of microbial translocation. Citrulline secreted by the epithelial cells of the small intestine is a by-product of glutamine and arginine metabolism. During HIV infection, a reduction in citrulline levels is an indication of the dysfunction of the epithelial cells and associated with malabsorption observed in HIV-infected individuals. An additional marker of enterocyte loss is the elevated plasma level of intestinal fatty acid-binding protein (I-FABP), expressed exclusively by enterocytes. However, the most critical marker of microbial translocation remains the detection of microbial products in serum of HIV-infected individuals. Elevated systemic levels of LPS, bacterial 16 s ribosomal (r) DNA, and lipoteichoic acid (LTA, part of cell wall of gram-positive bacteria) likely result from

microbial translocation; such changes have been frequently documented in HIV-infected subjects and serve as critical serum biomarkers of HIV-associated immune activation. As described above, the presence of microbial products in the systemic circulation leads to activation of immune cells (mostly innate) via TLR-TLR ligand interactions. The soluble markers secreted by these activated innate and adaptive cells are described below.

Soluble Activation Markers of Innate Immunity

As discussed above, innate cells represent the first line of defense against invading pathogens. During HIV infection, the outcome of pDC interaction with HIV in driving immune activation is a defining aspect of disease progression. pDCs are most susceptible to HIV due to the expression of CD4 and TLRs, especially TLR7 and TLR9, whose ligands are encoded by HIV. A model of HIV disease progression postulates that stimulated pDCs express high amounts of type I interferon (IFN- α/β) and indoleamine 2,3-dioxygenase (IDO) which modulate antiviral properties of T cells. Normally, type I interferons activate host restriction mechanisms, effectively exerting an antiviral function. However, systemic and persistent IFN- α/β expression as observed during HIV infection has deleterious effects on the immune system and drives HIV disease progression. The importance of IFN- α/β production by pDC in driving immune activation was demonstrated by studies showing that ex vivo, pDCs from nonpathogenic SIV-infected sooty mangabeys produce significantly less IFN- α/β compared to pDCs from pathogenic SIV-infected animals. This was corroborated by findings that in vivo, nonpathogenic SIV infection was characterized by a downmodulation of the initial IFN- α/β response, whereas in pathogenic infection, IFN- α/β production was uncontrolled and associated with chronic immune activation and disease progression. Further, during HIV infection, there is a correlation between disease progression and high titers of IFN- α . Additionally, women progress more rapidly to AIDS and ex vivo; pDCs from women produce more IFN- α after HIV

stimulation. An important downstream effect of HIV-induced IFN production is the activation of the interferon-stimulated genes (ISG) in immune cells especially CD4+ T cells that contribute to immune dysfunction and HIV disease progression. IFN- α/β and direct TLR7 stimulation are potent inducers of IDO, though, in vitro, HIV viral proteins have been shown to induce IDO expression in innate cells. IDO is involved in tryptophan catabolism, by cleaving tryptophan to kynurenine. During HIV infection, IDO contributes to immune dysfunction via two different mechanisms: (1) by suppressing T-cell functions either by depleting the important amino acid tryptophan or by producing metabolites that are toxic to T cells and (2) by altering the Th17/Treg ratio, thus increasing immune activation and HIV disease progression.

As discussed above, the presence of systemic bacterial LPS during HIV infection is a critical consequence of microbial translocation. Monocytes express high levels of TLR4, the receptor for LPS. LPS stimulation of monocytes is a significant driver of monocyte activation. Activated monocytes in turn secrete copious amounts of pro-inflammatory cytokines including IL-6 and tumor necrosis factor (TNF)- α . The most critical pro-inflammatory cytokine secreted by monocytes is interleukin (IL)-6. Serum IL-6 levels often correlate with viral load and even after ART-elevated serum levels of IL-6 persist and represent key biomarkers of non-AIDS-associated comorbidities and mortality (Deeks 2011). LPS-stimulated monocytes also express TNF- α , which in turn drives HIV replication. In the SIV model, nonpathogenic infection is characterized by dampening of TNF- α production by monocytes. In pathogenic infection, TNF- α production by LPS-stimulated monocytes is uncontrolled and associated with immune activation and disease progression. Activated monocytes also elevate the expression of surface CD14, and these activated monocytes shed CD14 (soluble, sCD14), which binds LPS. In some cohorts of HIV-infected individuals, serum levels of sCD14 have been shown to correlate with disease progression (Deeks 2011). Elevated serum levels of sCD14 persist during ART, and this is associated

with comorbidities including atherosclerosis progression and neurocognitive impairment (Deeks 2011).

In addition to TLR4, monocytes express TLR7/8, and the stimulation of monocytes by HIV-encoded TLR7/8 ligands as well as IFN- γ drives monocyte secretion of the chemokine C-X-C motif chemokine 10 (CXCL10) also known as IFN- γ -induced protein 10 (IP-10). IP-10 serves as a chemoattractant by binding to its receptor CXCR3 expressed by other immune cells including T cells, monocytes, and NK cells, effectively recruiting these cells to sites of inflammation. IP-10 is an important biomarker of disease progression, because serum IP-10 levels positively correlate with viral load and inversely with CD4 counts. Further, in patients on ART, IP-10 levels correlate with the frequency of CD16+ monocytes, suggesting monocytes are likely a significant source of IP-10.

Another marker of monocyte activation is soluble CD163 (sCD163). sCD163 is the shed form of the hemoglobin scavenger receptor. Serum levels of sCD163 are not normalized even in patients on ART correlating with aortic inflammation and a predictor of noncalcified coronary plaques.

Soluble Activation Markers of Adaptive Immunity

During HIV infection, activated adaptive immune cells secrete multiple proteins, some of which correlate with disease progression. Moreover, in patients on ART, some of these soluble markers are associated with the development of B-cell malignancies.

CD27 is a transmembrane glycoprotein, a member of the TNF receptor family and expressed on the surface of some T cells and antigen-experienced B cells. The receptor for CD27 is CD70, which is transiently expressed by activated B and T cells. Chronic activation leads to the shedding of CD27 and to the binding of soluble CD27 to B-lymphocyte-induced protein I (BLIMP-I) and X-box binding protein I (XBP-I) ultimately leading to increased IgG production. In HIV-infected individuals, sCD27 levels correlate with IgG concentrations. Even in

patients on suppressive ART, elevated serum levels of sCD27 persist and are associated with the development of non-Hodgkin lymphoma (NHL), a common malignancy in HIV-infected individuals on ART.

CD30 is another member of the TNF receptor superfamily, originally described as a marker for malignant B cells. CD30 is expressed on activated B- and T-helper 2 (Th2) cells. The ligand for CD30 is CD30L expressed by B and T cells, and CD30-CD30L interaction leads to the cleavage of the extracellular portion of CD30 resulting in the soluble form sCD30. In HIV-infected individuals, elevated serum levels of sCD30 correlate with other soluble markers of immune activation including sCD27 and sCD44 and, in some studies, with viral load. Similar to sCD27, elevated serum levels of sCD30 in ART-treated HIV-infected individuals are associated with the development of NHL.

CD23 is the low-affinity receptor for IgE expressed on IgD+ IgM+ B cells, though these B cells lose IgE after isotype switching. HIV viral protein gp160 has been shown to induce CD23 upregulation, and cleavage of CD23 (sCD23) further stimulates B cells. Elevated serum levels of sCD23 are also associated with the development of NHL.

The loss of memory B cells and the resulting impairment of antibody production are major hallmarks of HIV infection. It has been suggested that damage to the lymph nodes and the resulting impairment of B-cell trafficking contribute to B-cell deficiencies observed in HIV-infected subjects. The chemokine CXCL13 plays a key role in B-cell trafficking and is expressed by B cells in the secondary lymph nodes. After differentiation into plasma cells, B cells in the lymph nodes down-regulate CXCL13 expression and exit the follicles. HIV infection is associated with an elevated expression of CXCL13 on B cells, and some studies have shown a correlation with IP-10. However, B-cell CXCL13 expression is reduced during ART, though elevated levels are correlated to the development of NHL in some studies.

As previously discussed, monocytes are a major source of pro-inflammatory cytokines IL-6

and TNF- α ; however, TLR-stimulated B cells also secrete these cytokines, and B cells from HIV-infected subjects on ART express higher levels of IL-6 compared to healthy controls. This suggests that B cells likely contribute to the inflammatory milieu during HIV infection and even during ART.

During HIV infection, activated T cells also secrete important soluble biomarkers of immune activation. Activated Th1 helper cells express IFN- γ , and during HIV infection, IFN- γ -activated macrophages express elevated levels of neopterin, a catabolic product of guanosine triphosphate (GTP). In untreated HIV-infected subjects, serum levels of neopterin correlate directly with viral load and indirectly with CD4 count. Data from multiple studies suggest that during ART, the neopterin serum levels are not completely normalized indicating persistent immune activation.

Activated T cells as well as some innate cells upregulate CD87. CD87 is a urokinase-type plasminogen activator receptor, a transmembrane protein which can be cleaved and shed in serum (suPAR). Similar to neopterin, in untreated HIV-infected subjects, serum levels of suPAR correlate directly with viral load and indirectly with CD4 counts. In these untreated HIV-infected subjects, serum levels of suPAR are an independent marker of HIV-1-related early mortality. ART results in reduction of serum levels of suPAR, but these levels are still higher than in HIV-uninfected subjects.

Other Soluble Markers of Immune Activation

Some soluble markers of immune activation are secreted by a number of different immune cells, and these markers are described here.

Most nucleated cells and especially lymphocytes express the major histocompatibility complex I comprising beta-2 microglobulin (β -2 m) light chain and an alpha heavy chain. Activated cells shed β -2 m (s β -2 m), and in untreated HIV-infected subjects, the serum level of s β -2 m is an independent predictor of disease progression correlating positively with viral load and negatively with CD4 counts. These elevated serum

levels of β -2 m persist despite ART, reflecting the systemic immune activation and inflammation even in ART.

As discussed above, during HIV infection, activated monocytes express the pro-inflammatory cytokine TNF- α . Most immune cells express the receptors for TNF- α , the 55-kDa type I (TNFR-I) and 75-kDa type II (TNFR-II). Activation of these receptors leads to cleavage of the extracellular domains, sTNFR-I and sTNFR-II. In untreated HIV-infected individuals, elevated serum levels of sTNFR-I and sTNFR-II are predictive of disease progression, and despite ART, the levels remain elevated compared to HIV-uninfected subjects.

Conclusion

In HIV-infected individuals, ART is very successful in controlling viral replication leading to significant reduction in mortality due to AIDS. However, despite ART, persistent immune activation and specifically inflammation significantly increase the risk for non-AIDS comorbidities.

Multiple biomarkers of HIV infection are linked to clinical outcomes, and larger clinical trials are needed to confirm that these biomarkers can safely be employed as markers of a clinical outcome. Moreover, it may be possible to use our current knowledge about biomarkers of HIV-associated immune activation for tailoring antiretroviral treatment decision to individual needs of HIV-1-infected persons.

Cellular Cofactors for HIV-1 Transcription

Mauro Giacca
Molecular Medicine Laboratory, International
Centre for Genetic Engineering and
Biotechnology (ICGEB), Trieste, Italy

Definition

Several host cell factors, the chromatin structure of the viral LTR promoter, and the RNA-binding Tat transactivator regulate the transcription of the integrated HIV-1 genome. Transcriptional latency of the provirus in metabolically resting T cells generates cell reservoirs that are refractory to current combination antiretroviral therapy (cART).

Overview of Regulation of HIV-1 Transcription

Following ► [integration](#) into the host cell genome, the molecular mechanisms that regulate transcription from the HIV-1 provirus recapitulate the events that control the expression of most cellular genes transcribed by RNA polymerase II (RNAPII). Transcription is controlled by the U3 region of the long terminal repeat (LTR) positioned at the 5' of the provirus, which acts as an inducible promoter, with the essential involvement of several cellular specific transcription factors, the general transcription factor-RNAPII machinery, and the essential function of the virus-encoded Tat protein. Of note, the HIV-1 LTR sequence acts as a very strong promoter when analyzed as naked DNA in *in vitro* transcription experiments, while it is almost silent when integrated into the cellular genome. In the absence of cellular stimulation or the viral Tat

protein, the chromatin structure of the provirus bears marks of repressed, facultative heterochromatin, while RNAPII is still present in proximity to the LTR transcription start site, but stalled after the transcription of only a few tens of nucleotides.

Transcriptional activation of the LTR can be triggered by a variety of extracellular stimuli that lead to cellular activation, including phorbol esters, different cytokines, incubation with anti-CD3 antibodies, or inhibitors of histone deacetylases. In infected CD4+ T lymphocytes, the most relevant of these stimuli is the engagement of the T-cell receptor by its specific antigen. Following cell activation, different cellular histone acetyltransferases (HATs) are recruited to the promoter, chromatin acquires active chromatin marks, and RNAPII becomes elongation competent, the latter event being essentially catalyzed by the P-TEFb general transcription factor.

The Tat protein of HIV-1 is a small polypeptide of 101 aa – with the exception of the widely studied HXB2 strain, in which a point mutation truncates the protein at 86 aa – which is essential for the transcription of viral genes and for viral replication. The protein acts as a highly unusual transactivator that binds TAR (transactivation response element), a 59 nt long, structured RNA element positioned at the 5' end of the proviral transcript. Through this interaction, the protein activates HIV-1 transcription by promoting the assembly of transcriptionally active complexes at the LTR by multiple protein-RNA and protein-protein interactions. Tat was reported to bind specific transcription factors (e.g., Sp1), general transcription factors (including TBP, TAFII250, and P-TEFb), the RNAPII itself, and various transcriptional coactivators possessing HAT activity. A hallmark of Tat function is its interaction with the Cyclin T1 component of P-TEFb and its recruitment to the LTR to promote transcriptional elongation.

Regulation of HIV-1 Transcription by Cellular Transcription Factors

The viral LTR U3 region has a structure typical of promoters associated with cellular RNAPII,

which includes multiple upstream DNA regulatory elements that serve as binding sites for cellular transcription factors (Marcello et al. 2004). The basal promoter, which contains an initiator element in correspondence with the transcription start site, an upstream TATA box directing TFIID binding, and three further upstream tandem binding sites for the constitutively expressed Sp1 transcription factor, directs basal levels of LTR-directed RNA synthesis (Mbonye and Karn 2011). This basal promoter is very efficient *in vitro*, in the absence of chromatin, and very weak *in vivo*, when the provirus is assembled in nucleosomes. Functional analyses of LTR-driven reporter constructs have shown that the mutation of individual or pairs of Sp1 sites has little, if any, effect on these basal or Tat-transactivated levels of expression. However, the mutation of all three Sp1 sites markedly reduces the response to Tat.

Transcription initiation from the HIV-1 LTR is highly inducible by a variety of stimuli linked to the host T-cell or macrophage activation. Response to these stimuli is mediated by a short region which lies immediately upstream of the basal promoter, therefore named the “enhancer” region. This sequence contains two tandemly arranged binding sites for the dimeric transcription factors composed of several combinations of members of the Rel/NF- κ B or the NFAT families of polypeptides. Because their recognition sequences overlap, binding of these factors is mutually exclusive. The predominant complex that binds to these LTR κ B sites in activated cells is NF- κ B (p50/p65 heterodimer). In cells that are not stimulated, the p65 subunit of NF- κ B is retained in the cytoplasm through interaction with inhibitor proteins belonging to the I κ B family. The activation of NF- κ B occurs through the phosphorylation and proteolysis of the I κ B inhibitor and the subsequent translocation of p65 to join p50 in the nucleus where the factor binds to its cognate binding sites (Hoffmann and Baltimore 2006).

In the prototype HXB2 HIV-1 strain, different members of several other cellular transcription factor families (AP-1, COUP, USF, Ets, LEF-1) can bind the regulatory region upstream of the enhancer region. The arrangement of these

transcription factor binding sites in the LTR may vary in different HIV-1 subtypes. Most of these other factors binding to the LTR have a more modest effect on transcription compared to Tat or NF- κ B, and their primary function is most likely the modulation of transcriptional activity in different cell types.

Functions of P-TEFb

A unique feature of mammalian RNA polymerase II (RNAPII) is the presence of an extended C-terminal domain (CTD) in its largest subunit RPB1, which contains 52 heptad repeats with a consensus sequence, YSPTSPS. Phosphorylation of serines at positions 2 and 5 (Ser2 and Ser5) in these repeats is one of the essential molecular events that regulate gene expression in eukaryotic cells (Phatnani and Greenleaf 2006). The RNAPII CTD is hypo-phosphorylated when initially recruited to genes and undergoes sequential phosphorylation at Ser5 during promoter clearance and at Ser2 at the start of elongation (Core and Lis 2008). The former modification is imparted by the Cdk7 subunit of TFIIF; the nascent transcription complex, containing Ser5-phosphorylated RNAPII, however, is incompetent for processive elongation. The positive transcription elongation factor b (P-TEFb) is so far the best known characterized factor that can rescue the paused polymerase by inducing Ser2 phosphorylation (Peterlin and Price 2006). In the absence of P-TEFb, RNAPII complexes, phosphorylated on Ser5 only, accumulate 20–40 nt downstream of the transcription start site, due to the action of the inhibitory complexes NELF (negative-acting elongation factor) and DSIF (DRB sensitivity-inducing factor) (Core and Lis 2008). It is likely that this checkpoint serves to ensure proper capping of pre-mRNA, since the Ser5-phosphorylated CTD helps recruit capping enzymes to the 5' end of the nascent transcript. When P-TEFb is present, it relieves polymerase stalling by phosphorylating both NELF and DSIF; the former dissociate from the RNAPII, while the latter is converted into a positive elongation factor (Zhou and Yik 2006).

P-TEFb was originally discovered in the early 1990s as a kinase that phosphorylates the RNAPII CTD and is inhibited by 5,6-dichloro-1-beta-D-ribofuranosylbenzimidazole (DRB) at concentrations that have no effect on the initiation of transcription. Subsequent gene cloning from flies and humans revealed that P-TEFb was a cyclin-dependent kinase. The *cdc2*-type catalytic subunit, first identified as PITALRE, was later renamed Cdk9 and can be produced in two isoforms of 42- and 55-Kda (Cdk9-42 and Cdk9-55). Cdk9 associates with a C-type cyclin subunit; flies have one Cyclin T, while humans express Cyclin T1 and two forms of Cyclin T2 (T2a and T2b) (Peterlin and Price 2006). Possibly, human Cdk9 protein also binds Cyclin K, a partner of the Cdk12 and Cdk13 kinases, which also phosphorylate Ser2 in the CTD of RNAPII.

In addition to the role of P-TEFb in stimulating transcriptional elongation, multiple evidence indicates that this general transcription factor also assists in regulating pre-mRNA processing. In particular, the Cyclin T1 subunit of P-TEFb is known to interact with Tat-SF1, a factor taking part in the formation of a nuclear complex, together with spliceosomal U snRNPs, which stimulates both RNAPII elongation and splicing. Additionally, the splicing factor SKIP (c-SKi-interacting protein) also binds P-TEFb together with Tat-TAR. This factor is essential for Tat transactivation and couples transcription with pre-mRNA splicing (Zhou and Yik 2006).

Regulation of P-TEFb

Studies performed using either RNA interference or highly specific inhibitors have indicated that P-TEFb acts as a global cofactor important for most RNAPII-mediated transcription (Peterlin and Price 2006). Not surprisingly, therefore, its activity appears to be tightly regulated in different cell types, throughout differentiation, and as part of the cell response to various stimuli. The most relevant mechanism of P-TEFb regulation derives from its interaction with an inhibitory complex formed by 7SK RNA and one of the HEXIM proteins.

The 7SK RNA is a relatively abundant (2×10^5 copies per cell), noncoding RNA of 331 nt,

transcribed by RNA polymerase III. This RNA localizes in the nucleoplasm where, together with the HEXIM1 or HEXIM2 proteins, it sequesters P-TEFb in an inactive form. The mammalian HEMIX1 protein was originally identified as a hexamethylene bisacetamide (HMBA)-inducible protein in vascular smooth muscle cells (hence the name) and was later found to be inducible in several other cell types, acting as a potent cell growth suppressor and inducer of differentiation (Zhou and Yik 2006). A smaller homologue, HEXIM2, was later described, showing high homology to HEXIM1 in the region binding to 7SK while diverging significantly at the N-terminus.

Both 7SK RNA and a HEXIM protein are required to inhibit P-TEFb. HEXIM1/2 proteins form stable homo- or heterodimers that associate with two P-TEFb complexes, one 7SK RNA and, most likely, other cellular proteins, among which LARP7 and MePCE (Diribarne and Bensaude 2009). The 7SK RNA exerts a scaffolding role in this complex: by binding an arginine-rich basic region of HEXIM1, it determines an allosteric change that allows HEXIM1 to specifically bind P-TEFb, which culminates in the inhibition of transcription.

As a consequence of these interactions inside the cells, P-TEFb can be found in two forms: a “free,” active form and a “sequestered,” inactive, P-TEFb/7SK/HEXIM1/2 form. Physiological stimulations such as those occurring during cardiac hypertrophy or upon cell treatment with inhibitors of transcription or other cellular stresses induce the rapid release of HEXIM1/7SK from P-TEFb and the consequent switch toward the active P-TEFb form. Active P-TEFb associates with other cellular proteins to form the so-called super elongation complex (SEC), also containing other elongation factors and coactivators (Ott et al. 2011).

The enzymatically active P-TEFb complex can also be found in association with the bromodomain protein Brd4 (Zhou and Yik 2006). This is a ubiquitously expressed, nuclear protein belonging to the BET (bromodomains and extraterminal) family of proteins (Wu and Chiang 2007). Brd4 was found to bind to actively

transcribed genomic regions by directly associating to acetylated histone H3 and H4, through its bromodomain, and to be part of the mediator complex, a multicomponent complex bridging specific transcription factors to the general transcription machinery. The interaction with Brd4 might thus contribute to the transcriptional activation promoted by P-TEFb, in particular by tethering P-TEFb to gene regions bearing active chromatin marks (Zhou and Yik 2006).

Given the central role of P-TEFb in transcriptional activation, it is not surprising that several layers of additional mechanisms for its regulation exist. In different cell types, modulation of P-TEFb function is also attained by controlling the amounts of Cyclin T1, Cdk9, and HEXIM1 proteins, by modulating their function by post-translational modification by phosphorylation, ubiquitination, and acetylation and by regulating Cdk9 nucleocytoplasmic shuttling (Cho et al. 2010).

P-TEFb and HIV-1 Transcription

The cyclin cofactor of P-TEFb, Cyclin T1, was originally identified for its direct binding to the HIV-1 Tat protein in HeLa nuclear extracts (Wei et al. 1998). A current model for Tat transactivation envisions that Tat, through its specific binding to Cyclin T1, determines the recruitment of P-TEFb to the 5' trans-acting response (TAR) RNA sequence (nucleotides 1–59 of the nascent viral transcripts) to stimulate proviral transcription (Core and Lis 2008). In the absence of Tat, transcription from the HIV-1 LTR generates only short transcripts; however, the presence of Tat dramatically stimulates the efficiency of elongation and results in a large increase in the level of full-length transcripts that extend through the more-than-9-kb HIV-1 genome.

Tat, TAR, and Cyclin T1 form a stable, ternary complex, where Tat specifically binds the TAR RNA at a three-nucleotide bulge and several flanking nucleotides in the double-stranded RNA stem just below the apical loop and Cyclin T1 recognizes the TAR apical loop itself, while Tat adopts a structure complementary to the surface of P-TEFb and makes extensive contacts, mainly with the Cyclin T1 cyclin box but also with the

T loop of Cdk9 (Tahirov et al. 2010). These cooperative interactions allow the recruitment of P-TEFb in proximity to the stalled RNAPII and its consequent activation. Interestingly, rodent Cyclin T1 lacks a critical cysteine in the Tat recognition motif (TRM) that is required to interact with Tat. As a consequence, Tat is poorly active in terms of HIV-1 LTR transactivation in murine cells compared to primate cells (Peterlin and Price 2006; Zhou and Yik 2006). For a similar reason, human Cyclin T2 is also unable to bind Tat.

The Tat sequence involved in TAR binding, highly enriched in basic amino acids, is highly similar to the basic HEXIM1 sequence binding the 7SK RNA; in addition, Tat is capable of competing with HEXIM1 for 7SK association. These observations suggest that the Tat/TAR viral system has evolved in a manner that is architecturally similar to that of the cellular HEXIM1/7SK pair, with the evolutionary purpose to decoy HEXIM1/7SK and hijack P-TEFb for specific HIV-1 transcription (Zhou and Yik 2006).

Chromatin Architecture at the HIV-1 Provirus

In the nucleus of the infected cells, chromatin assembly essentially represses transcription (Marcello et al. 2004). Experiments performed both *in vivo* and *in vitro* using the HIV promoter reconstituted into chromatin have shown that, independent from the integration site, nucleosomes in the 5' LTR are precisely positioned with respect to *cis*-acting regulatory elements. In the transcriptionally silent provirus, these nucleosomes define two large nucleosome-free areas. The first is composed of the basal promoter, containing three tandem Sp-1 binding sites and the TATA box sequence, and the LTR enhancer, which is the target for the p50/p65 NF- κ B heterodimer; the same region also contains the binding sites for other transcription factors including Ets-1 and USF. The second open area spans the primer-binding site immediately downstream of the 5' LTR. These two open regions are separated by a single nucleosome called *nuc-1* that is

destabilized during transcriptional activation (Colin and Van Lint 2009). Genomic footprinting and chromatin immunoprecipitation (ChIP) experiments performed in both activated and in silently infected cells have indicated that most of the transcription factor binding sites at the promoter, including the TATA box, the Sp1 sites, the enhancer region, and the USF site, are occupied by cellular proteins independent from the state of activation (Marcello et al. 2004). ChIP experiments have also revealed that the modification of chromatin in proximity of the HIV-1 transcription start site precedes the onset of RNAPII transcription and is essential for viral gene expression to occur. Together, these are indications that the transcriptional activation of the integrated LTR is not primarily restricted by DNA target site accessibility but occurs through the modulation of chromatin conformation.

Transcriptional silencing of the HIV-1 provirus is achieved through mechanisms involving epigenetic changes of chromatin. Chromatin is maintained in a deacetylated state by different class I histone deacetylases (HDACs), which can be recruited to the LTR by the p50/p50 NF- κ B family homodimer, binding to the enhancer region, or the CBF-1 factor (Mbonye and Karn 2011). At the same time, latent HIV proviruses carry trimethylated histone H3 on Lysine 9 (H3K9met3) and Lysine 27 (H3K27met3), as well as dimethylated Lysine 9 (H3K9met2), and can be found in association with the respective histone methylases. Of note, H3K9met2 is a modification associated with facultative heterochromatin that marks the genes poised for transcription.

On the contrary, transcriptional activation coincides with acetylation of H3 and H4 histones in the LTR region, which precedes the actual onset of transcription. Histone acetylation is paralleled by the recruitment of specific HATs to the promoter, which is cell-type specific and depends on the stimulus used for transcriptional activation. Tat itself was shown to associate with different HATs, including the transcriptional coactivators p300 and the highly homologous cAMP-responsive binding protein (CREB) (CBP), the p300/CBP-associated factor (P/CAF), the general

control non-derepressible-5 (GCN5) protein, and the general transcription factor TFII250 (Marcello et al. 2004). Complexes containing HATs assist transcriptional activation through acetylation of the N-terminal tails of histones, an event inducing the destabilization of histone-DNA interactions.

Finally, it is of interest that, quite apart from histones, Tat itself is the subject of various post-translational modifications. Tat acetylation by P/CAF on Lysine 28 favors interaction of Tat with P-TEFb, while acetylation of Lysine 50 by p300 and GCN5 favors dissociation of the complex and release of P-TEFb from TAR. In addition, acetylation of Lysine 50 permits interaction of Tat with the subunits BRM and Ini1 of the SWI/SNF chromatin-remodeling complex, which is consequently recruited at the 3' end of nuc-1 in the 5' LTR to facilitate transcriptional elongation. In contrast, methylation of Tat by the arginine methyltransferases PRMT6 on its arginines at positions 52 and 53 decreases interaction with TAR and counteracts P-TEFb complex formation. Finally, one or several protein lysine methyltransferases, at least SETDB1, were demonstrated to methylate Tat on Lysines 50 and 51, thereby competing with acetylation of the same residues (Colin and Van Lint 2009). Together, these results again underline the strict molecular interplay connecting Tat with the molecular modifications regulating cellular gene transcription.

Conclusions

When considered collectively, the molecular interactions described above clearly indicate that transcription of the HIV-1 provirus, an essential step in viral replication, has evolved to perfectly adapt to its host cell environment. The regulation of transcription initiation relies on a patchwork of cellular transcription factors recruited by the viral LTR, including NF- κ B and NFAT that render the promoter highly responsive to the same stimuli that normally activate the host cell. On the other hand, proficient transcriptional elongation is achieved by exploiting the cellular P-TEFb complex, as with many cellular genes. The HIV-1 Tat

protein appears to be a central player in orchestrating these mechanisms, since it appears able to both mediate the recruitment of chromatin-modifying enzymes to the LTR for transcriptional initiation and to hijack P-TEFb to overcome polymerase stalling.

The peculiar property of the HIV-1 LTR to adapt to its cellular environment and to become transcriptionally silent in inactive T cells bears important practical consequences. HIV-1 efficiently infects metabolically active, CD4⁺ T cells, in particular activated T lymphocytes and macrophages. Once CD4⁺ T lymphocytes revert to a resting, memory state, HIV-1 undergoes reversible transcriptional silencing. Latently infected cells represent a major source of HIV-1 reservoirs, since these cells, not expressing any viral protein, are refractory to current combination antiretroviral therapy (cART), which only targets the replicative fraction of the virus and are not identifiable by the immune response. Therefore, understanding the molecular mechanisms controlling silencing and reactivation of the HIV-1 provirus at its integration site within the host cell genome has profound implications for both elucidation of the pathogenesis of HIV disease and for its pharmacological control.

Definition

Infection with the human immunodeficiency virus type 1 (HIV-1) remains a substantial public health as well as a socioeconomic problem worldwide. Although highly active antiretroviral therapy (HAART) effectively halts HIV replication and profoundly increases survival of patients, it has not been possible yet to achieve a cure. Interruption of HAART typically results in a rebound of virus replication. This is primarily due to the fact that HIV ingeniously escapes from the continuous immune surveillance in a small pool of latently infected cells that are not susceptible to drug

therapy. Moreover, the rapid replication rate and the generation of an extensive genetic diversity fuel the emergence of drug-resistant viral strains resulting in treatment failure. Therefore, there is a continuous demand to search for novel and better ARVs for a better control of the HIV pandemic with the hope to eventually induce permanent remission of the disease.

HIV relies on the host cellular machinery to complete its replication cycle. HIV hijacks several biological processes and protein complexes of the host cell through distinct virus-host protein-protein interactions (PPIs) (Van Maele et al. 2006). Since these host-pathogen interactions directly mediate viral replication and disease progression, their specific disruption can provide alternative targets for therapeutic intervention. PPIs represent an attractive group of biologically relevant targets for the development of small-molecule protein-protein interaction inhibitors (SMIPPIs) (Arkin and Wells 2004). Since protein-protein interfaces are often based on extended, flat, barely defined, and large hydrophobic surfaces, overcoming binding energy with small molecules is hard to achieve. Therefore, obtaining validated starting points for chemical optimization of SMIPPIs has been difficult. Moreover, the applicability of PPIs as therapeutic targets is not only defined by their physicochemical properties but also by the biological properties of the protein-protein interaction and requires meticulous target validation prior to drug discovery (see entry “► [Identification and Validation of HIV Cofactors](#)”).

Cofactors of HIV as Antiviral Targets

In recent years our understanding of the interactomics of HIV proteins has dramatically increased, opening the possibility for the discovery of novel classes of therapeutics (see entry “► [Identification and Validation of HIV Cofactors](#)”). Not surprisingly, there are numerous interactions between HIV and cellular proteins involved in all stages of virus replication (Jager et al. 2012). In principle, any distinct

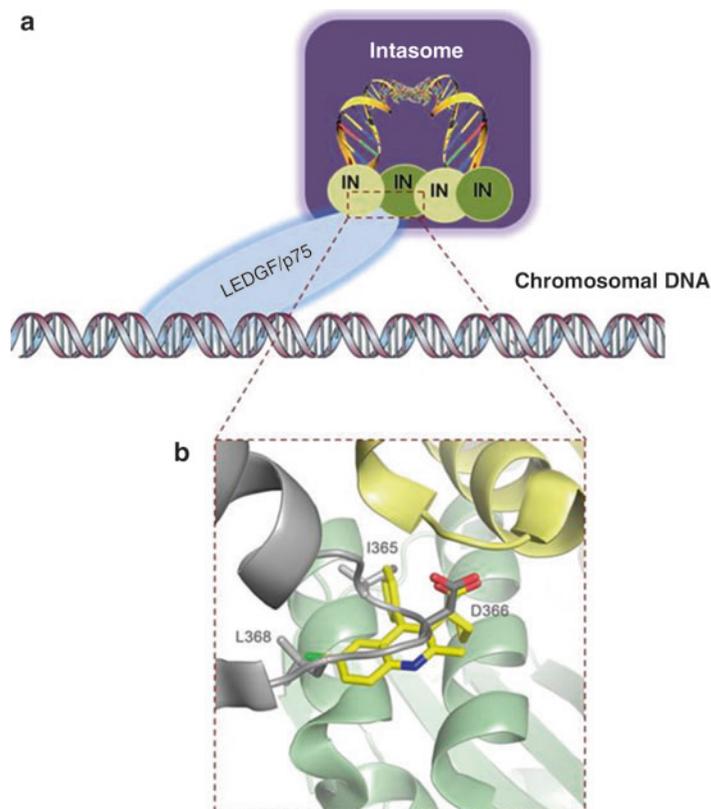

interaction between virus-encoded proteins and host cofactors has the potential to be a target for drug design.

The CCR5 antagonist, maraviroc, was approved as the first ARV targeting a host factor (Dorr et al. 2005). Maraviroc binds to the CCR5 coreceptor on the surface of cells and prevents interaction with the Gp120 envelop protein of the virus (Sayana and Khanlou 2009). Successful targeting of host-virus PPIs demonstrates that HIV-1 therapeutic drug targets are not limited to virus-encoded enzymes and that understanding of the virus-host interactome can be the basis for future HIV therapeutics (Greene et al. 2008; Busschots et al. 2009). In theory, this antiviral strategy is expected to make it more difficult for the virus to develop resistance. Since the host factor is genetically conserved in a biologically relevant host-virus interaction, resistance is less likely to occur, increasing the clinical potential of these drugs.

Cofactors of HIV Integrase as Potential Antiviral Targets

In recent years HIV-1 integrase (IN) joined the selection of important therapeutic targets to treat HIV infection. The enzyme orchestrates the insertion of the viral DNA into the host chromatin. HIV IN is a 32-kDa protein containing three canonical structural domains connected by flexible linkers: the N-terminal (NTD, residues 1–50), the catalytic core (CCD, residues 51–212), and the C-terminal domain (CTD, 213–270) (Fig. 1). All three domains are required for 3' processing and DNA strand transfer. The solution structure of the N-terminal HHCC domain revealed a three-helix bundle stabilized by zinc. The central catalytic core domain contains the DD(35)E motif conserved among retroviruses and retrotransposons. D64, D116, and E152 residues coordinate 2 Mg²⁺ ions necessary for catalysis. The C-terminal domain has a SH3-like fold. Full-length HIV-1 IN is a multimeric enzyme and forms stable tetramers in solution.

Despite the recent release of the crystal structure of full-length IN of the prototype foamy virus

Cellular Cofactors of HIV as Drug Targets,

Fig. 1 LEDGINs bind to the LEDGF/p75 binding pocket in HIV-1 integrase. (a) LEDGF/p75 has an N-terminal chromosomal DNA-binding region. The C-terminus contains the well-characterized integrase-binding domain (IBD) and acts as a protein interaction playground. The interaction of the catalytic core domain (CCD) of HIV integrase with the IBD of LEDGF/p75 is

crucial to facilitate the tethering of the HIV intasome on the chromatin. (b) Cartoon representation of the IN CCD dimer (*pale green* and *pale yellow*) with a LEDGIN superimposed with the IBD (PDB entry 2B4J, *gray*) reveals mimicry of the protein-protein interaction. LEDGIN phenyl, acid, and chlorine groups substitute for LEDGF/p75 residues I365, D366, and L368 side chains, respectively

(PFV) (Hare et al. 2010), there is no crystal structure of full-length HIV-1 IN. The main obstacle for structural studies of HIV IN is its propensity to aggregate. The published two-domain crystal structures of HIV-1 IN (comprising the N-terminal and the catalytic core or the catalytic core and the C-terminal domain) as well as the crystal and NMR structures of individual domains represent valuable but incomplete information on the functional structure of the HIV intasome. HIV integrase was the last HIV enzyme to be effectively targeted with small molecules. Reasons were the lack of homologous disease targets, as opposed to well-studied DNA polymerases and aspartyl proteases and the absence of a crystal

structure. Indeed, nowadays structural information is playing a central role in successful drug development.

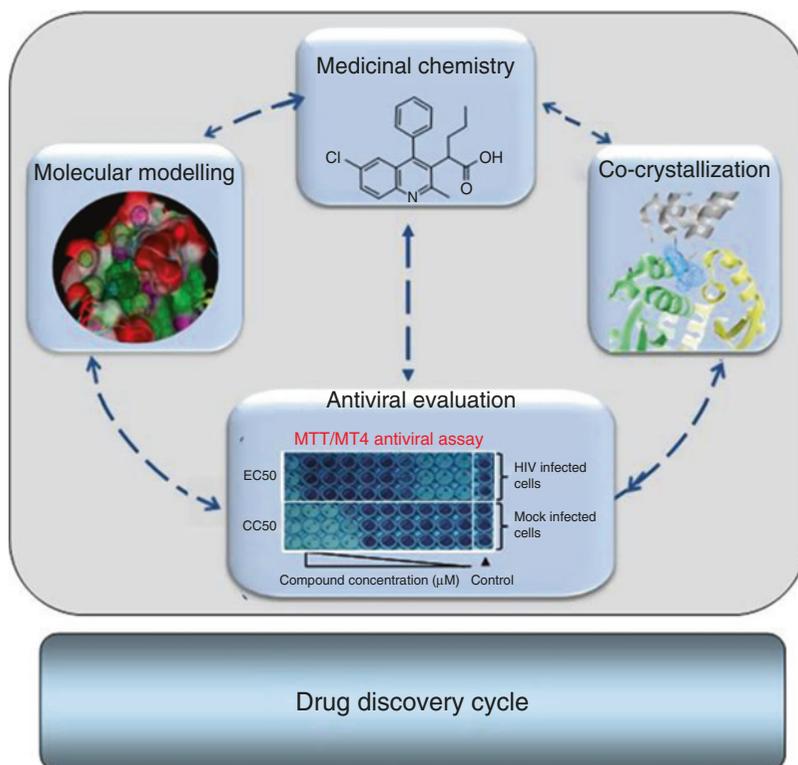

After completion of reverse transcription, the so-called pre-integration complex (PIC) is formed. Along with viral cDNA and IN, the PIC contains viral reverse transcriptase (RT), nucleocapsid (NC), matrix (MA), and Vpr. RT and NC are involved in the synthesis of viral cDNA, while MA and Vpr may affect nuclear import of the PIC. The PIC also contains host cell proteins, and nuclear import is mediated by the interaction with transport factors and nucleoporins. In the nucleus HIV IN catalyzes the stable insertion of the viral cDNA into a host chromosome.

The recent success in the application of structure-based rational drug design in the discovery and development of allosteric HIV-1 integrase (IN) inhibitors, the LEDGINs (Christ et al. 2010), was possible due to 7 years of intensive basic research on the cofactor lens epithelium-derived growth factor/p75 (LEDGF/p75). LEDGINs inhibit the interaction between LEDGF/p75 and HIV-1 IN and will be used as an example to discuss approaches, challenges, and future perspectives of SMIPPIIs.

Rational Design of LEDGF/p75-IN Interaction Inhibitors

Different approaches have been employed to design and identify small-molecule inhibitors of the LEDGF/p75-IN interaction. These include large-scale screening of chemical libraries (Du et al. 2008; Hou et al. 2008), computational three-dimensional (3D) database screening of chemical libraries, and structure-based de novo design (Christ et al. 2010; De Luca et al. 2009). High-throughput screening of large libraries of chemicals against a biological target is the prevailing method for the identification of new hit compounds in modern drug discovery. Alternatively, virtual screening is based on a computer-aided survey of large libraries of chemicals that complement targets of known structure and on experimentally testing of a limited set of compounds predicted to bind well. In order to obtain *bona fide* LEDGF/p75-IN interaction inhibitors, a structure-based drug design effort was initiated in 2007 (Christ et al. 2010). Drug design is based on a virtual screen of large libraries of small molecules to fit a consensus pharmacophore docked into the region of interest. The consensus pharmacophore consists of chemical groups critical for interaction with amino acid residues or peptide backbones in the proposed drug-binding pocket. In our case the pharmacophore was designed to bind to the LEDGF/p75 binding pocket located at the interface of a dimer of the CCD of HIV-1 IN. In principle, any drug discovery project requires design, prioritization,

analysis, and interpretation of results of consecutive experiments to ultimately facilitate the development of new therapeutic compounds. Often, it is the combination of methods, rather than a single experiment, that moves a drug discovery project forward. The scheme of the rational drug design work flow used during the discovery and hit-to-lead optimization process of LEDGINs is depicted in Fig. 2. The *in silico* screen for LEDGINs integrates a multidisciplinary approach where existing structural bioinformatics and chemoinformatics were employed in combination with a validated target-based PPI assay (Christ et al. 2010). Different crystal structures of the HIV-1 CCD and co-crystal structures with the IBD of LEDGF/p75 (Cherepanov et al. 2005) or ligand bound to the CCD were superpositioned to refine and construct more precisely a consensus pharmacophore model. Most important features in the final predictive pharmacophore model were a “hydrophobic/aromatic” moiety overlapping with Ile365 of the IBD, a “hydrophobic/aromatic” feature overlapping with Leu368 of the IBD, “acceptor” features mimicking the acid functionality of Asp366, and a “hydrophobic/aromatic” feature overlapping with the Lys364 side chain of LEDGF/p75. 200,000 commercially available and structurally diverse compounds were filtered using the established pharmacophore query. After serial filtering of the initial libraries, 25 promising molecules were ordered for biological evaluation in a bead-based *in vitro* LEDGF/p75-HIV-1 IN protein-protein interaction assay in the AlphaScreen™ format (Fig. 2). AlphaScreen™ is a bead-based medium throughput assay optimized to measure the interaction between LEDGF/p75 and HIV-1 IN (Christ et al. 2010). Of the 25 molecules retained from the initial screening, four hit molecules inhibited the LEDGF/p75-HIV-1 IN interaction. One of the hit molecules, LEDGIN 1, inhibited the PPI by 36% at 100 μM and served as a starting point for structure-activity relationship (SAR) investigations aimed at the identification of more potent LEDGINs (Christ et al. 2010). Medicinal chemistry optimization, aided by structural information provided by high-resolution co-crystals of LEDGIN 3 soaked into the

Cellular Cofactors of HIV as Drug Targets, Fig. 2 Work flow for rational design of LEDGINs. LEDGINs result from a rational drug discovery strategy involving a multidisciplinary effort. A 3D pharmacophore query was constructed for virtual screening of 200,000 molecules in commercial libraries. After performing stringent sequential scoring and filtering of the best scoring chemical entities, 25 molecules were retained and tested in the *in vitro* AlphaScreen™ assay. Hits emerging from

the screening were optimized by reiterative chemical refining and biological profiling in AlphaScreen™ and in a cell-based antiviral assay, MTT/MT4. Structure-activity relationships were deduced and used to guide synthesis of analogues with enhanced activity. The resulting early lead compounds were then further optimized in an integrated lead optimization strategy, while the molecular mechanism of action was investigated in cell culture. A similar approach may be used for other HIV cofactors

HIV-1 CCD, generated congeners of LEDGIN 3 (including LEDGINs 6 and 7) with improved biological activity.

Furthermore, LEDGINs did not interfere with the interaction between LEDGF/p75 and its cellular binding partners JPO2 or pogZ, confirming their specificity. Of note Hou et al. (Hou et al. 2008) identified several compounds inhibiting the LEDGF/p75-IN interaction through high-throughput screening of a compound library of more than 700,000 small molecules with AlphaScreen™. However, the quinolinylacetic acid derivatives are the first examples of potent and specific inhibitors of HIV-1 replication which

have been extensively evaluated for their therapeutic potential and mechanism of action in cell-based antiviral assays (including in primary cells) (Christ et al. 2010).

LEDGINs as Therapeutics

A critical evaluation of the mechanism of action and therapeutic potential of LEDGINs requires investigation of different drug characteristics: (a) a high binding affinity and specificity to HIV-1 IN, (b) potent and broad-spectrum anti-HIV activities in cell-based antiviral assays,

(c) lack of toxicity, and (d) an optimal pharmacokinetic (PK) and pharmacodynamic (PD) profile allowing a once a day administration in patients. Inhibition of the LEDGF/p75-HIV-1 IN interaction by LEDGINS blocks HIV integration (Christ et al. 2010). Integration inhibitors are characterized by a typical pattern of viral DNA species as measured by Q-PCR. 2-LTR circles are the dead-end by-product of non-integrated viral DNA; their number is increased upon integration block if steps upstream are not hampered. Both the classical integrase strand transfer inhibitor (INSTI) raltegravir and LEDGINS reduce the number of integrated proviral DNA and increase the number of 2-LTR circles without effect on reverse transcription. Resistance selection in cell culture against a new class of antiviral agents ultimately corroborates the antiviral target. By serial passaging of HIV-1 in increasing concentrations of LEDGIN 6, a resistant strain with the A128T substitution in IN was selected. The A128 residue is a hot spot of the IN-LEDGF/p75 interface and was included in the predictive pharmacophore model for the virtual screen. The resistance mutation thus corroborates the specificity of LEDGINS. The A128T mutation in integrase is not associated with resistance to INSTIs, and LEDGINS lack cross-resistance with other ARV classes corroborating their novel mode of action.

Other Cellular Cofactors of HIV with Potential as Antiviral Target

CCR5 and CXCR4, chemokine receptors, were identified as coreceptors of HIV in the 1990s (Deng et al. 1996). Natural resistance of individuals against HIV infection helped to identify the CCR5 coreceptor, whereas the antiviral bicyclam, developed in a random cell-based HIV replication screen, helped to understand the CXCR4 receptor.

DDX3 is an HIV cofactor that functions as an RNA-dependent ATPase/helicase in the Rev-RRE/CRM1 pathway for the export of unspliced/partially spliced HIV-1 transcripts (see entry “► [DDX3, Cofactors, and RNA Export](#)”). During screening for cellular factors induced by

Tat, the upregulation of DDX3 in human cell lines was observed (Yedavalli et al. 2004). Functional validation of a role of DDX3 in HIV nuclear export and HIV replication was obtained using antisense and dominant negative inhibition of DDX3 function. Co-immunoprecipitation showed interaction between DDX3 and CRM1 and DDX3 and Rev. Since DDX3 is a DEAD box helicase, it constitutes a possible antiviral target (Yedavalli et al. 2004).

Conclusion

PPIs represent an attractive group of biologically relevant targets for the development of small-molecule protein-protein interaction inhibitors (SMIPPIs). Direct interactions between HIV and intracellular cofactors provide novel druggable PPIs. This strategy is well exemplified by the discovery of drugs targeting LEDGF/p75-IN interaction. LEDGINS show a pathway of resistance development that is different from that of the INSTIs and lack cross-resistance with ARV in the clinic. Discovery of LEDGINS is a good example of structure-based rational drug design targeting a well-defined and biologically relevant PPI. Coreceptors and other cofactors presented in this entry may represent novel HIV drug targets.

Definition

T-cells play a central role in both the control and pathogenesis of HIV infection. While T-cell responses against HIV-1 infection have been studied in great detail, much less is known about T-cells in the context of HIV-2. This entry summarizes current understanding of the quantitative and qualitative characteristics of HIV-2-specific CD8⁺ and CD4⁺ T-cell responses, highlighting key areas in which they may differ from responses against HIV-1, and the clinical implications of such disparities.

Introduction

Although HIV-1 and HIV-2 share substantial similarity in terms of genome and life cycle, there are clear epidemiological and prognostic distinctions between them. An important distinguishing feature of infection is the distribution and time to clinical progression (Marlink et al. 1994). In contrast to HIV-1 infection, where the overwhelming majority of treatment-naïve patients develop AIDS within approximately a decade, the outcome of HIV-2 infection follows an unusual bimodal distribution, with more than half of untreated patients exerting strong control over the virus and the remaining patients progressing toward clinically indistinguishable end-stage disease (Brun-Vezinet et al. 1987; Clavel et al. 1987). Uniquely, the patients that do progress to AIDS

maintain significantly higher CD4⁺ lymphocyte counts and longer survival times following symptomatic onset than HIV-1 patients at the equivalent stage (Martinez-Steele et al. 2007). Additionally, long-term nonprogressors (LTNPs) and elite controllers (ECs) are significantly over-represented in HIV-2 infection, with rates as high as 37% in some cohorts (Thiebaut et al. 2011; van der Loeff et al. 2010) – markedly higher than the values below 1% typically recorded in the case of HIV-1.

The associated mortality rates of HIV-1 and HIV-2 infection are therefore vastly different. Relative to the uninfected population, HIV-1 patients present with a 10–20-fold increase in mortality, while in HIV-2 patients it is only twofold (Mulder et al. 1994; Poulsen et al. 1997; van Tienen et al. 2011). HIV-2-associated mortality risk is also significantly correlated with plasma viral load, with low levels of circulating viremia being strongly predictive of long-term survival and good clinical outcome (Ariyoshi et al. 2000; Berry et al. 2002; van der Loeff et al. 2010). It has been well established in the case of HIV-1 that the control of acute viremia and determination of the viral set point are themselves associated with efficient and timely T-cellular responses (Borrow et al. 1994; Koup et al. 1994; Ransinghe et al. 2012). Furthermore, recent studies have since revealed that robust T-cell responses are also elicited in seropositive HIV-2 patients. From these observations there is mounting evidence for an important role of T-cells in HIV-2 control and disease progression.

Background

T-cells are important players in the context of HIV-1 infection. The roles of CD4⁺ and CD8⁺ T-cells in both viral control and pathogenesis are extensive and will be discussed in detail in other entries (► [HIV and SIV, CD4 T-Cell Responses to](#), ► [HIV and SIV, CD8 T Cell Responses to](#)). Briefly, CD4⁺ lymphocytes orchestrate the immune response by activating a diverse range of innate and adaptive effector cells, while CD8⁺ lymphocytes lyse infected cells and secrete

antiviral factors that suppress infection through noncytotoxic mechanisms.

As a result of intense and long-standing investigation, much is known about the role of T-cells in HIV-1 infection. However, it is arguably less clear for HIV-2, due largely to the relative paucity of studies into this viral infection. Furthermore, investigations that draw direct comparisons between HIV-1 and HIV-2 often fail to stratify findings based on important clinical parameters, having substantial implications for proper interpretation of the data. For example, despite the characteristically lower viral load of HIV-2 patients, they are often directly compared to HIV-1 patients *as a whole*, rather than more appropriate subsets such as LTNPs.

Despite these limitations, a clear picture is being developed of not only the function of T-cells in the context of HIV-2, but also how the response differs from HIV-1 infection, and the potential consequences for viral control and patient prognosis.

CD8⁺ Virus-Specific T-Lymphocyte Responses: HIV-1 Versus HIV-2

The earliest published evidence for a role of CD8⁺ virus-specific T-cell responses in the control of HIV-2 infection came from observations in the macaque model that gag-, pol-, and env-specific cytotoxic responses could be detected in the blood of animals infected with HIV-2_{BEN} (Voss et al. 1992). However, the specific epitopes recognized by the generated lymphocytes were not identified at the time.

Soon after, the first description of HIV-2-specific T-cell responses in a human study was reported, following the observation that gag-specific cytotoxic T-lymphocytes against an identifiable epitope (1A; TPYDINQML) could be extracted from the peripheral blood mononuclear cells (PBMCs) of over 55% of study participants in a cohort of Gambian HIV-2-infected asymptomatic patients, without the need to first restimulate the cells in vitro (Gotch et al. 1993). The study had exciting implications, in that strong HIV-2 gag-specific responses were demonstrable

at a much higher prevalence than the detection in approximately 25% of healthy HIV-1 seropositive patients the group had reported previously (Gotch et al. 1990), indicating that the increased frequency and strength of HIV-2-specific responses could be responsible for mediating enhanced control of this virus, thereby explaining its unique pathology.

However, the sample size in the study was small, limited to only nine patients, and subsequent larger studies comparing HIV-1 and HIV-2 responses failed to corroborate any substantial difference in either frequency or magnitude of response in patients matched for disease stage (Gillespie et al. 2005; Jaye et al. 2004; Zheng et al. 2004). Instead, it has been suggested that the relatively reduced viral load of HIV-2 infection may be the result of either more efficient control exerted by a response of equivalent magnitude or conversely by reduced replication of the virus itself (Jaye et al. 2004).

An in-depth study of the functionality of HIV-1-/HIV-2-specific lymphocytes has since provided further support to the hypothesis that HIV-2-specific responses of equivalent magnitude may exert more efficient control on viral replication (Duvall et al. 2008). By measuring the production of cytokines and chemokines (IFN- γ , IL-2, TNF- α , & MIP-1 β), as well as degranulation (CD107a) and memory function by specific viral peptide-stimulated cells, it was determined that the degree of polyfunctionality exhibited by HIV-2-specific CD8⁺ T-lymphocytes is markedly higher than that of cells specific for HIV-1. Furthermore, polyfunctional HIV-2-specific lymphocytes release higher levels of IFN- γ and TNF- α than their monofunctional equivalents.

The more efficient response generated in HIV-2 patients has been linked to increased promiscuity of T-cell receptor (TCR) usage, leading to greater functional flexibility (Lopes et al. 2003). While the CD8⁺ cells of HIV-1 patients are known to undergo oligoclonal expansion in terms of TCR repertoire, HIV-2 patient cells were found to be much more heterogeneous. The authors inferred this to be functionally important as it suggests a greater ability to tolerate variation in recognized epitopes and, by

extension, generate protection against a broader range of HIV-2 strains. This is consistent with previous observations that highly oligoclonal TCR usage by HIV-1-specific cytotoxic lymphocytes is predictive of poor clinical outcome (Pantaleo et al. 1997). However, the study was not without its limitations, as the authors considered overall TCR usage, rather than performed a direct comparison between virus-specific T-cells in HIV-1 and HIV-2 infection.

A more recent study by Leligidowicz et al. – who set out to describe the TCR usage and broader characteristics of CTLs in the control of HIV-2 infection – identified a distinct differentiation phenotype from cells associated with HIV-1 infection (Leligidowicz et al. 2010). The cells were found to be CD27⁺ and CD28⁺, characteristic of early differentiation (Appay et al. 2002). The level of CD27⁺CD28⁺ cells was positively associated with CD4 count, suggestive of overrepresentation in patients with delayed progression. Furthermore, the patients unexpectedly demonstrated oligoclonal TCR V β segment usage in HLA-B*3501-restricted CTLs – contrary to previous evidence (Lopes et al. 2003; Pantaleo et al. 1997) – and all CTLs specific to the study epitope (HIV-2 gag NY9) made use of V β 17. These findings are consistent with the selective expansion of high-affinity V β segments by affinity maturation. Furthermore, the study demonstrated greatly enhanced secretion of IFN γ and pro-inflammatory cytokines by these cells at low peptide concentrations, indicating that they have high functional avidity.

While the protective effect of CD8⁺ lymphocytes is largely attributed to their role in mediating cell killing, they are also able to control infection by noncytotoxic means such as the release of soluble antiviral factors. The production of high levels of β -chemokines such as MIP-1 α (CCL3), MIP-1 β (CCL4), and RANTES (CCL5) by CD8⁺ cells plays a role in the prevention and/or control of HIV-1 and SIV infections (Ahmed et al. 2002, 1999; Cocchi et al. 2000), by inhibiting binding of the M-tropic virus to the co-receptor CCR5 on entry (Alkhatib et al. 1996; Cocchi et al. 1996). The importance of CD8⁺ T-cell-soluble factors in the control of HIV-2 is also becoming increasingly

apparent. In 1997, it was observed that filtered cell-free culture fluid containing unknown soluble factors secreted by CD8⁺ lymphocytes was capable of suppressing HIV-2 replication in baboon CD4⁺ cells, in vitro (Blackbourn et al. 1997); but the authors concluded that MIP-1 α , MIP-1 β , and RANTES were not responsible in this study. More recently, β -chemokine production by CD8⁺ lymphocytes has been shown to be greatly elevated in human HIV-2 patients relative to uninfected controls and correlates strongly with CD4⁺ lymphocyte count in these individuals (Ahmed et al. 2005).

Taken together, these findings suggest that homologous HIV-2 CD8⁺ T-cell responses – while neither more frequent nor higher in magnitude – may exert more efficient control over infection than the equivalent HIV-1 response. This is likely to be due to increased avidity and polyfunctionality: including direct cytotoxicity and the production of high levels of soluble antiviral factors. It is therefore conceivable that the reduced viral set point characteristic of HIV-2 infection may be the result of an enhanced CD8⁺ lymphocyte response.

CD8⁺ T-Cell Epitopes and Cross-Reactivity in HIV-1 and HIV-2 Infection

The known CD8⁺ and CD4⁺ epitopes of the HIV-1 genome have been comprehensively mapped, and the Los Alamos National Laboratory (LANL) maintains an up-to-date record of these on its website (available: <http://www.hiv.lanl.gov/content/immunology/maps/maps.html>; accessed June 2015). However, far fewer HIV-2 epitopes have been described to date – as summarized in Table 1.

The degree to which HIV-2-directed CD8⁺ responses are cross-protective against HIV-1 is not well established. An early report demonstrated substantial cross-reactivity of HIV-2 patient-derived CD8⁺ lymphocytes against HIV-1 (Bertoletti et al. 1998). Here, the cytotoxic lymphocytes (CTLs) of 11 HIV-2 patients were tested for their ability to recognize gag-derived from four subtypes of HIV-1. Strikingly, nine of the patients responded to at least one subtype of HIV-1, while five of these patients were able to

respond to at least three subtypes. Four of the five patients demonstrating broad cross-reactivity carried HLA-B*5801: a class-I human leukocyte antigen (HLA) allele associated with slow progression in HIV-1 infection (Navis et al. 2007).

However, more recent evidence suggests that HIV-2-directed CD8⁺ responses may in fact be less cross-protective than those generated against HIV-1 (Jennes et al. 2008). The authors found that responses from HIV-2 patient T-cells against HIV-1 gag peptides were both weaker in magnitude and narrower in breadth than the cross-reactive responses elicited by HIV-1 patients. However, responses to *homologous* gag were decisively broader and stronger in HIV-2 patients than HIV-1, perhaps contributing to the greater immunological control and reduced viral load characteristic of this infection.

Surprisingly, HIV-2 patient responses to homologous nef are rare (Leligdowicz et al. 2007; Zheng et al. 2007). Nef is one of the most abundant viral proteins and one of the earliest to be expressed, making it a prime target for cellular responses in HIV-1 infection. It is also a major target for cytotoxic lymphocytes in acute SIV infection (Mothe et al. 2002). As such, it is very unexpected that an equivalent response is not detected against HIV-2 nef. Possible explanations that have been proposed for the lack of HIV-2 nef-specific responses include difficulties with epitope processing, HLA-binding, TCR recognition, and/or antigen presentation resulting from the low degree of sequence homology between HIV-1 and HIV-2 nef.

CD4⁺ Virus-Specific T-Lymphocyte Responses: HIV-1 Versus HIV-2

HIV-1 specific CD4⁺ T-lymphocytes are preferentially targeted by the virus and depleted from the host repertoire. Conversely, in the majority of HIV-2 infected individuals, the CD4⁺ T-lymphocyte compartment remains preferentially targeted but quantitatively preserved (Duvall et al. 2007). As such, qualitative changes in their performance are likely to have a significant impact on disease control.

Cellular Immune Response to HIV-2 Infection, Table 1 List of known HIV-2 CD4⁺ T-lymphocyte epitopes and epitope-containing peptides and their relative

position mapped to the HXB2 reference genome. Publications referring to the listed epitopes can be accessed through the associated PubMed ID

The proportion of patients with detectable CD4⁺ T-lymphocyte responses against gag is higher in HIV-2 donors than in HIV-1 donors when subjects with equivalent CD4⁺ counts are compared; and HIV-2 specific CD4⁺ T-lymphocytes demonstrate higher proliferative capacity than those specific to HIV-1 (Duvall et al. 2006). HIV-2 gag-specific CD4⁺ T-lymphocytes also demonstrate higher poly-functionality than HIV-1 gag-specific cells when the production of IFN- γ , TNF- α , MIP-1 β , and IL-2 and mobilization of CD107a are considered (Duvall et al. 2008).

A characteristic feature of asymptomatic, non-progressive HIV-2 infection in humans is the maintenance of robust CD4⁺ T-lymphocyte help

(Zheng et al. 2004). Furthermore, macaques are less likely to develop early signs of Th dysfunction when infected with nonpathogenic HIV-2 than the more pathogenic SIVmac (Dittmer et al. 1994). In summary, the preservation and persistence of both qualitative and quantitative features of CD4⁺ T-lymphocyte function appear to contribute to HIV-2 nonprogression and may account for viremic control in nonprogressors.

T-Lymphocyte Responses in HIV-2: Controllers Versus Progressors

HIV-2 patients who develop AIDS progress in a manner and time frame that is clinically

indistinguishable from HIV-1 non-controllers (Hansmann et al. 2005; Martinez-Steele et al. 2007). It is therefore surprising that a substantial proportion of HIV-2 patients control the infection, despite it having a demonstrated potential to kill. Understanding how disease progression is avoided in these patients may provide insight as to how to control HIV-1 infection. This key interest in distinguishing LTNPs from progressors stems from a widely held hypothesis that LTNPs have acquired natural immunity against HIV and from the idea that HIV vaccines should ideally replicate the immune responses found in such patients. Unfortunately, LTNPs are extremely rare in HIV-1 infection, and it is in this regard that the paradigm of HIV-2 infection distinguishes itself (Rowland-Jones and Whittle 2007).

In HIV-2 infection, an inverse relationship has been demonstrated between CTL responses and proviral load, with stronger cytotoxic T-lymphocyte activity detected in donors with low viral load (Ariyoshi et al. 1995; Sarr et al. 2001). Moreover, type 1 Th (Th1) responses are more prolific in donors with undetectable HIV-2 RNA versus non-controllers (Alatrakchi et al. 2006). Similar to the case for CD4⁺ T-lymphocytes, cytotoxic and IFN- γ responses were more likely triggered by HIV-2 gag, and patients with undetectable viremia demonstrated increased competence in mounting such responses (de Silva et al. 2013; Leligdowicz et al. 2007). More specifically, CTLs from non-progressors were more likely to target gag, while equivalent responses were absent in the majority of progressors. Ultimately, the establishment of gag-specific CD8⁺ polyfunctionality shows a strong inverse relationship to HIV-2 viremia in infected subjects.

This leads to a further question that has remained relatively unanswered: what accounts for the more efficient T-cell responses that occur in HIV-2 controllers than in progressors? And furthermore, why are T-cell responses more effective against HIV-2 than HIV-1? How are high levels of antiviral T-cells maintained in controllers who have undetectable plasma viral load for prolonged periods? Studies have alluded to the enhanced infectivity of dendritic cells (Manel

et al. 2010) facilitated by the additional encoding of vpx by HIV-2, which antagonizes SAMHD1 (Laguette et al. 2011). The latter may have consequences for antigen processing and presentation and the elicitation of innate immune responses such as type I IFN and TRIM5 α which may be more effective against HIV-2 (Cordeil et al. 2013; Ylinen et al. 2005). Yet Duvall et al. showed the lack of permissibility of blood-derived mDCs and pDCs to HIV-2 infection in culture, which suggests the possibility of alternative protective mechanisms (Duvall et al. 2007). The increased susceptibility of the HIV-2 capsid to TRIM5 α recognition could potentially lead to more efficient proteasomal processing of HIV-2 proteins and thus facilitate antigen presentation.

HIV-2-Specific T-Lymphocyte Responses in Dual Infection

A highly controversial topic regarding HIV-2-specific T-cell responses is whether or not these responses confer a protective advantage against subsequent infection with HIV-1. Furthermore, in patients dually infected by both HIV-1 and HIV-2, do these responses reduce the rate of disease progression?

Dual infection of both HIV-1 and HIV-2 is extremely uncommon in developed nations, but has been reported at a prevalence of between around 0% and 3% of the population in some West African countries (Hamel et al. 2007; Mansson et al. 2009). A high-profile early study of Senegalese sex workers suggested that HIV-2 infection may have conferred a protective advantage against incident HIV-1 infection in these women (Travers et al. 1995). Conversely, subsequent studies failed to repeat this finding (Greenberg 2001; Norrgren et al. 1999), and the increased level of T-cell activation in dual infection is suggestive of more aggressive disease (Koblav-Deme et al. 2004). There is also evidence to suggest that over an extended time scale, HIV-1 may outcompete HIV-2 in dually infected individuals with low CD4 counts (Raugi et al. 2013).

However, a substantial limitation to studies of dual-infected patients – in addition to the scarcity

of suitable study candidates – is that often the patients recruited are those attending sexual health clinics with symptomatic HIV or coexisting sexually transmitted infections. As such, they are perhaps more likely to present with aggressive or late-stage illness. Supporting this claim, a study of individuals who were unaware of their positive status and were recruited from tuberculosis and occupational cohorts showed that the HIV-1 plasma viral load of dual-infected patients was significantly lower than patients infected with HIV-1 alone (Andersson et al. 2000).

In a comparative longitudinal study of patients either dually or singly infected, Esbjörnsson et al. found that dually infected patients progressed to AIDS on average 36 months slower than patients infected with HIV-1 alone (Esbjörnsson et al. 2012). The protective effect appeared strongest in patients first infected with HIV-2 who controlled the infection and subsequently became HIV-1 positive, suggestive of an inhibitory effect mediated by existing T-cellular responses against HIV-2 antigens (de Silva et al. 2012). The conclusion to be drawn here is that HIV-2 may provide a degree of protection against HIV-1 disease progression, rather than against infection.

The direct role of T-lymphocytes in the context of dual infection has not been extensively studied. However, a 2007 study by Zheng et al. compared the T-cellular responses of HIV-1, HIV-2, and dual-infected patients to different env, gag, and nef epitopes (Zheng et al. 2007). The study demonstrated that the magnitude and frequency of responses against HIV-1 proteins were greater than those against HIV-2 and that functional CD4⁺ T-cell responses could be detected in all dually infected patients. Moreover, in the dual-infected patients, the level of HIV-2 gag-specific CD4⁺ and CD8⁺ T-cell response showed a significant inverse correlation with HIV-1 plasma viral load, indicative of a protective effect.

Conclusions

While the role of the cellular immune response in the context of HIV-1 infection has been well established for some time, it is only recently that

a clearer picture of HIV-2-specific T-cell responses is developing, and even now we can see only the proverbial tip of the iceberg. However, with a growing number of studies comes growing evidence that T-lymphocytes play a major role in the control of the virus.

Virus-specific CD8⁺ cells are detectable in HIV-2 patients, but not at significantly higher frequency or magnitude than in HIV-1 infection: targeting of gag epitopes is a prominent feature of HIV-2 controllers that is frequently absent in progressors. However, T-cellular responses of equivalent magnitude may exert more efficient control on infection through increased avidity and broader functionality: for example, through direct cytotoxicity or the release of higher levels of inflammatory cytokines and soluble antiviral factors at low antigen concentrations. It is worth noting that high frequencies of virus-specific T-cells can be found in HIV-2-infected controllers who have maintained an undetectable viral load for many years.

Polyfunctional CD4⁺ lymphocytes may be detected in HIV-2 patients at higher levels than in HIV-1 and demonstrate substantially improved proliferative capacity. Furthermore, there is preliminary evidence from the macaque model that suggests Th cell dysfunction may be less likely to occur in HIV-2 infection than in infection with more strongly pathogenic retrovirus types, although this has not yet been corroborated in humans. The reason for the relative preservation of Th function in HIV-2 infection is not known, as HIV-2 shows the same preferential targeting of virus-specific Th cells as does HIV-1.

Collectively, these findings strongly suggest that efficient T-cellular responses may play at least a supporting role in explaining some of the significant prognostic differences between HIV-1 and HIV-2 infection. This hypothesis is supported by observations in dually infected individuals, which indicate that initial infection with HIV-2 may confer some degree of protection against subsequent infection with HIV-1, due to the presence of preexisting cellular responses.

While dissimilarities arguably exist between HIV-1- and HIV-2-specific T-cellular responses *in vivo*, the mechanisms by which these arise are

not currently well understood. Promiscuity of TCR usage and a unique differentiation phenotype have been proposed as explanations, which would allow functional flexibility and recognition of a broader range of antigens, giving rise to a response which may or may not be cross-reactive to some degree.

In summary, the cellular immune response to HIV-2 is a complex process, which appears to have an important role in controlling infection and promoting less aggressive disease progression than that seen in HIV-1 infection. The specific processes involved and the extent of the control that it exerts are currently not well established, but active research in this field is gradually filling these gaps and paving the way to the identification of potential therapeutic targets.

Central Memory CD4 T Cells

Shannon Murray, Rémi Fromentin and
Nicolas Chomont
Vaccine and Gene Therapy Institute of Florida,
Port St Lucie, FL, USA

Definition

Memory CD4 T cells can be divided into central memory (T_{CM}) and effector memory (T_{EM}) subsets, which are endowed with different homing

and proliferative capacities as well as distinct effector functions (Sallusto et al. 1999). T_{CM} cells can directly home to secondary lymphoid organs and express the lymphoid homing molecules CD62L (L-selectin) and CCR7 (chemokine receptor 7). In contrast, T_{EM} cells home to tertiary sites and tissues and have direct effector functions upon stimulation, including secretion of inflammatory cytokines such as interferon gamma ($IFN-\gamma$) and tumor necrosis factor (TNF). Thus, T_{CM} cells define a lymphoid homing subset without immediate effector function, whereas T_{EM} cells are defined as a subpopulation that localize to tissues, with rapidly induced effector function and less proliferative potential. A dominant theory is that T_{CM} represent a precursor to T_{EM} as T_{CM} have greater proliferative potential, are longer lived, and can generate T_{EM} and T effector cells upon stimulation. Furthermore, T_{CM} and T_{EM} homeostatic proliferations are distinct as T_{CM} respond to interleukin 7 (IL-7), whereas T_{EM} respond to interleukin 15 (IL-15).

The description of the two T cell memory subsets led to different models of memory generation. In the “divergent” model of memory T cell formation, naïve T cells, after antigen engagement, can directly differentiate into an effector T cell or a memory T cell. A variation of this divergent model is the “bifurcation” model, wherein daughter cells of naive T cells have an unequal cell division yielding a memory and an effector cell. This is in contrast to a “linear differentiation” model where effector cells are generated first and subsequently yield memory populations (Ahmed et al. 2009). What controls the memory subset composition in response to infection is not completely understood; however, duration, location, strength, and dose of antigen are thought to play critical roles (Kaech et al. 2002). Later work confirmed the T cell self-renewing properties of T_{CM} previously described, although the exact lineage relationship between effector T cells and the memory subsets *in vivo* has not been proved.

Subsequently, additional subsets have been identified including a transitional memory T cell subset (T_{TM}), an intermediate between T_{CM} and T_{EM} , which does not express CCR7 although retains other markers of T_{CM} cells such as CD27.

A stem cell-like memory T cell population (T_{SCM}) that expresses some classical markers of naïve T cells (CD45RA+) and of memory T cells (CD95) has also been identified. T_{SCM} cells have multipotency and increased survival and proliferative capacity and can generate all memory T cell subsets including T_{CM} (Gattinoni et al. 2011).

T_{CM} as a Target for HIV Infection and Replication

Memory CD4 T cells play a critical role in immune responses to viral infections and are a key target in HIV infection. Depletion of these cells results in alteration of immune function and progression to AIDS. As mentioned above, the memory CD4 T cell compartment is heterogeneous, with T_{CM} , T_{TM} , and T_{EM} cells displaying differences in their homing capacity, their ability to mount immediate effector responses, and their longevity. The relative susceptibility to HIV infection of these three memory CD4 T cells subsets is driven by a variety of cellular factors including the level of expression of the major HIV co-receptors CCR5 and CXCR4, the cellular abundance of viral restriction factors, and the preferential localization and homing capacity of these cells to anatomical sites in which HIV replication is promoted.

HIV Co-receptors

CD4 T cells displaying a T_{CM} , T_{TM} , and T_{EM} phenotype can all be infected by HIV *in vitro* (Flynn et al. 2014). However, the levels of expression of the two major co-receptors for HIV greatly vary between these subsets, with CCR5 levels increasing with the differentiation status, whereas CXCR4 expression gradually diminishes from T_{CM} , T_{TM} , to T_{EM} . As a result of this differential expression pattern, T_{CM} cells are more susceptible to infection by CXCR4-using viruses than by CCR5-using isolates. Similarly, the relative levels of expression of the co-receptors on the respective T cell subsets are a decisive factor for dendritic cell-mediated HIV transmission of memory T cells: CCR5-using viruses are most efficiently transmitted to T_{EM} cells, and CXCR4-using HIV

are preferentially transmitted to T_{CM} cells (Groot et al. 2006).

Restriction Factors

The relative abundance of restriction factors among the different memory subsets represents another parameter that greatly influences the sensitivity of a subpopulation to HIV infection. Indeed, resting memory CD4 T cells with the highest APOBEC3G protein levels display the lowest levels of provirus in vivo. Another example of the critical importance of restriction factors in T cell susceptibility to HIV infection is provided by the recently discovered restriction factor SAMHD1. SAMHD1 is expressed at high levels in all memory CD4 T cells displaying a quiescent phenotype (naïve and resting memory CD4 T cells), suggesting that a minimal state of activation, which leads to the downregulation of SAMHD1, is required to achieve productive infection (Baldauf et al. 2012; Descours et al. 2012a). As activation often leads to cell proliferation in T cells, this may provide an explanation for the greater susceptibility of cycling T cells to HIV infection compared to resting, quiescent T cells. Of note, those cycling CD4 T cells that are more susceptible to infection usually display a T_{CM} phenotype during chronic HIV infection (Sieg et al. 2005). Altogether, these studies suggest that cycling T_{CM} cells may be the preferential target for the virus during untreated HIV infection, at least in the peripheral blood.

Homing Capacities

The susceptibility of CD4 T cells to HIV infection may also be greatly influenced by their capacity to migrate to secondary lymphoid organs, in which HIV replication predominantly takes place. Indeed, it is well established that the bulk of HIV replication occurs in lymphoid tissues such as the gut-associated lymphoid tissue (GALT) and lymph nodes. The relative susceptibility to HIV infection of memory CD4 T cell subsets residing in these compartments has mainly been studied in animal models, particularly in simian immunodeficiency virus (SIV)-infected nonhuman primates. Productive infection and depletion of activated

resident CCR5+ CD4+ T cells at the earliest stage of SIV infection have been repeatedly observed. This is likely to mainly concern T_{EM} cells, as these cells predominate in the gut, whereas T_{CM} cells are rare in this tissue. Although T_{CM} cells are unlikely to be directly infected in the gut, they play a critical role in this site. In an attempt to replenish the pool of tissue cells, CD4 T cells (including T_{CM} cells) are recruited from the periphery and home to the gut, where they differentiate into effector cells and are eventually eliminated. In other words, effector-site T_{EM} cell populations show a slow, continuous decline, and their homeostasis is dependent on the production of new cells from T_{CM} precursors (Okoye et al. 2007).

As they express CCR7, T_{CM} cells have the capacity to recirculate between the periphery and second lymphoid organs and constitute the predominant memory CD4 T cells found in lymph nodes. The unique microenvironment of this compartment during viral infection (inflammation stemming from viral replication and limited accessibility to HIV-specific cytotoxic T lymphocytes) may greatly facilitate infection of this subset, even though the frequency of infection of T_{CM} cells residing in the lymph node of chronically HIV-infected subjects has never been directly measured. Recently, follicular helper T cells (T_{fh}), which express CXCR5 and are found in the B cell follicles of secondary lymphoid organs, have been identified as the major CD4 T cell compartment for HIV infection, replication, and production (Perreau et al. 2013). A fraction of circulating T_{CM} cells express CXCR5, and a preferential recruitment of these cells to CXCL13-rich B cell follicles promotes a quick and efficient protective secondary humoral immune response. Therefore, T_{CM} cells with T_{fh} functions are endowed with optimal homing capacities, functions, and survival features and thus may serve as an ideal subset to sustain HIV production in lymphoid tissues.

Infection of T_{CM} Cells in Acute and Chronic HIV Infection

Despite the aforementioned predicted resistance of T_{CM} cells to HIV infection as a result of low

CCR5 expression and high levels of restriction factors, HIV DNA is readily detected in the three subsets of memory CD4 T cells during the earliest stage of infection. Of note, although acute HIV infections are usually characterized by high levels of replication of viruses preferentially using CCR5 (which may restrict infection in T_{CM} cells), almost a third of the pool of infected CD4 T cells consists of T_{CM} cells within 1 month post-infection, and all three memory CD4 subsets can produce replication-competent virus after stimulation *in vitro* (Bacchus et al. 2003). Therefore, it is clear that T_{CM} cells are infected early during the natural history of HIV pathogenesis. More importantly, high CCR5 density on T_{CM} cells during acute HIV infection is associated with rapid disease progression (Yang et al. 2012), suggesting an important role for this particular subset in the depletion of the CD4 compartment.

In chronically HIV-infected subjects (receiving ART or not), resting memory CD4 T cells are the predominantly infected cells. Infection of naïve cells and terminally differentiated cells is rare (Brenchley et al. 2004; Chomont et al. 2009). Within the memory compartment, the T_{CM} subset is the predominantly infected subset and harbors a more diverse viral population compared to the others. Altogether, these observations indicate that although T_{CM} cells may be intrinsically relatively resistant to HIV infection, these restrictions are largely alleviated *in vivo*. Infection of T_{CM} cells has been clearly demonstrated in both SIV and HIV infections and may have a critical impact on disease progression during lentiviral infections.

Relative Protection of T_{CM} Cells to HIV as a Mechanisms for Control

Several lines of evidence indicate that a lower relative contribution of the T_{CM} subset to the HIV reservoir and a greater preservation of T_{CM} cells are elements integrally correlated to control of HIV infection. Widely differing models of viral control uniformly demonstrate that T_{CM} parameters are correlated to viral control and/or improved prognosis during HIV infection.

Long-Term Nonprogressors and T_{CM} Preservation

Protective HLA alleles, namely, HLA-B27 and HLA-B57, are associated with reduced plasma viral RNA levels and cell-associated HIV DNA levels as well as increased polyfunctional HIV-specific CD8 T cell responses. Long-term nonprogressors (LTNP) include subjects with or without the protective HLA-B27 or HLA-B57 alleles (Descours et al. 2012b). LTNPs with the protective alleles have a significantly lower percentage of T_{CM} cells that contribute to the viral reservoir than those without the protective allele (20% vs. 40% of the total CD4 T cell HIV reservoir, respectively). This lower contribution of T_{CM} cells to the HIV reservoir correlates to a greater T_{CM} pool size. The anti-Gag HIV-specific CD8 T cell responses in the LTNPs with the protective alleles are greater in number, as may be expected, but also correlate inversely to the relative contribution of T_{CM} cells to the viral reservoir. Thus, this model proposes that anti-Gag CD8 T cell responses in those with protective alleles are central to sparing HIV infection in T_{CM} cells, resulting in a preserved self-renewal capacity of this subset.

Posttreatment Controllers and Limited T_{CM} Viral Reservoir

Posttreatment controllers (PTCs) are a group of individuals who initiate ART early in infection and who are able to control viral replication for years after cessation of ART (Saez-Cirion et al. 2013). The PTCs, unlike other HIV controllers, do not have the protective alleles nor demonstrate potent anti-Gag CD8 T cell responses as measured by functional suppression assays. PTCs demonstrate less immune activation of CD4 T cells than their controller counterparts. In PTC, T_{TM} contribute the most to the viral reservoir, whereas in controllers, T_{CM} and T_{TM} contributed equally to the pool of infected cells. Furthermore, there were lower levels of HIV DNA in naïve T cells (T_N) in PTC compared to controllers. It may be that it is the limited viral reservoir in long-lived cells such as T_{CM} in PTC that results in “the gradual shrinking of the reservoir in PTCs for whom T_{TM} is the main reservoir” (Saez-Cirion et al. 2013).

Taken together, these different models of control – LTNP or PTC – indicate that while many aspects of pathogenesis differ, preservation of T_{CM} and a limited T_{CM} reservoir are common to disparate models of viral control.

Resistance of T_{CM} to Apoptosis in Elite Controllers

Underscoring the importance of T_{CM} in HIV pathogenesis (van Grevenynghe et al. 2008), T_{CM} from elite controllers (ECs) compared to those from successfully treated (STs) individuals have different half-lives. Examination of the lifespan of these cells after *in vitro* nonspecific T cell receptor (TCR) engagement indicates that T_{CM} from ECs are maintained for longer periods than T_{CM} from STs or HIV-uninfected individuals. This different lifespan is due to decreased apoptosis and not altered differentiation or proliferation. This preservation of T_{CM} in ECs is controlled, at least, in part, by FOXO3a (forkhead box O3a), a transcription factor whose phosphorylation inhibits activation of apoptotic-related factors and which is increased in T_{CM} from EC. An increased T_{EM} survival is also observed in EC, although the T_{EM} half-life is still relatively shorter than that of T_{CM} . T_{CM} in ECs and STs do not have different levels of activation marker expression, and the antiapoptotic phenotype in ECs is not correlated with protective alleles. Thus, it is likely that this antiapoptotic quality in T_{CM} from ECs increases the integrity of T_{CM} homeostasis, and it is this quality that plays a protective role in limiting HIV disease progression in ECs.

T_{CM} and Immune Reconstitution Post-ART

CD4 T cell immune reconstitution post-ART is an area of considerable interest. The strongest positive correlate of CD4 T cell levels after long-term ART is the absolute T_{CM} counts after long-term ART. This is even a stronger correlation than CD4 T cell counts at earlier time points after the initiation of ART, again, reinforcing the role of T_{CM} cells in T cell reconstitution. However, of note, the T_{CM} subset is defined, in some analyses including this one, by pooled T_{CM} and T_{TM} populations (i.e., using CD27⁺ and CCR7^{-/+} expression as population-defining markers). This is in

agreement to a previous work (Chomont et al. 2009) that had found that T_{CM} were under-represented in virally suppressed subjects with low CD4 counts, suggestive of T_{CM} depletion and/or differentiation of T_{CM} into T_{TM} in these individuals.

Subjects who initiate ART early after primary HIV infection that reach viral suppression after less than 6 months of ART have a higher proportion of T_{CM} cells in the peripheral blood than those who do not, suggesting that T_{CM} levels in the blood may be a good predictor of HIV suppression during ART (Karris et al. 2014). However, to note, there is a continuous decline of T_{CM} over time in the GALT in the same subjects, suggesting a different kinetic of viral suppression or an intensive cell death mediated by higher activation of CD8 T cells in tissues such as the GALT compared to peripheral blood.

SIV Infection Models and T_{CM} Preservation in Natural Hosts

The SIV model in the natural host, the sooty mangabey (SM), and the nonnatural host, the rhesus macaque (RM), indicate differences in the T_{CM} compartment. T_{CM} cells are preserved and have a longer half-life – 17 years compared to 16 months – in the SM nonpathogenic infection, compared to the RM pathogenic infection, respectively (McGary et al. 2014). In RM, the greater the fraction of T_{CM} cells, the greater the CD4 T cell numbers and the lower the plasma viral load. However, the levels of proliferating T_{CM} correlate negatively with CD4 counts in RM, while in the natural host, the SM, proliferation of T_{CM} correlates positively with CD4 counts. This indicates that increased levels of homeostatic proliferation of T_{CM} cells, possibly as a result of their continuous activation and/or depletion, are deleterious during SIV infection in RM. Other researches examining the SIV nonpathogenic and pathogenic models have corroborated this finding.

Thus, in various models of HIV disease progression, in the presence or absence of ART, or protective alleles, preservation of the T_{CM} compartment is correlated to control of viral infection, and improved prognosis or outcome, during HIV infection. Thus, T_{CM} preservation defines a

critical parameter of HIV pathogenesis, and interventions that preserve or enhance the T_{CM} subset warrant further evaluation for therapeutic effects.

T_{CM} Cells as a Reservoir for HIV During ART

Despite the fact that ART has dramatically reduced the death rate from AIDS and improved the quality of life of many HIV-infected patients, it is now clear that ART does not eradicate HIV. The virus persists in long-lived latently infected CD4 T cells that are the source of viral rebound when ART is discontinued. This HIV reservoir constitutes the major barrier to achieving a cure, and it is the T_{CM} cells that have been identified as a main reservoir for HIV during ART (Chomont et al. 2009).

Due to the long-lived nature and low levels of proliferation of T_{CM} cells, as aforementioned, latently infected T_{CM} cells can persist in HIV-infected individuals for their lifetime. T_{CM} cells are the main reservoir for HIV during ART in subjects who have reconstituted their CD4 T cell compartment (Chomont et al. 2009). Conversely, the reservoir is mainly localized to CD4 T cell displaying a T_{TM} phenotype in subjects with low absolute CD4 T cell counts. Genetic analysis of the proviral populations in T_{CM} show that this subset constitutes a stable reservoir with minimal proliferation levels, in agreement with their enhanced survival capacity.

The identification of the T_{CM} subset as a major reservoir for the virus prompted the development of in vitro models of latency that recapitulate the homeostatic and pro-survival features of this subset (Bosque and Planelles 2009; Lassen et al. 2012). Using these models, unique characteristics of the T_{CM} reservoir have been evidenced. For example, cellular proliferation induced by IL-7 is not accompanied by HIV reactivation in T_{CM} ; thus, there is a dissociation of cell cycle activation and transcription from the viral promoter (Bosque et al. 2011). Interestingly, in this model, stimulation with synthetic TLR1/2 ligands disrupts HIV latency, highlighting the potential use of TLR ligands as novel anti-latency agents. When compared to T_{TM} , T_{CM} cells appear

to be less sensitive to a variety of reactivation strategies including TCR stimulation and protein kinase C (PKC) activation, suggesting that this subset may represent the most critical barrier to the success of eradication strategies (Lassen et al. 2012).

The half-life of the replication-competent T_{CM} reservoir has not been measured as yet; however, the slow decay of total HIV DNA levels in this subset during ART suggests that T_{CM} encompass a highly stable reservoir for HIV (Buzon et al. 2014). Of note, the recently described T_{SCM} cells, which represent the earliest and most long-lasting developmental stage of memory T cells and are likely to act as T_{CM} progenitors, may constitute the most long-lived reservoir for HIV in vivo (Buzon et al. 2014).

Conclusion

T_{CM} cells play a critical role in the pathogenesis of HIV and SIV infections. Preservation of T_{CM} cells is correlated to control of HIV infection, indicating that this subset plays a crucial role in the maintenance of T cell immunity. T_{CM} cells also represent the main reservoir for HIV during ART in subjects who have reconstituted their CD4 T cell compartment. This illustrates the dual role of this subset in HIV infection: T_{CM} are essential to control viral replication in ART-naïve subjects. However, in virally suppressed individuals receiving ART, these same cells are responsible for the persistence of a long-lived reservoir for the virus.

decreased to one-third of pre-cervical cytology screening levels.

Cervical cancer was designated an AIDS-defining illness in 1993 (see “► [HIV-Associated Cancers](#)”). The widespread use of antiretroviral therapy (ART) has been associated with a substantial decrease in other AIDS-defining malignancies – Kaposi’s sarcoma and lymphoma; however, the incidence of cervical cancer has increased such that cervical cancer remains a significant cause of morbidity for HIV-positive women (Shiels et al. 2011) (see “► [Epidemiology of AIDS-Defining Malignancies](#)” and “► [Epidemiology of Non-AIDS-Defining Malignancies](#)”).

HPV is the causative agent for cervical cancer. Persistence of cervical infection with HPV is necessary but not sufficient for the development of cervical cancer. HPV prevention with prophylactic vaccination is likely to have a significant role in decreasing the future incidence of this and other HPV-associated malignancies.

Cervical Cancer and HIV

Elizabeth A. Stier

Obstetrics and Gynecology, Boston University Medical Center, Boston, MA, USA

Definition

Cervical cancer or cancer of the cervix uteri is an abnormal growth of squamous or glandular epithelial cells caused by persistent infection with the ► [human papillomavirus \(HPV\)](#). HPV infections of the cervix may cause cervical intraepithelial neoplasia (CIN) and subsequently develop into invasive cervical cancer (ICC). The successful introduction of cervical cancer screening programs with the cervical cytology, otherwise known as the Papanicolaou (Pap) test (which may detect treatable premalignant CIN lesions), is associated with a 70% decline in cervical cancer incidence and mortality.

Introduction

Cervical cancer is the second most common cancer among women worldwide; however, about 86% of the cases occur in low-resource countries. In countries where cervical cancer screening with cervical cytology is routinely performed, the incidence and mortality of cervical cancer have

Epidemiology

While in developed countries cervical cancer is the tenth most common type of cancer in women (9.0 per 100,000 women), in developing countries it is second only to breast cancer as the most common type of cancer (17.8 per 100,000) and cause of cancer deaths (9.8 per 100,000) among women. In Africa, Central America, and Southern Asia, cervical cancer is the number one cause of cancer-related mortality among women (WHO/ICO Information Centre on HPV and Cervical Cancer 2010). In Eastern and Western Africa, incidence and mortality rates of ICC have been estimated at 35 and 25 per 100,000 women, respectively (Forman et al. 2012).

The relative incidence of cervical cancer in HIV-positive compared with HIV-negative women is unclear – studies have estimated these rates at 1.5–8 times that of the general population (Einstein and Phaëton 2010) (see “► [HIV Cancers in Resource-Limited Regions](#)”). Unfortunately, cancer registries have not been established in lower-income countries; however, it has been estimated that in Uganda and South Africa, the

relative risk of cervical cancer in HIV-positive women is about twice that of the general population (Mbulaiteye et al. 2011). In Tanzania, 30% of women diagnosed with cervical cancer were HIV positive, and these women were significantly more likely to present with cervical cancer at a younger age and more advanced stage compared with women who were HIV negative.

Etiology

In the 1990s, HPV was identified as the causative agent of cervical cancer. HPVs are a large family of small double-stranded DNA viruses that infect squamous epithelia. The 30–40 HPV genotypes affecting the genitalia vary in their oncogenic potential; HPV types 16 and 18, accounting for approximately 65–70% of cervical cancers worldwide, are 2 of approximately 15 HPV types identified as oncogenic or high risk (HR). Certain low-risk HPV types, including types 6 and 11, are largely responsible for genital warts or condyloma.

Genital HPV infections are the most common sexually transmitted infections in women and have a peak prevalence between ages 18 and 25. Most of these HPV infections clear spontaneously (or at least become clinically undetectable), but in 10% of immunocompetent women, these infections persist (i.e., they are detected for greater than 1 year). It is the persistent HR HPV infections that may cause changes in the cervical epithelium leading to the development of cervical cancer precursors – high-grade squamous intraepithelial lesions (HSIL) also known as cervical intraepithelial neoplasia (CIN) 2 or 3 – and possible progression to ICC.

It is now understood that infection with HPV requires a micro-abrasion in the genital epithelium to the level of the basement membrane. In the cervix, the infection site is typically a group of cells in the transformation zone, where the squamous epithelium of the ectocervix transitions to the glandular epithelium of the endocervix. HPV is then able to infect a small group of basal keratinocytes. If the host immune system does not clear the infection, then the HPV infection

persists and may lead to cellular changes in the epithelium that are associated with the histologic findings consistent with an active HPV infection (koilocytosis, low-grade SIL and HSIL).

The timeline for these transformative changes in the cervix is best illustrated by the ages associated with peak prevalence: HPV infection is most commonly detected in women at ages 15–25, HSIL in women 25–35, and ICC in women over age 45. Thus, as a conservative estimate, HPV infection typically persists for at least 10–20 years before transformation to cervical cancer occurs.

HPV prevalence in women with normal cytology varies significantly with age and geographic location – in North America HR HPV prevalence in women under age 25 is 20+%, whereas the prevalence in women 35+ is under 10%. There does, however, seem to be significant regional variation – in the Caribbean and Eastern Africa, the regionally adjusted HPV prevalence is 35% (compared with 9% in Western Europe and 5% in North America) (Forman et al. 2012).

HIV-positive women have a far higher prevalence of HPV infections and a greater likelihood of persistent infection and are more likely to be infected with multiple HPV types compared with HIV-negative women (see “► [HIV-Associated Cancers](#)”). Some studies have found that HPV prevalence and persistence is higher in women with lower CD4 counts; however, results have not been consistent. In addition, the likelihood of prevalent HPV infections in HIV-positive women with normal cytology does not vary with age. Studies of HIV-positive women since the widespread availability of HAART do not consistently show lower HPV infection rates compared with studies from the pre-HAART era.

Studies in South Africa and Kenya of HIV-positive women with normal cervical pathology have revealed that HPV is detectable in 44–55% and that HPV 16 is detectable in 3–7% of subjects. Age has not been predictive of HPV infection. The relationship of low CD4 counts to HPV prevalence, incidence, and clearance has been inconsistent across studies. However, independent of CD4 count, HPV was more likely to persist in HIV-infected patients, with a South

African study finding that only 6% of women with HR HPV cleared the infection over the following 18 months (Denny et al. 2008; De Vuyst et al. 2012).

Approximately 70% of ICCs worldwide are associated with HPV 16 and/or 18. Although there is sparse data to date, multiple studies in Africa (including Kenya, South Africa, Mozambique, and Zambia) identifying HPV genotypes in ICC in HIV-positive women have found the combined prevalence of HPV 16 and/or 18 to be 54–86% (De Vuyst et al. 2012; Denny et al. 2012; Naucler 2011).

Screening and Early Detection

In countries where cervical cancer screening with Pap testing (cytology) is routinely performed, the incidence and mortality of ICC have decreased to one-third of pre-Pap screening levels. The standard of care based on cervical cytology screening is as follows: an abnormal cervical cytology will trigger a referral for colposcopic evaluation of the cervix with directed biopsy for histology. Colposcopy is evaluation of the cervix after application of acetic acid 5% (and sometimes Lugol's solution, a strong iodine stain) under magnification. Any abnormal areas are biopsied and then clinical follow-up is determined by the histologic findings. Untreated CIN3 has a 30% chance of progressing to invasive malignancy, whereas women who have undergone treatment for CIN3 are very unlikely to subsequently be diagnosed with ICC. Therefore biopsies showing HSIL or CIN2/3 are considered premalignant conditions. Treatment of HSIL involves ablation (e.g., cryotherapy or laser) or excision by cervical conization (loop electrical excisional procedure (LEEP) or "cold knife") of the entire cervical transformation zone. In HIV-negative women, recurrence rate of HSIL following treatment by ablation or excision of the transformation zone is under 10%. In addition, colposcopic directed biopsy or cervical conization may identify early, asymptomatic ICCs which can be treated by conization or simple hysterectomy. It is the treatment of premalignant lesions and diagnosis of earlier stage cervical

cancers that has contributed to the decrease in incidence and mortality of ICC.

Despite the apparent success of the Pap test, cases of cervical cancers still occur in countries where routine cervical screening is performed. This is likely due to missed Pap tests, inadequate follow-up, or inaccurate cytology results. While cervical cytology has been very effective in eradicating squamous cervical cancer, it has had minimal effect on lowering rates of glandular cervical cancers (which comprise 10–25% of cervical ICCs).

HIV-positive women are more likely to have abnormal cervical cytology, with prevalent rates of 25% and cumulative risk of abnormal cytology of 77% over 10 years (Massad 2008). Under current guidelines, a woman with an abnormal cytology would be referred for colposcopic evaluation of the cervix with directed biopsy. Similar to HIV-negative women, an HSIL cervical biopsy is an indication for treatment. However, the recurrence rate of HSIL in the HIV-positive patient is over 50% (Reimers et al. 2010) which is significantly higher than in HIV-negative women. Thus, in HIV-positive women, follow-up after treatment is critical, and the goal of treatment is cancer prevention, not HPV eradication.

As an abnormal cervical cytology may indicate abnormalities elsewhere in the lower genital tract, it is important to closely evaluate the vagina, vulvar, and peri-anus at the time of colposcopy, especially if the source of abnormal cells is not found in the cervix. In addition, CIN, especially in HIV-positive women, is strongly associated with intraepithelial lesions of the vagina, vulvar, peri-anus, and anus.

Commercial testing for HR HPV DNA (first commercially available in the 1990s) has been shown consistently to be superior to cytology in terms of its sensitivity and negative predictive value and is becoming a major tool in cervical cancer screening of women age 30 and older, at least in some developed countries. A single negative cervical HPV test with a normal cervical cytology in such women is associated with an exceedingly low rate of cervical cancer in the next 5 years, allowing screening intervals to be considerably lengthened.

Current recommendations for screening of HIV-infected women include more frequent surveillance and careful follow-up; this likely accounts for the minimal increase in cervical cancer incidence despite the higher burden of premalignant disease. The role of HPV testing for cervical cancer screening in HIV-positive women remains unclear as prevalence rates for oncogenic HPV are much higher in HIV-infected women 30 and over compared to the general population.

HPV testing has not been adopted as a standard cervical cancer screening strategy in HIV-positive women age 30 and older. However, there may be a role for this strategy in (at least) some populations of HIV-positive women. In a cohort of 420 HIV-infected and 279 HIV-uninfected women from the Women's Interagency HIV Study (WIHS) enrolled in 2001–2002, the 5-year risks of CIN2+ in women with baseline normal cervical Pap test and negative HR HPV testing were comparable to the risks in HIV-negative patients at 0.3–0.4%. Notably, within this WIHS cohort HPV prevalence was low; only 12% of the HIV-positive and 9% of the HPV-negative women had HR HPV detected at baseline with normal cervical cytology. For these women, the 5-year risks of CIN2+ were 5% regardless of HIV status. The risks of CIN2+ for HIV-infected women did not differ by baseline CD4 counts. No women in this cohort were diagnosed with cervical cancer at up to 9 years of follow-up (Keller et al. 2012). Thus, utilizing HPV testing as a component of cervical cancer screening strategies may be cost-effective, at least in populations of HIV-positive women with a low prevalence of HR HPV.

Cervical Cancer Screening in Developing Countries

Cervical cancer screening programs are being slowly introduced to sub-Saharan Africa where screening rates range from 2 to 20% in urban areas and 0.4–14% in rural areas (Brower 2011). Cytology specimens have to be transported to a central laboratory, processed, and read, and then the results need to be communicated to the patient;

if abnormal, follow-up evaluations then need to be conducted. Due to difficulty in accessing patients, especially in rural locations; inadequate transportation systems in which specimens may be lost, broken, or significantly delayed; central laboratories with slow processing; and poor communication systems, cervical cancer screening with cytology has proved especially difficult to successfully implement in low-resource settings.

Therefore, in low-resource settings, the emphasis has been on developing inexpensive techniques that can be implemented in a single visit by trained nurse providers (“see and treat”). Visual inspection with acetic acid (VIA) or visual inspection with Lugol's iodine (VILI) followed by treatment of abnormal findings with cryotherapy has been the most widely promoted, although with variable success.

A study of over 1,000 HIV-positive women from India with no prior history of cervical cancer screening compared VIA, VILI, HPV testing (HC2), and cytology to assess the test characteristics of the different screening options in a resource-limited setting. All women underwent colposcopy with directed biopsy regardless of findings from screening; 55 (5%) of the women were diagnosed with CIN2/3 and five with ICC. HPV testing detected all cases of CIN3+ and had 95% sensitivity for the detection of CIN2+ (95%); however, as 26% of the women tested positive for HPV, the specificity was only 77%. The likelihood of a positive test with VIA, VILI, and cytology (ASCUS+) was 15%, 15%, and 8%, respectively, whereas the sensitivity for CIN2+ was 84%, 89%, and 63%, respectively. Thus, in this setting, cytology was outperformed by all other modalities, and it was suggested that if HPV testing became affordable, then HPV testing followed by VIA would be the most effective means of screening for CIN2+ of the cervix (Joshi et al. 2013).

Prevention with Vaccination

Prophylactic HPV L1 virus-like particle vaccines are highly efficacious in preventing CIN2/3 lesions caused by HPV 16/18 for women without

HPV 16 and/or 18 at the time of vaccination. Data from clinical trials of these vaccines, together with post-vaccine surveillance, indicate that they have a good safety profile. As the current HPV vaccines provide protection against only two of the 15 oncogenic HPVs, they will not eliminate cervical cancer or other HPV-associated anogenital diseases but could reduce the incidence of cervical cancer by up to 65–70% if effectively delivered to adolescent females prior to the onset of sexual activity (Stanley 2012). Newer vaccines with activity against a wider range of HPV types are now under development.

Trials of HPV vaccination in HIV-positive men have shown that there is appropriate immunogenicity in this patient population. However, the efficacy of vaccination in HIV-positive women and men has not yet been demonstrated and is being evaluated in ongoing studies. HPV vaccination is recommended in HIV-positive women (and men) through age 26 and has an excellent safety profile.

Prophylactic HPV vaccination has not been shown to be effective in preventing persistent HPV infection and associated neoplasia in women with evidence of prior HPV infection of the genotypes within the vaccine.

As the prevalence of antibodies to HPV type 16 and/or 18 is very high (40%) in HIV-positive women from South Africa, Botswana, and Brazil, it is very important that vaccination occur prior to the onset of sexual activity to have maximal benefit (Firnhaber et al. 2011).

Invasive Cervical Cancer

In the general population, the majority (69%) of cervical cancers are squamous carcinomas (associated with HPV 16 (59%) and HPV 18 (13%)) and 25% are adenocarcinoma (HPV 16 (36%); HPV 18 (37%)). Data is limited on the histologic distribution of cervical cancers in HIV-positive populations. A retrospective analysis in South Africa found that squamous carcinomas represented more than 90% of invasive cancers detected among both HIV-positive and HIV-negative women (Simonds et al. 2012).

Early cervical cancer (stage IA–IB2) is typically asymptomatic and has an excellent prognosis. Cervical cancer can spread by direct extension (to the uterine corpus, vagina, parametria, bladder, or rectum) or by lymphatic or hematogenous dissemination. Advanced cervical cancer (stage 2+) may present with vaginal bleeding, pelvic or lower back pain, hematuria, or other bladder or bowel complaints.

The diagnosis of ICC is made by histologic examination of tissue. Early stage cervical cancers may be detected during the workup for abnormal results of cervical cancer screening. Abnormal cervical cytology or positive HPV testing is followed by colposcopic evaluation with directed biopsy. If a cervical cancer precursor (HSIL) is found on biopsy, removal of the transformation zone by conization may allow for the detection of an occult cancer. Women with clinical evidence of invasive cancer such as a gross lesion require a pelvic exam and biopsy for histologic verification.

A retrospective study from South Africa found that HIV-positive women were diagnosed with ICC at a younger age and more advanced stage than HIV-negative women. However, treatment outcomes were comparable when controlling for the stage and completion of radiation therapy (Simonds).

Recommended treatment options are based on cancer stage regardless of HIV status. Selected women with microscopic disease (stage IA1) may be treated with cone biopsy or simple hysterectomy (removal of the cervix and uterus). Women with a nonbulky (≤ 4 cm) tumor confined to the cervix, uterus, and upper third of the vagina (stage IA2, IB1, IIA1) without lymph node metastases are candidates for radical hysterectomy (removal of the uterus, cervix, and surrounding tissue including significant dissection around the ureters). However, chemoradiation is also a viable option for stage IB and IIA disease.

The standard of care for the treatment of locally advanced cervical cancer (LACC) is concurrent chemoradiotherapy using cisplatin as the chemotherapeutic radiosensitizing agent. The use of this regimen as standard of care is based on multiple randomized, controlled trials (RCTs) that showed improved efficacy when cisplatin was added to

radiation therapy, even in high-risk patients who had histologic evidence of metastatic disease in pelvic and/or para-aortic lymph nodes. There is little data available on the efficacy of standard chemoradiotherapy for the treatment of LACC in the HIV-positive woman.

Conclusion

Although cervical cancer treatments have been improving in recent years, there is no question the largest opportunity to decrease the burden of HIV-associated cervical cancer is in prevention. Prophylactic vaccination against HPV will likely have substantial clinical benefits in HIV-infected women, especially if the vaccine is administered prior to sexual debut. However, the clinical trials of vaccination in HIV are ongoing, the efficacy and duration of immunity are unknown, and likely only cancers attributed to HPV types 16 and 18 will be prevented with the current licensed vaccines.

Algorithms for screening in HIV-uninfected women might not apply to HIV, as the course of the disease from persistence to cancer appears to be different in the setting of HIV, particularly in those with poor immune status. Also, treatments for cervical precancerous lesions in HIV should focus on cancer control rather than cure, as clearance of HPV in the setting of HIV is unlikely.

Because most cervical cancer trials are conducted in developed countries and have typically excluded the enrollment of HIV-positive women, there is minimal data particular to cervical cancer treatment in the setting of HIV. The burden of disease of HIV-associated cervical cancer in developing and middle-income countries is large but only estimated at present. There is a pressing need to directly address potential drug–drug interactions of ART on standard and targeted cervical cancer treatments through pharmacokinetic trials, as well as finding ways to minimize dose delays and modifications due to marrow toxicities of both chemotherapy and pelvic radiation in the setting of HIV. Lastly, as locally advanced cervical cancer is more common among HIV-positive women, better-tolerated and

improved treatments need to be evaluated (Einstein and Phaëton 2010).

 Investigation on Immunology, Hospital das
 Clínicas, University of São Paulo, Sao Paulo,
 SP, Brazil

Definition

Coinfection *T. cruzi*/HIV occurs mainly in patients who acquired Chagas disease in endemic areas through vector transmission. The expansion of the HIV epidemic to periurban and rural areas and the urbanization of Chagas disease to non-endemic areas have impact on the prevalence of this coinfection. Reactivation of Chagas disease is considered an AIDS-defining condition in Brazil since 2004, and it is associated with severe

meningoencephalitis or myocarditis, increase of maternofetal transmission of Chagas disease, and a high mortality. Reactivation is immunodeficiency dependent and was observed in 10–20% of *T. cruzi*/HIV-coinfected patients.

Introduction

Chagas disease (American trypanosomiasis) was described by Carlos Justiniano Chagas in 1908, who characterized its etiological agent and the biological vector, host, animal reservoirs, and human disease. It is endemic in Latin América, from the South of the USA to the South of Argentina and affects approximately eight million infected people and causes 12,500 deaths per year (Moncayo and Silveira 2009). In endemic countries, the migration of the infected population from the rural areas to the urban centers associated with the control of the vector, and blood transfusion and derivatives transmissions led to the urbanization of Chagas disease in nonendemic regions (Schmuñis and Yadon 2010).

Chagas disease is now an emerging disease associated with congenital, blood, and organ transplant transmissions also in nonendemic countries (CDC 2006; Garcia et al. 2012; Salvador et al. 2015), in which approximately 1–26% of immigrants are infected, depending on the country and/or the immigrants' nationality. In the USA, approximately 300,000 individuals are estimated to be infected with *T. cruzi* (Schmuñis and Yadon 2010).

More recently, initiatives in nonendemic countries have been implemented to control the transmission of this disease by blood transfusion and transplants of organs from infected donors from endemic regions.

In the context of great morbidity of vector-transmitted Chagas disease due to the prevalence of millions of chronic cases in Brazil and Latin America, mainly in urban centers, the coexistence of *T. cruzi* infection in 1.3–2.6% of HIV-infected individuals (Dolcini et al. 2008; Almeida et al. 2010) allows the emergence of reactivation of Chagas disease in this population as well as in immunosuppressed patients under organ transplantation or treatment of autoimmune diseases.

In fact, many physicians are not aware of the occurrence of reactivation of chronic Chagas disease in patients under immunosuppression or with HIV infection neither about the occurrence of congenital infection.

Chagas Disease

Trypanosoma cruzi (*T. cruzi*), the etiologic agent of Chagas disease, is a protozoan characterized by flagellate forms in the peripheral blood and biological fluids and nonflagellate (amastigote) forms in the tissues of infected animals and humans. The biological vectors are domestic and sylvatic insects of the subfamily Triatominae (Hemiptera, Family Reduviidae); the most frequent vectors are *Triatoma infestans*, *Triatoma brasiliensis*, *Panstrongilus megistus*, *Rhodnius prolixus*, and *Rhodnius pallescens*. Triatominae are found from the United States (USA) and Mexico, the north to Argentina and Chile in the south, and a wide range of mammals and nonmammals (marsupials, Chiroptera, Rodenta, Edentata, native primates) can serve as reservoir hosts. Transmission occurs at the bite sites of blood-sucking triatomine bugs by the inoculation of the flagellate metacyclic forms of the feces through the bite wound and mucous membranes/conjunctiva. Endemic to Latin America, Chagas disease has a great impact on morbidity and mortality affecting vulnerable individuals. The main control strategy in endemic areas is controlling vector activity. In Brazil and Southern Cone, Andean, Central American, and Amazon countries, coordinated multicenter programs have led to a 70% reduction in the number of new infections in South America due to the interruption of vectorial and blood transfusion transmissions (Who, how, what and where? 2010; Dias et al. 2002). In this context, more recently outbreaks of Chagas disease transmitted by oral route emerged in Brazil, Colombia, Venezuela, and Ecuador, mainly in Amazon region.

Clinical Aspects

Clinical Phases of Chagas Disease

Two phases were described in human disease: acute and chronic (Umezawa et al. 2001).

In acute Chagas disease transmitted by vector, only one of 30 infected individual presents with apparent disease. The signs and symptoms started usually 1–3 weeks after the parasite inoculation and include: (a) a febrile syndrome (38–39 °C, myalgia, headache); (b) phagocytic mononuclear involvement represented by lymph node enlargement, splenomegalia, and hepatomegalia; (c) legs edema; and (d) unilateral swelling of the eyelids (Romaña's sign -Umezawa et al. 2001). Severe myocarditis and/or meningoencephalitis were reported in 5–10% of cases, mainly in newborns, breastfeeding infants, and older individuals with intense inflammatory reaction adjacent to ruptured nests of parasites and damaged muscle cells; pseudocysts are frequently seen. Parasitemia is high in the first 4 weeks, when trypomastigote were detected by direct microscopy of peripheral blood. Serological testing may reveal IgM antibodies to *T. cruzi*.

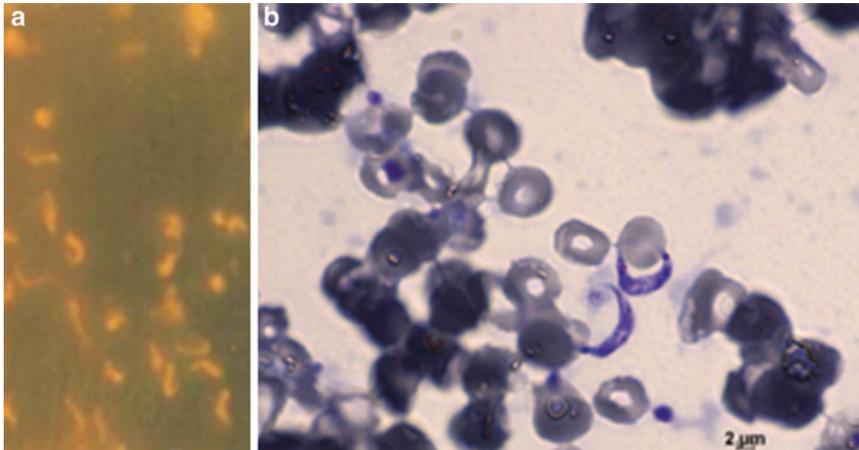

The chronic phase begins about 2–3 months after the initial infection and the parasitemia is low and intermittent.

In the chronic phase, the disease is classified in the following forms: (a) indeterminate form (without digestive or cardiac involvement) in 60–70% of the patients that lasts for the individual's entire life in the majority of the patients; however, 2–5% of the patients in this form change to cardiac or digestive forms each year; (b) cardiac form, observed in adults in 20–30% of the cases, presenting with disturbances of cardiac rhythm and conduction system, cardiac failure, and thromboembolism; and (c) digestive form, manifested by megaesophagus and/or megacolon or mixed form (cardiac plus digestive) in 5–15% of the cases.

Laboratory Diagnosis

Reactivation of Chagas disease is confirmed by the following criteria (gold standard):

1. Parasitological (the most reliable): the presence of trypomastigotes by direct microscopy upon fresh analysis of the peripheral blood (or other biological secretions, CSF) or smear stained with Giemsa or hematoxylin-eosin (Fig. 1a). Concentration methods such as

Chagas Disease and HIV, Fig. 1 *Trypanosoma cruzi* on direct microscopy of blood of a patient with Chagas disease reactivation: (a) stained smear from peripheral blood; (b) parasites seen on quantitative buffy coat (QBC),

preparation from Laboratory of Clinical Investigation on Parasitology LIM 46, Hospital das Clínicas da Faculdade de Medicina, University of São Paulo, Brazil

microhematocrit, Strout methods, buffy coat, and QBC (quantitative buffy coat + by orange acridine) – Fig. 1b – are much more sensitive than fresh preparation or stained smear of peripheral blood. For biological fluids, the precipitate of centrifuged material is examined. This method is much more sensitive in the site of infection, for example, CSF in meningoencephalitis, where motile trypomastigotes were observed and sometimes could be positive in the blood, particularly if patients present with fever or systemic signs.

2. Histopathological method – presence of amastigotes within acute inflammatory infiltrate. When peripheral blood did not reveal the parasite, biopsies can be performed in the site of the lesion.

When treatment had started and gold standard methods cannot not be applied, quantitative PCR might be useful for diagnosis of reactivation if the number of parasite DNA copies is very high, above the levels observed in coinfecting patients with high parasitemia (Freitas et al. 2011). However, the role of quantitative PCR as “unique tool” in the diagnosis of reactivation by a single sample is a matter of discussion since: (a) the reactivation occurs in the tissues and sometimes no changes are observed in the peripheral blood; (b) for mild

increase of parasitemia there is an overlap between higher parasitemia in *T. cruzi*/HIV coinfection without reactivation (Freitas et al. 2011) and the cutoff between coinfection and reactivation depends on the molecular type of parasite; (c) eventhough some less sensitive primers had been reported as indicative of reactivation. As PCR is positive in 45–95% of patients with chronic Chagas disease (Portela-Lindoso and Shikanai-Yasuda 2003), prospective monitoring with quantitative PCR is recommended to monitor reactivation by detection of increasing levels of parasitemia.

Coinfection *T. cruzi*/HIV

Chronic Chagas disease is confirmed by:

(1) Highly sensitive anti-trypomastigotes IgG (ELISA), which are the gold standard for diagnosis (>95% positivity) but may cross-react with *Leishmania*. (2) Immunoblotting (or other high-performance serological tests), such as radioimmunoprecipitation or recombinant assays using trypomastigote antigens) may be used as a confirmatory method (Umezawa et al. 1996). In immunosuppressed patients at least two different serological tests are recommended to confirm the diagnosis of Chagas disease.

In chronic phase, parasites can be found in the blood only by indirect parasitological enrichment

methods (in vitro xenodiagnosis and blood culture), presenting lower positivity (30–50%) than polymerase chain reaction (PCR, 45–95% positivity) (Portela-Lindoso and Shikanai-Yasuda 2003).

Coinfection *T. cruzi*/HIV

In addition to oral, congenital, and organ transplant transmission, *T. cruzi*/HIV coinfection has been found in urban centers of endemic and non-endemic regions, and HIV infection has spread to regions in which Chagas disease is endemic. As a consequence, the occurrence of Chagas disease globalization and the expansion of HIV epidemic might impact the prevalence of *T. cruzi*/HIV coinfection.

Considering the prevalence of two to three million people infected with *T. cruzi* and the estimated number of HIV-infected patients as well as the frequency of *T. cruzi* infection of 1.3% in HIV-infected patients (Almeida et al. 2010), a total of more than 16,000 *T. cruzi*/HIV-infected patients are under risk of Chagas disease reactivation in Brazil and more than 21,000 in Latin America on the basis of number of HIV/AIDS patients (Almeida et al. 2011). Further reports in Argentina (Dolcini et al. 2008) registered 2.6% of Chagas disease in HIV-infected patients and 8.2% in drug users infected with HIV. This frequency was 1.9% in Spain (Garcia et al. 2012), possibly increasing previous estimates for Latin America and emphasizing the importance of this coinfection in nonendemic regions.

In a systematic review only 291 cases of coinfection HIV/*T. cruzi* were reported up to March 2010 (Almeida et al. 2011), 76.2% from Brazil and 19.2% from Argentina, the remaining from Chile, USA, and Spain. Chronic form of Chagas disease is predominant (97.9%) in patients with coinfection, mainly in indeterminate form (50.8%) and cardiac form (37.3%). Digestive (5.1%) and cardiac + digestive forms were less frequent (6.8%). Since March 2010, more 15 cases of coinfection from Spain (Salvador et al. 2015) were described.

To provide health care for patients with this coinfection at basic and complex levels in non-endemic countries, a National Network for Attention and Studies on *T. cruzi*/HIV coinfection was created in Brazil in 2006, and later included centers in Spain and Argentina as an International Network, open for all countries (Ramos et al. 2010).

The main objectives of this network are: (1) to contribute for structuring a comprehensive care network for people living with Chagas disease under immunosuppression as well as to provide a continuing education network for health care professionals involved in management of these patients; (2) to contribute for the development of actions based on scientific evidence in accordance with ethical standards, including clinical, epidemiological, immunological, and laboratorial research; (3) to contribute toward identifying priorities for research in Brazil on this subject.

Reactivation of Chagas Disease

The occurrence of meningoencephalitis and myocarditis in patients under immunosuppression induced by oncohematological neoplasias have been reported since the late 1960s in Brazil and other endemic countries (França et al. 1969), usually without symptoms. Reactivation of trypanosomiasis induced by immunosuppressive therapy for graft rejection control in solid organ transplant patients and for treatment of autoimmune diseases was further reported. In experimental studies, reactivation of chronic trypanosomiasis was associated with increased parasitemia and mortality and severe myocarditis, confirming the role of *T. cruzi* as opportunistic parasite under immunosuppression (Brenner and Chiari 1971).

The first AIDS patient with reactivation of Chagas disease was described in 1990 (Del Castillo et al. 1990). In addition, in Spina França et al. (1988) had reported both anti-*T. cruzi* antibodies and parasites in the CSF of a patient with HIV and Chagas disease reactivation. The first case of reactivation of Chagas disease associated with AIDS was observed in the USA and described in a conference before 1990 but only published in 1992 by Gluckstein et al.

Most of the cases were further described in Brazil and Argentina (Ferreira et al. 1997; Sartori et al. 2002, 2007; Cordova et al. 2008), and three centers in Brazil and one in Argentina described about half of the reported cases. High morbidity and mortality and poor prognosis for severe cases even with early treatment were described as well as its association with decreased levels of CD4⁺T cells, commonly less than 200 cells/mm³ (Ferreira et al. 1997; Sartori et al. 2002, 2007; Cordova et al. 2008).

The reactivation of Chagas disease as an AIDS-defining condition was recognized in Brazil in 2004 and in 2005 by the Pan American Health Organization and World Health Organization (Ramos et al. 2010) since (a) HIV infection changes the natural history of Chagas disease and HIV infection, in terms of severe morbidity (meningoencephalitis and myocarditis) and high mortality of up to 100% in severe cases and depending on early antiparasitic treatment; (b) presents different response to the treatment with recurrence; (c) is associated with low levels of CD4⁺T cells: <200/mm³ in the majority of the cases (Rocha et al. 2006; Almeida et al. 2011); and increased rate of maternofetal transmission of Chagas disease (more than 15×).

From 291 cases of coinfection HIV/*T. cruzi* described up to March 2010, 41.2% represented reactivations of Chagas disease, 74.2% as meningoencephalitis, 16.7% as myocarditis, 3.3% in the duodenum, 0.8% in the pericardium, peritoneum, stomach, uterus cervix, and eye muscle (Almeida et al. 2011). In prospective studies, oligosymptomatic patients presenting as febrile syndromes or even without symptoms (mother of a newborn with Chagas disease) were found with positive microscopy on peripheral blood (Sartori et al. 2007).

Since March 2010, only five cases of meningoencephalitis in adults and three acute congenital Chagas disease were reported in Venezuela, Argentina, Chile, USA, and Brazil, possibly expressing the influence of highly active antiretroviral therapy (HAART) and the emphasis in special aspects of evolution of patients or maternofetal transmission.

Rate of Reactivation

The rate of reactivation is not well known and depends on many factors, such as deficiency of cellular immunity and lack of adherence to HAART. According to description in single centers, it could be as high as 15–20% but larger prospective multicenter studies are needed to establish this frequency in patients with follow-up longer than 6 months, where the estimation is lower (approximately 10%).

The proportion of immunosuppressed patients that will present reactivation of Chagas disease is not well known, and a prospective study employing xenodiagnosis indicates that 50% of those with higher parasitemia will reactivate in the next 5 years (Sartori et al. 2002). Prospective studies monitoring parasitemia and innate and acquired immune response in patients under immunosuppression could contribute to answer this question.

An imbalance of TH2 response in coinfection among patients with Chagas disease and HIV infection was shown by an increase of the IL4/IFN γ ratio in comparison to those without HIV infection. The association of Chagas disease reactivation in HIV-infected patients with <200 CD4⁺T cells/mm³ in 80% of the cases express the inability of macrophages to control parasite multiplication and to kill the parasites. In effect, experiments with SCID mice infected with *T. cruzi* showed decrease of IFN γ and increase of parasites in the myocardium, associated with lower tissue inflammation but early mortality (Silva et al. 1993). Additionally, in placental histocultures HIV decreases the production of inflammatory cytokines.

Bidirectional influences were observed in HIV/*T. cruzi* interaction: increased levels of parasite in the peripheral blood and tissues in human and mice are a cofactor for TH2 response and are associated with increased HIV replication in human and restricted systems such as placenta and human macrophage cultures.

An increased rate of reactivation and maternofetal transmission of Chagas disease were observed in HIV-infected patients in comparison with non-HIV-infected patients. Changes in the morbidity, mortality, and response to the

therapy were observed in comparison to acute disease without HIV infection. Changes in the natural history of both HIV and the parasitic infection are attributed to the reactivation since it causes death in severe cases. The natural history of Chagas disease may not change in coinfecting patients without increased parasitemia but the factors responsible for this are not well understood.

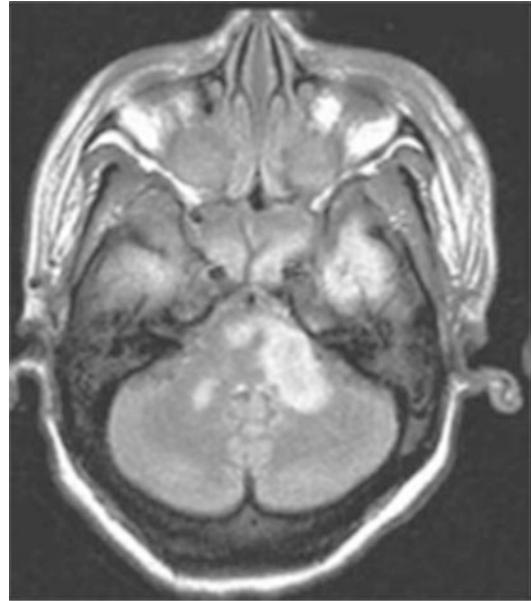

Clinical Syndromes

Meningoencephalitis

Central nervous system involvement is expressed by febrile syndrome associated with intracranial hypertension (headache, vomiting) and signs of cerebral involvement (seizures and focal signs). In the CSF, mild or moderate pleocytosis of more than 10 cells/mm³, mainly mononuclear cells, and mild or moderate increase of protein levels are usually observed. The gold standard for diagnosis is the presence of trypomastigotes on direct microscopic examination of the centrifuged CSF sediment (Sartori et al. 2007). This is found in about 74% of the tests performed. Less frequently this form was detected in the peripheral blood. From 44 patients with histopathological analyses, amastigote forms were identified in inflammatory lesions in the central nervous system (70.4%), myocardium (13.6%), duodenum (9%), skin (6.8%), and 2.3% in stomach and 2.3% in the uterus. In the brain, inflammatory infiltrates, hemorrhage, necrosis, and parasites were largely seen in the macrophages and glial cells.

The level of CD4⁺T cells was usually <200 cells/mm³, but some cases of reactivation could present with >350 cells/mm³. The average CD4 count in cases with reactivation was 98 cells/mm³ (range 1 cell/mm³ to 551 cells/mm³) versus an average of 562 cells/mm³ (range 44 cells/mm³ to 1,949 cells/mm³) in cases without reactivation.

Computed tomography or magnetic resonance imaging show in more than 90% of the cases hypodense lesions, predominantly in the subcortical region, with or without ring enhancement. But lesions can also be found in the thalamus, the cerebellum, or basal nuclei (Fig. 2) The lesions are single or multiple lesions simulating brain tumors

Chagas Disease and HIV, Fig. 2 CNS Magnetic Resonance Imaging of a patient with Meningoencephalitis (Courtesy of Division of Infectious Diseases, Hospital das Clínicas da Faculdade de Medicina, University of São Paulo, Brazil)

with mass effects due to hemorrhagic foci, preferentially involving the white matter.

Myocarditis

Heart involvement is described in about 20% of patients with reactivation. But this rate might be underestimated since it could be silent and not suspected in cases of meningoencephalitis. Additionally, it might be similar to the evolution of chronic cardiopathy. Based on necropsy series or in well-documented cases, the rate of simultaneous involvement of heart and CNS is supposed to be about 40–50%. Clinical signs are represented by arrhythmia (ventricular extrasystoles, supraventricular arrhythmia, atrial flutter, and fibrillation) and congestive heart failure (generalized edema, hepatomegaly, dyspnea, and tachycardia), and echocardiogram can show pericarditis or increased cardiac volume. Trypomastigotes can be detected in the peripheral blood and/or in the pericardial fluid. Amastigote nests can be identified in histopathological exams and/or immunohistochemical exams or electron

microscopy can confirm this diagnosis. Biopsy and/or autopsy studies not only confirm the diagnosis of Chagas disease reactivation but also exclude the presence of other protozoa such as *T. gondii* (Ferreira et al. 1997; Sartori et al. 2007).

Other Syndromes

Involvement of digestive tract, uterus cervix, peritoneum, and eye muscle were rarely described. In a prospective study (Sartori et al. 2007), mild oligosymptomatic cases with febrile disease (similar to infectious mononucleosis) and/or asymptomatic reactivation during pregnancy associated with maternofetal transmission were reported.

Maternofetal Transmission

A higher rate of transmission of the disease to newborn was described in pregnant women with coinfection HIV/*T. cruzi* (Sartori et al. 2007), in comparison with patients without HIV infection (1–13.8%). Although only one prospective study was published showing that maternofetal transmission occurred in three of four pregnancies (two with reactivation in the mother), other case reports of pregnant women with reactivation or no reactivation but high parasitemia detected by parasitological or molecular methods show more than 50% of transmission to the fetus. Transmission was associated with abortions, low weight for the gestational age, and even preterm newborn with meningoencephalitis or sepsis. Mortality is over 70%. There is not enough information about follow-up of newborns of mothers with this coinfection to better know the spectrum of signs and symptoms of congenital infection. In fact, higher parasitemia described in coinfection than in Chagas disease without HIV infection might be one of the explanations for the high rate of transmission of Chagas disease to the newborn.

Regarding the benefit of HAART in the pregnant coinfecting women, there are few reports of both noninfected or infected preterm baby in the follow-up.

Associated and Predictive Factors

Two variables were associated with Chagas disease reactivation in HIV-infected patients:

1. CD4⁺T cells <200/mm³ in the peripheral blood in more than 80% of the cases. However, this level is not predictive “per se” of this reactivation since some patients with this low level did not reactivate and additionally, a few cases of reactivation occurred in patients with >350 cells/mm³.
2. A high parasitemia in HIV-infected patients, expressed by >20% of nymphs positive in xenodiagnosis was shown to predict the reactivation in the next 5 years (Sartori et al. 2007) in 50% of these patients (Sartori et al. 2007). Quantitative PCR (Freitas et al. 2011) further confirmed the presence of two different groups in coinfecting patients: one with high levels of parasitemia and other with low levels, similar to those described in non-HIV-infected patients.

Some authors observed simultaneously high viral load in patients with Chagas disease reactivation, possibly associated with non-adherence to HAART and low levels of CD4⁺T cells, allowing the evasion of the parasite from the immune response. However, its importance as cofactor or reactivation is a matter of discussion.

Differential Diagnosis

Toxoplasmosis and tumoral lesions are important differential diagnosis since similar image findings are observed in these circumstances. The epidemiological data and the diagnosis of chronic Chagas disease by serology reinforce the clinical suspicion. Indirect parasitological methods such as blood culture or xenodiagnosis or PCR are not useful for diagnosis of reactivation, as they are also positive in chronic Chagas disease (Freitas et al. 2011). Therefore, the diagnosis of reactivation of Chagas diseases is only made by the finding of trypomastigotes in the CSF, peripheral blood or biological fluids, or amastigotes in histopathological lesion. These are very useful to confirm the diagnosis, since Chagas disease and toxoplasmosis may coexist.

Treatment

Benznidazole is the drug of choice and was used in 87% of treated patients. Antiparasitic treatment

should be introduced as soon as possible since the prognosis is poor in severe cases of meningoencephalitis and/or myocarditis especially if treatment is delayed. When patients received treatment for ≥ 30 days, the survival rate was approximately 80% versus 20% when they received the treatment for ≤ 20 days.

Nifurtimox was used for treatment for 14% of the patients in the literature and is recommended when benznidazole cannot be prescribed. Dosis for benznidazole was 5 mg/kg/d and for nifurtimox 7 mg/kg, 2–3 x/day for at least 60 days.

Although benznidazole is teratogenic, pregnant women should receive the treatment since reactivation of Chagas disease is a life-threatening disease for her and her baby.

Prescription of fluconazole was reported in 3% of the patients and itraconazole or ketoconazole in 2% of patients. These are not first-line therapies for Chagas disease reactivation but may be used as adjunctive therapy if drugs of choice cannot be prescribed because of uncontrolled adverse effects.

If therapy is successful, parasite will not be detected 2 weeks posttherapy and signs and symptoms decrease in the same period.

Adverse effects within the first weeks of treatment include exanthema, pancytopenia particularly granulocytopenia. Later on, peripheral neuropathy may occur. There is no consensus about the indication and duration of maintenance therapy, but benznidazole (5 mg/kg/d, three times a week) can be prescribed as long as $CD4^+$ T cells are below 350 cells/mm³ in patients on HAART.

Preemptive Therapy

There is data of preemptive benznidazole treatment of patients without reactivation but presenting high parasitemia (defined by persistent positive blood culture and/or xenodiagnosis or uncontrolled arrhythmia). These treatments resulted in negativation of PCR and or indirect parasitological enrichment methods in a percentage higher than observed in chronic disease. Severe adverse events were not registered but careful monitoring of adverse effects is highly recommended during the period of treatment (Sartori et al. 2007). There are no data on

treatment of patients with coinfection with very low/negative parasitemia.

Prognosis

Overall mortality in prospective studies was 73.3% in cases of reactivation and depended on the severity of involvement: 88.9% in meningoencephalitis and 0% in mild or oligosymptomatic cases reported (Sartori et al. 2007). In another series of *T. cruzi*/HIV coinfecting patients including the patients without Chagas disease reactivation, the overall mortality observed was 29.6% and average of survival time-period was three times longer in patients without reactivation (34 months) than in patients with reactivation (11 months) (Almeida et al. 2010).

The influence of HAART on the evolution of coinfection is not well. But HAART seems to have decreased the occurrence of reactivation in the last decade and maternofetal transmission was rarely described in women under HAART (Sartori et al. 2007). The control of viral replication and the increase in $CD4^+$ T cells possibly allow the recovery of cellular immunity and macrophage activity and the control of parasite multiplication and dissemination.

Regarding immune reconstitution syndrome (IRIS), there is concern but very limited data that introduction of HAART early during the course of antiparasitic therapy could induce a paradoxical inflammatory response (paradoxical or unmasking IRIS). Therefore, some experts recommend that HAART should be introduced some weeks after the start of antiparasitic therapy. Prospective studies did not find an influence of HAART on *T. cruzi* parasitemia detected by classical parasitological methods (Sartori et al. 2007).

Conclusion

Estimates of prevalence of *T. cruzi*/HIV coinfection in Brazil, Argentina, and Spain suggest that this coinfection is worldwide underestimated. Reactivation of Chagas disease in HIV-infected patients is considered as an AIDS-defining illness and should be diagnosed and treated as early as possible since the mortality of the untreated

reactivation is very high, but the survival increases to 80% if antiparasitic treatment of more than 30 days can be achieved. Monitoring patients with *T. cruzi*/HIV coinfection is useful to detect oligosymptomatic cases or to detect an increase of parasite levels which is an indication of therapy or preemptive therapy (Sartori et al. 2002; Sartori et al. 2007; Freitas et al. 2011).

Definition

Care and treatment of children affected by HIV refers to the bundle of services aimed at improving the lives of this vulnerable population. Affected children are those known to be infected with HIV or those at high risk of infection due to “exposure” from their HIV-infected mother during pregnancy. These services include prevention strategies, screening and diagnostic testing, provision of antiretroviral (ARV) medications, clinical and laboratory monitoring for treatment response and medication toxicities, management of co-occurring conditions, and an array of counseling services for patients and caregivers.

Overview

Globally, an estimated 3.3 million children (0–15 years of age) are infected with HIV (UNAIDS 2013). Most of these children were infected through vertical transmission – during pregnancy,

the birthing process, or through breast milk. The vast majority of children infected with HIV live in low- and middle-income countries where the HIV burden in adults is also high. More specifically, about 90% of children infected with HIV live in sub-Saharan Africa, while less than 0.2% live in North America and Western Europe combined (UNAIDS 2013). These differences are primarily a reflection of social and economic circumstances that impact access to and development of health services and healthcare infrastructure. Despite these differences, the principles underlying care and treatment of children affected by HIV are universal; however, guidelines on how to provide these services are context specific and vary from country to country. This essay will focus on international care and treatment standards as outlined by the World Health Organization (WHO) while highlighting key differences in the US guidelines proposed by the National Institutes for Health (NIH) and the Department of Health and Human Services (HHS).

Ideally, the continuum of care and treatment of children affected by HIV begins with prevention of mother-to-child transmission (PMTCT) services and continues as children transition through adolescence into adulthood. PMTCT will be discussed in detail in a separate chapter; however, the approach to care and treatment of the HIV-exposed infant and early infant diagnosis (EID) will be discussed herein. Similarly, adolescent care will be discussed elsewhere, but the topic of disclosure of one’s HIV status warrants review in this chapter as well. Other topics relevant to the care and treatment of children affected by HIV will also be reviewed and include HIV testing and counseling, antiretroviral therapy (ART), clinical and laboratory monitoring, and prevention of common coinfections.

HIV Testing and Counseling

HIV testing and counseling can be either patient or provider initiated. Historically HIV testing was primarily provider initiated and offered when patients accessed healthcare services for a variety of reasons. However, this resulted in many new diagnoses being made in persons who were

accessing care relatively late after acquisition of HIV and often with advanced disease. Now, in addition to this strategy, new emphasis is being placed on empowering patients to seek testing both in traditional healthcare settings and in their communities. Community-based testing and counseling with linkage to care and treatment services has been emphasized by the WHO as an important component of public health campaigns aimed at identifying and treating persons infected with HIV. Furthermore, targeting these interventions toward key populations such as adolescents and young adults engaged in high-risk behaviors may have added benefit and maximize resource utilization. In the case of infants and children, who are too young to understand the need for or importance of HIV testing and counseling, provision of these services requires the participation of their caregivers who may be parents, adult siblings, extended family, or orphanage attendants and as such necessitates unique strategies and approaches.

Available tests include antibody tests and nucleic acid tests. Antibody tests detect HIV-specific antibodies produced by the immune system as part of the normal host response to HIV infection. These tests are very sensitive and as such are the preferred tests for screening for HIV. However, antibody tests do not directly detect the HIV virus and thus have limited utility in those less than 18 months of age who have both endogenous and circulating maternal antibodies. Nucleic acid tests utilize polymerase chain reaction (PCR) technology to directly test for HIV infection by amplifying either HIV RNA (i.e., viral load) or HIV DNA (only present after reverse transcription has occurred in an infected cell). These tests are very specific for HIV and traditionally have been used for confirmatory testing and for monitoring response to ART. However, due to limitations of antibody testing in infants, PCR is an important part of the screening algorithm for HIV-exposed infants.

Early Infant Diagnosis

HIV testing and counseling services should be offered to all pregnant women during pregnancy. Identifying pregnant women with HIV and

connecting them with PMTCT services is integrally important to preventing vertical transmission. It also helps to identify HIV-exposed and potentially infected infants, and it can provide an opportunity for offering testing and counseling services to siblings and other family members.

HIV-exposed infants are those born to HIV-infected mothers and who have not yet had definitive HIV testing. Since vertical transmission of HIV can occur in utero, during the birthing process, or postpartum through breast milk, HIV testing should begin soon after delivery and continued until there is no longer exposure to HIV (i.e., cessation of breast feeding). If PCR is available, early infant diagnosis (EID) testing should be obtained soon after birth then repeated at specified intervals. NIH/HHS recommends PCR at 2–3 weeks of life, age 1–2 months, and at age 4–6 months (NIH/HHS 2014c). In the US, this testing is routinely available and results are usually reported within 1 week. However, due to expense and some technical aspects, PCR is not as readily available in resource-limited settings, though this is changing with recent global efforts to scale up HIV care and treatment services in countries with the highest HIV prevalences. WHO recommends that HIV-exposed infants receive PCR testing at 4–6 weeks of life. In many resource-limited countries, repeat PCR is recommended at age 3–4 months. Any positive PCR result should be confirmed with repeat testing. ART should not be delayed while awaiting confirmatory test results (WHO 2013a, 2014b).

HIV antibody testing is nondiagnostic in HIV-exposed infants less than 18 months of age and as such is not the preferred diagnostic test in this age group. It is normal for antibodies of all sorts, including antibodies formed against HIV, to be transferred from mother to fetus through the placenta. This in utero transfer peaks in the third trimester of pregnancy, and maternal antibodies can persist in the infant up to 18 months of age. However, during the first year of life, these circulating maternal antibodies start to wane while the infant begins to increase production of their own antibodies. Thus, if there is no ongoing exposure to HIV, then a negative antibody test can provide evidence that the infant is not infected with HIV,

but this is not definitive until at least 18 months of age. Any positive antibody test prior to 18 months should be followed up with PCR. After 18 months of age, antibody testing is considered definitive.

Antiretroviral Prophylaxis for HIV-Exposed Infants

Testing of the HIV-exposed infant should occur in conjunction with the provision of ARV prophylaxis aimed at preventing infection that may occur during the birthing process or due to ongoing exposure through breast milk. WHO recommendations on which ARV to use and for how long depend on whether there is ongoing exposure through breast milk. If replacement feeding is provided to the infant (i.e., no breast milk), then either once daily nevirapine (NVP) or twice daily zidovudine (AZT) can be administered to the child for the first 4–6 weeks of life. If the child is breastfeeding, then once daily NVP is recommended for the first 6 weeks of life. However, the latter recommendation assumes that the mother who is providing breast milk is also on ART per the most recent PMTCT guidelines. If the mother is not on ART, infant ARV prophylaxis should be continued until the mother is stable on ART or until cessation of breastfeeding (WHO 2013a, 2014b). NIH/HHS recommendations deviate slightly from WHO recommendations insofar as they explicitly discourage HIV-exposed infants from breastfeeding. NIH/HHS recommends twice daily AZT for the first 4–6 weeks of life (NIH/HHS 2014c).

If at any point a positive test result is obtained and a diagnosis of HIV infection is made, or if a presumptive diagnosis of HIV is made based on clinical findings in the absence of testing (i.e., if testing is unavailable), then ARV prophylaxis should be transitioned to ART.

Breastfeeding

The potential benefits of breastfeeding are numerous and beyond the scope of this essay. However, breastfeeding as it pertains to the care and

treatment of children affected by HIV remains a controversial topic. As such, recommendations on breastfeeding remain context specific and vary from country to country. That said, most low-income countries with high HIV prevalence promote breastfeeding with concomitant maternal ART and infant ARV prophylaxis as the preferred strategy to give infants born to mothers known to be infected with HIV the greatest chance of survival. There is evidence from these settings that early cessation of breastfeeding results in excess infant mortality, mostly due to diarrheal illnesses and malnutrition. Furthermore, exclusive breastfeeding for the first 6 months of life is associated with significantly lower risk of HIV transmission as compared to mixed feeding where both breast milk and any other food or liquid is given to the infant. Food insecurity, availability of potable water for mixing formula, and cost of replacement feeding all factor into these findings and ultimately influence context specific recommendations (Black et al. 2008).

Antiretroviral Therapy

Antiretroviral therapy (ART) refers to the use of a combination of ARV drugs to control HIV infection. ART is sometimes termed highly active antiretroviral therapy (HAART). The overall goal of ART is to improve the lives of those infected with HIV. ART accomplishes this goal by suppressing replication of the HIV virus, thereby preserving host immune function, avoiding opportunistic infections, and allowing for a long and productive life. For those who are able to access ART, HIV infection has been transformed from a progressive and eventually fatal disease to a chronic illness. That said, ART is not a cure and patients should be prepared to continue it lifelong.

There are several classes of ARV drugs, each attacking HIV at different points in its replication cycle. Nucleoside reverse transcriptase inhibitors (NRTIs) such as abacavir (ABC), zidovudine (AZT), lamivudine (3TC), and tenofovir (TDF) and non-nucleoside reverse transcriptase inhibitors (NNRTIs) such as nevirapine (NVP) and efavirenz (EFV) target the enzymatic conversion

of single-stranded HIV viral RNA into double-stranded DNA (i.e., reverse transcription). Protease inhibitors (PIs) such as lopinavir (“boosted” with ritonavir, LPV/r) block the enzyme that cleaves HIV viral transcripts into functional proteins. Fusion inhibitors and integrase inhibitors block the HIV virus from docking on host cells and from integrating into the host cell genome, respectively. Three or more ARV drugs from a variety of classes are used in combination with two main objectives: to achieve potent suppression of the HIV virus and to prevent the development of HIV drug resistance mutations that may limit the efficacy of one or more ARV. More recently, ART has also been considered an important form of prevention. HIV-infected persons who have achieved viral suppression on ART have fewer viral particles in body fluids that might transmit the HIV virus (blood, semen, breast milk, etc.), and thus are less likely to infect others who are exposed to these fluids.

Eligibility for ART Initiation

Untreated HIV infection results in high levels of mortality among infants in low-income and high HIV prevalence areas with approximately 50% mortality by 2 years of age (Newell et al. 2004), but by 5 years of age, mortality and disease progression without ART is similar to rates in young adults (Dunn et al. 2008; 3Cs4kids 2008). As such, the WHO recommends that ART should be initiated in all HIV-infected children under the age of 5 years, including those with a presumptive diagnosis of HIV infection. Priority should be given to children less than 2 years of age, those with advanced HIV disease as indicated by having WHO clinical stage 3 or 4 defining illnesses (Table 1) and those with CD4-positive T-cell count (“CD4 count”) less than 750 cells/mm³ or percentage of CD4-positive T-cells relative to total white blood cell counts (CD4%) less than 25%, whichever is lower (WHO 2013a, 2014b).

NIH/HHS recommendations for ART initiation are similar in that they recommend ART initiation for all HIV-infected children less than 12 months, but for children older than 12 months of age, ART eligibility is dependent on meeting clinical and laboratory criteria. Any child older than 12 months

Children, Care and Treatment, Table 1 A selection of WHO stage 3 and 4 defining illnesses for children 0–15 years of age

Stage 3	Stage 4
Unexplained moderate malnutrition	Unexplained severe malnutrition
Unexplained persistent diarrhea	Chronic diarrhea due to cryptosporidiosis or isosporiasis
Unexplained persistent fever	<i>Pneumocystis (jirovecii)</i> pneumonia
Persistent oral candidiasis (after first 6 weeks of life)	Esophageal candidiasis
Lymph node or pulmonary tuberculosis	Extrapulmonary tuberculosis
Severe recurrent bacterial pneumonia	Recurrent severe bacterial infections (not pneumonia)
Unexplained anemia, thrombocytopenia, or neutropenia	HIV-associated malignancy (e.g., Kaposi sarcoma)
Lymphoid interstitial pneumonitis	Central nervous system toxoplasmosis
Chronic lung disease, including bronchiectasis	Extrapulmonary cryptococcosis

of age with an HIV viral load greater than 100,000 copies/mL should be initiated on ART. ART should also be initiated in any child 1–3 years of age with CD4 count less than 1000 cells/mm³ or CD4% less than 25%. For children 3–5 years of age, they recommend ART initiation when CD4 count is less than 750 cells/mm³ or CD4% is less than 25%. Regardless of age, any child with a United States Centers for Disease Control and Prevention (CDC) classification system clinical category B or C condition (similar to WHO clinical stage 3 and 4 defining illnesses) should be initiated on ART (NIH/HHS 2014b).

Both the WHO and NIH/HHS use a CD4 count of 500 cells/mm³ as the cutoff for ART initiation in the general population including children older than 5 years of age, adolescents, and adults. ART should also be initiated in anyone in special populations including those with active tuberculosis (TB), hepatitis B virus infection and chronic liver disease, pregnant and breastfeeding women, and HIV-positive partners in serodiscordant couples, regardless of CD4 count (NIH/HHS 2014b; WHO 2013a; WHO 2014b).

ART Regimens

There are several classes of ARV drugs with multiple drugs in each class. Deciding which combination of ARV drugs to prescribe for a particular patient can be challenging. Considerations include the patient's age and weight, formulation and route of administration (e.g., tablet vs. liquid suspension), medication side effect profiles, prior ARV exposure (in utero as part of PMTCT, as infant ARV prophylaxis, or as part of a previously interrupted ART regimen), and interactions with other medications the patient is taking. When availability of ARV drugs and cost is not a limiting factor, the approach to deciding the most appropriate ART regimen also includes HIV genotyping to determine resistance patterns (NIH/HHS 2014b). That said, ARV availability as reflected by national formularies is much more limited in the low-income countries most affected by HIV.

With these factors in mind, current WHO recommendations for first-line ART in infants and children less than 3 years of age are for two NRTIs and a PI (e.g., ABC+3TC+LPV/r). The NRTI "backbone" should always include 3TC. ABC is often preferred over AZT, since AZT can induce anemia which is already often a problem in this age group and is potentially more problematic in environments where malnutrition and malaria are common (WHO 2013a, 2014b).

For children older than 3 years of age (including adolescents), the WHO recommends a first-line regimen composed of two NRTIs and an NNRTI (e.g., ABC+3TC+EFV). EFV is the preferred NNRTI. Again, the NRTI backbone should always include 3TC. TDF should be avoided in those less than 10 years of age or weighing less than 35 kg as to avoid potential adverse effects on bone development, though, in those older than 10 years of age and more than 35 kg, TDF is preferred as to align with the first-line recommendations for adults (WHO 2013a, b, 2014b).

If a patient develops treatment failure while on first-line ART, they can be switched to second-line ART. Ideally, development of this new regimen would be tailored to the individual and to results of HIV drug resistance testing. Resistance testing should be obtained, while the patient remains under the selective pressure of failing ART regimen as to

avoid the emergence of a subpopulation of nonresistant wild-type virus if ART were suspended. However, resistance testing is not routinely available in low-resource settings, so instead the WHO has proposed empiric second-line regimens, and country-specific guidelines further vary depending on national formularies. That said, the WHO recommends that after failing a NNRTI-based first-line regimen, second line should include a PI. If already on a PI-based first-line regimen, then the PI should be switched to an NNRTI. 3TC should remain a part of all second-line regimens while other NRTIs can be exchanged for one another. Maintaining 3TC is recommended because the most common mutation against 3TC (M184V) results in a virus that is less virulent than wild-type HIV virus (WHO 2013a, 2014b).

Weight should be checked at every clinical encounter and doses of medications adjusted, if necessary. This should be continued until weighing more than 35 kg when adult dosing can be prescribed. Similarly, liquids formulations should be switched to pill form once able. Furthermore, any changes that can be made to minimize the number of pills (pill burden) and the frequency of medication administration should be made. Simplified regimens are easier for children and caregivers and can potentially improve adherence to prescribed therapies.

Monitoring

Clinical and laboratory monitoring should start at the time of diagnosis of HIV infection or from birth in the case of HIV-exposed infants. Initial evaluation should include WHO clinical staging, screening for TB, CD4 count, and viral load testing if available. Additionally, screening for hepatitis B, hepatitis C, and sexually transmitted infections should also be considered.

After diagnosis of HIV but prior to ART initiation, serial evaluations occurring at least every 6–12 months should be performed to determine ART eligibility and should include repeat CD4 count, interval history, and a physical exam. Monitoring should be more frequent if there are active issues or comorbid conditions that require

Children, Care and Treatment, Table 2 Common ARVs and selected associated side effects and toxicities to guide monitoring

Antiretroviral drug	Potential side effects and toxicities
Abacavir (ABC)	HLA-B*5701-associated hypersensitivity reaction
Zidovudine (AZT)	Anemia, neutropenia, myopathy, lipodystrophy
Efavirenz (EFV)	CNS toxicity (confusion, depression, seizures), gynecomastia
Lopinavir/ritonavir (LPV/r)	QT interval prolongation, dyslipidemia, diarrhea
Nevirapine (NVP)	Hepatotoxicity, severe rash (Stevens-Johnson syndrome)
Tenofovir (TDF)	Tubular renal dysfunction, Fanconi syndrome, osteopenia

treatment and that may influence decisions regarding ART initiation.

Monitoring should also be more frequent in the weeks and months just after ART initiation. During this critical time period, it is important to ensure optimal adherence and to assess for potential drug toxicities. Once stable on ART, periodic CD4 count and viral load testing should continue to be obtained every 6–12 months to monitor treatment response, and additional laboratory monitoring should also be considered depending on the ART regimen and the potential short- and long-term effects attributable to its component ARV drugs (Table 2).

ART Response

Prior to the introduction of viral load testing, clinical and immunological criteria were used to define treatment failure. However, viral load testing allows for earlier and more sensitive detection of treatment failure and as such has become the gold standard for monitoring ART response. In high-resource settings, viral load testing is readily available, and NIH/HHS recommendations for monitoring rely on viral load testing as the main indicator of ART treatment success and failure. Treatment success is essentially synonymous with viral suppression which is defined as a viral load below the level of detection of available assays, generally less than 50 copies/mL. Treatment failure is defined as a viral load exceeding 1000

copies/ml on at least two consecutive measurements within a 3-month interval and after a minimum of 6 months of optimal dosing of and adherence to ART (NIH/HHS 2014b).

The WHO also recommends viral load testing as the preferred approach to monitoring ART success and treatment failure, but due to limited availability in resource-limited settings, it is considered complementary to clinical and immunologic measures of ART response. Clinical signs of treatment failure include new or recurrent clinical events suggestive of advanced or severe immunodeficiency (WHO clinical stage 3 or 4 illness) after 6 months of ART. Immunologic criteria for treatment failure in children under 5 years of age is persistent CD4 count less than 200 cells/mm³ or CD4% persistently less than 10%. For children older than 5 years of age, immunologic failure is defined by a CD4 count persistently less than 100 cells/mm³. Persistently declining or lack of improvement in CD4 count or CD4%, while not meeting values outlined in the definition of immunologic failure, might also be suggestive of treatment failure. Furthermore, to meet immunologic criteria for treatment failure, concomitant infection that might cause a drop in CD4 count or CD4% must also be excluded (WHO 2013a, 2014b).

Adherence

It should be noted that nonadherence to ART is the most common cause of treatment failure. Nonadherence is also the main risk factor for development of HIV drug resistance mutations. However, treatment failure due to nonadherence does not always translate to resistant virus necessitating a change in ART regimen. As such, evaluation of adherence and ongoing adherence education and counseling when indicated should be a part of all routine clinical encounters. When treatment failure is suspected, intensive adherence support should also be provided. Only after optimizing dosing, assuring optimal adherence, and/or confirming HIV drug resistance via genotyping should an alternative ART regimen be considered.

Adherence to ART prescribed for infants and children poses additional challenges including: the need for caregiver support for medication administration, use of liquid suspensions that

require precise measurement, and low literacy. When poor adherence is documented or suspected, caregivers and other treatment supporters should be involved in adherence education and counseling, and they should be encouraged to participate in creative and individualized solutions for improving adherence.

Prevention of Common Coinfections

HIV infection, if untreated, eventually results in severe immunocompromise and opens the door for a cadre of opportunistic infections that in the pre-ART era characterized AIDS. Now, these infections are preventable with maintenance of immune function via viral suppression with ART. However, many people who are eligible for ART still do not access care and treatment, and even when they initiate ART, they remain at increased risk for a variety of coinfections.

Co-trimoxazole Preventative Therapy

Co-trimoxazole is a sulfa-containing broad-spectrum antibiotic with activity against some Gram-positive and Gram-negative bacteria, fungi including *Pneumocystis jirovecii*, and protozoa including toxoplasmosis and malaria. Co-trimoxazole preventive therapy (CPT) refers to the prophylactic use of this antibiotic to prevent coinfection with the aforementioned microbes in susceptible hosts.

The WHO recommends CPT for all infants, children, and adolescents infected with HIV. In areas where malaria and/or severe bacterial infections are highly prevalent, they recommend continuing CPT until adulthood, regardless of ART status, WHO clinical stage, or CD4 count. In settings where there is low prevalence of malaria and bacterial infections, CPT may be discontinued for HIV-infected children older than 5 years of age, on ART for at least 6 months, who are clinically stable or virally suppressed, and with a CD4 count greater than 350 cells/mm³ (WHO 2014a).

NIH/HHS recommends CPT for all children under 12 months of age, for children 1–6 years of age when CD4 count is less than 500 cells/mm³ or CD4% is less than 15%, and for children older

than 6 years when CD4 count is less than 200 mm³. Discontinuation of CPT can be considered in children 1–6 years of age after receiving ART for at least 6 months, and CD4 count is greater than 500 cells/mm³ or CD4% is greater than 15%. For children older than 6 years, the cutoff is a CD4 count of more than 200 cells/mm³ (NIH/HHS 2014a).

For HIV-exposed infants, CPT can be started at 4–6 weeks of age and continued until HIV infection has been definitively excluded.

Tuberculosis

Globally, TB is among the most common opportunistic infections and a leading cause of mortality in people infected with HIV. TB can cause active or latent infection, but primary active TB and reactivated latent TB are more common with HIV infection. Any form of active TB in a child infected with HIV is an indication for ART initiation. As such, screening for TB should be a part of the every clinical encounter for HIV-infected children in TB-endemic areas. If active TB is identified prior to ART initiation and the patient is stable, the intensive phase of antitubercular treatment (ATT) should be started prior to ART to minimize the risk of developing TB immune reconstitution inflammatory syndrome (IRIS). Regardless of the timing of ATT, care should be taken to avoid drug interactions between the components of ATT and ART.

The WHO also recommends 6 months of isoniazid preventive therapy (IPT) for HIV-infected children who do not have active TB but who are at risk for acquiring TB or having reactivation of latent TB. IPT is recommended for HIV-infected children in the following situations: (1) when there is a known exposure to someone with active TB, regardless of age, (2) when living in a TB-endemic area and older than 1 year of age, and (3) after completing treatment for active TB disease, an additional 6 months of IPT should be administered.

Mycobacterium Avium Complex

Non-TB mycobacteria such as *Mycobacterium avium* complex (MAC) are ubiquitous in the environment, and in the pre-ART era, MAC was the second most common opportunistic infection in

HIV-infected children in the USA. Similar to TB, MAC can cause of spectrum of disease ranging from isolated lymphadenitis to primary pulmonary infection to disseminated disease. That said, severe disseminated disease almost exclusively occurs in the setting of severe immunocompromise. As such, recommendations for MAC prophylaxis are dependent of CD4 count. MAC prophylaxis with clarithromycin or azithromycin is recommended for HIV-infected children less than 1 year of age when CD4 count is less than 750 cells/mm³, for children 1–2 years of age when CD4 count is less than 500 cells/mm³, for children 2–6 years of age when CD4 count is less than 75 cells/mm³, and in children age 6 and older when CD4 count is less than 50 cells/mm³ (NIH/HHS 2014a).

Vaccines

HIV-infected and HIV-exposed children stand to greatly benefit from protection against vaccine-preventable diseases. Availability of vaccines and immunization schedules vary widely from country to country, but in general HIV-infected children should receive all of the recommended vaccines available to the general population. The only exception is that children with severe immunosuppression due to advanced HIV should not receive live-attenuated vaccines.

All inactivated vaccines can be safely administered to children with severe immunosuppression; however, due to impaired cellular immunity, they may not be as effective at eliciting a lasting immune response as in children with normal immune systems.

Live-attenuated vaccines include the varicella, measles, mumps, and rubella vaccines. These vaccines can be considered for HIV-infected children who are not severely immunocompromised, but should be avoided in children 6 months to 5 years of age with CD4% less than 15% or those 5 years and older with CD4 counts less than 200 cells/mm³.

Disclosure

Disclosure of HIV status to children affected by HIV is a crucial component to the long-term care

and treatment of this vulnerable population, and it involves both the child and their caregivers. This is a subject that must be broached gradually and with sensitivity to an individual's circumstances, family dynamics, and caregiver concerns.

Disclosure to children of their own HIV status is limited by maturity and understanding that develop with time. Thus, disclosure should be a gradual process that begins at school age with simple concepts of disease and is completed during adolescence with full disclosure of the implications of HIV infection and chronic disease management. Along with full disclosure, there should also be a transition of responsibility with a shift from caregiver-dependent care to self-directed care. Healthcare providers and caregivers sometimes worry that this process will be psychologically or emotionally traumatizing for children, but there is little evidence to support these concerns. To the contrary, disclosure is actually associated with improved health outcomes. Furthermore, risks to the affected child's well-being can be minimized by ensuring that the person(s) disclosing information have a strong and positive relationship with the child.

Concurrent with disclosure to children of their own HIV status, affected children should also be informed of the HIV status of their caregivers. Similarly, this should be an incremental process. This element of disclosure is also associated with improved health outcomes.

Disclosure should also be accompanied by counseling about the potential risks and benefits of disclosing their own or their caregivers' HIV status to others. Education about the importance of privacy and realities of stigma should be components of this counseling. That said, there are certainly situations where disclosure to others is necessary, so counseling should also assist them in how, to whom, and under which circumstances to disclose this information (WHO 2011).

Conclusion

Currently there is no cure for HIV. However when ART is administered as early as possible in the course of infection, children with HIV can lead

longer, healthier lives. Coordinated efforts are needed between health workers responsible for the care of children and those responsible for the care of pregnant mothers. Early infant diagnosis and the identification and management of opportunistic infections are critical. Psychosocial support is equally important, and the failure to provide such services can result in a lack of compliance with medications and appointments. Despite these ongoing challenges, progress in the field to date has provided “achievable targets” in our mission to eliminate pediatric AIDS and the hope for a healthy future for children and families living with HIV throughout the world.

Definition

Pediatric HIV disease is due to infection with human immunodeficiency virus-1. The first pediatric cases were identified in the early 1980s

(Lindegren et al. 2000). Almost all transmission of HIV-1 to infants and young children occur through mother to child transmission of HIV with a smaller number of cases related to blood product transfusion, injections with contaminated needles, or sexual abuse (Lindegren et al. 2000). Among newly infected adolescents, transmission most commonly occurs through sexual transmission (Idele et al. 2014).

Introduction

The global HIV/AIDS epidemic has left a heavy toll since the HIV-1 virus was first identified in the early 1980s with over 39 million deaths reported due to HIV/AIDS-related causes. Important segment of this intergenerational pandemic are HIV-infected infants and children less than 15 years of age and young persons between 15 and 24 years of age. As of 2013, there were an estimated 35 million persons living infected with HIV/AIDS, which included 3.2 million children less than 15 years of age and close to 11 million young persons between the ages 15 and 24 years of age. It is estimated that 24.7 million (71%) of these HIV-infected adults and children live in Sub-Saharan Africa (UNAIDS 2014a; Gillespie et al. 2015).

Incidence and Mortality: In terms of incident HIV infections reported worldwide in 2013, an estimated 240,000 were children <15 years of age. In addition, among the 2.1 million newly infected adults in 2013, about one third or close to 700,000 were young persons between the ages of 15 and 24 years (UNAIDS 2014a; Gillespie et al. 2015). In the United States, the rates of new pediatric infections declined dramatically from 1994 when it was estimated that there were 1650 new pediatric infections each year to less than 200 new infections annually in most recent years (CDC Surveillance 2011). In 2013, new infections among US adolescents ages 13–19 years of age were reported at 1,931 of whom 81% were males and 67% were African American, 18% Hispanic, and 11% Caucasian. In the age group 13–24 years, 40,634 young persons were living with HIV/AIDS in 2013 including

30,222 males and 10,412 females (CDC-DHAP 2013). Worldwide, in 2013 there were 1.3 million adults and 190,000 children less than 15 years of age who died of HIV-related causes (UNAIDS 2014a; Gillespie et al. 2015).

Modes of Transmission: Most children living with HIV have become infected from their mothers either during pregnancy, labor and delivery, or postnatally during breastfeeding in settings where breastfeeding is essential to infant survival. In resource-limited international sites, up to a third of infections occur during breastfeeding (DeCock et al. 2000). In contrast, the majority of young persons between the ages of 15 and 24 who are living with HIV usually became infected from sexual transmission, either heterosexual transmission or among young men who have sex with men (MSM). Internationally, incident infections among young persons have been primarily due to heterosexual transmission whereas in the United States, MSM incident infections represented 92% of new infections among adolescents and young adults aged 13–24.

Trends: The worldwide statistics, while grim, show progress in reduction of incident pediatric cases of HIV with greater than a 50% reduction in the numbers of new infant infections when compared to the mid 2000s where over 500,000 infants were newly infected each year (Gillespie et al. 2015). Most of these advances have built on findings from clinical trials demonstrating effective combination antiretroviral interventions for prevention of mother to child transmission of HIV (PMTCT) and which have subsequently been rolled out under international donor and Ministry of Health programs.

UNAIDS estimates that between 2005 and 2013, 1.1 million new pediatric infections were averted by PMTCT programs (UNICEF 2014d). Overall coverage of PMTCT has increased with 67% of pregnant women in low and middle-income countries receiving antiretrovirals (ARVs) for PMTCT in 2013, compared to 47% in 2010 (UNICEF 2014; UNAIDS 2014b). In the United States, HIV screening coverage is universal during pregnancy and with rapid testing for those who present late or at labor/delivery.

In contrast, new infections among adolescents and young adults have continued to fuel the HIV pandemic. These new infections in young persons are occurring despite proven effective preventative interventions such as condom use, circumcision, and pre-exposure prophylaxis. In 2013, WHO launched new treatment guidelines (WHO 2013) which emphasize early treatment of adults including pregnant HIV-infected women in order to decrease the risk of HIV transmission to sexual partners and mother to child transmission of HIV.

In this entry, we will discuss approaches to early diagnosis and treatment of young children infected with HIV including recommended first-line treatment. We will also review the unique challenges of diagnosis and treatment of HIV-infected adolescents along with strategies to improve long-term adherence to antiretroviral treatment and highlight some innovative research approaches toward achieving long-term remission of pediatric HIV infection.

Young Children Living with HIV – United States and internationally: Strategies in the First Decade of Life (Birth to Age 9 Years) to Ensure Early Diagnosis and Prompt Initiation of Treatment

As noted above, great progress has been made in PMTCT over the past decade. In high-income countries such as the United States, the MTCT rate is less than 1% through PMTCT interventions including use of triple antiretrovirals during pregnancy, at labor/delivery, and with provision of formula and avoidance of breastfeeding (Whitmore et al. 2012). However, in low and middle-income countries, national PMTCT program coverage remains low. Thus, transmission rates remain high despite known effective antiretroviral interventions: Nearly 700 children are newly infected with HIV each day (UNAIDS 2014b). To ensure their health and survival, it is crucial that the HIV-exposed infants receive early infant diagnosis (EID) and initiate ART as early as possible after confirmation of their HIV infection.

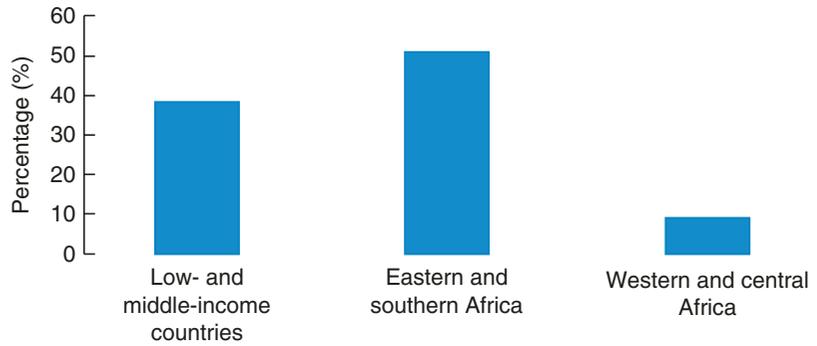

Strategies for Early Infant Diagnosis: WHO 2013 guidelines for low and middle-income

countries recommend initial testing of all HIV-exposed infants within 4–6 week of birth (WHO 2013). However, guidelines in higher income countries recommend HIV testing within 48 h of birth (Panel ART 2015). Diagnosis of HIV in infants >18 months and older children can be done using serologic antibody testing. However, serologic testing among children under 18 months is complicated by the presence of maternal anti-HIV antibodies and only determines HIV exposure. Therefore, nucleic acid testing (NAT) using HIV DNA, RNA, or total nucleic acid or viral p24 antigen is required to confirm HIV infection among infants up 18 months of age (WHO 2013; Panel ART 2015). This creates challenges in that nucleic acid testing is more expensive than serologic rapid antibody testing which be done with older children and adults. In addition NAT assays are technically demanding, require high technology laboratories, and are not easily accessible or locally available in most rural areas. To overcome these challenges, blood samples from HIV-exposed infants are often collected at local health centers on dried blood spots (DBS) which can then be sent to central laboratories for NAT.

While EID coverage has expanded over the last 5 years, there remain significant gaps in testing: only 6 out of 22 priority countries (South Africa, Swaziland, Botswana, Namibia, Zambia, and Zimbabwe) reported coverage above 50% (WHO 2013; Prendergast et al. 2015; UNAIDS 2014c). In addition, only 40–50% of all HIV-exposed infants received a test before 2 months of age as noted in Fig. 1 (UNAIDS 2014a; WHO 2013). In high-income countries, NAT testing of HIV-exposed infants is recommended at birth (for high risk perinatally exposed infants), 14–21 days, 1–2 months, and then again at 4–6 months of age (Panel ART 2015), at which point NAT negative infants can be considered HIV uninfected since they are formula fed and not HIV exposed through breast milk. In comparison, repeat NAT testing of HIV-exposed infants in low and middle-income countries who are mostly breastfed is recommended at 4–6 weeks and then 9 months of age with either serologic or viral testing to assess ongoing exposure through breastfeeding

Children, Epidemiology of HIV/AIDS,

Fig. 1 Percentage of children born to HIV infected women who had HIV testing done within 2 months of birth in low and mid income settings; eastern and southern Africa, western and central Africa (Source: Global AIDS Response Progress Reporting 2013)

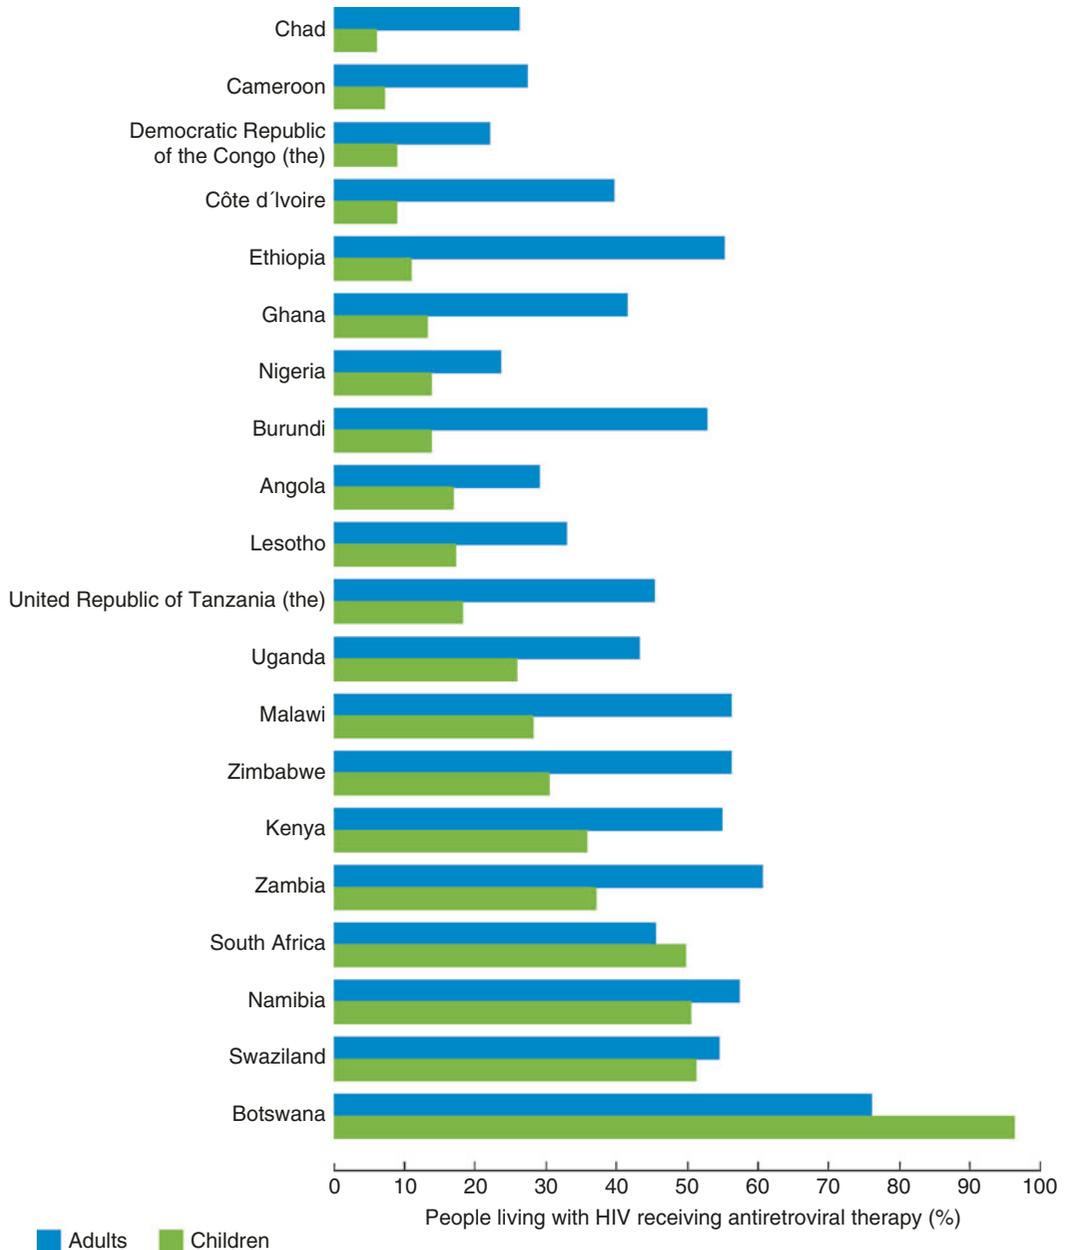

and confirm diagnosis respectively. A final serologic assessment of status can only be made at >18 months if there is no ongoing exposure or at 4–6 weeks after the breastfeeding period ends.

EID has increased the number of HIV-infected infants identified; however, challenges remain with linkage to care and treatment. There are often long turnaround times for receiving infant HIV results from central laboratories and high rates of loss to follow-up are an issue in many PMTCT programs (Chatterjee et al. 2011; Ciaranello et al. 2011). To overcome these problems, point-of-care (POC) virologic testing is being piloted which can give results on the same day of the clinic visit. It is hoped this may improve retention in care if mothers are able to receive results in real time. However, the majority of POC instruments are still in the development stage and not ready for clinical use (UNAIDS 2014a; Jani et al. 2014). Another challenge is that postpartum retention within PMTCT programs is low, with some studies reporting up to 80% of women lost to follow up by 6 months postpartum (Marcos et al. 2012; Ghadrshenas et al. 2013) and only 30–40% of HIV-infected infants initiated on ART (UNAIDS 2014a; Chatterjee et al. 2011). Integrating HIV testing into expanded program on immunization, pediatric wards, nutrition clinics, under-five and community based health programs can reach more mothers and infants who may have missed opportunities for testing, linking to care and treatment, and improve earlier identification of HIV-exposed children (UNICEF 2013a). This approach aims to strengthen systems and provide more comprehensive, effective, and efficient care.

When to Start ART

Before ART was available, 50% of HIV-infected infants died before their 2nd birthday (Newell et al. 2004). However, the CHER study demonstrated that early initiation of HIV-infected infants with ART before 12 weeks of age reduced the probability of early mortality by 75%, compared to delaying treatment until the infants met clinical or immunologic criteria (Violari et al. 2008). Likewise, studies in the United States and Europe have shown that infants initiated early on ART infants are less likely to progress to AIDS or death compared to those who are initiated later (Chiappini et al. 2009; Goetghebuer et al. 2012). Because the risk of rapid disease progression and death is high in young infants (Panel ART 2015; Violari et al. 2008; Palumbo et al. 2010) recommendations for high, middle, and low-income countries are similar with expedited initiation of ART for infants <12 months of age. Despite these recommendations, most children living with HIV in resource-limited international settings do not receive ART: In 2014 WHO reported only 23% of children (0–14 years) who are eligible are receiving ART worldwide (WHO 2014b). As noted in Fig. 2, ART coverage among children lags significantly behind HIV adults in the 22 priority countries (UNAIDS Global Report 2013).

The decision of when to initiate ART in HIV-infected children and adolescents varies by region and age and continues to generate controversy among HIV experts. The median age of ART initiation for children living with HIV in many countries is 4 years of age (Fenner et al. 2010); and countries vary on the criteria used to make the decision for treatment initiation

Children, Epidemiology of HIV/AIDS, Fig. 2 Percent-age of adults (aged 15+) and children (aged 0–15 years) living with HIV who were receiving antiretroviral therapy

in 2013, in 21 high priority countries (Source: 2013 esti-mates from UNAIDS, WHO and UNICEF)

for children 12 months and above. A comparison of United States (Panel ART 2015) and WHO ART guidelines (WHO 2013) is shown in Table 1. In the United States, the factors to consider in making the decision when to initiate therapy in children >12 months of age include:

- Increasing HIV RNA level (>100,000 copies/ml)
- CD4 count/percentage values approaching the age-related threshold for treatment
- Development of clinical symptoms
- The ability of caregiver and child to adhere to the prescribed treatment

Children, Epidemiology of HIV/AIDS, Table 1 Comparison of United States and WHO treatment guidelines for HIV-infected infants and children

Age	Criteria	Recommendation
US guidelines		
<12 months	Regardless of clinical symptoms, immune status, or viral load	Urgent treatment
1 to < 6 years	CDC stage 3 – defining opportunistic illnesses	Urgent treatment
	CDC stage 3 immunodeficiency, CD4 < 500cell/mm ³	Urgent treatment
	Moderate HIV-related symptoms	Treat all
	Plasma HIV RNA level >100,000 copies/ml	Treat all
	Age 1–<6 years, CD4 500–999 cell/mm ³	Treat all
	Mild HIV-related symptoms or asymptomatic and CD4 ≥ 1000 cell/mm ³	Consider treatment
>6–15 years	CDC stage 3 – defining opportunistic illnesses	Urgent treatment
	CDC stage 3 immunodeficiency, CD4 < 500cell/mm ³	Urgent treatment
	Moderate HIV-related symptoms	Treat all
	Plasma HIV RNA level >100,000 copies/ml	Treat all
	CD4 count 200–499 cell/mm ³	Treat all
	Mild HIV-related symptoms or asymptomatic and CD4 count ≥500cell/mm ³	Consider treatment
WHO 2013 guidelines		
<12 months	Irrespective of CD4 count and WHO stage	Treat all
1–5 years	Irrespective of CD4 count and WHO stage	Treat all
>5–15 years	CD4 ≤ 500 cells/mm ³ irrespective of WHO stage	Treat all
	WHO clinical stage 3 or 4	Treat all

According to the US guidelines, ART does not need to be started urgently for healthy HIV-infected children >1 year of age; and caregivers may postpone therapy on a case-by-case basis or providers may elect to defer therapy based on clinical and or psychosocial factors (Panel ART 2015). Close monitoring of virologic, immunologic, and clinical status is provided every 3–4 months (Panel ART 2015).

Most low and middle-income countries use the WHO guidelines to inform health policy. In 2013, WHO HIV consolidated treatment guidelines were revised based on review of the evidence, operational considerations, and preferences expressed by care providers to simplify and expand treatment in children (WHO 2013). These modifications included initiating ART for all HIV infants and children under 5 years of age regardless of CD4 cell count and to increase the threshold for ART initiation to ≤500 cell/mm³ in children 5 years and older in alignment with adult treatment guidelines. The guidelines development group made these changes despite the lower risk of disease progression in children 2–5 years compared to those <2 years and limited clinical trial

data evidence. However, programmatic data suggest that retention is better among children on ART than those in care but not yet started on ART (WHO 2013; Massavon et al. 2014; Penazzato et al. 2012). Increased mortality has also been reported among the children and adolescent enrolled in care programs but not yet started on ART compared to those on ART (Massavon et al. 2014). Access to immunologic testing required for decision-making is still limited in countries with a high burden of pediatric disease and low pediatric coverage (UNAIDS 2014a; Barker and Mate 2012). The need for access to CD4 cell testing to initiate treatment is avoided with the new guidelines. Therefore, simplification of the eligibility criteria may significantly improve the overall health outcomes for children with HIV.

HIV-Infected Children Under 3 Years of Age

Optimizing treatment of young HIV-infected children is important to promote viral suppression, survival, and growth. Other considerations include the fact that young HIV-infected children are exposed to various antiretroviral drugs, used

Children, Epidemiology of HIV/AIDS, Table 2 Comparison of US based and WHO (2013) recommended first-line antiretroviral treatment regimens for children

Preferred regimen (US guidelines UNAIDS 2014b)	
Children aged 14 day to <3 years	Two NRTI plus LPV/r
Children aged >3 years to <6 years	Two NRTI plus EFV
	Two NRTI plus LPV/r
Children aged ≥6 years	Two NRTI plus ATV plus low-dose RTV
	Two NRTI plus EFV
	Two NRTI plus LPV/r
Alternative regimens(US guidelines UNAIDS 2014b)	
Children aged ≥14 days	Two NRTI plus NVP
Children aged ≥3 month to <6 years and weighing >10 kg	Two NRTI plus ATV plus low-dose RTV
Children aged ≥2 years	Two NRTI plus RAL
Children aged ≥3 years to <12 years	Two NRTI plus twice daily DRV plus low-dose RTV
Children aged ≥12 years and weighing >40 kg	Two NRTI plus once daily DRV plus low-dose RTV
	Two NRTI plus DTG
Preferred NRTI (US guidelines UNAIDS 2014b)	
Children from birth to <3 months	ZDV plus (3TC or FTC)
Children aged ≥3 months and ≤12 years	ABC plus (3TC or FTC)
	ZDV plus (3TC or FTC)
Adolescents 13 years at Tanner 3	ABC plus (3TC or FTC)
WHO 2013 preferred regimen UNAIDS 2014a	
Children < 3 years	ABC or AZT + 3TC + LPV/r
Children 3 years to <10 years and adolescents <35 kg	ABC + 3TC + EFV
Adolescents (10–19 years) and ≥35 kg	TDF + 3TC (or FTC) + EFV

for PMTCT, especially NNRTIs. In addition, young children have high viral replication, thus require a potent first-line regimen to achieve viral suppression. The 2013 WHO guidelines recommended lopinavir/ritonavir (LPV/r) based ART for all infants regardless of exposure to PMTCT. A systematic review of two randomized trials showed that children younger than 3 years had a reduced risk of virologic failure or death and discontinuation of treatment on LPV/r based ART compared to NVP (Palumbo et al. 2010; Violari et al. 2012). In addition, there is evidence of emerging NNRTI resistance among children under 18 months without exposure to ARV drugs or PMTCT (Paredes et al. 2013; Chakanyuka-Musanhu et al. 2013). While LPV/r is the preferred first-line regimen, it is still not readily available in resource-limited countries; therefore, NVP-based regimens are an effective alternative.

WHO promotes the use of non-thymidine analogues (ABC) in first-line regimen to preserve the

response to zidovudine (ZDV) or d4T for second-line ART. ABC is available in pediatric fixed-dose combination and can be dosed once daily. Harmonization of the preferred regimen with older children and adults may also increase availability in resource-limited settings. Therefore, ABC and lamivudine (3TC) are the chosen preferred NRTI backbone. In the United States, first-line treatment regimens are similar for children under 3 years; however, alternative regimens are available based on age (Table 2).

Children 3 Years and Older

Internationally, Efavirenz (EFV) is the WHO preferred NNRTI for first-line treatment of children 3 years and older. Observational data suggest that EFV has a better short-term toxicity profile and better virologic suppression than NVP (Shubber et al. 2013). ABC and 3TC are the preferred NRTI to enable once a day dosing as well as harmonization with adolescents and adults regimens. Tenofovir (TDF) is approved by the US Food

and Drug Administration and European Medicines Agency for children 2 years and older. However, TDF is known to reduce bone mineral density (Hazra et al. 2005; Purdy et al. 2008). In addition, there is limited experience with TDF in young children and knowledge of its effect on growth and future fracture risk is unknown. While TDF is a recommended alternative to ABC, its use for children between 2 and 15 is very limited in low and middle-income countries.

New pediatric formulations (PIs and integrase inhibitors) are available in high-income countries and included in the first-line treatment regimen (Table 2) (Panel ART 2015). However, these formulations are not yet readily available in low and middle income countries. Therefore, second line is limited to protease inhibitor based ART with LPV/r or Atazanavir. Low and middle income countries need expanded access to new formulations and also need to plan for options for third-line ART, as more HIV-infected children initiated on ART are surviving to adolescence and adulthood.

Adolescent and HIV Second Decade of Life (10–19 Years)

WHO defines adolescents living with HIV (ALHIV) as children between the age of 10–19 years and were perinatally HIV-infected or acquired HIV through sexual activity or exposure through injection drug abuse or unsafe blood products (UNAIDS 2014b). By the end of 2013, UNAIDS estimated 2.1 million adolescents living with HIV worldwide of which 56% were girls, with 80% living in Sub-Saharan Africa and unaware of their HIV status (UNAIDS 2014b; UNICEF 2013b). Approximately 300,000 new infections worldwide occurred among adolescents aged 15–19 years in 2012, which accounted for about 13% of the 2.3 million new infections globally in 2012 (UNICEF 2013b). In contrast, the Centers for Disease Control and Prevention (CDC), estimates that by the end of 2012, approximately 7,300 adolescents aged 13–19 years were living with HIV in the United States. HIV/AIDS is the number one cause of mortality among adolescents in Africa and second worldwide (WHO 2014b). Globally AIDS-related deaths fell by

40% between 2005 and 2013 except for adolescents. There is limited data to explain why deaths among adolescents with HIV are not decreasing. However, the low level of testing among adolescents could potentially contribute to the increase in AIDS-related mortality (Idele et al. 2014). Those who do not know their HIV status are unlikely to seek care and treatment with antiretroviral therapy, which results in a delay in treatment and advancement of HIV disease (Idele et al. 2014). In addition, mortality among adolescents in pre-ART HIV care has been reported to be significantly higher when compared to adults (Massavon et al. 2014; Okomo et al. 2012).

Modes of Acquisition

The modes of transmission for adolescents include perinatally acquired transmission with increasing numbers of long-term survivors, infection acquired through blood products or contaminated needles, and those who acquired HIV behaviorally through unprotected sex or by drug abuse and sharing of needles.

The high rate of undiagnosed HIV infection, poor rates of linkage to care because of poor health seeking behavior among adolescents, and low antiretroviral adherence rates with resultant poor viral suppression may be a factor that will fuel the future of the epidemic. Adolescents living with HIV are a heterogeneous group and global aggregate data on the epidemic among them can mask significant regional and population variances. Although data is limited studies available from low and high burden countries suggest that HIV prevalence is disproportionately high among adolescents belonging to “key populations,” especially sexually exploited adolescents, adolescents who inject drugs, and adolescent MSM, (UNAIDS Global report 2013; Thailand Bureau of Epidemiology 2012; Busza et al. 2013). Heterosexual transmission is the predominant mode of HIV acquisition in adolescent females. In addition, HIV prevalence among adolescent females tends to be higher than among adolescent males in countries with generalized epidemic (UNAIDS Global Report 2013; UBOS 2011).

The reasons for this gender disparity are thought to be related to the early sexual debut

before the age of 15 in some females and increased risk related to having sex with older male sexual partners (Kelly et al. 2003).

ART and Mortality Among Adolescents

Despite the progress made in the AIDS response in recent years, emerging evidence suggests that (UNAIDS 2014d) adolescents are falling behind as a result of not receiving the attention and services they require (UNAIDS 2013). Currently there is insufficient data to accurately determine the number of adolescents who need and receive ART. In addition, AIDS-related mortality among adolescents has increased by 50% over the past 7 years but fell for all other age groups, according to UNAIDS estimates (UNAIDS 2014d). Adolescents (10–19 years) are the only age group in which AIDS-related deaths increased from 2001 to 2012. From 2005 to 2012, the annual number of AIDS-related deaths among adolescents almost doubled. The inability of adolescents to benefit equally from treatment underscores the need for more HIV testing and counseling among this age group and for adolescent friendly health services (UNAIDS 2015).

Adherence

HIV-infected adolescents encounter adherence challenges including pill burden and dealing with their sexuality in the face of HIV. In addition, adolescents commonly face issues of denial and anxiety related to their HIV infection. This is especially common among the youth who have been recently diagnosed, and this may result in refusal to start or continue combined ART. Misinformation about HIV, lack of trust in health care workers, and lack of knowledge about the availability and effectiveness of ARV treatments can also be barriers to retaining adolescents in care and maintaining them on ART.

Perinatally infected youth often have longstanding histories of inadequate adherence. Adolescents in southern Africa are less adherent to ART and have lower rates of virologic suppression and immunologic recovery compared to adults (Nachega et al. 2009). Regimen fatigue

also has been identified as a barrier to adherence in adolescents. Studies have shown that depression and anxiety are associated with poorer adherence, especially to complex ARV regimens. HIV-infected adolescents often have concomitant mental illnesses low self-esteem, chaotic lifestyles, and do not cope well with their illness. Alcohol or substance abuse, poor school attendance, psychiatric disorders, and advanced HIV disease are associated with poor adherence. Additional challenges include nondisclosure of HIV status to parents or partners (Lowenthal et al. 2014).

Secondary Prevention Strategies for HIV-Infected Adolescents

High adherence to taking ART can play an important role in preventing HIV transmission. To have effective prevention of HIV transmission requires: (1) ART capable to achieve continuous viral suppression, (2) high adherence to an effective ART, and (3) an absence of a concomitant STD. In spite of the cultural difference among adolescents around the world, they have two common characteristics, they want respect and to be sure that their confidentiality is protected. With the growing number of adolescents, WHO promotes implementation of adolescent friendly services. To be considered adolescent friendly, health services should be accessible, acceptable, equitable, appropriate, and effective (WHO 2006). Interventions that focus on adolescents, youth, and the three elements for preventive transmission are needed for secondary prevention and reduction of new infections.

Future Directions

The Search for a Cure

Since the first cases of HIV were reported in the early 1980s, the research and public health communities have sought both an effective preventive vaccine as well as a cure or long-term clinical remission for those already infected with HIV. Both efforts have proved daunting over the past three decades. For preventative HIV vaccine

development, these challenges relate to several factors: the virus mutates rapidly and the correlates of immunity are still not clearly understood. For already infected individuals, challenges for development of an effective long-term remission or cure include that the virus incorporates into the DNA of host immune cells and the presence of long lived reservoirs containing HIV-infected memory cells which make it extremely difficult to eradicate the virus. However, the case report of the adult Berlin patient who appeared cured after receiving a bone marrow transplant from a donor who was homozygous for the delta 32 deletion of the CCR5 gene do provide a proof of concept for development of strategies that could prevent attachment of the virus onto host cells (Yuki et al. 2013). Likewise, documented “elite controllers” whose virus is nondetectable in plasma despite no ongoing treatment suggest that it may be possible to at least achieve long-term remission from HIV disease progression among chronically infected adults. In pediatrics, there is also encouragement related to the “Mississippi baby” case where a newborn with acute infection was begun on treatment in the first days of life and who was subsequently lost to follow-up and stopped therapy around 18 months. The infant was relocated and found to be without detectable virus in plasma for close to 2 years without treatment, before the virus then became detectable again (Persaud et al. 2013).

In response to the “Mississippi baby” case, several pediatric protocols are underway to see if newborns infected around the time of birth can be treated soon after birth, with a goal of achieving long-term remission. Among those infected children treated from birth who remain undetectable for plasma viral load for a long period, treatment interruptions will be attempted with close monitoring among those children where no virus has been detectable for several years. Other approaches toward a pediatric cure will be use of stem cell transplants when bone marrow transplants are already scheduled for other indications.

In addition to the research focused on achieving long-term remission and prevention of HIV disease progression, programmatic efforts need to continue to focus on a comprehensive approach to

treating children with pediatric HIV as a chronic illness that addressing developmental and psychosocial needs of infected children as they age into adolescence and adulthood.

HIV Chronic Care

There are limited data on long-term outcomes of ART adherence, retention within programs in resource-limited settings. Although there is progress in the availability of child friendly ART formulations, there is still a need to develop more fixed-dose combinations and granules especially for protease inhibitor based regimens. Improvements of supply chain of pediatric ART and diagnostics will help ensure adequate care and monitoring response to treatment. Over the years, attempts have been made to simplify the guidelines for children because of the differences in initiation criteria. However, there are still barriers in access to CD4 cell testing which is necessary to determine eligibility for ART in low and middle-income countries. Some countries like Uganda have already simplified their treatment guidelines further by implementing test and treat for all children under 15 years, regardless of CD4 count and WHO stage.

Conclusion

The pediatric HIV epidemic worldwide is showing major progress in reduction of new cases of mother to child transmission, but adolescent infections continue to fuel the epidemic. In addition, treatment coverage continues to lag behind for both children and adolescents compared to adults. Further research is needed to address better adherence support, age appropriate disclosure, and chronic complications of HIV infection and treatment among children and adolescents.

Chronic Immune Activation in HIV

Denise C. Hsu and Irini Sereti
 HIV Pathogenesis Unit, Laboratory of Immunoregulation, Division of Intramural Research, National Institute of Allergy and Infectious Diseases, NIH, Bethesda, MD, USA

Definition

The term immune activation describes the activation of the cellular components of the immune system, which may in turn lead to systemic inflammation. It is usually detected by the expression of cellular or soluble markers derived from innate or adaptive immune responses. Immune activation is associated with HIV disease progression as well as the increased morbidity and mortality in HIV-infected patients despite antiretroviral therapy. A number of interventions that target immune activation have been or are being investigated. Currently, there is no conclusive evidence that interventions other than antiretroviral therapy (ART) lead to clinical benefit.

Introduction

HIV infection is characterized by a global activation of the immune system. Cellular activation is evident in T cells with higher CD38 and HLA-DR expression, in NK cells with higher CD69 and HLA-DR expression, in monocytes with higher expression of CD16 and tissue factor (TF), and in

B cells manifesting as expansion of immature/transitional B cells expressing CD10. Soluble markers of monocyte and macrophage activation including neopterin, soluble (s)CD14 (a marker of LPS-induced monocyte activation), and sCD163 (a monocyte- and macrophage-specific hemoglobin scavenger receptor) are also increased. In addition, serum or plasma levels of pro-inflammatory cytokines such as interleukin (IL)-6 and tumor necrosis factor (TNF), C-reactive protein (CRP), and beta-2 microglobulin (β 2M) are also elevated (Nixon and Landay 2010).

In untreated HIV infection, immune activation is associated with the decline in CD4 T cell count and progression to AIDS. The use of combination ART has revolutionized the management of HIV-infected patients, resulting in a dramatic reduction in morbidity and mortality. Despite ART, however, patients may still have greater mortality when compared to the general population, with serious non-AIDS events (SNAEs) such as cardiovascular, liver, and end-stage renal disease and non-AIDS-defining malignancies being the predominant causes of mortality.

Immune activation is an important contributor to the elevated morbidity and mortality of HIV-infected patients despite ART. A number of interventions to reduce immune activation in patients on ART are currently under investigation. To date, there is little conclusive evidence on which strategy will lead to clinical benefits. Given that the majority of patients respond well to ART and enjoy a good quality of life, interventions to reduce residual immune activation must have low adverse effect profiles and robust evidence for clinical benefit before they can be implemented.

Immune Activation in Chronic HIV Infection

Immune Activation and HIV Disease Progression

Immune activation is a critical factor in HIV and simian immunodeficiency virus (SIV) disease progression. Natural hosts of SIV such as sooty

mangabeys, African green monkeys (AGM), and mandrills rarely develop immunodeficiency or pathogenic SIV infection. On the other hand, non-natural hosts such as rhesus macaques (RM) develop AIDS after infection with SIV. Though both groups have high viremia, natural hosts are able to dampen immune activation after acute infection and have low levels of immune activation in chronic infection (Chahroudi et al. 2012).

Immune activation is detrimental in HIV infection (reviewed by Paiardini and Muller-Trutwin 2013). The levels of T cell activation and plasma cytokines (such as IP-10 and IL-6) during acute HIV infection predict CD4 T cell decline and HIV disease progression. Immune activation can lead to activation-induced cell death or apoptosis, CD4 T cell depletion, and progressive restriction in T cell repertoire in both CD4 and CD8 T cells. It may also promote HIV infectivity whereby a vicious cycle is set up as HIV replication promotes immune activation which leads to increased targets for HIV to infect (as HIV preferentially infects activated CD4 +CCR5+ T cells), thereby leading to greater viral production. Furthermore, ongoing immune activation is associated with increased numbers of regulatory T cells (Tregs) in the lymphoid tissues. Tregs secrete transforming growth factor- β (TGF- β), triggering collagen production that results in structural damage and fibrosis of the lymph node. Fibrosis of lymph nodes is associated with apoptosis of naïve CD4 T cells by inhibiting their access to IL-7 (Zeng et al. 2012). Hence, HIV-infected patients with higher levels of immune activation have greater CD4 T cell depletion, faster progression to AIDS, and shorter survival independent of HIV viral load (Giorgi et al. 1999).

Factors Contributing to Immune Activation in Chronic HIV Infection

A number of factors contribute to the stimulation of immune responses in chronic HIV infection. These include the presence of HIV and its antigens, microbial translocation, the presence of coinfections, and homeostatic proliferation in

response to CD4 T cell depletion (Paiardini and Muller-Trutwin 2013).

HIV and Its Antigens

HIV RNA can activate plasmacytoid dendritic cells through binding to pattern recognition receptors (PRR) such as TLR 7, leading to the secretion of type I interferon (IFN). HIV can also cause immune activation through antigenic stimulation of HIV-specific CD8 and CD4 T cells. Though the level of HIV viremia correlates with T cell activation (Deeks et al. 2004), it is not the sole cause of immune activation. Markers of immune activation can remain elevated even when plasma HIV viremia is undetectable by conventional assays in patients on ART or elite controllers with spontaneous control of HIV viremia.

Microbial Translocation

In HIV infection, mucosal immune responses in the gastrointestinal tract are impaired. CD4 T cells in gut-associated lymphoid tissue (GALT) are targets for HIV infection as high proportions of these cells express CCR5 and are activated. This leads to substantial depletion of CD4 T cells in GALT. In addition, TH17 cells are preferentially lost in the gut in HIV infection. TH17 cells secrete IL-17 and IL-22, promote neutrophil recruitment, and are important in the defense against bacterial and fungal infections and the maintenance of epithelial barrier function (Brenchley 2013). The loss of TH17 cells is associated with systemic T cell activation in SIV-infected macaques, and the reduction of TH17/ Tregs ratio is related to SIV disease progression.

Furthermore, gut mucosal barrier integrity is also impaired in HIV infection. It is postulated that exposure to HIV envelope glycoprotein gp120 leads to disruption of tight junctions, enhanced mucosal permeability, as well as induction of pro-inflammatory cytokines, especially TNF (also known to disrupt epithelial cell tight junctions). Increased mucosal permeability then allows the translocation of bacterial products, eliciting further inflammatory responses through binding to pattern recognition receptors on monocytes, macrophages, and plasmacytoid dendritic cells, and

may also indirectly cause bystander polyclonal T cell activation (Brenchley 2013).

AGM (natural hosts of SIV) maintain mucosal barrier integrity and display little immune activation in chronic SIV infection, while RM have disruptions of the epithelial barrier of the colon and increased lipopolysaccharide (LPS) staining. The levels of LPS staining in the colon also correlated with the levels of LPS in the draining lymph nodes and remote peripheral lymph nodes. LPS can bind to membrane or sCD14 and TLR4 complex leading to the production of IL-6, IL-1, and TNF by monocytes and macrophages. The injection of LPS into SIV-infected AGM was associated with increases in T cell activation, sCD14, and SIV viremia. These data suggest that microbial translocation due to impaired mucosal barrier integrity is a potential contributor to immune activation in chronic HIV infection.

Coinfections

Immunodeficiency associated with HIV infection also leads to the reactivation and replication of highly prevalent coinfection pathogens such as cytomegalovirus (CMV) and Epstein-Barr virus (EBV), leading to stimulation of pathogen-specific immune responses. HIV viremia has been associated with the activation and expansion of CMV and EBV-Sp-CD4 and CD8 T cells. Thus, sustained CMV-mediated immune activation may contribute to overall immune activation in HIV-infected individuals.

Homeostatic Proliferation

CD4 T cell depletion in HIV infection may stimulate physiologic homeostatic mechanisms, leading to persistent lymphocyte proliferation in response to homeostatic cytokines (IL-2, IL-7, and IL-15). This may also lead to the differentiation and the generation of effector T cells that are proinflammatory, thereby contributing to immune activation. Evidence for decreased expression of the IL-7 receptor α chain (CD127) with blunted responses to IL-7 in T cells as well as defective IL-7 utilization by naive T cells and lower IL-7 production by reticuloendothelial cells due to lymph node fibrosis suggests possible defects in

compensatory responses to lymphopenia in HIV infection.

Immune Activation in Patients on ART

ART leads to virologic suppression and reduction in immune activation. However, levels of markers of immune activation do not fully normalize in all patients. When compared with the general population, the levels of CRP, IL-6, and D-dimer, markers of monocyte activation such as sCD14 and sCD163, and markers of T cell activation, particularly CD38+HLA-DR⁺ co-expression, remain elevated in HIV-infected patients despite ART.

Though the use of ART has resulted in a dramatic reduction in morbidity and mortality, patients on ART still have greater mortality when compared to the general population (reviewed by (Nakagawa et al. 2013), with SNAEs including cardiovascular, liver, and end-stage renal disease and non-AIDS-defining malignancies being the predominant causes of mortality (Hsu et al. 2013).

Immune Activation and Clinical Associations in Patients on ART

Inflammation is central to the process of atherosclerosis, tumor progression, and liver fibrosis. High levels of biomarkers associated with inflammation (CRP and IL-6) and coagulopathy (D-dimer and fibrinogen) are associated with increased risk of cardiovascular disease, malignancies, and mortality in the general population.

Higher levels of CRP, IL-6, D-dimer, sCD14, and lymphocyte activation have all been associated with increased mortality in HIV-infected patients despite ART. Furthermore, higher baseline levels of CRP, IL-6, and D-dimer are also associated with increased risk of non-AIDS malignancies and cardiovascular disease (CVD), independent of other CVD risk factors. Higher levels of IL-6 and CD8 T cell activation have been associated with functional impairment and frailty and higher levels of TNF with SNAEs in patients on ART (reviewed by Ledenman et al. 2013). Therefore, immune activation is

likely a key contributor to the elevated morbidity and mortality in HIV-infected patients despite ART. Other factors that may also play a role include the insults sustained secondary to the direct effect of HIV and associated immunodeficiency prior to ART initiation, underlying co-morbidities and coinfections, as well as ART toxicities.

Factors Contributing to Persistent Immune Activation in Patients on ART

The drivers of persistent immune activation in patients on ART are diverse. Intermittent HIV viremia can occur in 20–30% of ART-treated patients and is associated with higher IL-6, D-dimer, and sCD14 levels and SNAEs. The presence of persistent coinfections also contributes to continual stimulation and activation of the immune system. Asymptomatic CMV infection has been associated with CD8 T cell activation in patients on ART. CMV-specific CD4 T cells can cause a systemic inflammatory response that is sustained even during latent infection and is associated with atherogenesis. Hepatitis C coinfection is also associated with increased CD8 T cell activation when compared with HIV mono-infected patients despite ART. Furthermore, impairment in mucosal barrier integrity may not be fully reversible, and markers of microbial translocation, e.g., LPS, sCD14, and bacterial 16s rDNA, do not always normalize with ART. LPS can induce tissue factor (initiator of the coagulation cascade) expression on monocytes and may contribute to atherogenesis and increased CVD in patients on ART.

Strategies to Reduce Persistent Immune Activation Despite ART

As mentioned before, ART results in a reduction in immune activation. However, levels of immune activation do not normalize in a substantial number of patients. Furthermore, persistent immune activation despite ART is associated with increased SNAEs and mortality.

The 2013 World Health Organization guidelines recommended the initiation of ART in

asymptomatic HIV-infected patients at CD4 T cell count of ≤ 500 cells/ μL . The use of ART within 6 months of HIV infection has been associated with reduced reservoir size and reduced T cell activation when compared to ART initiation at ≥ 2 year after HIV infection. Whether earlier ART initiation can reduce the levels of immune activation to that of uninfected persons is not clear (reviewed by Sandler and Sereti 2014). Results from the START study (ClinicalTrials.gov identifier: NCT00867048), a multicenter international trial designed to assess the risks and benefits of initiating ART at CD4 T cell count of >500 or <350 cells/ μL , will shed further light on the clinical benefits of earlier ART initiation.

Given that mean CD4 T cell count at the time of presentation to care is <400 cells/ μL in a number of cohorts, the majority of newly diagnosed patients will meet the 2013 WHO recommended threshold for ART initiation soon after presentation to care. Therefore, the remaining discussion will focus on the strategies that reduce persistent immune activation in patients on ART.

The interpretation of currently available data on strategies to reduce immune activation in patients on ART is often difficult. Firstly, a significant number of studies targeted untreated patients. Although these studies may assist in understanding the underlying pathophysiology, HIV viremia is a strong stimulator of immune activation, and data from untreated cohorts may not be generalizable to patients on ART. Secondly, though many studies used biomarkers of immune activation as endpoints, few used clinical outcome measures. Therefore, it is difficult to determine whether reduction in a particular marker of immune activation will translate into clinical benefit. Thirdly, studies were often of short duration and involved only small number of patients and may not have adequate power to detect clinical responses or long-term adverse effects associated with the intervention.

A number of strategies to reduce persistent immune activation despite ART have been under investigation. These include reducing chronic antigen stimulation from residual HIV viremia or from coinfection pathogens, dampening global inflammation, improving immune recovery, modulating

lymphoid tissue fibrosis, and reducing microbial translocation. Given that this manuscript is an overview, it will focus on interventions that have robust data and studies that involved patients on ART.

Suppressing Chronic Antigen Stimulation

Reducing Residual Viremia

Intensification studies have been performed to assess the impact of adding antiretroviral agents to a suppressive ART regimen (as measured by conventional assays). None of the raltegravir (an integrase inhibitor) intensification studies performed to date were able to demonstrate reduction in ultra-sensitive plasma HIV RNA levels. In addition, the majority of studies also found no reduction in markers of T cell or monocyte activation. However, a few studies have noted a reduction in T cell activation and D-dimer levels as well as an early transient increase in 2-LTR circles after raltegravir intensification, suggesting that residual viremia was occurring prior to raltegravir intensification and was contributing to immune activation in some patients.

Maraviroc (a CCR5 antagonist) intensification studies have also been performed and yielded conflicting data. Some found reduction in T cell activation while others found an increase in CD4 and CD8 T cell activation both in the peripheral blood and in the rectal mucosa as well as an increase in sCD14 after maraviroc intensification (Hunt et al. 2013). The binding of maraviroc to CCR5 might have prevented the interaction between CCR5 and its natural ligands. Excess CCR5 ligands might then bind to other chemokine receptor such as CCR3 and CCR4 on T cells, leading to T cell activation (Hunt et al. 2013). Therefore, the beneficial effect of adding antiretroviral agents to an already suppressive ART regimen is uncertain based on currently available data.

Treatment of Coinfections

HCV treatment and suppression of HCV viremia are associated with a reduction in CD4 and CD8 T cell activation. Sustained virologic response is also associated with reduced liver-related complications as well as both liver-related and non-liver-

related mortality in coinfecting patients. Unfortunately, HCV treatment may be limited by contraindications, adverse events, high costs, and drug interactions. Next-generation agents with higher efficacy and better side-effect profiles may revolutionize the management of HIV/HCV coinfecting patients and may reduce the incidence of non-AIDS malignancies, specifically hepatocellular carcinoma.

Treatment of other persistent viral infection has also been investigated (reviewed by Hsu et al. 2013). Eight weeks of valganciclovir in CMV seropositive patients on ART led to a reduction of CMV viremia as well as a reduction in CD8 T cell activation. The study was too short and small to observe for effects on CD4 T cell count or clinical outcome measures. However, the results suggest that residual CMV replication is a contributor to CD8 T cell activation in patients on ART.

In a study targeting HSV coinfection using 12 weeks of valacyclovir in HSV-1 and HSV-2 seropositive patients on ART, no change in T cell activation and CRP or IL-6 levels was demonstrated. The authors postulated that the negative findings may be because the dose of valacyclovir used was insufficient to suppress HSV shedding or that HSV-2 reactivations are too localized to cause systemic immune activation.

Anti-inflammatory Agents

Statins

Statins are 3-hydroxy-3-methyl-glutaryl-coenzyme A reductase inhibitors. Not only do statins reduce serum cholesterol; they may also have anti-inflammatory properties. Statin use has been associated with reduced monocyte activation, a decline in CRP, and reduced T cell activation in patients on ART as well as in untreated, HIV-infected patients. A retrospective observational study of patients on ART showed that statin use is associated with a threefold reduction in mortality (Moore et al. 2011). Though not statistically significant, a trend for reduction in SNAEs and mortality has also been seen in other retrospective observational studies. Therefore, statins hold promise as an agent

that reduces immune activation in patients on ART and warrant further clinical investigation.

Hydroxychloroquine

Hydroxychloroquine (HCQ) and its analogue chloroquine (CQ) have immunomodulatory, anti-inflammatory, and anti-HIV properties. These drugs have been investigated in patients with uncontrolled HIV replication as well as in patients on ART. However, the findings are inconclusive at this stage.

COX-2 Inhibitors

COX-2 inhibitors inhibit cyclooxygenase type 2, reducing prostaglandin E2 production, thereby reducing activation of T cells through the cyclic adenosine monophosphate (cAMP) pathway. Studies on COX-2 inhibitors have been small and reduction in T cell activation tended to occur in viremic patients. However, it is important to bear in mind that COX-2 inhibitors are associated with increased cardiovascular risk, via a direct pharmacologic consequence of inhibition of COX-2. Therefore, assessing the utility of COX-2 inhibitors without using clinical outcome measures may be insufficient.

Aspirin

Aspirin is a cornerstone in the secondary prevention of vascular disease. In a pilot study, aspirin use was associated with reduced platelet activation, a decrease in sCD14, and reductions in CD38 and HLA-DR on CD4 and CD8 T cells. However, there was no change in IL-6, D-dimer, and CRP levels. An aspirin study with larger number of participants is in development with the AIDS Clinical Trials Group and should provide further data.

Prednisone

Conflicting data exist regarding the effect of prednisone on immune activation in patients on ART. Long-term prednisone use, especially at doses >7.5 mg/day, is associated with significant adverse effects such as osteoporosis, impaired glucose tolerance, dyslipidemia, weight gain, cataract formation, and increased risk of infections. Even short courses have been associated with

increased risk of osteonecrosis in HIV-infected patients. Therefore, the adverse effects of prednisone may outweigh any potential benefits.

Cytokine Inhibitors

Several inhibitors of proinflammatory cytokines such as TNF, IL-6, and IFN inhibitors are currently being evaluated in nonhuman primate/SIV models especially in regard to their efficacy in reducing persistent immune activation and their safety profiles.

Improving Immune Recovery

Given that homeostatic proliferation, depletion of TH17 cells, and imbalance in TH17/Tregs ratio are possible sources of persistent immune activation, a number of studies have thus been done to assess interventions that optimize immune recovery.

Cytokine Therapies

Subcutaneous administration of IL-2 in concert with ART resulted in a reduction in CD4 T cell proliferation and CD38+/HLR-DR+ expression on CD4 and CD8 T cells as well as a sustained increase in CD4 T cell count with improved CD4 T cell survival. However, this did not translate into measurable clinical benefits as shown in the largest to date immune intervention randomized clinical trial in ART-treated patients (Abrams et al. 2009).

Subcutaneous administration of IL-7 also led to increase in CD4 and CD8 T cells in the peripheral blood and increased CD4 T cells in the colonic mucosa. There were also concomitant reductions in colonic and systemic inflammation with decreased neutrophil infiltration and TNF expression in the colon and decreased plasma sCD14 and D-dimer (Sereti et al. 2014). These results are of interest but it remains unclear if the effects are persistent.

Modulating Lymphoid Fibrosis

As previously discussed, fibrosis of the lymphoid tissues impairs T cell survival and impedes their homeostatic proliferation by limiting both utilization and local IL-7 production. Binding of angiotensin II to the angiotensin II receptor on cardiac

fibroblast, hepatic stellate cells, or mesangial cells leads to proliferation as well as collagen and TGF- β synthesis. In a small pilot study, the use of lisinopril was associated with a small but statistically significant reduction in CRP and TNF levels when compared with placebo. A number of trials on the effect of angiotensin-converting enzyme (ACE) inhibitors or angiotensin II receptor antagonists in modulating lymphoid tissue fibrosis are currently underway.

Both TNF blockade with adalimumab and pirfenidone administration were associated with attenuated TGF- β expression, reduced lymph node fibrosis, and preservation of lymph node CD4 T cells in rhesus macaques with SIV infection. Data on patients with HIV infection are not yet available.

Targeting Microbial Translocation and Impaired Mucosal Barrier Integrity

Given that HIV infection has been associated with depressed levels of beneficial gut microbiota and elevated levels of pathogenic microbiota in a few studies, a range of prebiotics (selectively fermented ingredients that change the growth and/ or activity of certain gut microflora, resulting in health benefits), probiotics (live microorganisms that when consumed confer a health benefit), and synbiotics (a combination of pre- and probiotics) are under investigation. Data from patients with untreated HIV infection suggest that pre- and probiotic agents may be associated with improvement in microbiota composition and reduction in microbial translocation. Data on patients on ART are inconclusive at this stage.

A number of novel agents that have shown promise in nonhuman primates with SIV infection are currently under investigation in patients with HIV infection: rifaximin is a minimally absorbed oral rifamycin antibiotic that has activity against both gram-positive and gram-negative enteric bacteria; sevelamer is a phosphate binder that is used in patients with end-stage renal failure but can also bind to endotoxins; lubiprostone is a chloride channel activator that has the potential to enhance recovery of mucosal barrier function; mesalamine (5-aminosalicylic acid) is an anti-

inflammatory agent used in the management of inflammatory bowel disease; and IL-21 is essential in the maintenance of TH17 cells and mucosal function. Data on the efficacy of these agents in reducing immune activation in patients on ART are pending.

Therefore, though a number of studies have been performed to evaluate strategies to reduce persistent immune activation on ART, there is little conclusive evidence on which strategy will lead to clinical benefit. The use of statins seems to show the most promise at this stage. Given that the majority of patients respond well to ART with, for the most part, a good quality of life, interventions to reduce persistent immune activation must be tolerable, have low adverse effect profiles, and have robust evidence for clinical benefits before they can be implemented. Furthermore, it is also possible that earlier ART initiation may negate the need for adjuvant therapies.

Conclusions

Immune activation is detrimental in chronic HIV infection, causing progressive depletion in CD4 T cells and immunodeficiency. Despite the use of ART, the levels of immune activation do not fully normalize. Persistent immune activation despite ART is associated with increased risk of SNAEs and morbidity. Data on interventions to reduce persistent immune activation while on ART are increasing. At this stage, however, no conclusive evidence exists regarding which intervention results in clinical benefit. Further studies investigating better the biology of pathways involved in residual immune activation in HIV infection will be instrumental in designing targeted interventions. Currently, early diagnosis with prompt initiation of ART remains the most successful intervention in HIV infection.

Definition

Male circumcision is an ancient ritual that is now being used in a medical context to prevent HIV transmission to men. This is based on three randomized clinical trials showing that medical male circumcision (MMC), where there is complete surgical removal of the foreskin (FS), in east and southern Africa significantly reduces HIV infections by up to 60%. Voluntary MMC is now a public health HIV prevention strategy in many African countries, although the mechanisms of

reducing viral acquisition by removal of the foreskin are uncertain.

Introduction

Male circumcision is one of the oldest cultural rituals and dates back to 2300 BC in ancient Egypt and is also known to have been practiced by South Sea Islanders, Australian Aborigines, Sumatrans, Incas, Aztecs, and Mayans. Today it is still practiced by Jews, Muslims, and ethnic groups in east and southern Africa, where in the latter it is termed traditional male circumcision. At least three types of ritualistic circumcision procedures have been identified: (1) the complete removal of prepuce tissue to expose the whole glans of a flaccid penis (the most common), (2) snipping the frenum and leaving the foreskin (FS) being left intact, and (3) partial removal of the FS and cutting the remnant remaining as lateral flaps of loose skin. Traditional male circumcision in South Africa is practiced in males between the ages of 17 and 22 years, and 10–27% of men have partial circumcision with some or all of the FS remaining. Importantly, in the context of high rates of HIV transmission, partially circumcised men have a 7% greater risk of being HIV infected than fully circumcised men and an equal risk compared to uncircumcised men. The risk of becoming HIV infected increases if circumcision is delayed until males are older. A seminal epidemiological study that established the relation between lack of male circumcision and HIV susceptibility found that 43% of uncircumcised men in Kenya who acquired a genital ulcer also seroconverted to HIV-1 after a single sexual exposure (Cameron et al. 1989). This association was further supported by the inverse association between low (<1%) HIV prevalence in countries where more than 90% of the male population practiced circumcision versus higher prevalence (>15%) where only a quarter of the male population practice circumcision (Bongaarts et al. 1989). These studies led to the implementation of three randomized controlled trials showing that surgical complete removal of the FS by MMC provided up to 60% protection against HIV

acquisition (Gray et al. 2007; Bailey et al. 2007; Auvert et al. 2005) and an uncircumcised man had a 1.8- to 8.2-fold increased chance of acquiring HIV compared to a circumcised man. While there is very strong evidence that MMC shows preventative efficacy, there still exist communities in the world in which the practice is unacceptable due to cultural or social reasons. However, the prevailing thoughts are that acceptability of male circumcision in areas of HIV prevalence is critical for a reduction of HIV transmission.

The Role of the Foreskin

The foreskin is predominantly responsible for protecting the underlying glans epithelium and acts as a chemical, physical, and immune barrier against foreign assault by microorganisms and environmental damage. Its architectural structure varies depending on localization ranging from the single columnar epithelia of the urethra to the stratified squamous epithelium of the outer foreskin. The barrier function of the skin is maintained on three levels:

- (1) Physical barrier. The outermost skin layer, the stratum corneum, composed of anucleated, protein, and lipid-rich terminally differentiated keratinocytes is the most involved skin layer in maintaining the physical barrier.
- (2) Biochemical/chemical barrier. Antimicrobial peptides and amino acids such as the defensins form a chemical response to microbes. Melanin produced by melanocytes prevents UV-associated DNA cell damage.

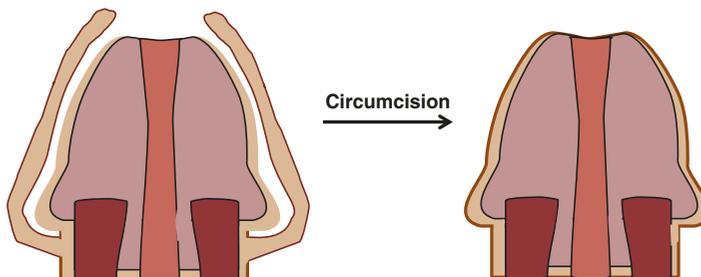

- (3) Immune barrier. Disruption of the physical barrier of skin induces immune responses, such as T-cell activation and increased numbers of Langerhans' cell (LC) density and proliferation (Ganor et al. 2010).

The foreskin physical barrier is maintained by various proteins. Intracellular proteins such as the intermediate filaments, keratin and filaggrin, have been shown to be integral to epithelial barrier function. Tight junctions such as the desmosomes and their proteins such as the cadherins also maintain barrier function by keeping the epidermal layer intact.

MMC involves the removal of the inner foreskin that is in direct contact with uncircumcised glans penis and the attached outer foreskin. Therefore, anatomically, it removes the inner foreskin and some of the outer foreskin resulting in the exposure of the head of the glans penis, as shown in Fig. 1.

Evidence of Potential Mechanisms of MMC

The foreskin has a higher density of HIV target cells and may be susceptible to epithelial disruptions during sexual intercourse, providing additional portals of entry for HIV-1 (Weiss et al. 2006). The removal of the foreskin would therefore reduce the number of target cells for HIV (McCoombe and Short 2006; Fischetti et al. 2009). There is yet no definitive evidence for the mechanism of MMC, but removal of LCs and CD4+ T cells, along with epidermal dendritic

Circumcision and AIDS, Fig. 1 Circumcision involves the removal of the inner foreskin that is in direct contact with uncircumcised glans penis and the attached outer foreskin (Courtesy of Rachel Esra, Division of Immunology, UCT)

cells that are known to be rich in the FS epithelial tissue, would lower the potential for cellular viral infection. While HIV transmission has been extensively studied in the FGT, very little is known about the actual HIV acquisition in males. Keratin is considered by some investigators to form an impermeable barrier to HIV, and as a result heavily keratinized sites such as the glans penis are protected against invasion by the virus. Conversely, the poorly keratinized inner foreskin and the penile urethra which are lined by non-keratinized squamous epithelium are thought to be the sites of HIV invasion during penile-vaginal or penile-anal intercourse (Hladik and McElrath 2008). However, immunohistochemical studies on the differences of the inner and outer foreskin with regard to keratin thickness have been inconclusive. Keratin thickness (stratum corneum layer of the skin) of the inner foreskin has been reported to be significantly thinner, thicker, and the same in different studies. Thus, the precise mechanism of MMC remains unclear, and further studies are required to pin-point how the surgical removal of this epithelial flap can profoundly influence the manner by which HIV is acquired.

Benefits of MMC

MMC has also been shown to reduce STI acquisition. The randomized circumcision trials in Uganda and Kenya were associated with the decreased frequency of genital ulceration (Mehta et al. 2012; Gray et al. 2007). Prior to these circumcision trials, other observational studies showed that male circumcision may play a role in the decrease of infection with high-risk human papillomavirus (HPV) and 35% reduction of HPV incidence in general. Additionally, MMC decreases the chance of herpes simplex virus-2 (HSV-2) infection by 25%. Male circumcision was also evaluated on the risk of bacterial STI acquisition among men. A South African trial found that male circumcision decreased *Chlamydia trachomatis* (CT) but had no impact on *Neisseria gonorrhoeae* (NG) (Auvert et al. 2009) and a Kenyan trial found no protective effect for *Neisseria gonorrhoeae*, CT, or *Trichomonas*

vaginalis (TV) but only found a protective effect for *Mycoplasma genitalium*. Although male circumcision has been shown to reduce the prevalence of STIs in heterosexual contact, the effects among men who have sex with men (MSM) is not clear. MMC may also confer protection for female partners. Two studies have shown that MMC reduces the risk of cervical cancer in females, while only one study has shown no protective effect. Furthermore, circumcision has also been shown to decrease the risk of HPV infection, bacterial vaginosis (BV), and TV in female partners.

Although MMC can reduce the risk of HIV infection by 60%, and has motivated implementation of voluntary circumcision in multiple countries, there remains approximately 40% of circumcised men vulnerable to viral acquisition after engaging in risky sexual practices. This raises the likelihood that HIV acquisition in the male genital tract (MGT) can also occur independently of the FS and is likely through the epithelium of glans and the urethral opening in the penis. These possibilities are at the cutting edge of our current knowledge, and it will be important to understand immunological events in the MGT so that alternatives to MMC can be developed.

Penile Immunity

The first line of defense in the MGT is the epithelia barrier reinforced with the chemical barrier as discussed above. Pathogens that are exposed to the host through the urethra/foreskin will be recognized by pattern recognition receptors on keratinocytes which are the most abundant cell type along with other specialized immune cells. These PRRs include the Toll-like receptors TLRs and the nucleotide oligomerization domain (NOD)-like receptors (NLRs) which sense what pathogen is present in order to elicit an immune response (Nguyen et al. 2014). TLRs were found to be widely distributed in the male genital tract with higher expression in the urethra (Anderson et al. 2011) and correlates with the finding that sexually transmitted infections affect the urethra. The other components of the innate immune

system involved in penile immunity are the natural killer (NK) cells and have the same function of killing virally infected cells as class I HLA-restricted cytotoxic T cells. HIV susceptible cells have been found dispersed within the genital tract and are a natural phenomena associated with cellular immunity in the MGT which HIV appears to exploit for successful infection. Macrophages are the predominant immune cell type in the male genital tract (Nguyen et al. 2014), and dendritic and Langerhans cells have been identified as the most abundant HIV target cells in stratified squamous epithelia and to efficiently transmit HIV to T cells (Ganor et al. 2010). These cells are CD1A⁺ DC-SIGN⁻ and are abundant in the FS. LCs are thought to play a dual role in HIV infection depending on their activation state. These cells are thought to act as carriers of the virus to establish systemic infection during specific states of activation, and once in the mature state, they are capable of degrading virus particles in their Birbeck granules (de Witte et al. 2007). While LCs are distributed widely in the penis, the other HIV target cell macrophages and $\alpha\text{E}\beta 7^+\text{CD}4^+$ T cells are preferentially resident in the urethra including CCR5⁺ and CXCR4⁺ cells on the urethral opening.

Penile Microbiome and Immunity Interplay

In addition to anatomical and immunological changes, MMC leads to microbiological changes in the penis, which are believed to be one of the mechanisms by which MMC reduces the risk of HIV acquisition by circumcised men. Furthermore, these microbial changes confer STI and BV protection to the female partners of circumcised men (Gray et al. 2007; Bailey et al. 2007; Avert et al. 2005), thus, in turn, reducing the susceptibility of female partners to HIV infection. Prior to circumcision, the anoxic microenvironment of the inner foreskin may support the survival of anaerobic genital microbes. For example, the most common coronal sulcus microbes pre-MMC are *Prevotellaceae*, *Veillonellaceae*, *Clostridiales*, *Actinomycetaceae*,

and *Porphyromonadaceae*, the most abundant being *Prevotella* spp. (Liu et al. 2013). Anaerobic microbes are associated with increased inflammation, and penile inflammation may lead to recruitment of HIV target cells to various regions of the penis, thus increasing the risk of HIV acquisition. During inflammation, cytokines and chemokines are responsible for the migration of T cells from the lower vascularized dermis to the epithelium of the inner foreskin. Furthermore, a higher density of CD4⁺ T cells and Langerhans' cells (LCs) has been reported in the inner foreskin compared to the outer foreskin, particularly in the presence of inflammation, thus, making the inner foreskin a potent site of HIV acquisition.

MMC has been shown to decrease the prevalence and abundance of anaerobic bacteria at penile mucosal surfaces and thereby remove the inflammation potential. In addition, bacterial biodiversity and heterogeneity decrease after MMC, while aerobic and skin bacterial taxa increase (Nelson et al. 2012). The reduction in anaerobic bacteria may lead to decreased inflammation and thus decreased HIV target cell recruitment. Apart from physical removal of the vulnerable inner foreskin, this is one of the proposed mechanisms by which MMC reduces the risk of HIV acquisition (Nelson et al. 2012).

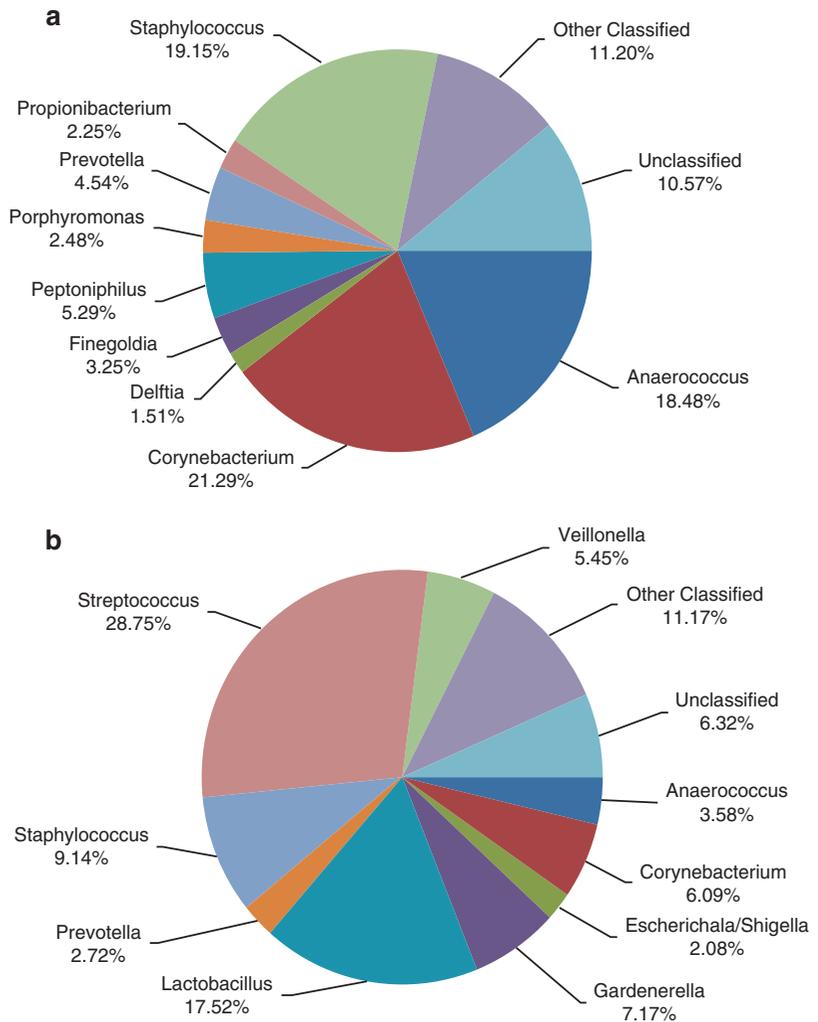

Urethral Microbiome

As discussed, HIV infections still occur in a proportion of circumcised men, suggesting that the foreskin proximal to the glans is not the only important penile HIV entry point. This has led to the exploration of the possibility of the penile urethra being another important HIV entry point in both circumcised and uncircumcised men. Similar to the foreskin microbiome, the urethral microbiome may also be a key determinant of the risk of HIV acquisition through exposure of the urethral orifice to the inner foreskin microbiome.

The penis does not support a single characteristic microbiota; it is therefore important to note that different regions of the penis exhibit slightly different microbiota (Nelson et al. 2012), as

Circumcision and AIDS,

Fig. 2 Distribution of major taxa in the coronal sulcus (a) and urine/urethra (b) (Nelson et al. 2012)

shown in Fig. 2. Therefore, in light of the relationship between the microbiome, inflammation, and the risk of HIV acquisition, different regions of the penile anatomy could be impacted differently subsequent to MMC. The most abundant taxa in penile urethra are rare or absent in the coronal sulcus microbiome. For example, *Veillonella*, *Aerococcus*, *Ureaplasma*, *Gardnerella*, and *Mycoplasma* have been reported to be found only, or almost exclusively, in the penile urethra prior to circumcision, Fig. 2a. There are however some similarities between the coronal sulcus and penile urethra microbiota. BV-associated taxa including *Mycoplasma*, *Ureaplasma*, and *Sneathia* were detected only in

sexually experienced participants. Therefore, similar to the coronal sulcus microbiome, the composition of the penile urethral microbiome is also influenced by partnered sexual behavior. In addition, the urethral microbiome is also comprised mostly of obligate/facultative anaerobes, e.g., *Streptococcus*, *Lactobacillus*, *Gardnerella*, and *Veillonella*, Fig. 2a. This may partly be due to the fact that in most uncircumcised men, the foreskin covers the urethral orifice of the non-erect penis, thus exposing the urethral orifice to the anoxic microenvironment of the inner foreskin which has been shown to support the survival of anaerobic microbes. Similar to what occurs in the coronal sulcus, these anaerobes possibly enhance

HIV acquisition at the urethral orifice via increased inflammation and HIV target cell recruitment. The urethra may therefore be a very fertile site leading to HIV infection upon viral exposure. Furthermore, the risk of acquiring HIV via urethral opening may differ between circumcised and uncircumcised men. In uncircumcised men, the microbiome around the urethra and under the foreskin may modulate the risk of HIV acquisition through the urethra. However, in circumcised men, the lower diversity of anaerobic microflora likely also impacts on the risk of HIV acquisition, and the urethral orifice may be the primary site of infection (Anderson et al. 2011).

Limitations of Current Knowledge and Research

MMC as a primary HIV prevention strategy may not be feasible on a worldwide scale due to cultural, social belief/acceptability, logistical, and financial barriers. It is therefore important to know and build on the current knowledge of the mechanisms by which MMC reduces the risk of HIV infection as this may lead to the development of novel, nonsurgical HIV prevention strategies (Price et al. 2010). Limitations in current knowledge/research of MMC however impede novel HIV prevention strategy development. It has been reported that although the reductions in the prevalence of anaerobic bacteria are often substantial, MMC does not significantly reduce all anaerobes showing no significant decrease after MMC (Liu et al. 2013). It is however not known why these anaerobes persist after MMC, and the magnitude of the contribution these anaerobes make toward the HIV incidence observed in men who have undergone MMC is also not known. This knowledge may lead to the development of novel ways of removing these anaerobes from penile mucosa in order to further reduce the risk of HIV acquisition among men who have undergone MMC.

As already discussed, the urethra may be a fertile HIV entry point in both circumcised and uncircumcised men. However, there is limited knowledge on the impact of MMC on the

reduction of HIV acquisition via the urethra. Although the urethral microbiome has been determined, an understanding of the impact (or lack thereof) of MMC on the urethral microbiome and inflammatory profile in the context of HIV infection may provide insight for the observed 40% of circumcised men who remain at risk of infection. Here, novel ways of altering the urethral microbiome and inflammatory profile may then need to be developed in order to reduce the risk of HIV acquisition in these remaining “unprotected” men.

Current MMC research is mainly based on identification of factors that modulate the risk of HIV acquisition from vaginal sexual intercourse. However, a substantial number of men engage in anal sex with women and/or other men. Knowledge on the utility of MMC in reducing the risk of HIV acquisition during anal sex is limited. It is not known whether or not the mechanisms of protection conferred by MMC are as effective in reducing the risk of HIV acquisition during anal sex as they are during vaginal sex. HIV viral shedding in the rectum is higher than that in the blood, semen, and in vaginal and cervical secretions. Circumcision may reduce HIV target cells in the penile mucosa of circumcised men, but if rectal mucosal secretions contain higher HIV concentrations than vaginal secretions, any potential protective effect of circumcision for the insertive partner may be overwhelmed by excess virus. Therefore, the risk of acquiring HIV from anal sex may remain high regardless of circumcision. There is therefore a need to study the effectiveness of MMC in reducing the risk of HIV infection specifically in men who engage in anal sex (and are the insertive partners in the case of men who have sex with men).

Conclusion

Evidence for the effectiveness of MMC in reducing the risk of HIV needs to continuously be expanded for all groups of sexually active men to further substantiate the recommendation of MMC as an effective HIV prevention strategy. Identity of changes in the urethra after MMC can provide insight into HIV acquisition in

circumcised men, but also allow the potential development of alternative preventive tools that lowers the inflammatory profile of penile epithelial tissue that may not have to rely on an ancient surgical intervention. Understanding these immune events and how HIV is acquired in males is key to this.

²Center for Biomedical Ethics and Society, Vanderbilt University Medical Center, Nashville, TN, USA

Definition

Ethics refers to standards of right and wrong behavior, as well as to the systematic study of the norms, values, and principles that underlie those standards. *Morals* and *ethics* are often used as synonyms, although *ethics* typically refers to a set of social or professional norms while *morals* or *morality* are more personal. Ethics and law are also closely related; law is the codification of ethical standards and legal requirements often provide a practical framework for ethical decision-making. In contemporary health care, ethics is multidisciplinary, drawing on the professional standards and experiences of medicine,

public health, nursing, the behavioral sciences, social work, chaplaincy, health education, and law, as well as ethical theories of philosophy and theology. The ethics of clinical care and biomedical research are typically grounded in the principles of (1) *beneficence*, acting in the best interest of one's patient or research participant, and its corollary, *nonmaleficence*, the duty to avoid doing harm; (2) *respect for persons*, including both the right of *autonomous* individuals to make their own decisions and the duty to protect *vulnerable* individuals from exploitation and related harms; and (3) *justice* or *fairness*, the duty to treat similar cases similarly and distribute resources, benefits, and burdens equitably (Beauchamp and Childress 2012).

Introduction

The surprising emergence of HIV/AIDS in the early 1980s came at a time when many physicians believed that medical science had all but conquered the threat of infectious disease. Its appearance in the United States and Europe coincided with marked social changes, especially in sexual mores and drug use; in developing countries the pandemic followed the social and economic disruption that accompanied decolonization. These forces both fostered the spread of the virus among already marginalized populations and stigmatized those affected by it (Harden 2012).

HIV/AIDS also challenged the young field of bioethics and tested the limits of established ethical norms in health-care and biomedical research (Pinching et al. 2000). Many of the ethical issues and related standards in HIV/AIDS care, prevention, and research have differed between industrialized and low-income nations and have evolved markedly with the availability of antiretroviral (ARV) medication (Heitman and Ross 2002). Even in its current contexts, however, HIV is characterized by unique biological, social, and geographic factors that shape the experience of individuals and communities affected by the disease and who participate in its prevention, care, and/or research. After over three decades, there

are still unsettled ethical questions about the treatment, research, and prevention of HIV/AIDS for which policy is uneven and the law is silent.

Clinical Care

Key ethical issues in clinical care for HIV/AIDS include confidentiality and disclosure of HIV status, access to health services and disparities in care, and informed consent to testing and treatment.

Confidentiality, Disclosure, and Stigma

Since the initial identification of HIV infection as "gay-related immunodeficiency (GRID)" (Harden 2012), HIV has carried powerful stigma and confidentiality has been a fundamental ethical concern in its diagnosis and treatment. Physicians have known since Hippocratic times that unless patients trust their caregiver's promise of confidentiality, they will not disclose potentially shameful information that might be essential to their diagnosis and treatment. The stigma associated with the sexual practices and illicit drug use through which HIV is commonly transmitted highlighted this ethical issue early in the pandemic (Pinching et al. 2000). Clinicians worldwide recognized an essential link between maintaining confidentiality and controlling the spread of infection: at-risk individuals were unlikely to seek diagnostic testing or counseling on preventing transmission if they feared disclosure of their infection or personal behaviors (Bayer 2003; Brewster 2011). Because confidentiality was particularly central to the effective delivery of HIV services before ARV treatment became available, early AIDS-related law in the United States prohibited caregivers from disclosing a patient's HIV status without his or her consent.

However, certain conditions have always limited health-care providers' ethical obligation to maintain their patients' confidentiality, particularly the professional duty to warn identifiable others of known danger. HIV infection created ethical tension between caregivers' commitment to their patients' privacy and the duty to warn, particularly in regard to the public health practice

known as *contact tracing*. Since the early 1900s, public health officials have attempted to control and prevent certain contagious diseases, particularly sexually transmitted infections (STIs), through structured systems of testing, reporting, identifying, warning, and treating those exposed (Bayer 2003). Such programs require physicians to report the name of an infected patient to their local health department; health department officials then communicate with the patient to identify everyone he or she may have exposed; they then locate and offer testing and treatment to each contact, repeating the process until no unidentified/unwarned/untreated contacts remain.

Prior to the availability of effective treatment for HIV, health authorities encouraged at-risk individuals to be tested and to inform their partners if they tested positive. Although many who tested positive did not reveal their status, medical and public health professionals argued that mandatory reporting and contact tracing were not warranted because, without real options for treatment, it was not ethical to sacrifice known patients' confidentiality to alert unknown others to take preventive action (Bayer 2003). In this context, however, many health professionals recognized a professional duty to warn their HIV-positive patients' *known* sexual partners, especially spouses, and many states enacted laws permitting such disclosure even without the patient's consent. By the late 1990s, the development of ARV treatment changed this policy, and US public health officials instituted mandatory reporting of persons testing positive for HIV so that their contacts could be tested and treated as quickly as possible (Pinching et al. 2000; Bayer 2003). Today, HIV is one of several infectious diseases, along with tuberculosis (TB) and syphilis, for which most states maintain such a reporting and tracing system.

Globally, guidelines from the World Health Organization (WHO) and the United Nations Programme on HIV/AIDS (UNAIDS) recommend that public health legislation authorize, but not require, health-care professionals to notify their patient's sexual partners of the patient's HIV

infection (UNAIDS 2006). Where the person testing positive does not consent to partner notification, UNAIDS stipulates the following conditions for involuntary disclosure:

- (a) The HIV-positive individual has been counseled about the risks of transmission.
- (b) Counseling has not achieved behavioral changes.
- (c) The HIV-positive person refuses to notify or permit notification of his/her partner(s).
- (d) There is a real risk of HIV transmission to his/her partner(s).
- (e) The HIV-positive person is given reasonable advance notice of the planned notification.
- (f) The HIV-positive person is not identified to his/her partner(s), if this is possible in practice.
- (g) The health-care provider ensures follow-up and support of the patient.

Another exception to the general rule of confidentiality in the United States concerns HIV-infected health-care workers. In response to reports of possible transmission of HIV from caregivers to their patients, the CDC published guidance in 1991 on preventing transmission of HIV from health-care workers to their patients. States were required either to adopt this recommendation or develop their own policies. In general, state laws reflect that the risk of HIV transmission is low when health-care workers follow universal precautions and that the mandatory testing of caregivers would be stigmatizing with no medical benefit. However, most policies have recommended that HIV-infected health-care workers who perform exposure-prone, invasive procedures have their circumstances reviewed by an expert panel and that they inform patients of their serologic status before undertaking exposure-prone procedures (Center for HIV Law and Policy 2008). In 2011, the American Medical Association (AMA) released parallel recommendations emphasizing that "when the scientific basis for patient protection policy decisions are unclear, HIV-infected physicians or other health care workers must err on the side of protecting patients" (AMA 2011, p. 18).

Access to Medical Care

When AIDS was first identified as a form of acquired immunodeficiency, effective treatment was unknown and the diagnosis was almost always fatal. Patients with health insurance or other financial means had some access to medical care for symptom management and sometimes to clinical trials that offered experimental interventions. But even well-insured patients soon exhausted their coverage. Moreover, insurance companies often sought to limit their liability by requiring HIV testing for new applicants and refusing to provide health and life insurance coverage for those who tested positive. Poor and uninsured patients, who often learned of their diagnosis only when they became gravely ill, typically received care from residents in public teaching hospitals, as many senior physicians and those in the private sector questioned their legal and ethical obligation to treat people with HIV/AIDS (Harden 2012). AIDS activists, particularly in gay communities across the United States and Europe, advocated for increased access to care, increased research funding targeting AIDS, and improved education about its causes and prevention (Pinching et al. 2000). Many also organized their own information clearing houses and sources of alternative treatments.

The first drug approved by the US Food and Drug Administration for treatment of HIV, zidovudine (AZT), became available in 1987. At a cost of \$8,000 per year, many people simply could not afford treatment. Soon thereafter, the federal Health Resources Services Administration (HRSA) started the AZT Drug Reimbursement Program, which provided grants to the states to cover drug treatment for those without the means to pay for it themselves (Harden 2012). In 1990, Congress passed the Ryan White Comprehensive AIDS Resources Emergency (CARE) Act, which established funding for an array of services for people with HIV/AIDS (Harden 2012). Over the past 25 years, as improved drug treatment for HIV infection dramatically increased survival, programs funded through the Ryan White Act grew to provide necessary medication, primary care, mental health care, addiction treatment, case management, and related ancillary services. The

Affordable Care Act has also improved access to HIV/AIDS care by prohibiting lifetime caps on health insurance payments and denial of coverage for preexisting conditions. However, expansion of AIDS care services, successful treatment, and high survival rates have come at significant financial cost, as federal spending on AIDS care and research reached over \$24 billion in 2015 (AIDS.gov 2015).

From the outset, HIV has disproportionately affected marginalized populations in the United States. Members of historically disenfranchised groups, including men who have sex with men, sex workers, IV drug users, and members of racial and ethnic minority groups, continue to be at higher risk for HIV infection than the general population. Even with publically funded prevention, testing, and treatment programs in place, stigma, low health literacy, homelessness, incarceration, and instability related to drug abuse are significant barriers to access. And despite efforts to improve equity in access and health outcomes, racial and ethnic disparities remain significant: African Americans account for almost half of new infections each year, and over 60% of Americans living with HIV are African Americans or Hispanics (AIDS.gov 2015).

Internationally, access to treatment for AIDS has also posed significant ethical challenges. In the countries most affected by HIV in the first two decades of the pandemic, the lack of effective treatment for HIV was exacerbated by the lack of even basic medical care, particularly in Africa, Central and South Asia, and the Caribbean. Far more than in the United States or Europe, in developing countries, the cost of AZT and more advanced drugs kept treatment out of reach of most patients.

In 2003, President George W. Bush announced the President's Emergency Plan for AIDS Relief (PEPFAR), through which the United States would commit \$15 billion to combat HIV/AIDS internationally (AIDS.gov 2015). PEPFAR's initial goals centered on providing testing, counseling and ARV treatment, developing and strengthening the health services infrastructure needed to provide them, and developing systems for care and support of children orphaned after their parents' deaths from AIDS. PEPFAR's

specific focus on treating of pregnant women had the important benefit of preventing maternal-fetal transmission. Together with the Global Fund to Fight AIDS, Tuberculosis, and Malaria, PEPFAR has dramatically changed the landscape of HIV care and treatment in those countries most affected by the disease. There is still significant unmet need for services, however, especially for AIDS-related mental health services, family planning, and palliative care.

Informed Consent in Clinical Care

Informed consent is a cornerstone of ethical health care, even in an epidemic. Successful informed consent practices promote trust between health professionals and patients, enhance patients' understanding of treatment regimens, and improve outcomes by fostering their adherence. Basic informed consent requires the caregiver to tell the patient about the nature, expected benefits, risks of harm, and alternatives to a recommended intervention so that the patient has a sound basis on which to accept or refuse it. In the United States, the standard for informed consent is the disclosure and discussion of information that a "reasonable person" would want to know or find useful in making specific treatment choices.

Early ethical concerns around informed consent in AIDS care focused on the need for formal consent to HIV testing and screening. Because of the stigma associated with a diagnosis of HIV/AIDS, even an offer of testing carried the implication of immoral sexual activity or drug use, and for many years patients were typically asked to sign a specific consent form before HIV testing was conducted. However, practices changed after the introduction of ARV medication, especially once AZT was found to prevent maternal-fetal transmission of HIV. Many states soon required pregnant women to be offered HIV testing in prenatal care and institutions implemented screening programs (Heitman and Ross 2002). Documentation of informed consent to HIV testing was typically incorporated into the more general consent for diagnostic blood work across clinical contexts.

One situation in which informed consent is often not required for HIV testing is in response

to accidental sharps injuries and occupational exposures to patients' blood or potentially infectious bodily fluid. Prompt testing of both the person exposed and the source of exposure lets the caregiver and employer begin appropriate prophylaxis as soon as possible. In many states the patient may be tested for HIV without being asked for consent (US Department of Veterans Affairs 2015).

In the early years of AIDS, informed consent to treatment was complicated by patients' desperate hope that the disease was treatable and uncritical acceptance of treatment offered. However, once ARV treatment was introduced, the complex dosing regimens and common side effects made adherence difficult. Clinicians and public health practitioners worried that drug-resistant strains of HIV would develop if patients did not adhere to treatment regimens and debated how soon after diagnosis patients could truly understand the demands of treatment well enough to give meaningful consent to treatment (Heitman and Ross 2002). For high risk-populations affected by mental illness, homelessness, or substance abuse, and especially for preventing maternal-fetal transmission, many public health programs advocated for directly observed therapy (DOT), in which a case manager ensures that the patient takes prescribed medication on schedule. Development of single-dose combination therapy simplified adherence for most patients and limited the call for DOT to individuals whose difficulty providing self-care poses identifiable health risks for the larger community.

Prevention

In the early era of HIV/AIDS, when effective treatment was not available, behavioral strategies were essential to the prevention of transmission, and the ethical goals of harm reduction and countering stigma featured prominently in most AIDS prevention plans. Today, multifaceted prevention strategies include a central role for effective treatment, placing new ethical pressures on patients to adhere to their medication regimens. The promise of a vaccine remains an international research goal.

Behavioral Interventions and Harm Reduction

Early in the pandemic, recognition that HIV/AIDS is transmitted through contact with certain bodily fluids led to a number of preventive strategies focused on avoiding or limiting such contact. For example, early prevention campaigns in both the United States and abroad stressed the traditional morality of abstinence, monogamy, sobriety, and avoidance of intravenous drug use. However, public health experts soon acknowledged that effective prevention of HIV required finding ways to make stigmatized sexual practices and drug use “safe” because the prevalence of high-risk activities themselves was not easily reduced. Thus “safe-sex” programs promoted consistent use of condoms in all sexual encounters and needle decontamination and exchange practices for injection drug use on the grounds that they reduced the harms of HIV transmission, even if they appeared to promote behavior otherwise considered immoral or harmful (Harden 2012).

The goal of preventing transmission of HIV in clinical contexts similarly led to new standard behaviors in the late 1980s regarding physical contact with both infected and uninfected people. “Universal precautions” were instituted for clinical care in which all human blood and bodily fluids were treated as if they were infectious and all patients were treated as if they were HIV-positive. Not only did universal precautions improve caregivers’ overall infection control practices, the widespread use of gloves and other barrier protection in general patient care reduced their associated stigma for patients with HIV/AIDS (Harden 2012).

Treatment as Prevention (TasP)

The effectiveness of ARVs in reducing treated individuals’ viral load has given universal treatment ethical importance as a preventive strategy. Because ARVs can reduce viral load to virtually zero, the early treatment of HIV infection not only has life-saving benefits for the individual being treated but also directly reduces the risk of transmission, irrespective of other behaviors. TasP offers significant public health advantages in settings with limited resources. However, whereas traditionally the uninfected partner was the focus

of preventive efforts, TasP places a disproportionate emphasis on HIV-infected individuals to adhere to medication regimes over other behavioral forms of prevention (Haire and Kaldor 2013). Not only must the at-risk person trust in the adherence of their HIV-infected partner, an undetectable viral load may lead infected individuals to withhold information or lie about their seropositive status altogether (Heitman and Ross 2002).

Pre-exposure Prophylaxis (PrEP)

PrEP, the use of oral ARV drugs by members of high-risk groups prior to potential exposure to HIV, is another new prevention strategy that raises questions of relative benefit and harm from administering medications to uninfected individuals. In addition to the risk of side effects from the drug, as with TasP, the prophylactic use of ARVs shifts prevention strategies away from other effective and less inexpensive behavioral measures (Haire and Kaldor 2013). In low-resource settings where the supply of ARV drugs is limited, their use for prophylaxis may also make them unavailable to infected persons who will likely suffer significant harm from ineffective or non-treatment (Sugarman 2014).

Research

The fundamental ethical challenge in all clinical and public health research is determining when and how an individual may be exposed to potential harms in pursuit of generalizable knowledge of uncertain benefit to participants or future others. The AIDS pandemic not only illustrated the ethical imperative of well-designed research into the causes, prevention, and effective treatment of disease, it also forced the reassessment of ethical standards for infectious disease research, particularly in low-resource environments. Ethical consideration of HIV/AIDS research has emphasized the complexity of informed consent, the definition of standard of care for control groups, the meaning of “vulnerable population,” and the ethical tensions inherent in international collaboration.

Informed Consent in Research

Just as informed consent for treatment is intended to ensure that patients understand and freely agree to the interventions that they receive, the informed consent process in research aims to ensure that individuals understand that they are being recruited into a study, the nature of the study intervention, and its intended benefits, risks of harm, and alternatives. Early in the pandemic, the informed consent process in HIV was confounded by the lack of intervention outside of research settings and a general misunderstanding that the health professional's commitments in research are to answering the study question, not to advancing the patient's individual interests (Harden 2012). Controversy over informed consent in international AIDS drug trials in the late 1990s led to revision of the World Medical Association's Declaration of Helsinki and the Council for International Organizations of Medical Sciences' (CIOMS) International Ethical Guidelines for Biomedical Research (Macklin 2008). Both documents stress that physicians who involve their patients in research must point out this double role, identify which aspects of care are related to research, and have another person from the research team carry out the research informed consent process.

In international research, the informed consent process may also be complicated by cultural and linguistic differences and its significance may vary with local customs and norms. International standards call for the recruitment and informed consent process to be conducted with the would-be participant as an individual, in his or her own language, and for their individual consent to be documented in writing, if possible. However, in many lower-income countries, especially where there are low rates of literacy, a community leader's acceptance of a study is often essential to community members' willingness to participate. Similarly, the male head of household in some societies may be responsible for making decisions on behalf of female family members, while US and international standards of informed consent hold that each participant must consent as an individual (Macklin 2008). Nonetheless, family, community, and self are closely linked in

many societies where HIV is prevalent, and AIDS research may indirectly affect sexual partners, needle sharers, transfusion recipients, and health-care workers, from whom no one gets consent.

Research and the Standard of Care

Even with enhanced informed consent processes, AIDS research continues to present ethical tensions in low-resource settings where treatment options remain more limited than in industrialized nations. The definition of "standard of care" in international treatment and prevention research first became a prominent ethical issue in the late 1990s, in randomized controlled trials (RCT) of AZT for prevention of maternal-child transmission of HIV. RCTs are the "gold standard" in clinical research, evaluating two or more interventions presumed to provide equal benefit against each other. Promising new interventions are typically tested against the standard of care, but by definition one or more groups in an RCT will receive less beneficial or more harmful treatment than that which is ultimately shown to be the most effective.

Because the standard of care in low-resource settings where HIV/AIDS is most prevalent is generally much less effective than in industrialized settings, research there is more likely to subject participants to the risks of research with none of the benefits. There is ongoing debate among international ethicists about whether a "double standard" in the calculation of risks and benefits in research improves health care in low-income countries or perpetuates injustice (Macklin 2008). The National Institutes of Health's (NIH) ethical priorities for prevention trials call for researchers to engage multilevel stakeholders in ethical study design, including provisions to ensure that the research is responsive to the host country's needs and that potential barriers to future access to the study intervention are minimized (Garner et al. 2014).

Vaccine Research and Development

The development of an HIV vaccine has been a central goal of HIV prevention research since the inception of the pandemic. In the late 1990s,

UNAIDS sought to address the ethical tension between the urgency for vaccine development and the protection of research participants created by the high rate of HIV infection in many low-income countries with little infrastructure. Rather than imposing protections against phase I and II trials, UNAIDS recommended that countries define their own readiness to participate in early clinical trials and gain the direct experience and infrastructure needed for more complex phase III studies (Guenter et al. 2000).

To be considered successful, vaccine efficacy studies must show a difference in incidence between the intervention and control groups, meaning that there is an inherent need for new infections to occur among trial participants. In addition to this apparent conflict of interest between researchers and study participants, it is essential to determine in advance what provisions will be made for participants who become infected during the trial. Not only may the projected costs of lifelong treatment be prohibitive, offering treatment may be an unfair inducement in regions where access to treatment remains subpar (Guenter et al. 2000).

Vulnerable Populations

As evidenced in the complexity of informed consent in HIV/AIDS research, certain groups may be more subject than others to coercion or undue influence to take part in research that is not in their interests. Such vulnerability occurs typically as a result of social circumstances, health status, or other limitations on members' understanding or freedom to choose. US regulations classify children, pregnant women, and prisoners as de facto vulnerable populations whose recruitment into studies requires special attention to informed consent processes and protection from coercion. In the case of HIV/AIDS research, other recognized categories of vulnerable populations include such stigmatized groups as men who have sex with men, transgendered persons, injection drug users, and sex workers, as well as children, the homeless, the poor, and persons from resource-limited settings (Presidential Commission 2014).

In May 2001, the US National Bioethics Commission (NBAC) recommended an alternative to

the categorical definition of vulnerability, highlighting how individuals or groups might be vulnerable in multiple ways in different contexts. *Contextual vulnerability* includes six areas: cognitive, institutional, social, economic, deferential, and medical vulnerability. NBAC concluded that, when vulnerability is due to external circumstances, consideration of these contextual areas may identify potential for coercion or involuntariness better than categorical definitions. In research on HIV/AIDS, the same factors that put the potential research participants at risk for HIV also place them at risk for other vulnerabilities such as cultural exclusion, social and economic inequality, limitations to health-care access, and political oppression. NBAC cautioned that ethical review should analyze "how to identify and avoid situations that render some participants or groups vulnerable to harm or coercion" (Presidential Commission 2014, p. 6).

International Collaborative Research

Many of the countries where HIV/AIDS remains an enormous public health threat have relied upon international collaborations and expertise for the scale-up and expansion of HIV/AIDS care services and related research. Emanuel et al. (2004) recommend an 8-point framework for researchers and ethics review committees to use in determining whether international research is ethical. These principles are (1) collaborative partnerships, (2) social value, (3) scientific validity, (4) fair selection of study participants, (5) favorable risk-benefit ratios, (6) independent review, (7) informed consent, and (8) respect for study participants and their communities.

"Collaborative partnerships" are fundamental to ensure that all studies are responsive to the host country's identified needs and that exploitation is minimized. Collaborative partnerships require mutual respect, specifically related to the incorporation of cultural norms, values, and social practices within the study design. Host countries and communities should receive equal or a fair allotment of benefits from the conduct and results of the study, and the tangible and intangible rewards of each study (such as authorship, intellectual property rights, etc.) should be shared. Whenever

possible, disparities between countries should be minimized, such that the research study incorporates a component of capacity building or infrastructure development.

Conclusion

Over the 35 years since HIV/AIDS was identified as a new disease, the ethical questions raised by its treatment, prevention, and research have been as complex as its epidemiology. The development of ARV therapy for HIV has seen ethical issues raised by an untreatable and quickly fatal infection in a young population replaced by more difficult questions about stigma and skyrocketing costs of chronic care. Internationally, ethical issues raised by HIV/AIDS illustrate how social, cultural, and economic differences affect the health of different populations and emphasize the importance of international collaboration in efforts to reduce and ultimately eliminate the disease worldwide.

Cofilin, Trafficking

Yuntao Wu

Department of Molecular and Microbiology,
National Center for Biodefense and Infectious
Diseases, George Mason University, Manassas,
VA, USA

Definition

Cofilin is an actin-binding protein, one of the members of the ADF/cofilin family of proteins ubiquitously present among eukaryotes. ADF/cofilin proteins bind and depolymerize filamentous F-actin in a pH-dependent manner and are responsible for the high turnover rates of actin filaments. Currently, there are three highly conserved proteins in the ADF/cofilin family: ADF (actin depolymerizing factor) or destrin, cofilin 1 (non-muscle cofilin or cofilin), and cofilin 2 (muscle cofilin). In cells, cofilin and the Arp2/3 complex work together to regulate actin treadmilling, a process in which G-actin is preferentially incorporated into the filaments at the (+) end and then dissociated from the (−) end. The actin treadmilling process has been suggested to facilitate HIV trafficking across the cortical actin layer.

Introduction

The first member of the ADF/cofilin family proteins was identified in extracts of embryonic chick brain. Cofilin was later purified from porcine brain and named cofilamentous structures with actin, or cofilin for short. Cloned human cofilin has 166 amino acids and a deduced molecular weight of 18 kD (Bamburg 1999). Structurally, human cofilin possesses a core

consisting of a five-stranded mixed β -sheet ($\beta 1$ – $\beta 5$). The first four strands ($\beta 1$ – $\beta 4$) are antiparallel, and $\beta 5$ runs parallel to $\beta 4$ and antiparallel to $\beta 3$. In addition, the residues 159–161 at the C-terminus form a short strand, $\beta 6$. Five helices ($\alpha 1$ – $\alpha 5$) surround the central β -sheet, and a salt bridge is formed between His¹³³ and Asp⁹⁸ that may influence the pH sensitivity of cofilin in actin binding and depolymerization. Cofilin binds to G-actin, and the binding site is located in a region centered around Tyr¹¹⁷, which includes several residues in $\alpha 4$ (such as Lys¹¹², Lys¹¹⁴, Met¹¹⁵, and Ile¹²⁴) and $\beta 5$. In addition, a few other residues such as Ile¹², Pro¹¹⁰, and Leu¹²⁸ are also suggested in G-actin binding. Cofilin also binds to F-actin, and this requires two sites on cofilin, a G site that interacts with actin subdomains 1 and 3 and an F site that interacts with actin subdomains 1 and 2. Residues important for F-actin binding on cofilin have been identified through mutagenesis and include several residues in $\beta 4$ (such as Lys⁹⁶ and Asp⁹⁸) and $\alpha 5$ (such as Glu¹⁵¹, Lys¹⁵², and Gly¹⁵⁵). Other regions including $\beta 3$ and $\beta 5$ may additionally be involved in F-actin binding (Pope et al. 2004).

Cofilin depolymerizes actin filaments through two mechanisms: direct severing and increasing the off-rate of actin subunits from the (−) end. Cofilin has a higher affinity for ADP-actin than for ATP-actin, and cofilin binding to actin filaments facilitates phosphate dissociation from ATP-actin. Hydrolysis of ATP increases cofilin-binding affinity, changing the twist of the actin helix and severing actin filaments to shorter segments. These severed actin filaments can increase the speed of actin polymerization by providing more free (+) ends for nucleation by the Arp2/3 complex (Pollard and Borisy 2003).

The binding of cofilin to ADP-actin present at the (−) end also promotes dissociation of cofilin-ADP-actin. Cofilin in the released ADP-actin complex is competitively replaced by profilin, which then converts ADP-actin monomers to ATP-actin monomers to recycle them for new actin polymerization at the (+) end. Thus, it is suggested that cofilin and the Arp2/3 complex work together to regulate actin treadmilling, in which ATP-actin is preferentially incorporated into the filaments at the (+) end and then hydrolyzed into “older”

ADP-actin and dissociated from the (–) end (Carlier et al. 1997).

In cells, the activity of cofilin is mainly regulated by phosphorylation of serine 3 at the N-terminus, which inhibits cofilin binding to G-actin and F-actin. The kinases responsible for cofilin serine 3 phosphorylation are the LIM domain kinases (LIMK) and Tes kinases, which are targets of the Rho family GTPases such as Rho, Rac, and Cdc42. Rho family GTPases activate PAK1, PAK2, PAK4, ROCK, or MRCK α (myotonic dystrophy kinase-related Cdc42-binding protein kinase) which then activate LIMK through direct phosphorylation. Cofilin is activated through dephosphorylation of serine 3 by phosphatases such as PP1, PP2A, slingshot IL (SSH1L), and chronophin, which couple cofilin activity to different Signaling pathways. Recent studies have suggested that tyrosine 68 (Y68) can also be phosphorylated, and this phosphorylation appears to increase cofilin ubiquitination and proteasome degradation. In chemotactic cells, cycles of cofilin phosphorylation and dephosphorylation are required to sustain actin dynamics essential for driving directional cell migration (Bernstein and Bamburg 2010).

The ability of cofilin to modulate actin polymerization or depolymerization may depend on the local concentration of cofilin. Low concentrations of cofilin may favor severing, whereas high concentrations may favor actin nucleation. Nevertheless, it is unknown how this concentration-dependent mode of action demonstrated *in vitro* plays out in cells (Bernstein and Bamburg 2010). In general, decreasing cofilin expression through siRNA increases the amounts of cellular actin filaments, whereas overexpression of cofilin induces the formation of cofilin-actin bundles (Yoder et al. 2008). *In vitro*, cofilin also competitively interacts with the Arp2/3 complex by inducing structural changes in the actin filaments; these changes reduce the affinity for Arp2/3 and cause a loss of actin filament branches. This debranching process may play a role in modulating Arp2/3-induced actin branch growth in the leading edge of migrating cells (Chan et al. 2009).

In addition to regulating actin dynamics in cells, cofilin has also been shown to mediate actin nuclear

localization, which may be involved in the regulation of gene expression. Actin and actin-related proteins such as Arp7, Arp9, and Baf53 are parts of the chromatin-remodeling complex RSC and SWI/SNF (Cairns et al. 1998). Actin is also part of the pre-initiation complexes and is necessary for transcription by RNA polymerase II. Cofilin-mediated actin nuclear localization may serve to connect the cytoskeletal processes to chromatin remodeling and the initiation of transcription.

Inhibition of cofilin expression through siRNA knockdown in human T cells triggers apoptosis (Yoder et al. 2008). Cofilin is found to be translocated to mitochondria in apoptotic cells. Cofilin mitochondrial translocation seems to be necessary for the opening of the permeability transition pore and the release of cytochrome *c*. The relationship between cofilin-mediated actin dynamics and cell apoptosis is not completely understood. It is suggested that reduction of actin dynamics may promote a loss of mitochondrial membrane potential and an increase in oxidative stress. In addition, actin dynamics are implicated in the movement of mitochondria and proper mitochondrial partitioning during cell division (Bernstein and Bamburg 2010).

Cofilin serine 3 phosphorylation inactivates the actin-binding ability of cofilin. However, phospho-cofilin is recently shown to activate phospholipase D1 (PLD1). Cofilin directly and specifically interacts with PLD1 upon phosphorylation by LIMK1. Phospho-cofilin also stimulates PLD1 activity, suggesting that phospho-cofilin may control a variety of cellular functions by its stimulatory effect on PLD1 (Bernstein and Bamburg 2010).

In the human immune system, cofilin plays important roles in regulating T-cell migration, chemotaxis, and T-cell activation. Within the immunological synapse, cofilin is required for the formation of the supramolecular activation clusters critical for sustaining signaling and T-cell activation. Cell-permeable peptides that block cofilin interaction with F-actin impair receptor capping and immunological synapse formation, resulting in inhibition of T-cell activation. In transformed or pre-activated T cells, cofilin activation and dephosphorylation occur spontaneously, whereas in human resting T cells, in the absence of T cell activation or chemotactic stimulation, cofilin exists

largely as the serine 3 phosphorylated form. T-cell activation or chemotactic stimulation leads to cofilin activation by dephosphorylation, and the signaling cascade is mainly transduced through costimulatory receptors such as CD2 and CD28 and through chemokine receptors such as CXCR4. While TCR/CD3 stimulation activates the Arp2/3 complex for actin polymerization, CD28-mediated costimulation triggers cofilin activation, which is required for dynamic actin reorganization and sustaining T-cell signaling (Samstag et al. 2003). The GTPase Ras and PI3K (phosphatidylinositol-3-kinase) signaling cascade is suggested to mainly regulate dephosphorylation of cofilin in unstimulated human blood T cells. Inhibition of either MAPK/ERK kinase or PI3K blocks Ras-induced and costimulation-induced cofilin dephosphorylation, whereas transient expression of a dominant negative form of H-Ras inhibits PI3K activation and cofilin dephosphorylation (Wabnitz et al. 2006).

Role of Cofilin in HIV Infection

HIV-1 entry into cells is mediated through binding to CD4 and the chemokine coreceptor, CXCR4 or CCR5. During this entry process, HIV-1 binding to CXCR4 also triggers a transient course of cofilin phosphorylation and dephosphorylation to increase actin dynamics in resting CD4 T cells (Vorster et al. 2011; Yoder et al. 2008). It is suggested that the cortical actin in resting T cells is relatively static in the absence of T-cell activation or chemotactic stimulation. This lack of actin activity limits viral early processes such as entry, DNA synthesis, and nuclear migration (Yoder et al. 2008). Cofilin increases cortical actin dynamics and actin treadmilling, facilitating viral intracellular migration toward the nucleus (Yoder et al. 2008). Cofilin and actin-mediated HIV nuclear localization is suggested to be essential for the establishment of HIV-1 latency in resting CD4 T cells (Cameron et al. 2010; Yoder et al. 2008). Knockout or severe inhibition of cofilin activity in T cells triggers apoptosis, but slight inhibition of cofilin expression through siRNA knockdown increases cortical actin

density, which leads to an increase in HIV DNA synthesis but a decrease in the amounts of HIV-1 nuclear DNA and early transcripts (Yoder et al. 2008). Induction of cofilin activity using a human cofilin-derived peptide (S3), carrying the N-terminal 16 residues, competitively inhibits cofilin phosphorylation through LIMK1, and this induction enhances HIV latent infection of resting CD4 T cells. A pharmacological drug, staurosporine, is also shown to induce gradual cofilin activation that enhances HIV latent infection of resting CD4 T cells following a transient treatment during infection (Yoder et al. 2008). In addition, pretreatment of resting CD4 T cells with chemokines such as CCL19, CXCL9, CXCL10, and CCL20 leads to cofilin activation and changes in actin filaments which greatly promote HIV nuclear migration and DNA integration (Cameron et al. 2010). Interestingly, exposing cells to mechanical shear stress, such as infecting cells under conditions of low-speed spinning or spinoculation, also promotes cofilin activity and actin dynamics, resulting in the upregulation of CXCR4 and a great enhancement of HIV-1 DNA synthesis and nuclear migration (Guo et al. 2011).

Regulation of Cofilin Activity during HIV Infection

HIV-1-mediated cofilin activation in resting CD4 T cells is shown to be through the G α i-dependent signaling from CXCR4; pertussis toxin (PTX), a bacterial toxin inhibiting G-protein-coupled receptors by the ADP-ribosylation of G α i, inhibits cofilin activation and HIV-1 latent infection of resting T cells in the presence or absence of cytokines such as IL-2 and IL-7 (Yoder et al. 2008). Cofilin can be phosphorylated by LIMK, and HIV-1 binding to blood CD4 T cells and macrophages triggers rapid activation of LIMK1, coincident with HIV-mediated early actin polymerization in T cells (Vorster et al. 2011). It is suggested that HIV-1 hijacks LIMK1/cofilin activity to directly regulate actin and CXCR4 dynamics critical for viral entry, postentry DNA synthesis, and nuclear migration. Inhibition of LIMK1 activity through siRNA knockdown

decreases filamentous actin and T-cell chemotaxis toward SDF-1. The decrease in cortical actin density also leads to an increase in CXCR4 internalization and surface recycling. Thus, LIMK-mediated early cortical actin polymerization may result in a temporary block to CXCR4 internalization, facilitating viral fusion and CXCR4 signaling. The LIMK1 knockdown cells also support lower viral entry, DNA synthesis, and nuclear migration. In addition, transient treatment of resting CD4 T cells with a pharmacological agent, okadaic acid, activates LIMK and promotes HIV latent infection of resting CD4 T cells. The signaling pathway that mediates LIMK activation by HIV-1 is identified as the Rac1, PAK1/2, and LIMK pathway in blood resting T cells. The activation is likely triggered by gp120 signaling through both CD4 and CXCR4, as well as from both G α i and G α q (Vorster et al. 2011). HIV gp120-mediated cofilin phosphorylation may also inhibit T-cell chemotaxis toward SDF-1.

In addition to HIV-1 gp120, another HIV pathogenic factor, Nef, is also suggested to regulate cofilin activity (Stolp et al. 2009). Overexpression of Nef in human Jurkat T cells inhibits SDF-1-induced membrane ruffling, actin rearrangement, and cell migration toward CXCL12, CCL3, and CCL19 (Stolp et al. 2009). Overexpression of Nef in hamster CHO cells also inhibits wounding-induced cofilin activation in a cell wound-healing assay. It has been suggested that the Nef-PAK2 complex is involved in the phosphorylation of cofilin, although Nef does not appear to alter the activity of PAK2 in an *in vitro* cofilin phosphorylation assay. Functionally, Nef-mediated cofilin dysregulation may affect migratory behavior of infected T cells (Stolp et al. 2009).

Potential Role of Cofilin in HIV Pathogenesis

A potential pathogenic role of HIV-1-mediated cofilin dysregulation is proposed from studies of cofilin activation in blood resting CD4 T cells treated with HIV or gp120 (Wu et al. 2008). It was shown that HIV-1 or gp120 stimulates cycles of cofilin phosphorylation and dephosphorylation,

suggesting that chronic exposure of CD4 T cells to HIV or gp120 may have a lasting impact on cofilin activity and T-cell functionality. A small-scale clinical study has found that in the peripheral blood of HIV-1-infected patients, levels of active cofilin in their resting CD4 T cells are significantly higher. It is suggested that HIV-1-mediated dysregulation of cofilin may lead to abnormalities in T-cell migration and activation that could contribute to viral pathogenesis (Wu et al. 2008).

Conclusion

Cofilin is a major regulator of actin dynamics in cells. Cofilin activity is normally controlled by extracellular stimuli that transduce signals from surface receptors to regulate cell motility. HIV binding to the chemokine coreceptors also induces a transient cofilin activity that promotes actin dynamics necessary for HIV intracellular trafficking. In addition, other viral proteins such as Nef may modulate cofilin activity to facilitate infection. The interaction between cofilin and components of HIV may lead to dysregulation of normal chemotactic responses in T cells.

maintained and where pathological consequences, such as inflammation, immune activation, CD4+ T cell loss, collagen deposition, and fibrosis, ensue during HIV infection (Pantaleo et al. 1991; Schacker et al. 2002a). CD4+ T cell count is a hallmark for disease progression in HIV infection and a hallmark for immune reconstitution after initiating combination antiretroviral therapy (cART). In HIV infected individuals who have received cART treatment for many years, CD4+ T cell restoration is heterogeneous (Kelley et al. 2009). Among patients who delayed cART until their CD4 T cell count was less than 200 cells/mm³, a quarter of the population cannot restore their CD4+ T cells to a normal level even after a decade of effective therapy (Julg and Walker 2009; Kelley et al. 2009). This poor CD4 + T cell recovery after long-term cART is related to multiple factors, of which LT collagen deposition and fibrosis is an important one (Julg and Walker 2009; Schacker et al. 2002a, b, 2005; Zeng et al. 2012b). In what follows, the current understanding of LT collage deposition and fibrosis in HIV infection will be reviewed; the underlying mechanism of LT fibrosis and intervention strategies to prevent or to reverse collagen deposition and fibrosis in HIV infection will also be discussed.

Functional Microanatomy of Lymphatic Tissues and Stromal Cells

The secondary lymphatic tissues (LTs), such as lymph node (LN), tonsil, spleen, and Peyer's patches, are strategically located where immune cells encounter cognate antigens to initiate humoral and cellular adaptive immunity. Anatomically and functionally, LTs can be divided into B cell zones (resting primary B cell follicles or activated secondary B cell follicles) and T cell zones. In these zones, stromal cells-fibroblast reticular cells (FRC) in T cell zones and follicular dendritic cells (FDC) in B cell zones-form the three-dimensional network for immune cells to migrate, interact with each other, secrete chemokines to attract and retain immune cells, and produce cytokines to support immune

Collagen Deposition and Fibrosis in the Lymphatic Tissues of HIV-1 Infected Individuals

Qingsheng Li

Definition

HIV/AIDS is primarily “a disease of secondary lymphatic tissues (LTs)” because LTs are the principal sites where HIV is produced, stored, and

Collagen Deposition and Fibrosis in the Lymphatic Tissues of HIV-1 Infected Individuals,

Reticular network in T cell zones and the germinal centers in the secondary B cell follicles are illustrated. **(b)** The schematic of a fibrotic lymph node at the end stage of HIV infection with involuted B cell follicles. **(c)** A simplified model of the collagen deposition and fibrosis in lymphatic tissues driven by persistent immune activation of HIV-1 infection

cell survival (Fig. 1; Victora and Nussenzweig 2012).

During humoral immune response, B cells, follicular helper CD4+ T cells (Tfh), and unprocessed antigens trapped on FDC interact to form germinal centers (GC) of the secondary B cell follicles. Germinal centers can be divided into two morphologically distinct areas: dark zone (DZ) and light zone (LZ) (Fig. 1). B cells undergo clonal expansion and mutate their antibody encoding genes (somatic hypermutation) primarily in DZ, then migrate along FDC networks to the FDC- and Tfh-rich LZ, where B cells actively engage with cognate antigen trapped on FDC, present processed antigen in the form of peptide-MHC II complex to

residential Tfh cells, and are then selected for survival based on the costimulation mainly from Tfh cells (Victora and Nussenzweig 2012). This process is called the germinal center reaction, the products of which are antibody class switching and affinity maturation within B cells. Recent studies using intravital imaging revealed that the germinal center reaction is a highly dynamic and iterative process, and B cells in LT and DZ may be more similar than previously thought (Victora and Nussenzweig 2012). FDC networks exist in both the DZ and LT but are enriched in the LZ. FDC is of importance as an antigen repository to support the GC reaction and also for production of B cell homeostatic cytokines such as BAFF and

IL-7 and secretion of chemokines CXCR4 and CXCL13, which can attract CXCR5⁺ GC B cells and Tfh cells into the germinal centers (Victoria and Nussenzweig 2012).

T cell zones are in the paracortical region between follicles and extend deep into the cortex above the medulla, where the adaptive cellular immune response is initiated by encounters of rare naïve T lymphocytes with cognate antigens on antigen-presenting cells (APC) (Gretz et al. 1996, 1997; Itano and Jenkins 2003). The T cell zones are framed with the infrastructure of a reticular network (RN), a three-dimensional conduit system, of which collagen fibers form the core, which is surrounded by basement membrane extracellular matrix molecules ensheathed by a layer of nonhematopoietic fibroblast reticular cells (FRC) and occasionally dendritic cells (DC) (Gretz et al. 1996, 1997, 2000; Sixt et al. 2005). The RN supports and maintains LN overall structure and provides an organized conduit for naïve T cells and DCs to migrate, interact, and access the paracortex (Bajenoff et al. 2006; Gretz et al. 1996, 1997, 2000) and to transport chemokines and other small molecules (<70 kDa) from the afferent lymph to the T zone and lumen via high endothelial venules (HEV) (Bajenoff et al. 2006; Gretz et al. 2000; Sixt et al. 2005) while excluding high-mass molecules, and particles such as pathogens that would exploit the RT system (Mueller and Germain 2009). Furthermore, The FRC secretes collagens and basement membrane extracellular matrix molecules, and produces naïve T cell and DC chemoattractant CCL19 and CCL21 (Bajenoff et al. 2006; Link et al. 2007; Luther et al. 2000) as well as key naïve T cell survival signal IL-7 (Link et al. 2007; Schluns et al. 2000). This RN microenvironment, providing the central stage for FRC, naïve T cells, and DC trio to interplay, is critical for maintaining T cell homeostasis and in mounting effective cellular immunity.

Damage of the Secondary LTs During HIV-1 Infection

It was well documented in the 1980s that HIV-1 infection can cause histopathological changes in

both B and T cell zones of LTs (Fernandez Richard et al. 1983). There is follicular hyperplasia in acute infection and follicular involution in the end stage of infection and in between during chronic infection. Similarly, the paracortical T zone expands during the acute infection, and the paracortical T cell zone structure depletes throughout the course of prolonged infection. Subsequently, it was observed that FDC is a major reservoir for HIV-1 in LTs and HIV-1 trapped on FDC can infect CD4⁺ T cells (Heath et al. 1995). Although the mechanism of the involution of FDC networks in the later stage of HIV-1 infection remains elusive, the damage to the FDC network contributes to humoral immune dysfunction. Subsequently, it was reported that reticular fibers in LTs of HIV chronically infected individuals became thicker and sometimes collapsed in the paracortical T cell zone (Paiva et al. 1996). However, the linkage between collagen deposition, fibrosis, and CD4⁺ T cell loss in LTs during HIV-1 infection was first demonstrated by Dr. Schacker and his colleague in 2002 (Schacker et al. 2002a). They found that the LT collagen deposition in HIV-1-infected and treatment-naïve individuals were inversely correlated with LT CD4⁺ T cell counts and the extent of LT collagen deposition before initiating cART was also inversely correlated with the changes in the peripheral CD4⁺ T cell counts (Schacker et al. 2002a), indicating that collagen deposition in LTs can perturb the homeostasis of CD4⁺ T cells and impact the extent of CD4⁺ T cell reconstitution after receiving cART (Schacker et al. 2002a). The subsequent study from the same group found that the amount of LT collagen deposition before starting cART can predict the magnitude of recovery of the peripheral CD4⁺ T cells with cART (Schacker et al. 2005); the extent of LT collagen deposition in T zones in HIV-1 chronic infection was inversely correlated with LT- naïve CD4⁺ T-cell population (Schacker et al. 2006), indicating that fibrotic changes in LT have more effect on the homeostasis of naïve CD4⁺ T cells than other CD4⁺ T cell subsets (Schacker et al. 2006). Moreover, it was reported using SIV-rhesus macaque model of HIV infection that at 1 week post infection, type I collagen level was

significantly increased in LTs, which positively correlated with increased LT-immune activation and TGF β 1 expression and inversely correlated with the LT CD4⁺ T cell counts, indicating that LT collagen deposition can occur during acute infection (Estes et al. 2007).

Mechanisms of LT Fibrosis in HIV-1 Infection

Fibrosis is defined by accumulating excessive fibrous extracellular matrix (ECM), such as collagen and fibronectin, and is the final and common pathological consequence of host response to tissue damage during persistent inflammation (Wynn and Ramalingam 2012). Fibrosis can occur in almost every tissue and organ in the body, including liver, lung, kidney, and cardiac and lymph node. Furthermore, FRC damage leading to the disruption of LT architecture has been observed in other viral infections such as LCMV (Mueller et al. 2007).

The fibrotic change in LTs during HIV-1 infection is thought to be one of the consequences of generalized immune activation and inflammation (Estes et al. 2007). Chronic immune activation is a major theme of HIV-1 infection (Grossman et al. 2006) and is manifested as an increase in the turnover of CD4⁺ T cells, CD8⁺ T cells, NK cells, and B cells, increases in production of cytokine and chemokines, and increased frequency of T and B cells expressing immune activation markers, such as CD38, HLA-DR, and Ki67 (Grossman et al. 2006). Furthermore, the extent of generalized immune activation can predict HIV-1 disease progression. The current proposed model of collagen deposition and fibrosis in HIV-1 infection is that persistent immune activation in LTs resulting from HIV-1 infection leads to the activation of T regulatory cells (Treg) to produce TGF β 1, which stimulates collagen production and deposition in the T cell zone. The LT collagen deposition reduces naïve CD4⁺ T cells to gain access to survival cytokine IL-7 secreted by FRC, and the FRC network loss also results in the decrease of IL-7 production, thus resulting in naïve T cell death, which in turn reduces the

secretion of lymphotoxin β , a survival molecule for FRC (Fig. 1; Estes et al. 2007, 2008; Zeng et al. 2011, 2012a). Despite the substantial progress made in this area, more detailed mechanisms remain to be understood since the current model is mainly derived from correlative data.

Conclusion

LTs are the core of the immune system. Non-hematopoietic stromal cells-FDC in B cell zones and FRC in T cell zones-provide the structure of LTs for B cells and T cells to mount adaptive immune responses. HIV-1 infection impacts both types of stromal cells and contributes to immune deficiency. LT collagen deposition as a consequence of persistent immune activation disrupts the architecture of LTs and contributes to the CD4⁺ T cell loss, especially the naïve CD4⁺ T cells. Damaged LTs by collagen deposition also prevent the CD4⁺ T cells from recovery after receiving cART. Further studies delineating the mechanism underlying the stromal cell damage in LTs, especially collagen deposition in the T cell zone and FRC loss, may identify new therapeutic strategies to enable HIV-infected individuals who receive cART to better restore their immune function.

Combination Approaches to HIV Prevention

¹Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA, USA

²Department of Medicine, University of Pittsburgh School of Medicine, Pittsburgh, PA, USA

Definition

Combination HIV prevention is defined by UNAIDS (2010) as: “rights-based, evidence-informed and community-owned programs that use a mix of different classes of prevention interventions (biomedical, behavioral, and structural), that operate on the individual, community and societal levels, prioritized to meet the current HIV prevention needs of particular individuals and communities, so as to have the greatest sustained impact on reducing new infections.”

The term *combination prevention* is relatively new but the concept itself is not. Complex packages of prevention interventions have been implemented in different countries and have partially addressed risk factors at multiple levels – individual, dyadic, sexual, or drug use networks and community – within the cultural and epidemiological context (Hankins and deZalduondo 2010). However, well-defined biomedical interventions are often prioritized, overlooking the less definable sociocultural and environmental contexts. Combination HIV prevention strategies are more likely to be effective if they target different points along the pathway to HIV infection, meaning strategies to reduce infectiousness of HIV+ individuals combined with strategies to reduce HIV susceptibility in the HIV- individual. The strategies incorporated in these coordinated prevention packages vary

depending on target population, socio-epidemiological context (Dodd et al. 2010), and levels of evidence for effectiveness.

We review the different components of the combination prevention intervention, discuss the assessment of the combination packages, and address barriers and challenges.

Core Components of Combination HIV Prevention

A combination HIV prevention approach includes different variations and components of three interventions: biomedical, behavioral, and structural. Most of the combination prevention packages need a consistent behavioral component to be effective and are likely to incorporate one or more of the biomedical interventions:

- (a) *HIV Testing*: HIV testing is a critical component of the combination prevention package and remains the gateway to the offering of and linking to appropriate and individualized services for HIV-positive persons. It is well established that most individuals who are aware of their positive status reduce their risky behaviors, thus reducing risk of HIV transmission to others (Marks et al. 2005). However, testing has not resulted in reduced risk behaviors among individuals testing negative. An estimated 21% of people with HIV in the United States are unaware of their status; even fewer know the status of their partners. Furthermore, results of HIV testing conducted as part of the National HIV Behavioral Surveillance System (NHBS) indicated that 19% of men who have sex with men (MSM) who were tested in 2008 were HIV positive; of these, 44% were unaware that they were infected (CDC 2010). Lack of awareness of one’s own status and one’s partner’s status is associated with a 50–66% decrease likelihood of condom use (Celum et al. 2005).

- (b) *Condoms*: It has been well established that the use of condoms reduced HIV transmission in serodiscordant heterosexual couples by 85% (Weller and Davis-Beatty 2002). The correct and consistent use of condoms has been shown to reduce both HIV and STI transmission probabilities. Incorporating motivational and skills components to condom use has been shown to reduce unprotected sex among HIV-positive individuals (Johnson et al. 2006). Condom use remains problematic due to reports of condom slippage and breakage, poor ability to negotiate use with sexual partners, and limited access in developing countries (Rugpao et al. 1997). Additional prevention benefits can be seen when condoms are used with condom-compatible lubricants because they reduce condom breakage and rectal trauma in MSM.
- (c) *Antiretroviral Therapy (ART)*: ART has been shown to markedly reduce HIV infectiousness in HIV-serodiscordant couples (Donnell et al. 2010). Early initiation of ART as compared to delayed therapy led to a reduction of 96% in the number of linked HIV transmissions in serodiscordant couples and a reduction of 89% in the total number of HIV transmissions regardless of viral linkage with the infected partner (Cohen et al. 2011). Reported HIV cases have diminished contiguous with the expansion of ART in British Columbia and San Francisco (Das-Douglas et al. 2010). However, the risk of transmission is not completely eliminated by ART, possibly due to poor ART adherence or persistent replication of the virus in the genital tract despite treatment (Kalichman et al. 2008).
- (d) *Screening, Diagnosis, and Treatment of Sexually Transmitted Infections (STIs)*: It is difficult to demonstrate that syndromic treatment of STIs with antibiotics prevents HIV acquisition. Treatment of STIs to reduce HIV incidence has been evaluated in randomized trials, of which just one showed a substantial decrease in overall HIV incidence due to STI treatment. Bacterial and viral STIs can increase the efficiency of HIV transmission (Chin-Hong et al. 2009). Incident STIs are a clear marker of history of sexual risk and are predictive of future acquisition of HIV infection among MSM (Menza et al. 2009). Therefore, screening, diagnosing, and treating STIs in MSM offer a teachable moment to discuss risky behaviors and risk-reduction strategies. Treatment of STIs is predicted to reduce the infectiousness of HIV+ men.
- (e) *Vertical Transmission Risk Reduction*: There is clear evidence that ART reduces antepartum, intrapartum, and postpartum HIV transmission (Sturt et al. 2010). Alternatives to breastfeeding have decreased postpartum transmission as well. Delivering effective contraception to reduce unwanted pregnancies and coordinating it with HIV testing and ART to pregnant women is particularly challenging in developing countries.
- (f) *Parenteral Transmission Risk Reduction*: Effective interventions to reduce transmission from injection drug use include treatment of the drug use disorder such as the use of opioid substitution therapy for opioid use disorder, needle exchange programs to reduce blood exposure, and behavioral interventions to reduce sexual risk behaviors occurring in the context of substance use (Gowing et al. 2008). Adherence to infectivity-reducing ART is similar among HIV-positive injection drug users and non-injection drug users (Malta et al. 2010). Opioid substitution treatment provided as maintenance therapy is associated with a reduction in the risk of HIV infection among injection drug users (MacArthur et al. 2012).
- (g) *Medical Male Circumcision (MMC)*: MMC is one of the most effective one-time interventions that reduces HIV acquisition risk for men by 50% (Mills et al. 2008). The effects of MMC on HIV risk for women are not well determined. Combining MMC with other strategies, such as HIV testing, condom use, and STI screening and treatment potentially has a highly synergistic effect.

However, their scale-up and implementation are very challenging.

- (h) *Microbicides*: When applied to the vaginal or rectal mucosa, microbicides prevent or significantly reduce the acquisition of HIV or other STIs (McGowan 2010). Vaginal microbicide gel 1% Tenofovir has been shown to reduce HIV acquisition in women by 39% compared with placebo (Abdool-Karim et al. 2010); however there was a trend toward decreasing effectiveness after 18 months possibly due to adherence issues.
- (i) *Other Strategies*: The efficacy of other approaches such as post-exposure treatment with antiretrovirals (PEP) and use of pre-exposure (PrEP) ART for prevention are supported by some evidence (Golub et al. 2010).
- (j) *Structural Approaches*: Social, economic, legal, cultural, political, and environmental factors can significantly affect HIV risk and vulnerability (Gupta et al. 2008). More evidence points to the association between structural factors and HIV risk and vulnerability without a clearly established direct causal effect. Structural factors can act as significant barriers to individual-level HIV prevention, delivery of services, and adoption and implementation of HIV-preventive behaviors. For example, gender-related violence and inequality can affect the ability of some women to negotiate safe sex practices out of fear of physical violence and/or fear of losing financial support (Pronyk et al. 2006). Fear of HIV/AIDS-related stigma and discrimination can deter people from being tested and from disclosing their status to their sexual partner. Structural approaches address these factors – such as gender or income inequality and social marginalization that can be deeply rooted in the societal environment and very challenging to confront (UNAIDS 2010). Structural approaches are viewed as long-term initiatives that should be implemented in a context-specific way. Structural approaches, regardless of whether they are single policies or majorly transformational processes, may address social norms,

regulatory barriers, community engagement, and environmental laws in order to facilitate the development and implementation of HIV prevention packages for vulnerable most-at-risk populations (MARPs) such as women, MSM, injection drug users, or sex workers (Kurth et al. 2011). Structural interventions involving efforts to increase availability of clean needles and syringes by modifying restrictive laws and regulations and outreach to increase pharmacy involvement in syringe sales have been effective in reducing HIV infection in injection drug users (Bertozi et al. 2008). Structural approaches have been minimally incorporated into combination HIV prevention approaches. Formally assessing structural approaches is very challenging due to multiple interacting components and methodological limitations which require more than a simplistic list of individualized approaches, instead an integrated multi-sectoral context-based initiative (Gupta et al. 2008).

Evaluation and Implementation Issues in Combination HIV Prevention

The evaluation of the impact of combination HIV prevention programming has been identified as an urgent global need (Lancet 2010). The *impact* or community-level effectiveness of combination prevention programs is defined as the effect of a program on a population level as measured by changes in incidence, prevalence, mortality, and/or other ultimate outcomes of interests (Lancet 2010). So far, data on impact are limited, and most evaluations assessing the impact of combination programs have failed to implement rigorous cluster randomized designs that have demonstrated any effects on HIV incidence (Padian et al. 2011). Key considerations in evaluating the impact of combination programs include specifically defining the evaluable package and evaluating the entire package or each component of the package. Another key challenge in any impact evaluation is identifying a valid *counterfactual* – the hypothesized scenario of what would have happened if the program had

not been implemented (Padian et al. 2011). Experimental and quasi-experimental methods offer pros and cons in the identification of a counterfactual for a combination prevention program. Furthermore, methodological considerations unique to HIV include the absence of a reliable incidence assay, ethical dilemmas with having a control group, and poor surrogate markers that cannot replace outcomes such as HIV incidence, prevalence, and infections averted, which potentially affect the evaluation process (Padian et al. 2011). The need to integrate monitoring and evaluation strategies into the prevention programs requires collaboration between implementers, evaluators, and policy makers. The fact that effective combination programs cannot be easily randomized or evaluated with the most rigorous methodological designs does not mean that they should not be implemented.

Conclusion

Combination HIV prevention programs have the advantage of delivering biomedical, behavioral, and structural interventions concurrently to maximize synergies among these interventions. If designed and implemented effectively, combination prevention packages can significantly affect the HIV epidemic. However, these types of prevention packages, when implemented at scale, face significant methodological and evaluation challenges, including how best to determine their impact and how and whether to measure the effectiveness of specific component interventions. Continuing to build a better understanding of “what works” in HIV prevention and – particularly in the combination HIV prevention – is necessary to curb the rate of the epidemic (Padian et al. 2011).

Community Viral Load

Moupali Das
 HIV/AIDS and Infectious Diseases, University of
 California San Francisco, San Francisco,
 CA, USA

Definition

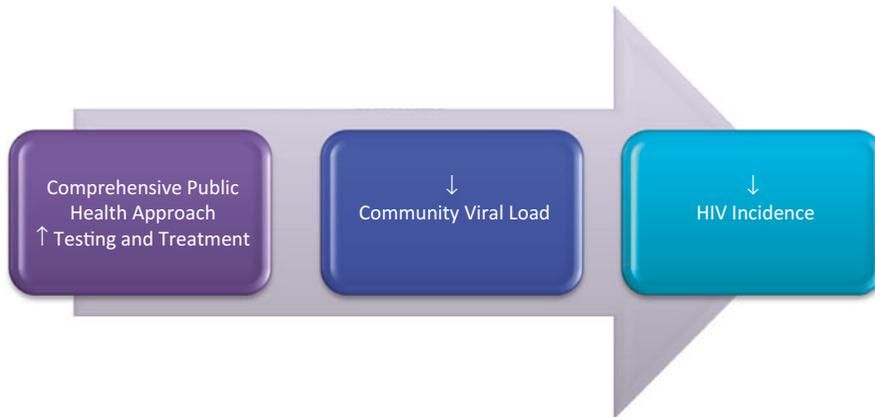

Community viral load (CVL) is defined as an aggregate population-level biomarker of a

community's viral burden over a specific time period and has recently been operationalized as (1) an indicator of a community's level of infectiousness and transmission probability; (2) a measure of the effectiveness of combination of HIV prevention, care, and treatment interventions; and (3) a proximal marker for HIV incidence and potential epidemic propagation.

Background

Accumulating evidence at the individual level has demonstrated both the direct relationship between plasma HIV viremia and HIV transmission and the positive effects of antiretroviral treatment (ART)-mediated virologic suppression in reducing or eliminating perinatal and sexual HIV transmission (Dickover et al. 1996; Garcia et al. 1999; Quinn et al. 2000; Wawer et al. 2005) (Chung et al. 2007; Cohen et al. 2011; Connor et al. 1994; Garcia et al. 1999; Mofenson et al. 1999). It is hypothesized, analogous to the individual case, that the community viral load or CVL is directly related to the magnitude of transmission in the community and that, furthermore, ART-mediated virologic suppression or decreases in CVL at the population level will be associated with reductions in HIV incidence. At the community level, there are currently no definitive randomized controlled trial findings that support this hypothesis (pictured in Fig. 1); however, there are a growing number of prospective observational cohort studies, ecologic analyses, and modeling studies that demonstrate how increasing diagnoses, linkage to care, ART uptake, and engagement in care will ultimately decrease the population-level viral burden, which can be measured by CVL, and therefore reduce HIV incidence (Charlebois et al. 2011; Fang et al. 2004; Granich et al. 2009; Katz et al. 2002; Montaner et al. 2010; Porco et al. 2004; Wood et al. 2009).

In this entry, an overview of the current approaches to measure and apply CVL will be discussed, including an examination of the limitations of the biomarker.

Community Viral Load, Fig. 1 The hypothesis. Increased testing, diagnosis, promoting linkage to care, and therefore increasing treatment will reduce the overall community viral load, and this will ultimately reduce new HIV infections

Definition of “Community”

As noted earlier, CVL is defined as the aggregate biological measure of the viral load (VL) for a population living with HIV. The term “community” refers to either a particular geographic location, such as a city or a particular neighborhood or census tract, or to a particular group of people who share sociodemographic characteristics. Although people who inject drugs (PWID), men who have sex with men (MSM), or particular ethnicities may not necessarily constitute a “community” in the sense of complete social interconnectedness or shared networks, here the term is used broadly to refer to populations defined by demographic, geographic, or behavioral commonality with an elevated probability of connections to other members of the population, including those through needle sharing or sexual partnerships.

Measures

There are several different ways to calculate CVL. Generally, CVL is calculated for a particular time period. The most common reported measure is a measure of the central tendency of the viral load distribution over a particular period of time. For example, the mean annual CVL is the total CVL (sum total of all unique VLs of the population of HIV-positive individuals in a particular jurisdiction during a given year) divided by N , the total

number of HIV-positive individuals. Table 1 below lists the most commonly used CVL measures and their uses, as well as some caveats and limitations:

$$CVL = \left(\frac{\sum_{i=1}^N (VL)}{N} \right)$$

Sources of Data

CVL may be calculated for a clinic population (Geng et al. 2012), for persons participating in cohort studies (Jain et al. 2012a, b; Wood et al. 2009), or from public health surveillance HIV case registries if the VL data are systematically reported and abstracted (Castel et al. 2012; Das et al. 2010; Henard et al. 2012; Montaner et al. 2010; Terzian et al. 2012). A variety of approaches have been used to calculate CVL, often depending on the source of data, number of measures per person, completeness of the data, and distribution of the VLs. For example, Wood et al. demonstrated that the median CVL among a cohort of HIV-positive PWID predicted HIV incidence density among HIV-negative PWID (Wood et al. 2005). As noted in Table 1 above, in samples where over half the viral loads are undetectable, using the mean or log transformed mean CVL for such analyses is more

Community Viral Load, Table 1 CVL measures

CVL measure	Use	Caveats/limitations
Mean (most recent) (Das et al. 2010)	Useful for comparisons between sub-populations (e.g., disparities)	Influenced by outliers
Mean (of the mean) (Das-Douglas et al. 2009b)	Useful for comparisons between sub-populations (e.g., disparities)	Relative contributions of multiple measurements (e.g., those started on ART, trended towards suppression in year)
Median (Wood et al. 2009)	ART uptake and treatment effectiveness	If >50% of VLs are undetectable, then the median is undetectable; limits analyses
Maximum (peak) (Das et al. 2011b; Montaner et al. 2010)	Most conservative estimate of viral burden	Could overestimate true average burden
Minimum (Das et al. 2011b)	Least conservative or most optimistic estimate of viral burden	Could underestimate true average burden
Total (sum of most recent) (Das et al. 2010, 2011b)	The prevalent viremia: takes into account both number of PLWHA and magnitude of the most recent VL	The proportion missing VLs can have greater influence
Time-weighted average (Das et al. 2011c)	Alternate approach to handling multiple measures in year	
Population virologic suppression (Das-Douglas et al. 2009a, c)	Evaluate universal treatment policies at the population level	Includes all comers, including those not on treatment, more helpful for estimate of transmission probability
Maximal virologic control (Horberg et al. 2010)	Evaluate HIV quality of care among those on ART for a given time	Includes only those on treatment for particular time period, more helpful for evaluating quality of care
Log transformation of any of the above measures (Das et al. 2010)	Reduces the influence of outliers	

useful than examining the median (which would be undetectable). In samples where individuals have repeated measures during a calendar year or particular time period, investigators have either used the most recent VL value or have employed traditional statistical approaches for handling repeated measures.

Applications

CVL has been used as (1) an indicator of a community's level of infectiousness and transmission probability, (2) a measure of the effectiveness of combination HIV prevention care and treatment interventions, and (3) a proximal marker for HIV incidence and potential epidemic propagation.

Comparing the mean CVLs of different sub-populations and communities can be useful to

evaluate disparities by specific demographic characteristics, such as race/ethnicity, transmission risk, or other clinical attributes. Mean CVL can be mapped using geographic information systems (GIS) software by neighborhood or census tract to demonstrate geographic differences within a jurisdiction. Neighborhoods with higher mean CVLs also tend to have higher rates of both AIDS mortality and poverty (Das et al. 2011a).

Establishing overall and subpopulation or neighborhood CVL baselines and following trends over time can be helpful for municipal health departments making decisions regarding the effectiveness of current HIV/AIDS strategies and/or the reallocation of resources for HIV prevention and treatment.

Disparities in mean CVL among different sub-populations may help to explain disparities in access to and engagement in care among these different groups and may be a possible

explanation for disparities in HIV incidence. For example, numerous studies have demonstrated that African-American MSM do not have higher levels of sexual risk and drug-using behavior than white MSM; however, HIV incidence is disproportionately higher among African-American MSM (Millett et al. 2007). Higher CVL among African-American MSM may be a potential explanation (Christopoulos et al. 2011). Jurisdictions can examine the relationship between temporal trends in CVL and estimated HIV incidence using public health surveillance data. Planned cluster randomized controlled trials evaluating “treatment as prevention” or “test and treat” can examine CVL as a marker of transmission probability, to evaluate the effectiveness of the strategy, as well as a proximal marker for HIV incidence (Granich et al. 2011). As clinics or health systems increase efforts to increase the prompt initiation of ART to achieve durable virologic suppression, CVL measures for a provider panel, different clinics, or parts of health systems can be used to monitor quality of HIV care.

Critiques and Limitations

There are several potential limitations about the estimation of CVL using different data sources as well as critiques regarding the interpretation of the applications of CVL.

Case Registry and Surveillance Data

When CVL is calculated using an HIV/AIDS case registry from public health surveillance data, the accuracy of the CVL estimate is affected by the testing efforts and the timeliness and completeness of HIV case reporting in that jurisdiction. The CVL estimate is further limited by the fact that the HIV case registry contains only the information from those individuals who have been diagnosed and reported in a jurisdiction, presenting two significant issues. First, a public health case registry does not include persons who are unaware of their HIV status, which includes any persons in the acute phase of infection who may have a negative

HIV antibody and high VLs – a population that may account for a disproportionate number of onward infections (Cohen et al. 2012; Das et al. 2010; Smith et al. 2012; Wilson 2012). These gaps in the calculation of CVL cannot be addressed using current standards of public health surveillance but may change in the future as HIV testing technology advances and policies are updated. However, it will continue to be very difficult to include estimates of VL from acutely infected persons who will rarely be detected in population-based surveys or public health surveillance systems. For those individuals who are chronically infected but as of yet undiagnosed, population-based surveys – such as National HIV Behavioral Surveillance, a CDC-coordinated series of population-based, and cross-sectional surveys among populations at risk for HIV in 21 US cities (Gallagher et al. 2007) – can provide an estimation of the VL distribution of those chronically infected but unaware of their HIV-positive status. Second, there may be individuals who are in the case registry but who may be missing VL data. This may be because the individual is in care but not having VL testing for a variety of reasons, e.g., difficult venipuncture, not on ART, or because the individual is out of care and not being monitored. Individuals in a case registry may also be missing VL data because surveillance departments have historically defined HIV/AIDS case ownership for a particular jurisdiction as those diagnosed within that jurisdiction. This essentially means that an individual diagnosed and reported in a particular jurisdiction remains on the case registry for that jurisdiction, even if they move to another jurisdiction. Earlier in the epidemic, especially when many jurisdictions primarily had AIDS-only case reporting, this attribution of cases was reasonable. In the current era, many people diagnosed with HIV have much longer life expectancies and can feasibly be expected to move out of the jurisdiction in which they were diagnosed. Current laws and policies around exchanging information regarding HIV cases between jurisdictions, especially between states, hamper the ability of surveillance registries to confirm whether a person has moved out of the

jurisdiction. As a result, CVL estimates derived from surveillance case registries may (1) exclude those who live and are receiving care in the jurisdiction but were diagnosed elsewhere and therefore will remain a case within their jurisdiction of diagnosis and (2) be hampered by jurisdictional HIV cases which are missing data because the individual has moved out of the jurisdiction and no longer are having clinical data such as VLs reported to the public health department. The former limitation can be addressed by simply including VL data from those living in the jurisdiction but diagnosed elsewhere. The latter limitation can potentially be addressed with statistical techniques such as multiple imputation to predict VL values for those missing, assuming that individuals who are missing data are missing VL data at random. The assumption that the data are missing at random holds for the majority of cases if most VLs are missing because individuals moved. However, if most individuals are missing VLs because they are out of care, there is a systematic bias and multiple imputation should not be used. Lastly, there will be individuals who were diagnosed elsewhere who have moved into a particular jurisdiction but are not in care. There is not a way to quantify those individuals, who most likely have detectable VLs and are in need of care, unless surveillance registries are allowed to share information across jurisdictions, including across state and other territorial lines. In calculating and interpreting CVL estimates from surveillance case registry data, it is vitally important to have estimates of completeness and timeliness of case reporting, as well as completeness of current address data, and status of efforts to de-duplicate cases across jurisdictions.

Clinical or Cohort Data

Many of the concerns raised above could potentially be addressed by calculating CVL estimates from clinical databases or cohort studies of HIV-positive individuals. These estimates are likely to be more complete than estimates from the surveillance registry. However, these estimates are less generalizable beyond the clinical system or

cohort study and may reflect more the quality of care in a particular clinic system than the effectiveness of combined HIV prevention, treatment, and care interventions in an entire jurisdiction. Exceptions to this concern would include a cohort which purportedly contains all HIV-positive individuals in a geographic area, for example, all PWID in Vancouver (Wood et al. 2009), which demonstrated that the cohort VL predicted HIV incidence density 6 months later; however, there have been critiques challenging whether CVL can be used as a proximal marker for HIV incidence and potential epidemic propagation.

Alternative Explanations

The aforementioned hypothesis that increases in testing and treatment uptake will reduce population-level viremic burden, as measured by CVL, which will reduce HIV transmission, has been challenged (Cohen et al. 2012; Smith et al. 2012; Wilson 2012). Alternative explanations to account for reductions in HIV incidence have been posited, such as ecologic fallacy or reductions in risk behavior including serosorting or decreased syringe sharing. Cohort studies are able to adjust for individual-level risk behavior and address these critiques. In analyses conducted with HIV case registry data, triangulating data from other public health surveillance data – such as trends in rectal gonorrhea cases which reflect rates of unprotected anal intercourse among MSM – can be examined to evaluate the role of changing sexual risk behavior. Finally, while neither the biologic plausibility of the relationship between HIV viremia and HIV transmission nor the role of ART-mediated virologic suppression in reducing HIV transmission has been challenged, questions have been raised as to whether, at the population level, it is prevalent viremia rather than HIV prevalence driving HIV infection.

Conclusion

It has long been recognized that examining trends in newly diagnosed HIV cases and HIV

prevalence is no longer sufficient to track the full burden of HIV disease or the potential for further transmission; this point is all the more true in the current era of wider use of ART and reduction in transmission due to ART-mediated virologic suppression (Cohen et al. 2011). Moreover, direct measures of HIV incidence and acute infection face logistical and theoretical challenges and are consequently rare on a population level. In the context of expanded efforts to promote earlier and durable viral suppression, the measure of CVL provides additional insight to mitigate the effects of HIV and thereby reduce transmission. In the United States with a well-characterized epidemic and mature surveillance systems, establishing a baseline for CVL and population-level virologic suppression rates and examining temporal trends in these measures can help evaluate the impact of the National HIV/AIDS Strategy and the Affordable Care Act on the health outcomes of people living with HIV. Internationally, mapping CVL trends may contribute to understanding the stage, progression, and spread of HIV as well as the effectiveness of ART scale-up. Additionally, mapping the spatial distribution of CVL may delineate new “hotspots” or areas that have high HIV incidence, allowing a rapid response to target resources and interventions to populations at greatest risk. In summary, monitoring trends in CVL can help to characterize the burden of disease within a community, efficiently target resources, identify disparities, and help set goals for maximizing outcomes along the implementation cascade and ultimately achieving health equity. Examining CVL trends in upcoming international individual and community cluster randomized trials of ART as prevention (Granich et al. 2011) will further refine the current understanding of the relationship between population-level viremic burden and HIV transmission.

Comorbidity: Opioids

Thomas J. Rogers

Center for Inflammation, Translational and Clinical Lung Research, Temple University School of Medicine, Philadelphia, PA, USA

Definition

Opiate abuse is a major global health concern, due to the fact that the HIV infection frequently occurs in individuals who abuse opiates. Both clinical and preclinical evidences show that opiate abuse impairs resistance to opportunistic infections and alters both innate and adaptive immunity. Moreover, opiate use results in greater susceptibility to the development of neurodegeneration that can occur in association with HIV infection. Opioid drugs, most notably morphine and heroin, exert both pro- and antiinflammatory activities for the immune system and, following HIV infection, can exert direct neurotoxic effects on neuronal cells. In addition, opiate administration exacerbates the neurotoxic properties of some of the HIV products, and these drugs can alter blood-brain barrier integrity. Finally, the activation of opioid receptors by morphine or heroin can alter both the expression and function of the major HIV coreceptors CCR5 and CXCR4. Taken together, opiate abuse has the potential to contribute substantially to the pathology associated with this infection.

Introduction

Opiate drug abuse is a major contributor to the global AIDS epidemic, and approximately 35% of HIV infections in the USA are linked to intravenous drug abuse. Moreover, global estimates show that 20% of intravenous drug abusers are infected with HIV (Mathers et al. 2010). Due to the increase in the misuse of prescription opioid drugs in the USA, chronic opioid abuse is a growing problem. Both clinical and basic research

shows that heroin or morphine inhibits elements of both adaptive and innate immune responses, and this leads to a decline in resistance to a number of opportunistic infections (Dutta and Roy 2012). For patients who become infected with HIV, the use of shared needles offers a portal of entry for the virus. It is not clear that the opiate use necessarily alters susceptibility to HIV infection by this route. However, clinical evidence indicates that opiate abuse leads to higher rates of encephalopathy following HIV infection when compared to infected nondrug abusers (Bell et al. 1996).

Opiates and Opioid Receptors

The use of alkaloids derived from the seedpods of the opium poppy *Papaver somniferum* has been common for centuries. Heroin, or diacetylmorphine, is chemically synthesized from opium, and morphine is the major bioactive metabolite of heroin. Three opioid receptors have been identified (designated μ -, κ -, and δ -opioid receptors), and while morphine is primarily an agonist for the mu-opioid receptor (MOR), this drug can also activate the δ - and κ -opioid receptors (DOR and KOR). This is an important issue since MOR and KOR can mediate opposing activities in cells of the immune system. The opioid receptors are expressed in both the central and peripheral nervous system by most of the neuronal cell types, and it is now clear that these receptors are also expressed by hematopoietic cell populations. It is important to appreciate that levels of expression vary depending on the tissue location and leukocyte subtype.

Opioid-Mediated Neurotoxicity

Opiates exert both direct and indirect toxic effects on neuronal cells, and this is important given the higher rates of encephalitis in opiate abusers who are infected with HIV. For example, morphine exerts a direct toxic effect on Purkinje cells in vitro, and the MOR agonist fentanyl induces damage to the limbic system when administered to rats in vivo. MOR-selective opiates also

exacerbate cerebral ischemia in the forebrain, and this may be due, at least in part, to the capacity of these drugs to exert a proapoptotic effect when combined with other apoptotic agents. This is consistent with findings which show evidence of astrogliosis and inhibition of dopaminergic function of tyrosine hydroxylase terminals in the nucleus accumbens in heroin abusers. Moreover, chronic administration of either morphine or heroin in rodents results in reduced striatal levels of synaptic dopamine and dopamine transporter. These findings suggest that opiate administration, particularly when given chronically, exerts a neurotoxic effect, and these effects have been associated with the accumulation of perivascular macrophages and lymphocytes (Hauser et al. 2012).

This suggests that the opiate-mediated toxicity is the result of an inflammatory response, and this is somewhat surprising given the well-documented capacity of opiates to exert immunosuppressive activity (Dutta and Roy 2012). It is now apparent that MOR activation can have pleomorphic effects on the immune response, and this is particularly apparent with respect to the inflammatory response. Morphine administration inhibits the expression of several proinflammatory cytokines, including interferon- γ (IFN γ), interleukin-2 (IL-2), tumor necrosis factor- α (TNF α), IL-1, and IL-12 (Roy et al. 2006). Morphine also upregulates the expression of the immunosuppressive cytokine transforming growth factor- β (TGF β). In contrast, administration of morphine or other MOR agonists has been shown to induce increased expression of the proinflammatory chemokines CCL2, CCL5, and CXCL10 (Wetzel et al. 2000) and the proinflammatory chemokine receptors CCR5 and CXCR4 (Steele et al. 2003). These apparently opposing effects of opiates on the inflammatory response suggest that opiates exhibit a complex immunomodulatory effect on the immune response.

Opiate administration may also promote neurodegeneration by degrading the integrity of the blood-brain barrier (BBB). Morphine has been shown to inhibit the expression of the tight-junction zona-occludin proteins and increase the

production of the junctional adhesion molecule-1, resulting in increased BBB permeability. Morphine also upregulates the production of platelet-derived growth factor (PDGF) by brain microvascular endothelial cells, a mediator which can contribute to ischemic stroke, and this cytokine weakens BBB stability. This cytokine is also produced by a subset of macrophages which are referred to as “alternatively activated” or “M2” cells, and in general these cells exert a pro-fibrotic effect in inflamed tissues. The accumulation of macrophages in the perivascular space in the brain in HIV-infected patients may provide a source of PDGF which can act locally to promote additional recruitment of inflammatory cells.

Opioid-HIV Interactions Associated with Neurodegeneration

Recent evidence shows that the combination of opioid abuse with HIV infection creates a greater level of neurodegeneration than observed with virus infection or opiate use alone. It is well established that MOR opiates directly induce functional activation of neuronal cells including neurons, microglia, astrocytes, neuronal precursors, and oligodendrocytes, as one would expect since each of these cell populations express MOR. However, when HIV infection is combined with mu opiates, a greater degree of toxicity is induced, and astrocytes and microglia are the primary targets (reviewed in (Hauser et al. 2012)). HIV products, including gp120 and tat, which are released from infected cells into the surrounding brain tissue, exert potent proinflammatory direct effects on microglia and astrocytes. It is clear that other neuronal cells, including neurons, are susceptible to the toxic effects of these inflammatory mediators, and altered neuronal function is the end result of the combination of these direct and indirect effects of opiates and HIV products.

The activation of both microglia and infiltrating perivascular macrophages is a hallmark of the histopathology that is observed with HIV infection (Hauser et al. 2012), and the degree of activated microglial/macrophage infiltration correlates with the severity of HIV-associated

neurocognitive disease (HAND). Research carried out with experimental animals shows that systemic administration of morphine induces an increase in the infiltration of inflammatory cells at sites of HIV Tat injection. This is consistent with the observation that the abundance of both macrophages and activated microglia in the gray matter of the thalamus and hippocampus is greater in opiate abusers.

Astrocytes are not targets for productive infection with HIV, but these cells are susceptible to the potentially toxic products of HIV that are released from infected microglia and macrophages. Astrocytes perform a number of critical functions in the maintenance of neuronal cells and are essential for the integrity of the BBB. Toxic products elicited from HIV-infected cells lead to astrocyte damage, and this can exacerbate the neurodegenerative effects of HIV infection through the release by astrocytes of potentially toxic mediators such as nitric oxide and proinflammatory cytokines. This mix of HIV products and astrocyte mediators collectively serves to promote HIV-mediated neuropathology. Moreover, the combination of morphine and HIV Tat can augment cytokine and chemokine expression and astrocyte death (Hauser et al. 2012). Both HIV Tat and gp120 induce astrocyte activation, and this results in the production of elevated inflammatory cytokines and chemokines. The combination of these HIV products with elevated MOR opiates boosts astrocyte activation, leading to greater glutamate release and a drop in the glutamate excitation threshold.

Neurons are also directly susceptible to the toxic effects of HIV products including Tat, gp120, and Vpr, and their release into the brain interstitium results in neuronal damage. As these HIV proteins are produced by macrophages and microglia, the expression of opioid receptors by these cells drives a response to endogenous and exogenous opioids which promotes HIV-related toxicity. Current evidence suggests that opiate exposure reduces the threshold required for HIV product-mediated neuropathology. There is growing evidence that opiate abuse leads to an exacerbation of HIV-induced synaptodendritic damage, and this damage directly contributes to the

development of neurobehavioral abnormalities. The administration of MOR agonists in the presence of products of HIV infection leads to a reduction in the complexity of dendrites and lessens the density of dendritic spines.

Immune Activation

It is clear that the opiate contribution to neurodegeneration is due in part to the MOR-dependent induction of a proinflammatory immune response. This may initially seem surprising since MOR agonists are capable of exerting antiinflammatory activity in many circumstances. It is well established that MOR agonists, including heroin, morphine, and endogenous opioid neuropeptides (including the MOR-selective agonists endomorphin-1 and endomorphin-2), are all capable of modulating proinflammatory cytokine expression. The degree of immunomodulation can be substantial, and this has led some to speculate that a major mechanism for the immunomodulatory activity of opioids is mediated through altered cytokine expression (Dutta and Roy 2012). Altered cytokine expression could provide a common basis for the well-documented opioid-mediated modulation of innate immunity and both cell-mediated and antibody-mediated adaptive immune responses. Based on both *in vivo* and *in vitro* studies conducted using both human and experimental animal systems, it is clear that MOR opiate administration alters both pro- and antiinflammatory cytokine expression (Rogers and Peterson 2003). For example, morphine induces a significant inhibition of the human peripheral blood leukocyte expression of the very proinflammatory cytokines IFN γ and IL-2. Morphine has also been reported to inhibit the human and murine leukocyte production of the highly proinflammatory cytokines IL-1 β , TNF α , and IL-12, although under certain conditions the effect of morphine treatment on the expression of these cytokines may be the opposite. Overall the activation of MOR leads to alterations of both pro- and antiinflammatory cytokine expression, and the selectivity of these immunomodulatory activities is not fully understood.

Balance in the immune response, and control of inflammatory responses, is maintained in part through the production of antiinflammatory cytokines which include both IL-10 and TGF β . These cytokines are typically produced during an inflammatory response, and while they may not be sufficient to terminate an inflammatory response, they often reduce the intensity of the inflammation and attenuate the expression of some of the proinflammatory cytokines. The levels of TGF β in the CNS are elevated in AIDS patients, as well as several other neurodegenerative disease states, including multiple sclerosis and Alzheimer's disease. The astrocytosis which is frequently observed in the brain tissue of HIV-related dementia patients is attenuated by TGF β , and this is likely due to the ability of this cytokine to inhibit the response of astrocytes to growth signals. In addition, TGF β reduces the expression of several proinflammatory cytokines in the CNS, including IL-1 and TNF α , and downregulates the production of potentially toxic glutamate and nitrogen oxide. These anti-inflammatory activities are beneficial for the brain tissue in the HIV-infected patient and serve to limit the toxicity of proinflammatory cytokines and HIV products.

The administration of MOR opiates upregulates TGF β expression, and the production of this cytokine has been shown to be responsible for the downregulation of TNF α under conditions of immune activation. However, TGF β is also a cytokine that exhibits proinflammatory activity under certain circumstances. For example, MOR opiates induce the expression of the proinflammatory chemokine CCL5, and the opioid-induced upregulation of this chemotactic cytokine is dependent on the initial induction of TGF β expression (Happel et al. 2008). Moreover, TGF β has been shown to enhance the adhesive properties of monocytes by inducing the expression of both lymphocyte function-associated antigen-1 (LFA-1) and the fibronectin receptor. These effects are likely to promote the adherence of monocytes to vascular endothelial cells and enhance the traffic of these cells across the blood-brain barrier.

Studies conducted on the expression of the chemokines have, for the most part, shown that

treatment with MOR agonists increases expression. The consequences of the influence of opiate administration are particularly significant, given the critical role of chemokines in the neurodegeneration associated with HIV infection. These cytokines are essential for the migration of infected and noninfected but activated monocytes into brain tissue where these cells reside in the perivascular space. The most important of the chemokines for the traffic of infected monocytes across the BBB is CCL2, but other chemokines including CCL3, CCL4, CCL5, and CX3CL1 are also involved. Recent evidence suggests that a relatively minor subpopulation of monocytes which express both CD14 and CD16 (designated “nonclassical monocytes”) are preferentially susceptible to infection by HIV, and the migration of these cells across the BBB appears to be driven in part by CX3CL1. The receptor for CX3CL1, CX3CR1, is strongly expressed by CD14+16+ monocytes, and this population expresses viral pattern recognition receptors. By virtue of the “viral-response” nature of their receptors, this monocyte subpopulation performs “patrolling” functional activity as a part of antiviral immunity (Geissmann et al. 2010). Nevertheless, the expression of these chemokines, particularly CCL2, increases in the brain as the infected monocytes differentiate into macrophages and the levels of CCL2 increase.

The expression of the critical chemokine CCL2 increases with exposure to elevated levels of MOR agonists, including morphine (Wetzel et al. 2000). Opiate administration also induces significant increases in the expression of chemokines CCL5 and CXCL10 from both HIV-infected and noninfected monocytes and macrophages. The production of both of these chemokines, particularly in the presence of elevated levels of CCL2, would be expected to promote the attraction of additional monocytes into the infected tissue. In addition, the combination of morphine and HIV Tat administration has been shown to upregulate the production of CCL2, CCL3, and CCL5 from astrocytes (El-Hage et al. 2005). As the HIV infection proceeds in the brain, the accumulation of HIV products such as Tat and gp120 promotes a

proinflammatory cytokine response, and much of this response is augmented in the presence of elevated levels of MOR opiates.

The localized inflammation in the brain tissue of HIV-infected patients is an important contributor to the progression of disease. It is also important to consider that systemic inflammation is also an important aspect of HIV pathogenesis, both for the neurodegenerative disease and for peripheral manifestations of the disease. There is good evidence that systemic inflammation contributes to the development and severity of HAND, and biomarkers of systemic inflammation can correlate well with symptoms of neurodegeneration. Of course, systemic inflammatory processes are well established to contribute to HIV replication both in the brain and in the periphery, but systemic inflammation promotes neurodegeneration independent of the replication of the virus. For example, recent clinical studies show that circulating levels of the proinflammatory biomarkers C-reactive protein (CRP), D-dimer, IL-6, and fibrinogen are significant predictors of mortality in HIV-infected patients. Moreover, systemic proinflammatory biomarker levels exhibit predictive significance independent of circulating viral titers or CD4 T cell counts.

Most HIV-infected patients exhibit detectable evidence of systemic “immune activation,” and this is consistent with the systemic biomarker evidence described above. Immune activation in these patients is, in large part, the result of microbial translocation in the gut, and this is likely to be a common element of the pathogenesis of this infection. Results from a number of studies show that deterioration of the gut wall occurs following infection, which compromises the integrity of the gut wall epithelium, leading to translocation of gut flora through the wall and the appearance of microbial products in the blood. This process leads to elevated levels of gram-negative bacterial endotoxin in the bloodstream and the activation of leukocytes through endotoxin-responsive toll-like receptors. The levels of endotoxin in the plasma obtained from these patients significantly correlate with the progression of the disease, and circulating monocytes can exhibit impaired (or refractory)

responses *in vitro* to endotoxin suggesting that these cells were pre-stimulated with endotoxin in the bloodstream. There is also a loss of lymphocytes from the gut-associated lymphoid tissue as a part of this process, and the reduction in the levels of these cells contributes substantially to the drop in circulating lymphocytes in a portion of these patients.

The contribution of opiates, particularly the chronic use of MOR agonists such as heroin or morphine, on the bacterial translocation process in HIV-infected patients is largely unknown. However, studies carried out with slow-release pellet delivery of morphine in mice show that a high percentage of these animals develop bacterial sepsis as a result of bacterial translocation (Hilburger et al. 1997). This result is very significant given the critical role of immune activation in the progression of HIV-related disease. Additional work will be necessary to evaluate the effect of the combination of both HIV infection and chronic opiate administration on bacterial translocation and the resulting immune activation.

Interactions Between Opioid and Chemokine Receptors

The major coreceptors for HIV-1 are CCR5 and CXCR4, two chemokine receptors which are also important for inflammatory responses. The HIV-1 envelope protein, gp120, binds to either CCR5 or CXCR4, or both, and this is required for attachment and subsequent internalization of the virus. HIV gp120 is a highly polymorphic protein, and those strains of HIV-1 which express a gp120 sequence which binds predominantly to CCR5 (rather than CXCR4) are monocyte/macrophage tropic (R5 strains). Virtually all HIV-1 strains isolated from the brain are R5 tropic, and this is somewhat surprising since the expression of CXCR4 in the brain is upregulated in patients with HAND, while the expression of CCR5 in these patients is reduced. This is in contrast to isolates obtained from the blood during the later stages of AIDS, which are frequently either CXCR4-dependent T cell tropic (X4 tropic) or dual R5/X4 tropic.

The acute administration of MOR opiates induces the leukocyte expression of both CCR5 and CXCR4, and this effect appears to be most prominent for monocytes and T cell lymphoblasts. As expected, the increase in expression of CCR5 and CXCR4 is closely associated with an increase in susceptibility to infection by R5 and X4 strains of HIV-1, respectively (Steele et al. 2003). Moreover, the opioid-induced increase in expression of CCR5 is likely to promote the capacity of monocytes and T cells to migrate within and between tissues and would increase the distribution of infected cells in the body.

The activation of MOR by opiate administration also leads to the regulation of chemokine receptor functional activity through a process of cross-desensitization (or “heterologous desensitization”). Cross-desensitization is believed to be a common element of the regulation of G protein-coupled receptor (GPCR) functional activity. This process takes place when a GPCR is activated and initiates a signaling pathway which leads to the inactivation (or desensitization) of an unrelated GPCR. There is a hierarchy of GPCRs which has been documented, so that there is a group of GPCRs that are strong inducers of cross-desensitization, while other GPCRs are moderate or weak inducers. Similarly, the strongest inducers are typically the least susceptible to the process of cross-desensitization (Steele et al. 2002). It is apparent that the activation of MOR leads to the cross-desensitization of susceptible GPCRs, including CCR5, CCR1, CCR2, CXCR1, and CXCR2, but not the formyl peptide receptor or CXCR4 (Szabo et al. 2003). Additional works show that the MOR-induced desensitization of CCR5 also results in a loss of the ability of CCR5 to function as an HIV coreceptor. The signaling pathway responsible for the cross-desensitization of CCR5 is dependent on the activation of PKC ζ , and this signaling pathway is induced within the first 5–10 mins following activation MOR. Recent results show that an unrelated signaling pathway is also induced by MOR in the CNS which results in the inactivation of neuronal CXCR4 functional activity, and while this pathway requires a longer induction period, the desensitization of CXCR4 leads to a loss of the

neuroprotective activity of CXCR4 (Patel et al. 2006).

Taken together, the interaction of MOR with CCR5 is particularly significant given the impact on susceptibility to HIV infection. It appears the administration of MOR opiates induces a change in CCR5 functional activity that is composed of two phases. In the first or early phase, MOR activation induces a rapid desensitization of CCR5 functional activity. This occurs without loss of CCR5 from the outer membrane and persists for several hours. This period can be sustained for longer periods of time with prolonged exposure to the MOR opiates. This first phase is followed by a delayed phase, which begins at about 24–48 h, and is composed of elevated CCR5 and CXCR4 expression. The increase in the expression of CCR5 in the second phase is associated with elevated susceptibility to infection with R5 HIV, while the decrease in CCR5 functional activity in the first phase is associated with decreased susceptibility. More work is necessary to evaluate the impact of long-term or chronic exposure to MOR opiates on the HIV coreceptor activity of CCR5.

Conclusion

Recent advances have improved our understanding of the impact of opiate administration on the neurodegeneration associated with HIV infection. It is now clear that opiates participate in this process at several levels. First, the exposure to MOR opiates alters the expression and functional activity of the HIV coreceptors, and this is likely to alter the progression of the infection both in the periphery and in the CNS. Second, MOR opiates alter the transit of infected leukocytes, and activated monocytes, across the blood-brain barrier. Third, opiate exposure increases the degree of immune activation as a result of the deterioration of the gut mucosa (see chapter on ► [Chronic Immune Activation in HIV](#)). And fourth, MOR opiates contribute to the pathology in the CNS that is promoted by products of HIV infection. The combination of these effects on the progression of neurodegeneration is clearly very

complex, and the variability that occurs between individuals is likely to be due to individual variances in the degree or intensity of one or more of these individual opiate effects. Finally, there is still a great deal that we need to learn in order to have a complete understanding of the comprehensive effects of chronic opiate abuse. For example, research at this point has placed emphasis on our understanding of the effects of opiates alone on the pathology associated with HIV infection. However, the actual clinical situation is much more complex, and we need to evaluate the impact of chronic opiate exposure in the context of the use of other drugs, including both long-term tobacco use and alcohol abuse. Of course, these additional considerations create a much more challenging research area, but in the end should yield information which is more clinically valid.

²Department of Neurology, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA

Introduction

Progressive multifocal leukoencephalopathy (PML) is a progressive infection of the brain by reactivation of the JC virus that manifests

clinically as a subacute decline in neurologic function in the setting of significant immune suppression. It was first named in 1958 after histological definition of autopsy cases. All patients suffered underlying lymphoproliferative disorders (Astrom et al. 1958). PML has since continued to be a rarely occurring complication of these diseases, such as myelodysplastic syndrome, chronic lymphocytic leukemia, and Hodgkin disease. Reviewing the world's publications through 1984 and adding cases from their own extensive experience, Brooks and Walker were only able to identify 230 cases (Brooks and Walker 1984). With the emergence of the HIV pandemic, PML became exponentially more common, typically emerging in the HIV-infected when CD4 counts waned below 200 cells/ μ L. In fact, it was diagnosed in 4% of the HIV-infected population (Berger et al. 1998), and mortality was high, with only 10% survival at 1 year. With the advent of combination antiretroviral therapy (cART), JC virus (JCV) was recognized to be a target for the reconstituting immune system, provoking the immune reconstitution inflammatory syndrome (IRIS) in a subset of those recently started on treatment. This created a complicated conundrum, as the only unequivocally effective treatment for PML is restoration of immune function.

PML reached its next stage of recognition in 2005 when three cases were discovered complicating the use of natalizumab, an α 4 integrin inhibitor used in the treatment of multiple sclerosis and Crohn's disease. This precipitated the drug's temporary removal from the market, but in 2006, it was reintroduced with intensive ongoing scrutiny. Three factors have been identified as increasing the risk of natalizumab-induced PML, namely, JCV serostatus, duration of natalizumab treatment, and prior immunosuppressive therapy. Those without JCV antibodies had a risk of <0.09/1,000 patient years, but those with all three risk factors had a risk of 11.1/1,000 patient years (Bloomgren et al. 2012). Once patients developed PML associated with its use, the standard protocol is immediate discontinuation of the drug. Plasma exchange has been used frequently in order to remove drug expeditiously from the patient's circulation, but this may precipitate an

IRIS phenomenon, which in some cases can be fatal.

Concomitantly with the introduction of natalizumab, the use of other biologic immunosuppressive therapies for the treatment of a variety of autoimmune diseases and malignancy was recognized to potentially increase the risk of PML. These medications include rituximab, efalizumab, adalimumab, infliximab, etanercept, brentuximab vedotin, dimethyl fumarate, and ruxolitinib among others. Mycophenolate mofetil has also been implicated, and it is likely that careful study will identify a risk, albeit small, for widely used immunosuppressive agents. Notably, the association of rituximab and PML actually predated that of natalizumab (Goldberg et al. 2002), but until the latter entered the limelight, little attention was paid to the former. Although currently still dwarfed by the number of AIDS-related cases, in developed countries where HIV control has substantially improved from early in the disease and autoimmune disease is common, the growth in number of iatrogenic PML cases has spawned new fear of this disease (Fig. 1).

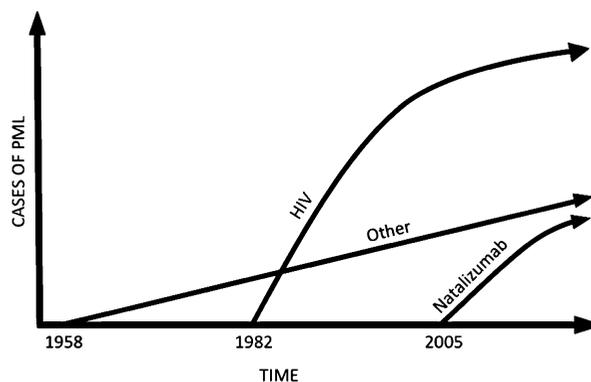

Epidemiology and Evolution of JC Virus

The JC virus is ubiquitous throughout the world. It has been divided into seven types by sequencing

complete genomes and determining coding region polymorphisms. The types are labeled 1–8, with several subtypes (indeed, type 5 is actually a subtype of 3) (Ferenczy et al. 2012). Virus types have been used to track human migration patterns, and all seem to have originated in sub-Saharan Africa.

Type 6 is thought to be the original virus from which other types evolved (Hirsch et al. 2013). The major types in North America are 2A, coming from Asia via the Northwest, and 4, which came trans-Atlantically from Europe. The different types appear to impact clinical disease expression. Differences in VP1 between type 4 and type 2B, the latter of which is common in Eurasia, are associated with lower and higher PML risk, respectively (Ferenczy et al. 2012; Hirsch et al. 2013).

Around 70–80% of adults are found to be seropositive for JCV antibodies (Berger 2010), and most initial infections are thought to occur during childhood. Since seroprevalence increases with advancing age, it follows that those not infected as children have a high risk of asymptomatic infection at some point. A single negative titer in an adult may need to be repeated in the future if there is new concern for risk, as there remains both a risk of JCV infection into adulthood and currently employed serological tests have substantial false-negative rates (Berger et al. 2013). Since the majority of all populations regardless of demographics are exposed to JCV, it

Comorbidity: Progressive Multifocal Leukoencephalopathy, Fig. 1 Graphic representation of cumulative PML cases (X axis) over time by associated condition. PML was first described in 1958 as a complication of hematologic malignancy and has been steadily associated with this and several autoimmune conditions at a low rate

since. In 1982, HIV heralded an exponential increase in the diagnoses of PML due to the AIDS pandemic. With the use of biologics, most notably natalizumab for relapsing-remitting multiple sclerosis, came the inception of a third wave of PML diagnoses

logically follows that the epidemiology of those who develop PML reflects that of the underlying predisposing condition. For instance, in the 1980s and 1990s, mostly men aged 20–50 were affected (Berger et al. 1998), pursuant to the epidemiology of HIV. Since 2005 when natalizumab became a dominant risk factor, the epidemiology in that population follows that for MS in general, being mostly young adult females (Bloomgren et al. 2012).

JCV antibody positivity is measured by a variety of mechanisms all targeted at the main capsid protein, VP1. Seropositivity is higher in those above the age of 60 and in men. Reported false-negative rates vary from 2.5% to 2.7% (Hirsch et al. 2013) to more than 30% (Berger et al. 2013). This latter observation is important in iatrogenically immune-suppressed populations at risk for PML such as those with MS receiving natalizumab, as a negative JCV antibody could be misconstrued as conferring lower risk of disease (Major et al. 2013). However, the JCV antibody is not protective, and the fact that deficiencies in cell-mediated immunity predispose to PML demonstrates that humoral immunity has no or little role in clearing reactivated virus.

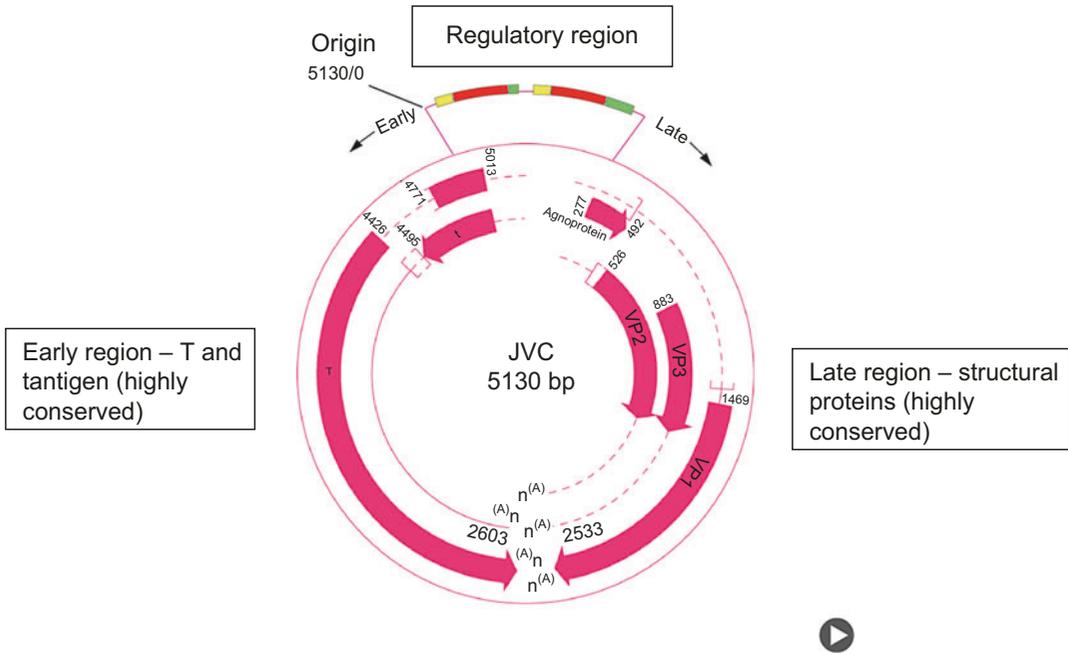

Molecular Biology of JC Virus

PML was named in 1958 when Aström, Mancall, and Richardson described it pathologically; they are credited for initial pathological descriptions, although in their review in the literature, they raise the possibility that earlier investigators may have reported the same disease (Astrom et al. 1958). The initial descriptions were all entirely pathologic. They detailed large plaques of myelin breakdown in the subcortical white matter involving U fibers and even the deepest layers of cortex, but largely there was axonal sparing. These plaques started small and often posteriorly, but became progressively larger to the point of confluence. The investigators also remarked about reactive astrocytes of bizarre shapes and sizes as a commonality among cases. Macroscopic exam did not show lesions in the brainstem or cerebellum. The precise etiology of the lesions was

unknown. In 1959, Cavanagh and Greenbaum proposed a viral etiology given the electron microscopic appearance of nuclear inclusion bodies in the enlarged oligodendrocytes (Cavanagh et al. 1959) that appeared to be what is seen in papovavirus infection. This virus was not previously known to result in central nervous system disorders. Subsequently, Padgett described confirmation of papovavirus as the culprit after viral isolation from glial cell cultures of a patient with PML named John Cunningham (Padgett et al. 1971), whose initials became attached to this new polyomavirus, formerly a genus of the *Papovaviridae* family. Other polyomaviruses include Merkel cell, BK, and SV40. Although there previously have been descriptions of PML associated with these latter two viruses, those reports remain questionable (Stoner and Ryschkeiwitsch 1995).

JCV replication is only possible in human cells, and therefore, there are no animal models for PML. Among the attempts to understand the biology of JCV in an animal model is the development of a humanized mouse model of the virus (Tan et al. 2013). Immune-deficient, irradiated mice transplanted with human fetal bone marrow, thymus, and liver produce a replica of the human immune system, after which they are inoculated with either archetype virus (whose noncoding region matches that from JCV isolated from urine of asymptomatic individuals) or prototype JCV (whose noncoding region matches that from subjects with PML), also known as Mad-4. Inoculated animals remained asymptomatic, but JCV was detected in urine and/or blood periodically from several of the mice. This provides a basic framework for animal study of JCV and promises future advances in the study of PML specifically. Additionally, it may provide a platform in which to study therapeutics given that currently there are no specific effective medications to combat PML. Another animal model that has been proposed for the study of CNS infection with polyomavirus is the SHIV-infected rhesus monkey (Axthelm et al. 2004). Despite these efforts, there remains no animal model of PML.

JCV is a non-enveloped, double-stranded, circular DNA virus within an icosahedral capsid

Comorbidity: Progressive Multifocal Leukoencephalopathy, Fig. 2 The JC virus genome

(Fig. 2). The genome encodes early and late transcripts by counterclockwise and clockwise transcription, respectively. A total of six proteins are encoded, and additionally there is a 200-base pair noncoding region that helps orchestrate tropism to the nervous system and neurovirulence. Notably, differences in the noncoding region are found in the isolates of JCV from urine of asymptomatic individuals and those from the brains of patients with PML. Although it is unknown which type causes primary infection, the ubiquity of the archetype JCV in urine strongly implies that most, if not all, persons are initially infected with that form of the virus and in those individuals developing PML, alterations in the genomic sequence in the noncoding control region (NCCR) convert the virus to a neuropathogenic strain (Berger and Khalili 2011). T antigen, an early, nonstructural protein, directs expression of the alternatively spliced transcript, which encodes three structural proteins and agnoprotein. T antigen also hijacks cell cycle machinery for replication, arresting the cell in S phase. This has potential for oncogenesis, but the role of JCV in promotion of tumors in humans remains

controversial (Beltrami and Gordon 2013) despite its association in vitro (Walker et al. 1973). The three structural proteins, VP1, VP2, and VP3, comprise the capsid. VP1 is the principal component of the virus's structure, making pentamers that assemble into an icosahedral capsid. It is responsible as such for viral binding to host cells; notably, a mutation in VP1 appears to be responsible for the ability of JCV to infect cerebellar granule cells, producing a clinically distinct clinical syndrome from PML referred to as JC virus granule cell neuronopathy (Dang and Koralknik 2006). VP2 and VP3 are present at a fraction of the amount of VP1 and are integral in viral assembly and subsequent uncoating and delivery. Agnoprotein assists in cell cycle dysregulation and interferes with DNA repair in order to promote viral replication; mutant forms of this protein enable JCV to productively infect cortical pyramidal neurons, producing JCV encephalopathy, another clinically distinct entity from PML (Dang et al. 2012). A small T-antigen protein is an early protein associated with JCV pathogenicity (Beltrami and Gordon 2013).

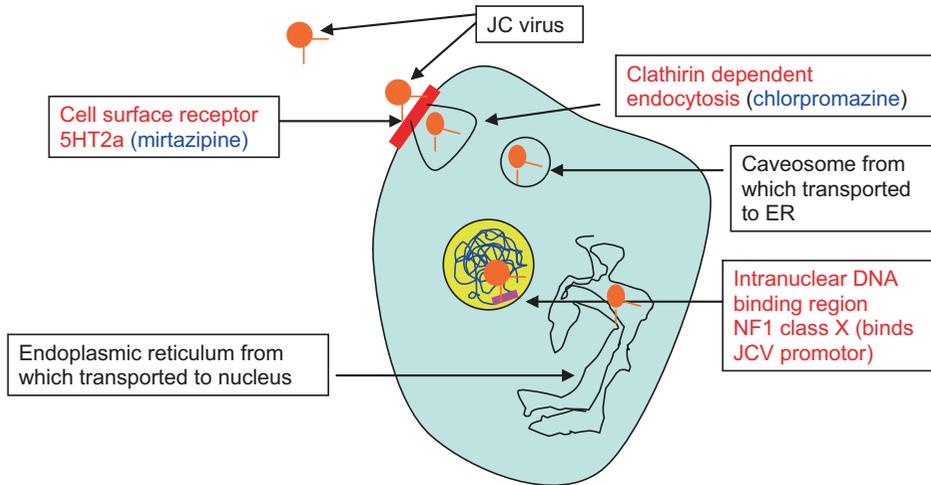

Pathogenesis of PML

Initial infection by JCV generally occurs within the first two decades of life, based on antibody seropositivity of up to 70–80% in adults (Berger 2010), and is asymptomatic. The inoculation site is thought to be along the oral or respiratory routes; JCV DNA has been detected in tonsils (Monaco et al. 1998; Kato et al. 2004) and gastrointestinal tissues (Laghi et al. 1999; Ricciardiello et al. 2000) of infected individuals. As mentioned above, it is presumed that archetype is the principal infecting agent, but conceivably prototype may initiate infection in some individuals. The mechanism by which people are infected and whether repeated infection can occur remains uncertain. The virus is asymptotically detected in blood and urine periodically regardless of HIV status; its reservoir is debated but thought to be principally the renal system or peripheral blood mononuclear cells (Berger 2010). However, JCV has been detected in the brain of patients without PML, and so clinically silent brain infection may be possible. Notably, despite the predominance of population-wide infection with JCV, only a vanishingly small fraction develops PML, indicating that establishing symptomatic brain infection is a formidable task for the virus. That is to say, in order for an individual to develop PML, he or she must have had primary infection by the virus followed at some point (and not necessarily in this order) by loss of immune capability of suppressing viral spread, noncoding viral genome alteration to the neuroinvasive form, dissemination of virus to the brain, establishment of productive infection in susceptible cells, and lesion expansion to the point of symptomatic presentation.

Where latent virus is cached and the events leading up to clinically overt brain infection and PML are incompletely understood. Primary infection gives rise to viremia, which could allow for virus to be deposited at multiple sites throughout the body. Hence, JCV DNA can be occasionally detected in the tonsil, kidney, white blood cells, and brain without detection of proteins, indicating a dormant infectious state, unless the virus has attached to or been phagocytosed by the cell, not

truly infecting it (White and Khalili 2011). While this may argue against B lymphocytes as a reservoir for subsequent JCV infection of the brain, there is compelling evidence for the role of the B lymphocyte in the pathogenesis of PML. For instance, intact JCV DNA without viral progeny has been found in CD34+ hematopoietic stem cells in the bone marrow, and experimentally these cells have correspondingly expressed a nuclear factor required for JCV replication in the brain (Monaco et al. 2001). Additionally, intact JCV virions can be detected inside B cells and have been demonstrated to be able to infect naïve glial cells in vitro (Chapagain and Nerurkar 2010). Furthermore, the B cell is the one somatic cell that has the genetic machinery necessary to rearrange the viral genome. A leading hypothesis for the pathogenesis of PML is that latent archetype JCV in the kidney and renal pelvis seeds B lymphocytes where the virus is transformed to a prototype virus by genomic rearrangement of the NCCR and is rendered capable of replicating effectively in glial cells. At the time of immune suppression, the virus enters the brain establishing active infection. An alternative explanation is that the latency lies actually in the brain itself, and periodic replication, perhaps influenced by Tat, could result in productive demyelinating infection. However, there has been evidence of JCV DNA peripherally circulating prior to the onset of PML that was genetically identical to that isolated from the brain after the emergence of clinically manifest disease, which argues against this postulate (White and Khalili 2011).

How JCV enters the brain is another topic of debate. Several plausible mechanisms have been proposed. First, as infected B lymphocytes can be found in the vicinity of PML plaques, there is potential for a “Trojan horse” mechanism whereby these infected cells are chaperoned across the unsuspecting blood-brain barrier (BBB) by cytokines and chemokines. This is a scenario whereby the most parsimonious explanation for latency is indeed in B cells. Additionally, however, there is evidence that brain microvascular endothelial cells can harbor virus, which may allow for cell-free virus to cross the BBB.

Comorbidity: Progressive Multifocal Leukoencephalopathy, Fig. 3 Steps to viral entry and transfer to the nucleus

In order to gain entry into cells for initial infection and spread, JCV binds sialic acid moieties on cell surface glycoproteins and glycolipids (Fig. 3). It also secondarily uses the 5HT_{2A} receptor. This leads to clathrin-mediated cell entry, delivery into the endoplasmic reticulum, and retrograde transport to the cell nucleus. The virus subsequently replicates and packages progeny virions, ultimately lysing the cell and propagating infection. In the brain, oligodendrocytes are usually the primary targets of productive infection. Astrocytes and even cortical neurons can have viral proteins identified within them, suggesting potential for infection. Additionally, productive infection of cerebellar granule cells (Dang and Koralknik 2006) and even cortical pyramidal neurons (Dang et al. 2012) require VP1 and agnoprotein mutations, respectively, and produce distinct clinical entities. The time to development of PML from infection of brain cells is unknown given recent work unmasking asymptomatic infection, but regardless, the disease is strongly associated with immune compromise-mediated reactivation of latent virus. As cytotoxic CD8 T cells are responsible for clearance of infection and CD4 T-cell trafficking and signaling to these cells is important in keeping infection at bay, a backdrop of low CD4 counts in the HIV-infected population predominantly precedes the development PML. The obverse is that in IRIS, once CD4 and CD8

cells are disproportionately rebounding, antigen detection can precipitate an exaggerated cytotoxic response, which in turn mediates potentially severe bystander damage.

Outside of the context of IRIS, however, PML is actually characterized by a lack of inflammation. In large measure, this is due to the nature of the disorder, but the inability to mount an effective immune response in affected individuals is likely contributory. There are several points along the pathway of JCV clearance that are susceptible to failure. CD4 T cells are charged with antigen recognition of JCV, mostly of the VP1 protein; any physical or functional infirmity of these cells will cause a decline in their surveillance ability. In HIV, infection of CD4 cells results in massive loss. Next, CD4 cells present recognized antigen to cytotoxic CD8 cells, which target and destroy infected cells to prevent viral propagation. In monoclonal antibody treatment, one theory is that these cells are either sequestered in the periphery and therefore are unable to cross the blood-brain barrier to reach infected cells (Diotti et al. 2013). As such, JCV infection itself leads to necrosis of the oligodendrocyte, releasing virions to neighboring cells and causing death to the myelin sheath of neurons, thereby exposing axons and impairing conduction. The result is clinical symptomatology depending on site and extent of demyelination. Histologically, infected

oligodendrocytes display viral inclusions and nuclear enlargement prior to death. Viral particles are spread to adjacent cells, and infection spreads progressively. Astrocytes, also infected by JCV but incapable of supporting complete viral replication, develop bizarre cellular forms with mitotic activity. Histiocytes and macrophages enter the scene to phagocytose the myelin debris.

Host Factors and Underlying Diseases

As a general rule, PML does not occur in young, otherwise healthy individuals. However, profound immune suppression due to HIV or iatrogenic immune modulation is not always required for its emergence, although these are the most common scenarios. Indeed, the first cases were reported in the setting of non-Hodgkin lymphoma and chronic lymphocytic leukemia. While any hematologic malignancy may predispose to PML, B-cell malignancies appear to carry the greatest risk. Additionally, there have been reports of PML in patients with otherwise subtle forms of immune suppression not typically thought to be overwhelming enough to place one at risk for PML, such as idiopathic CD4 cell lymphocytopenia, pregnancy, dermatomyositis, alcoholic liver cirrhosis, dementia, renal failure, or advanced age (Gheuens et al. 2010; Christakis et al. 2013). That said, a PML diagnosis in a patient without HIV or predisposing treatment with immunosuppressive or biologic agents for autoimmune disease, malignancy, or organ transplantation is extremely rare and noteworthy.

Far and away, the most common scenarios for PML to manifest are that of advanced HIV followed by autoimmune disease treated with biologic agents, in particular, multiple sclerosis treated with natalizumab. The contribution of the underlying autoimmune disease to the development of PML is often difficult to separate from that of the immunosuppressive treatment used for the condition, but it clearly appears that some disorders predispose to PML, including rheumatoid arthritis, sarcoidosis, and systemic lupus erythematosus (Brooks and Walker 1984; Amend et al. 2010). Solid tumor malignancies

treated with chemotherapeutic agents such as cyclophosphamide have also been a backdrop for the development of PML (Marshall and Major 2010; Pugnet et al. 2013), and PML is seen as well in the setting of hematological and solid organ transplantation (Mateen et al. 2011; Kaufman et al. 2014).

PML in the Era of AIDS

The HIV pandemic greatly increased awareness of PML. Prior to, PML was extremely rare, but it became much more common after the appearance of HIV. Before the advent of cART, studies showed that 4% of patients with AIDS had PML (Berger et al. 1987, 1998); some studies showed even higher numbers of 7% (Lang et al. 1989) and 9.8% (Kuchelmeister et al. 1993), although referral bias may have been at play in the higher numbers. It is an “AIDS-defining illness,” hallmarking advanced infection. Although PML epidemiology is evolving, given the sheer numbers of people with HIV worldwide, PML remains most commonly observed in this population.

There are several potential reasons why PML is disproportionately seen in HIV+ individuals due to many aspects of the nature of HIV infection. First are the specifics of immune suppression elicited by HIV. CD4 cells, infected and destroyed by HIV, are important in prevention of PML, as although it is the cytotoxic CD8+ cell that clears the virus, HIV-mediated loss of CD4+ surveillance, and subsequent activation of CD8+ cells likely heralds PML. Next is the long duration of HIV infection prior to overt evidence of profound CD4 loss that seems to be necessary to develop PML. This is corroborated by the data on PML in MS patients treated with natalizumab, as the risk increases with duration of treatment (Bloomgren et al. 2012), suggesting that prolongation of immune suppression increases the likelihood of PML. Next, HIV enters the brain early in the course of infection and from there establishes a state of chronic infection, immune dysregulation, and/or BBB disruption, which may facilitate JCV entry into the brain and/or promote viral replication. Additionally, the HIV

protein Tat, which is constitutively active in HIV infection and can be released extracellularly, has been shown to increase JCV replication and transcription (White and Khalili 2011). Finally, HIV infection activates B cells, which have been proposed to serve as a reservoir of JCV as well as a potential site for the evolution of the neurotropic form of the virus from the archetype.

With the advent of cART, not only has survival from PML improved, but also the incidence overall has dropped. Although the numbers of those with HIV continue to swell, those with AIDS-defining illnesses have substantially diminished (Deeks et al. 2013); this is indicative of better control of HIV overall and less profound immune suppression, thereby greatly reducing the risk of PML. Additionally, with improved diagnostics and understanding of PML and HIV, prompt initiation and efficacy of antiretroviral therapy have also played a role. In a study of AIDS patients diagnosed with PML divided into groups based on cART era (1996–2000, 2001–2006, and 2007–2011), the incidence of PML diminished, and the survival increased in the later cART groups (Casado et al. 2013). Incidence dropped from 14.8 cases/1,000 persons/year to 2.6 and 0.8, respectively, for each of the groups. Additionally, the 2007–2011 group had higher CD4 counts at the time of diagnosis and a more inflammatory CSF profile, which were also linked to prolonged survival. Other studies have borne out that higher CD4 counts at the time of PML diagnosis in AIDS, along with lack of prior AIDS-defining illness, portend prolonged survival (Berger et al. 1998; Antinori et al. 2003a). With this as an example, as we continue to improve on initiation of antiretrovirals earlier in HIV infection, the statistics for AIDS-associated PML may continue to improve.

PML in Other Populations

After the shift in PML epidemiology from being rare and associated with hematologic malignancy to being relatively common in association with advance HIV in the 1980s, the face of PML

again changed in 2005 after three cases were reported as complications of the monoclonal antibody to $\alpha 4$ integrin used in the treatment of multiple sclerosis and Crohn's disease (Kleinschmidt-DeMasters and Tyler 2005; Langer-Gould et al. 2005; Van Assche et al. 2005). This opened a Pandora's box of PML cases in association with various scenarios of immune suppression. Biologic agents targeted at specific points of the immune system seem to carry the highest risk (Berger 2010), particularly, the $\alpha 4\beta 1$ integrin inhibitor, natalizumab, and the antilymphocyte function-associated antigen antibody, efalizumab (Zaheer and Berger 2012). Less specific immunosuppressive medications, such as chemotherapeutic agents, mycophenolate mofetil, and even dysregulated immune systems due to underlying autoimmune diseases have been implicated. As the immune system in these individuals is not irreversibly compromised as in HIV, survival rates have been better than with AIDS-associated PML provided the offending agent can be removed and its effects reversed.

Natalizumab is the most efficacious medication for preventing MS relapses, and it is thought to do so by preventing immune cell diapedesis across the blood-brain barrier. This may also be the predisposing factor for development of PML, as periodic immune surveillance in the CNS is critical to prevent infection. Once there were cases of PML linked to natalizumab, it was removed from the market but subsequently reinstated with a strict surveillance program, and cases of PML were scrutinized for risk factors and outcomes. The major risk factors for developing PML in natalizumab treatment were three: evidence of prior JCV exposure as measured by JCV antibody positivity, prior use of immunosuppressive agents, and duration of natalizumab therapy longer than 24 months. Five categories of risk were then created. The first was those who did not have JCV antibody positivity. Their risk was 0.09 or less/1,000 patient years. Those with JCV antibodies but who did not have prior immunosuppressant use and had less than 24 months of natalizumab treatment had a risk of 0.56/1,000 patient years. For those who had prior immunosuppressant use in addition to JCV antibodies but

who had less than 25 months of natalizumab, the risk was 1.6/1,000 patient years, regardless of type or duration of prior immunosuppressant. Next, those with JCV antibodies, no prior immunosuppressant use, and 25 or greater months of natalizumab therapy had a risk of 4.6/1,000 patient years. Finally, those with all risk factors, that is to say JCV antibody positivity, prior immunosuppressant use of any sort, and 25 or greater months of natalizumab therapy, had the highest risk of PML at 11.1/1,000 (Bloomgren et al. 2012). This information has helped select the patient appropriate for natalizumab therapy.

Other biologic agents and immunosuppressive agents have been associated with PML, but not nearly to the degree of natalizumab, as mentioned above. Dimethyl fumarate, approved in the United States in 2013 for the treatment of multiple sclerosis, is attractive because of its oral route of administration and superior efficacy and adverse effect risk profile over the other oral agents. As such, it promises widespread use for MS treatment, but soon after its release, it had already been linked to PML (Ermis et al. 2013).

The majority of PML cases occur in the setting of HIV and natalizumab treatment. A study that predated the natalizumab era of PML found that between 1998 and 2005, 80% of the nearly 10,000 cases identified were in the setting of HIV. Less than 10% were due to hematologic malignancies, and diagnoses of autoimmune diseases, such as rheumatoid arthritis and systemic lupus erythematosus, accounted for less than 1% each (Molloy and Calabrese 2009). From a database of nearly 175,000 patients with autoimmune disease, non-Hodgkin lymphoma, chronic lymphocytic leukemia, and transplants, frequencies per 100,000 cases of 2.4 for SLE, 10.8 for autoimmune vasculitis, 8.3 for NHL, and 11.1 for BMT were reported (Amend et al. 2010).

Clinical Disease

The clinical manifestations of PML are protean, but the most common threads in patient

presentations are cortical or cerebellar dysfunction. Hemiparesis, sensory ataxia, limb apraxia, gait disturbance, hemianopia, and cognitive decline are typical and owe to the large areas of subcortical white matter involvement in corresponding areas, such as frontal lobes for motor weakness, occipital lobes for visual field deficits, and cerebellar inflow tracts for gait ataxia. Cortical weakness occurs in about 60% of PML presentations, gait disturbance in 65%, and visual field cut in 20% (Aksamit 2012). The most common cognitive complaints are memory loss and behavior disturbances and are the presenting symptoms about 30% of the time. Headache often accompanies. Focal seizures that can secondarily generalize occur in as many as 10% of patients. Although white matter in the basal ganglia and brainstem can be involved, referable symptomatology is relatively uncommon, especially in PML that is not associated with HIV. Additionally, as the spinal cord is spared, presentations indicative of transverse myelitis are essentially never seen.

Historically, PML has been the AIDS-defining illness about 1% of the time (Berger et al. 1998). The overall prevalence is estimated at up to 4–5% in presumed clade B cohorts (Berger et al. 1987). As most research is with HIV-1 clade B, statistics for HIV-2 and other HIV-1 clades are largely unknown, but a study of a clade C cohort found a similar prevalence of PML at 2.8% (Netravathi et al. 2013). In a series of HIV-associated PML patients, PML was the AIDS-defining illness for 27% (Berger et al. 1998), indicating that the disorder may herald the diagnosis of HIV.

As mentioned above, JC virus genetic variants give rise to disparate cellular tropism and, as such, produce distinct clinical presentations. JCV encephalitis, produced by JCV infection of cortical pyramidal neurons, to date has only been described in a single HIV-negative lung cancer patient who presented with aphasia and cognitive decline (Wuthrich et al. 2009). JCV cerebellar granule cell neuronopathy spares supratentorial brain to preferentially infect cerebellar granule cells, producing cerebellar atrophy that manifests as ataxia, speech disturbance, and gait abnormalities (Koralnik et al. 2005).

Neuroimaging

In the appropriate clinical context, characteristic neuroimaging can be used with CSF studies to diagnose PML (Berger et al. 2013). Computed tomography (CT) of the head is not as sensitive as magnetic resonance imaging of the brain but can reveal patchy hypodensities in the affected subcortical white matter (Fig. 4). There may be sub-gyral scalloping where there is involvement of U fibers.

MRI is extremely sensitive for demonstrating JCV-mediated abnormalities in symptomatic patients and is the imaging modality of choice for PML. A normal MRI in fact argues strongly against the diagnosis. Characteristic MRI findings are of bilateral, asymmetric, multifocal white matter plaque-like lesions that are T1 hypointense and T2/FLAIR hyperintense. Unifocal lesions affecting but one hemisphere are observed and may be more common with natalizumab-associated PML than with HIV. Notably, in the absence of PML-IRIS, there is no edema or mass effect (Fig. 5). Diffusion

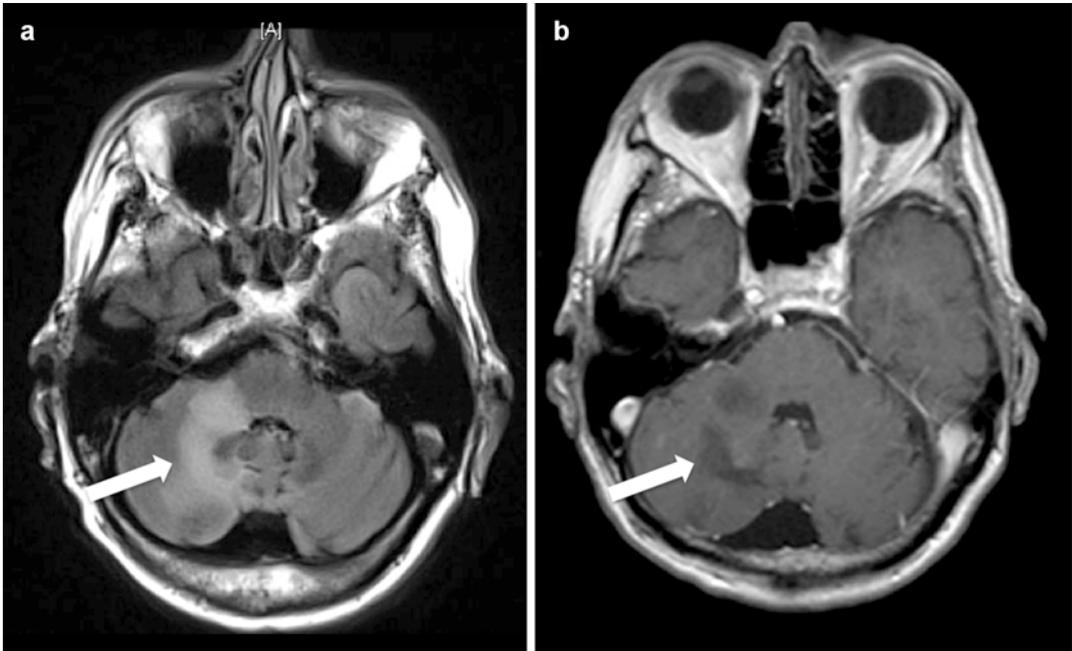

restriction is common at the advancing edge of the lesions, but this finding wanes with time (Sahraian et al. 2012). Additionally HIV-associated PML demonstrates enhancement in only about 15% of cases (Berger et al. 1998). Enhancement is more commonly seen in natalizumab-associated PML or PML-IRIS, although even in this scenario, enhancement is only seen about 40% (Yousry et al. 2012) and 50% (Tan et al. 2011) of cases, respectively.

MR spectroscopy, a modality that evaluates parenchymal health by measuring metabolites and often comparing to creatine as an internal control, demonstrates low ratios of N-acetylaspartate to creatine and high ratios of choline to creatine and lactate to creatine (Sahraian 2012). These findings reflect increased cell death and membrane turnover. A longitudinal MRS study showed less neuronal loss, but higher membrane turnover at the periphery of a PML plaque in a single patient, suggesting increased activity of the virus at the leading edges of the lesion (Yoon et al. 2007); this finding logically follows the pattern of pathologic advancement of PML lesions.

Magnetic resonance neuroimaging in PML is usually quite distinct from other intracranial lesions that are seen in HIV when the CD4 count is low (Fig. 6). Toxoplasmosis and primary CNS lymphoma (PCNSL) are typically associated with surrounding edema and mass effect, and enhancement is not uncommon. Deep gray structures are commonly affected. Toxoplasmosis lesions frequently have blood products evident on gradient echo imaging, and rim enhancement is common. PCNSL can have variable enhancement patterns, and because the middle cerebellar peduncle (MCP) is a common site for lymphoma, a well-placed solitary PML lesion in the right MCP has been reported as an imaging mimic of PCNSL (Westwood et al. 2013). Infarcts obey vascular boundaries and also tend to involve the cortical ribbon, both in contradistinction to PML. Also unlike PML, meningitides commonly seen in immune suppression, such as tuberculosis and *Cryptococcus*, can show sulcal and basilar meningeal abnormalities on T2/FLAIR or after the administration of gadolinium, but the imaging in these maladies can also be normal. Other

Comorbidity: Progressive Multifocal Leukoencephalopathy, Fig. 5 Magnetic resonance brain imaging in PML. (a) Axial T2-weighted fluid-attenuated inversion recovery (FLAIR) sequencing at the level of the cerebellopontine angle in a 63-year-old with untreated HIV and no prior AIDS-defining illness demonstrates

hyperintensity without mass effect in the *white matter* tracts of the middle cerebellar peduncle on the right. (b) Axial T1-weighted imaging after the administration of gadolinium at the same level demonstrates characteristic hypointense signal without enhancement

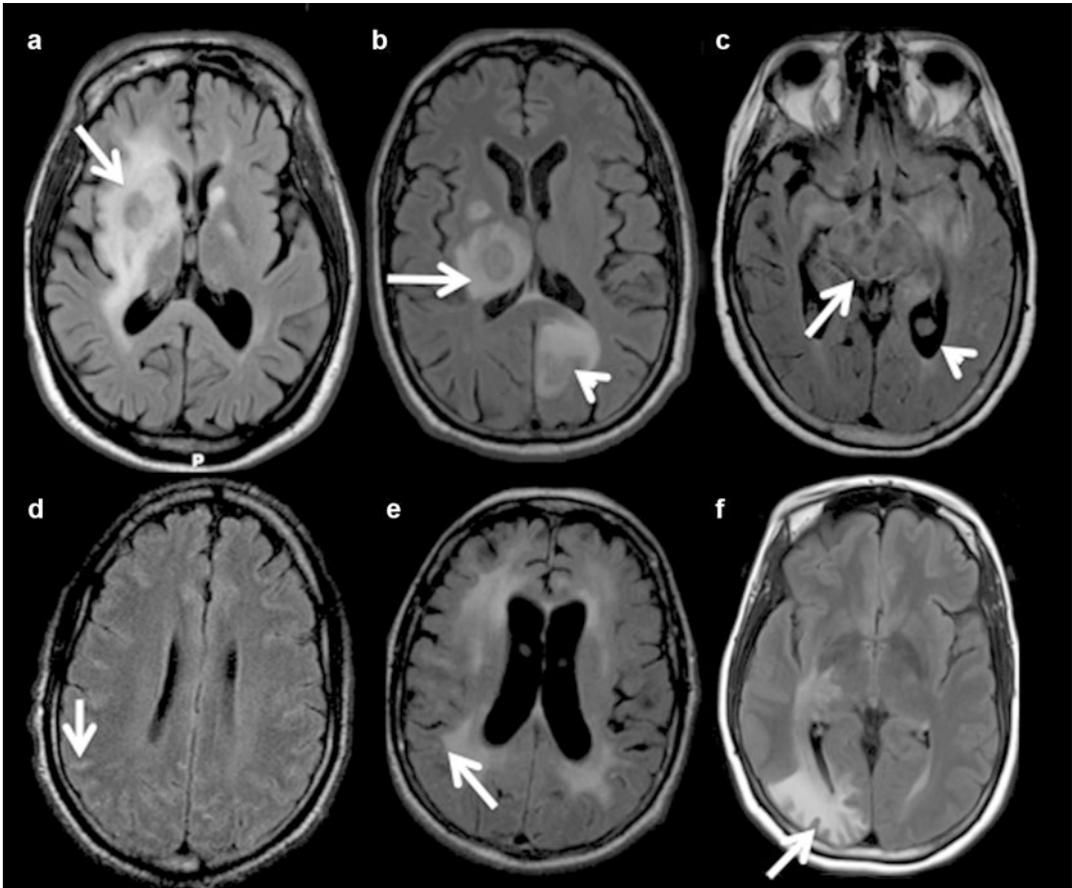

infections, such as bacterial brain abscesses, tuberculomas, or cryptococcomas, also differ from PML in both the presence of one or more mass lesions, the presence of surrounding edema, and the presence and characteristics of contrast enhancement. In differentiating from other demyelinating diseases, such as multiple sclerosis (MS) or acute disseminated encephalomyelitis (ADEM), the large size and confluence of plaques, predominantly subcortical location with involvement of subcortical U fibers, and sparing of spinal cord coupled with the appropriate clinical presentation argue in favor of PML. Finally, HIV infection alone frequently causes white matter hyperintensities on T2/FLAIR imaging, but these are typically diffuse, are T1 isointense, and heavily involve basal ganglia and periventricular white matter, sparing the U fibers. There is also a significant amount of global atrophy seen secondary to HIV infection although this can be seen in PML owing to the fact that there is

underlying HIV that likely also is affecting the brain.

Laboratory Studies

In HIV-associated PML, advanced disease causing immune suppression to a CD4 count below 200 cells/mL or 14% in blood is the general tenet. Although in some series, the mean has been around 90 cells/mL (Berger et al. 1998), numbers can be higher. According to one PML series, about 10% had CD4 counts greater than 200 cells/mL (Berger et al. 1998). In HIV, there have been no studies on JCV antibody positivity and risk, but in natalizumab-associated PML, JCV antibody positivity was found in nearly all patients with PML (Bloomgren et al. 2012; Major et al. 2013).

CSF studies are helpful both in diagnosis of PML and in evaluation of other diseases. The

Comorbidity: Progressive Multifocal Leukoencephalopathy, Fig. 6 Characteristic magnetic resonance fluid-attenuated inversion recovery (MR FLAIR) findings in the brain for various infections complicating advanced HIV. (a) EBV-associated primary CNS lymphoma typically demonstrates solitary deep lesions, here seen in the right basal ganglia (*arrow*), with significant surrounding mass effect and rim enhancement on T1 post-gadolinium imaging (*not shown*). (b) Toxoplasmosis typically demonstrates multifocal deep lesions, here seen in the right thalamus (*arrow*) and left temporal/parietal subcortical gray matter (*arrow head*), which rim-enhance on T1 post-gadolinium imaging (*not shown*) and may have elements of microhemorrhage on susceptibility-weighted imaging (*not shown*). (c) Tuberculous meningitis typically shows

brainstem leptomeningeal hyperintensity (*arrow*), better visualized on T1 post-gadolinium imaging, with ventricular enlargement (*arrow head*), indicating obstructive hydrocephalus. (d) Cryptococcal meningitis may show sulcal hyperintensity (*arrow*) and cortical leptomeningeal enhancement on T1 post-gadolinium imaging (*not shown*), with ventricular enlargement (*not shown*), but imaging may also be entirely normal. (e) HIV leukoencephalopathy demonstrates diffuse atrophy and periventricular *white matter* hyperintensity without mass effect that spares the subcortical U fibers (*arrow*). (f) PML demonstrates confluent subcortical *white matter* hyperintensity without mass effect, which involves the subcortical U fibers (*arrow*) and may not demonstrate concomitant ventricular enlargement, as shown here

typical profile is an acellular or perhaps lymphocytic-predominant paucicellular (up to 20 cells/mL) CSF with normal to moderately elevated protein and normal glucose (Berger et al. 1998). Oligoclonal bands can also be detected but are usually best ascribed to concomitant HIV infection. Other viral etiologies or

syphilis, especially in advanced immune suppression, may have a similar profile. Notably, HIV by itself can give this CSF profile. Marked pleocytosis, especially if polymorphonuclear cell predominance and/or with hypoglycorrhachia, should raise suspicion of other diagnoses. Bacterial meningitis, for example, tends to give a very

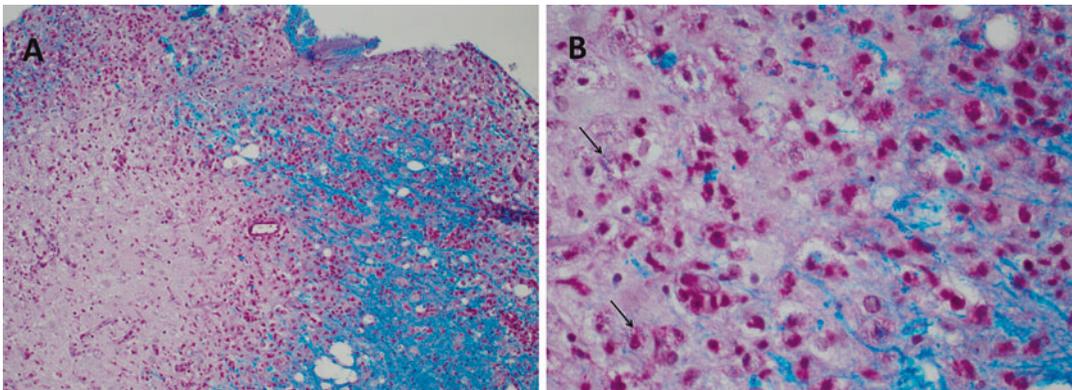

high, neutrophil-predominant CSF pleocytosis with low to undetectable glucose and extremely high protein. Tuberculosis and fungal infections also typically show a moderate to high pleocytosis and low glucose. As such, evaluation for HIV RNA, cryptococcal antigen, acid fast bacillus PCR, Venereal Disease Research Lab (VDRL) testing for syphilis, varicella zoster DNA, cytomegalovirus DNA, herpes simplex 1 and 2 DNA, and/or Epstein-Barr virus DNA may be included in the CSF studies where clinically appropriate. In 1992, polymerase chain reaction (PCR) detection of JCV DNA from CSF is available (Telenti et al. 1992), and this has proved to be extremely useful. In fact, detection of JCV DNA in CSF coupled with characteristic imaging in the correct clinical setting obviates the need for biopsy to diagnose PML. The sensitivity is only about 75–90%, owing to one or more of low copy number, specimen handling, or specimen quantity. Specificity is upward of 100% (Koralnik et al. 1999). Recent quantification assays boast ability to detect JCV in CSF at ten copies/mL (Ryschewitsch et al. 2013).

Pathology

Historically, PML has been a pathological diagnosis. The initial descriptions depict widespread multifocal demyelination (Fig. 7), bizarre

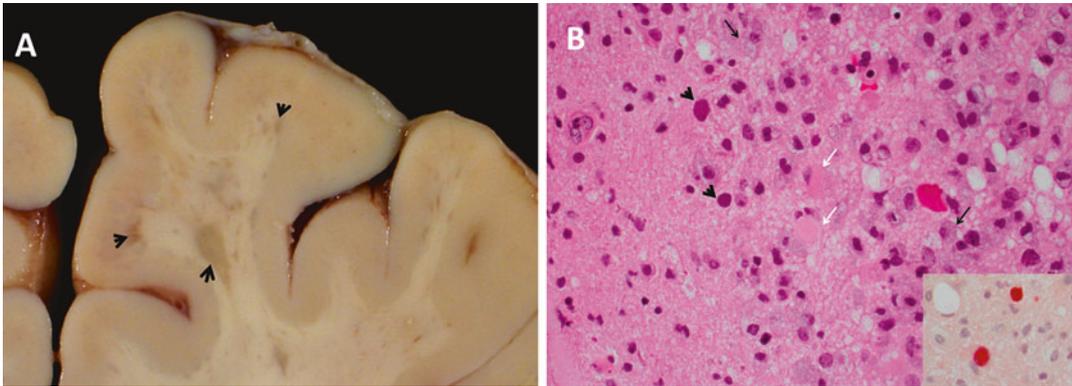

astrocytes with lobulated nuclei, and enlarged nuclei in oligodendroglial cells by immunohistochemistry stain for JCV (Fig. 8). There is also characteristically a lack of inflammatory cells in the lesions, and neurons are spared of infection. Astrocytes may harbor infection but largely are thought to be reactive (Astrom et al. 1958). As noted elsewhere, the combination of neuroimaging, CSF studies, and clinical picture has largely supplanted the necessity of biopsy in PML.

Other clinical entities produced by JCV that depend on various genomic mutations to produce varied proclivity within the central nervous system include granule cell neuronopathy (JCVGCN) and JC virus encephalopathy (JCVE). Both entities are extremely rare. The pathology underlying these entities is distinct from PML. In JCVGCN, the white matter appears spared and oligodendrocytes are not infected. Instead, there is selective depletion of cerebellar granule cells, Purkinje cell sparing, and enlarged, hyperchromatic, atypical nuclei in surviving granule cells; immunohistochemistry reveals evidence of JCV infection restricted to cerebellar granule cell neurons (Koralnik et al. 2005). JCVE demonstrates laminar necrosis at the gray/white junction and bizarre, multinucleated astrocytes. Immunohistochemical staining reveals JCV infection of pyramidal neurons and astrocytes but overall sparing of oligodendrocytes (Wuthrich et al. 2009).

Comorbidity: Progressive Multifocal Leukoencephalopathy, Fig. 7 (a) Luxol fast blue (LFB) stain for myelin and periodic acid-Schiff (PAS) stain for glycogen from a PML lesion at 100× magnification show myelin

loss on the left hand side of the photo. (b) 400× magnification of lesion from (a) shows highlights macrophages (arrows) containing PAS+ and small amount of LFB+ debris (Photos courtesy of Rebecca D. Folkerth, MD)

(b) Hematoxylin and eosin (H&E) stain of a plaque at 400 \times demonstrates

infiltrate of macrophages (*black arrows*), glial cells with “smudgy” nuclear inclusions (*arrowheads*), and enlarged, bizarre astrocytes (*white arrows*). Inset: immunohistochemistry for polyomavirus is positive in glial nuclei and corresponds to the “smudgy” changes seen on H&E (Photos courtesy of Rebecca D. Folkerth, MD)

PML-IRIS is yet another pathological entity related to JCV; the difference between PML and PML-IRIS is the fact that the reconstituting immune system causes an inflammatory parenchymal brain reaction in addition to typical PML pathology. This phenomenon has not been described for JCVGCN or JCVE. In these lesions, there is accentuated PML pathology with massive demyelination and macrophage reaction, and additionally there is a perivascular CD3+ cell infiltrate predominated by CD8+ cells (Vendrey et al. 2005).

Diagnosis

Diagnostics for PML have improved considerably since its initial description. Whereas the gold standard initially for diagnosing PML was based on histopathological demonstration of the characteristic triad of demyelination, bizarre astrocytes, and oligodendroglial nuclear inclusions, a recent consensus statement from the American Academy of Neurology proposed alternative means to reach a definitive diagnosis (Berger et al. 2013). Given the accuracy of characteristic neuroimaging and detection of JCV DNA in CSF, in a symptomatic patient with immune suppression or on immune modulatory therapy, these findings obviate the

need for biopsy to diagnose PML. If the clinical and neuroimaging pictures fit the diagnosis but the JCV PCR from CSF is negative, repeat testing should be performed along with work-up for other diagnoses. If there still remains diagnostic uncertainty, biopsy should be sought.

PML-Immune Reconstitution Inflammatory Syndrome

The immune reconstitution inflammatory syndrome is seen when a previously suppressed immune system recovers. It is neither specific to PML nor HIV infection. The events that occur basically amount to an expansion of CD4+ cells followed by a rapid expansion of CD8+ cells once the immune system is free to manufacture these cells. Antigen recognition activates the cytotoxic T cells, which in the setting of immune restoration can result in generation of a massive antigen-specific inflammatory reaction. This can occur when antigens are already present in sufficient quantities, meaning that the disease was overt prior to the ability of the immune system to recognize it; this is termed “paradoxical IRIS” because the previous disease clinically worsens once the immune system that predisposed to the disease is ramped up. Alternatively, if there is only

a minute amount of antigen around and/or the disease was not clinically manifested prior to the onset of IRIS, the situation is termed “unmasking IRIS” because the underlying disease was not known prior to the inflammatory reaction to it. In HIV, risks for developing IRIS are mostly related to rapidity of immune restoration, with precipitous drop in plasma HIV RNA levels and/or marked increase in CD4 T-cell counts. Given the amount of time for the cytotoxic cells to expand, this entity typically develops about 4–8 weeks after initiation of cART in the setting of HIV.

Treatment and Prognosis

Therapeutic strategies for PML have involved immune function restoration and the use of antiviral agents. The only unassailable favorable clinical responses have come from the former approach. In HIV, successful initiation and maintenance of combination antiretroviral therapy (cART) has changed the epidemiology of PML from a rapidly fatal disease to a potentially survivable one. The dismal survival rate of less than 6 months for most prior to cART with only 10% surviving past 1 year (Berger et al. 1998; Hall et al. 1998) has improved significantly. A study from 2003 found a cumulative survival beyond 1 year to be 58% in those who initiated cART at diagnosis of PML, who had been naïve prior to, and who had no other AIDS-defining illnesses, compared to 0% of those failing to receive antiretroviral therapy. Additionally, those with higher CD4 counts to begin with had a higher likelihood of survival (Antinori et al. 2003b); conversely, those with higher JCV DNA levels in CSF have been shown to have worse outcomes (Koralnik et al. 1999). The authors (JL and JB) continue to follow patients who suffered PML years ago but who have survived with variable disability after initiation of cART. It has also been mentioned previously that cART initiation to prevent immune suppression has also decreased the incidence of PML. As such it should go without saying that prevention is the best strategy. IL-2 (which stimulates T cells) and adoptive cytotoxic T-cell infusions of patients with T-cell deficiencies

unrelated to HIV have anecdotally been successful in patients battling PML (Przepiorka et al. 1997; Buckanovich et al. 2002; Balduzzi et al. 2011). These are notably case reports, making generalizability difficult, despite having conceptual logic. In PML associated with iatrogenic immune suppression, removal of the offending agent along with supportive care is the current recommendation, and survival rates are around 80% (Aksamit 2012). Reversal of natalizumab immune suppression by means of plasmapheresis has been frequently associated with an IRIS phenomenon that can be severe, although the relationship of plasma exchange to IRIS is not well understood, as nearly all patients in this scenario develop IRIS regardless (Tan et al. 2011).

Specific treatments for PML have also been studied, albeit not rigorously. These strategies have included targeting JCV replication and/or cell entry. For the most part, the supportive evidence for these strategies is derived from case reports or small series evaluated without standardized outcome assessments, which again limits generalizability and future clinical applicability of the information difficult. That said, there have been several concepts tested that have advanced the experience with the disease and may be able to help guide future work in the field.

Since JCV uses the 5HT_{2A} receptor for entry into cells, drugs that act to bind up the receptor ostensibly would prevent viral spread and have been tried as treatment. Indeed, ziprasidone, olanzapine, and risperidone have shown in vitro inhibition of JCV infection (Altschuler and Kast 2005). Such drugs have been tried alone or in conjunction with viral replication inhibitors with varying results, but unfortunately no appropriate large-scale trials have been undertaken. Chlorpromazine, a serotonin agonist, combined with the replication inhibitor cidofovir in a single patient was unsuccessful (Pohlmann et al. 2007). Several reports on mirtazapine have demonstrated promising results, with early initiation of treatment proposed as a positive prognosticator (Cettomai and McArthur 2009; Lanzafame et al. 2009). A report on the combination of mirtazapine with the nucleoside analog cytosine arabinoside also described a favorable outcome

(Vulliemoz et al. 2006). This all provides only a small amount of anecdotal evidence, however. What has recently been shown and what could explain the variable results of 5HT2A blockade are that JCV can infect cells independently of the 5HT2A receptor (Marshall and Major 2010). This fact may mean that successful treatment of PML may require medications that interrupt multiple sites along the pathway of productive infection.

Inhibition of viral replication using nucleoside analogs has also been attempted with varying results. Although there has been one trial for this concept by the AIDS Clinical Trial Group, the data is outdated (Hall et al. 1998). Most of the data for the use of viral replication inhibition again comes from anecdotal evidence. Agents that have been tried include acyclovir, cidofovir, cytarabine, zidovudine, and vidarabine. Toxicities with each of these medications can be devastating, though, and so their use is not without deleterious effect regardless of efficacy. However, several reports have demonstrated efficacy in AIDS-associated PML (Marshall and Major 2010). These are frequently not combined, but adding cytarabine and cidofovir has given favorable outcomes (Terrier et al. 2007). The only clinical trial of intrathecal or intravenous cytarabine added to antiretroviral therapy compared to antiretrovirals alone for the treatment of PML was a failure (Hall et al. 1998). The most notable point about the trial is that it was conducted before widespread use of cART. As such, the underlying antiretroviral therapeutic strategies used are now considered well antiquated, as NRTI therapy with zidovudine and didanosine was administered as the preferred therapy. Given what is now known about PML survival based on immune restoration, this regimen falls well short of what is currently accepted. Additionally, as cytarabine is not specific for JC virus, further immune inhibition without adequate design to reconstitute the HIV-infected immune system may very well have contributed to the failure. Finally, as has been argued above, the strategy of using combination therapy for cell entry plus viral replication inhibition may prove more successful than use of solitary agents.

Other inhibitors of viral replication have been identified. A drug screening study to identify inhibitors of JCV replication turned up diclofenac, mefenamic acid, flunixin meglumine, isotretinoin, and mefloquine (Brickelmaier et al. 2009; Marshall and Major 2010). As only mefloquine has activity beyond the blood-brain barrier, it has been studied for clinical utility in PML (Clifford et al. 2013). Notably, its mechanism of action is unknown, and in the study, it was not used in combination with any of the above anti-JCV medications. The trial was halted early due to interim data lacking a benefit to the treatment group.

Treatment for PML-IRIS is occasionally with judicious administration of high-dose corticosteroids followed by a prolonged taper. The CCR5 antagonist, maraviroc, has been advocated as a treatment of PML-IRIS (Giacomini et al. 2014). Importantly, there have been no controlled trials for the treatment of PML-IRIS, and the suggested therapies carry a potential pernicious effect on controlling JCV in the brain (Berger 2009). In severe IRIS, there is sometimes consideration of stronger immune suppression, although this practice would also pose a serious threat to the delicate immune system, especially if there is potential for other underlying infections. Notably, and particularly in PML whereby the only treatment known to be of utility is immune restoration, cessation of cART in IRIS, even temporarily, is largely not advised.

Risk Mitigation Strategies

Given that initial infection with JCV typically predates the situations in which patients develop risk for PML and that the virus is ubiquitous, prevention and surveillance strategies for primary infection are of low yield, at least in adults. Additionally, employing experimental agents such as mefloquine, mirtazapine, or cytarabine as prophylactic measures has not been evaluated, although in treatment studies these have failed to show convincing benefit.

In HIV, PML is strongly associated with immune suppression and typically with a CD4

count of <200 cells/mL. Therefore, prevention of immune suppression is paramount in reducing risk of PML in this population. At this time, the general practice in developed countries is to consider initiation of antiretroviral therapy at the time of HIV diagnosis regardless of CD4 count. The World Health Organization guidelines from 2013 prioritize treatment for the profoundly immune suppressed but recommend expanded access to all individuals with HIV at a CD4 count of 500 cells/mL or less.

For other populations at risk for PML, several strategies have been employed to mitigate risk. In multiple sclerosis patients treated with natalizumab, JCV antibody seropositivity, duration of exposure to the medication, and prior use of immunosuppressive therapy impart a much higher risk than the lack of these clinical factors (Bloomgren et al. 2012). Therefore, careful selection of the patient population in which to use the implicated medications is a prudent measure to lower risk. Those who are seronegative for JCV antibody and remain as such have a decreased risk, although as mentioned above, there have been false negatives in patients who developed PML (Major et al. 2013). Additionally, serial magnetic resonance imaging has been used as a surveillance tool for early or asymptomatic lesions that could be due to PML. Additionally, predictive biomarkers could be useful in forestalling disease; a recent study on I-selectin, an adhesion molecule expressed on the surface of CD4 cells, demonstrated significantly lower levels in MS patients treated with natalizumab who developed PML. For patients treated with dimethyl fumarate who developed PML, low lymphocyte counts have predated disease (Ermis et al. 2013). Prompt discontinuation of the offending agent once PML does develop is critical, although aggressive removal of drug via plasma exchange may precipitate an IRIS phenomenon, which can be fatal.

Risk mitigation strategies for PML-IRIS are not described. Given the teleology for JCV entry into cells utilizing the 5HT_{2A} receptor, an argument could be made for prophylaxis once starting cART at least in individuals with known

PML. However, since it is unknown how well these agents actually work to combat the virus, this argument is entirely speculative. Additionally, viral replication inhibitors, especially those with high rate of toxicities, would have to be validated in treatment before theorizing on their utility prophylactically.

Conclusion

PML is the clinical manifestation of the reactivation of the polyomavirus JC, which initially infects the majority of individuals around the world at a young age. Primary infection is asymptomatic, but the virus enters a dormant state and essentially lies in wait of barriers to PML development to be overcome. These include breakdown of immune function, specifically CD4 T-cell physical or functional loss; genetic rearrangements in the noncoding control region that permit neurovirulence; and passage from their site of latency to the brain parenchyma. Productive infection primarily of oligodendrocytes is established, and massive demyelination ensues, producing a clinical syndrome dominated by motor weakness, ataxia, and cognitive dysfunction. Diagnosis is now primarily made by characteristic neuroimaging combined with detection of JCV DNA from CSF, with histopathology becoming important in confusing cases. Treatment primarily lies in restoration of immune function, although if return is too rapid, a paradoxical, potentially fatal clinical worsening known as the immune reconstitution inflammatory syndrome can occur, requiring delicate orchestration of immune modulation to temper immune overactivity all the while continuing to allow for immune system rebuilding. This has changed the epidemiology of PML, which prior to cART was a primarily HIV-associated condition, to, increasingly, a complication of iatrogenic immune suppression for treatment of autoimmune disease and cancer. Although specific targets along the JCV infection cycle could elicit therapeutic options, to date none has proven efficacious.

Conjunctival Carcinoma

Kenneth O. Simbiri and Erle S. Robertson
 Department of Microbiology, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA

Definition

Conjunctival carcinoma encompasses several eye neoplasms that include squamous cell carcinoma (SCC) and malignant melanoma. In both cases the

patients tend to be older males, often with a significant history of chronic sun exposure. Ocular surface squamous neoplasia (OSSN) is a term used to describe conjunctival or corneal neoplastic growth; it encompasses a range of conditions from simple dysplasia to conjunctival intraepithelial neoplasia (CIN) and invasive SCC. There is evidence that conjunctival squamous cell carcinoma (CSCC) is becoming more common, more aggressive, and affecting more young people, especially women. Immunocompromised patients, including those infected with HIV, are predisposed to developing these neoplasms. There is mounting evidence that one or more infectious agents, especially types of human papillomavirus (▶ HPV), may be involved in the pathogenesis of CSCC, but there is still some uncertainty about the etiologic role of these agents and additional research is needed.

Introduction

Squamous cell carcinoma (SCC) is among the most common neoplasm of the conjunctiva (Kestelyn et al. 1990). The etiology of cancer of the conjunctiva appears to be multifactorial. Several risk factors have been identified or suggested, such as smoke, human immunodeficiency virus (HIV) infection, ultraviolet (UV) light, history of pterygium, and human papillomavirus infection (▶ HPV) (Newton et al. 1996). It is most often seen in sub-Saharan Africa and other regions with a high prevalence of HIV and intense sunlight. HPV has been proposed as an etiologic agent, but its role remains uncertain.

While there has been considerable interest in HPV as a cause of conjunctival squamous cell carcinoma (CSCC), the heterogeneous prevalence of high-risk HPV types in different studies suggests that only a subset of cases of CSCC can be attributed to these viruses (McDonnell et al. 1986). Differences in detection methods, populations, or geographical distribution could contribute to the variation in HPV infection rates in CSCC (McDonnell et al. 1986). HPV is considered the main etiologic agent in proliferative ocular surface, lacrimal sac lesions, and

Conjunctival Carcinoma, Fig. 1 (a) Representative patient with OSSN and a closer lateral view (b) and (c) H&E staining showing features of in situ carcinoma

characterized by full thickness changes in nuclear to cytoplasm ratio, nuclear pleomorphism, dyskeratotic cells, and presence of koilocytes (Simbiri et al. 2010)

pterygium worldwide, and it has been suggested that HPV types 16 and 18 may play a critical role in the oncogenesis of conjunctival cancers (Hirst et al. 2009; Palazzi et al. 2000). HPV is a group of host-specific DNA viruses with oncogenic subtypes that have also been shown to act as carcinogenic agents in the development of ► cervical cancer, anal carcinoma (► Anal Cancer), penile carcinoma, and oropharyngeal carcinoma (Hirst et al. 2009; Simbiri et al. 2010). The E6 oncoprotein, encoded by HPV16 or HPV18, is known to interact with the well-known tumor suppressor p53 to promote its degradation, while the E7 oncoprotein interacts with the retinoblastoma protein (pRB) and results in E7-induced pRB inactivation. The E5 virus protein cooperates with E7 to transform cells and enhances the ability of E7 to induce proliferation and, with E6, to immortalize cells (Helt and Galloway 2003; Scott et al. 2002; Song et al. 1998; Peralta-Zaragoza et al. 2006).

Clinical Presentation of CSCC and Related Conditions

Ocular surface squamous neoplasia (OSSN) is a term used to describe a conjunctival or corneal neoplastic growth; this term encompasses a spectrum of conditions, ranging from simple dysplasia to conjunctival intraepithelial neoplasia (CIN) to invasive CSCC (Simbiri et al. 2010). CSCC is typically a “low-grade” malignancy with relatively little potential for invasion and metastasis

(Chisi et al. 2006). Given its location on the eye, it can cause substantial morbidity, patient distress, and disability even when small. Also, similar to cancer of the uterine cervix, CSCC has a high rate of recurrence after treatment and may in some cases metastasize. Moreover, CSCC often shows rapid onset and progression, and in the early stages, a mild dysplasia, often resembling a pinguecula, pterygium, or even a phlyctenule, may occur. Progressive growth of the lesion results in an elevated, fleshy mass of pink tissue that develops in the interpalpebral space. These irregularly shaped neoplasms develop a rich intrinsic blood supply from the surrounding conjunctiva and episclera, with large-diameter “feeder vessels” emanating from the mass. Thus, conjunctival neoplasms may initially pose cosmetic concern for patients on routine ocular examination. Larger lesions may interfere with lid function, causing dry eye complaints and possibly dellen formation on the adjacent cornea. Advanced, invasive lesions may compromise the episclera, sclera, cornea, or angle structures. Pain may be a significant factor in later stages due to associated keratitis, uveitis, or rise in intraocular pressure. A representative HIV-1-infected OSSN patient from Botswana is shown in Fig. 1.

Other Conjunctival Tumors

Melanomas can develop in the conjunctivae, although these tumors are relatively rare. The lesions may present as flat or nodular pigmented

area, although amelanotic conjunctival melanomas have been documented. Like squamous cell carcinoma, they typically develop at the limbal margin. As with the carcinomas, vascularization takes place, with numerous feeder vessels supplying the lesion. Unlike carcinomas, however, conjunctival melanomas tend to become multicentric if not promptly diagnosed and managed. Melanomas tend to progress more rapidly and are more invasive into underlying ocular tissues. Hence, it is not uncommon to see associated uveitis or secondary glaucoma if the lesion invades the anterior chamber.

Prior to the AIDS epidemic, ocular involvement of Kaposi sarcoma (► **KS**) was an extremely rare phenomenon, with fewer than 30 cases reported before 1982. However, KS is one of the most common AIDS-related tumors, and up to one in five patients with AIDS-related KS may have some form of ocular involvement (conjunctiva, eye lids, or orbit) (Grulich et al. 2001; Mikropoulos et al. 2011). Conjunctival Kaposi sarcoma has been reported as the initial sole manifestation of HIV infection in a number of reports.

Lymphoma (► **Lymphoma**) can also involve the conjunctivae. In particular, mucosa-associated lymphoid tumor (MALT) can arise in the conjunctivae, appearing as a salmon-colored patch. This tumor is relatively benign and, like gastric MALT, has been hypothesized to be related to local infection with *Helicobacter pylori* (*H. pylori*).

Epidemiology of CSCC and Association with HIV Infection

The incidence of CSCC varies geographically (declining with greater distances from the equator), with Uganda having 1.2 cases per 100,000 persons per year, compared to the UK with fewer than 0.02 cases per 100,000 per year (Ateenyi-Agaba 1995). In the USA, it is a rare disorder, with an incidence of 0.03 per 100,000 persons per year. It has been noted that the relatively high incidence in Kampala, Uganda, is in part due to the high prevalence of HIV infection. Multiple case series have shown a higher prevalence in

male patients and the elderly, with the most frequently reported location being the limbus (Ateenyi-Agaba 1995).

CSCC has for some time been suspected as having an infectious origin. One reason for this is the sharp increase in the incidence of CSCC among patients infected with HIV (Restelli et al. 2005; Chisi et al. 2006), as well as in patients with other forms of immunodeficiency, such as transplant recipients (Macarez et al. 1999; Shelil et al. 2003). CSCC has emerged as an HIV-associated cancer that is increasing in incidence in Uganda and other sub-Saharan African countries over the past two decades, and this increase has been particularly striking in the young and in women (Chisi et al. 2006; Porges and Groisman 2003). The striking association of CSCC with HIV infection and its geographic localization in certain regions of Africa, where there is a high prevalence of several oncogenic viruses, are consistent with, although not proof of, an infectious etiology.

Prior to the HIV pandemic, OSSN was noted to occur predominantly in the elderly, for whom it is the third most common oculo-orbital neoplastic condition after melanoma and lymphoma. In addition to advanced age and male sex preponderance, other risk factors linked to its pathogenesis have included ultraviolet light B, immunosuppression in organ transplant recipients, cigarette smoking, and in some settings HPV (Simbiri et al. 2010). In Africa it is becoming more common, more aggressive, and more likely to affect young people, especially females. Africa also has a high prevalence of HPV infection with prevalence of about 25% in women of age 15–74 years. OSSN is currently the most common ocular neoplastic condition overall among adults in Africa. Findings demonstrated a strong association between OSSN and HIV-1 infection applying to all tumor stages. In a study in Uganda, HIV-positive participants were often markedly immunosuppressed at the time of diagnosis, and their early mortality was high. Almost all of the tumors were in the interpalpebral area of the conjunctiva, which supports the concept of UV radiation as a cofactor in the etiology of OSSN (Simbiri et al. 2010). In a high percentage of HIV-infected patients

presenting with OSSN, the conjunctival tumor was the first sign of HIV, and, in the majority of cases, OSSN was also the only detectable manifestation of HIV (Spitzer et al. 2008).

The increasing incidence and prevalence of OSSN and its association with the HIV pandemic have been described in many sub-Saharan African countries. The role of HIV pathogenesis in CSCC is hypothesized to be through immunosuppression, which then permits activation of oncogenic viruses such as HPV and other herpesviruses, as well as the growth of other infectious pathogens in the conjunctiva (Simbiri and Robertson 2012). Moore and colleagues using a digital transcriptome subtraction (DTS) method did not detect viral sequences from 3 conjunctival carcinoma tissues from Uganda (Feng et al. 2007). As noted, CSCC is also on the rise in developing nations, particularly in sub-Saharan Africa. The increased use of highly active antiretroviral therapy (HAART) in some of the sub-Saharan countries is beginning to show some impact on the risk of HIV-associated tumors, as has been seen in developed countries, although data are scanty at this time. It is hoped that these HIV therapies will also lower the rates of conjunctival cancers, although it is also possible that rates will increase as patients live longer with HIV infection (Spitzer et al. 2008).

Pathogenesis and Possible Role of Infectious Agents

It has been established that infectious agents play an important role in the etiology of certain human malignancies and are thought to be responsible for around 18% of the worldwide cancer burden (less than 10% in developed nations and up to 27% in developing nations). Much of the burden of cancer incidence, morbidity, and mortality occurs in the developing world, with infectious agents attributing to most malignancies of the cervix and vulva (HPV), stomach (*H. pylori*) (Fox et al. 2000; Ferreri et al. 2006a), and liver (hepatitis B and C viruses) (Ferreri et al. 2006c). Other important tumors caused by infectious agents include Kaposi sarcoma (Kaposi-sarcoma-

associated herpesvirus, also called human herpesvirus-8 [KSHV/HHV-8]) and most types of non-Hodgkin lymphoma (Epstein-Barr virus (▶ EBV) and for certain types also KSHV/HHV-8).

Infectious agents display diverse geographic variation in their prevalence and patterns of disease, including oncogenesis. There is evidence that several microorganisms may play a role in different conjunctival malignancies, including HPV in conjunctival papilloma and CSCC, human immunodeficiency virus in CSCC and Kaposi sarcoma, KSHV/HHV-8 in conjunctival Kaposi sarcoma, and *H. pylori*, *chlamydia*, and hepatitis C virus in ocular adnexal mucosa-associated lymphoid tissue (MALT) lymphomas. Unlike cervical cancer, where a predominantly single infectious agent HPV was found in greater than 99% of lesions, multiple organisms may play a role in the etiology of certain ocular neoplasms by acting through various mechanisms of oncogenesis, including chronic antigenic stimulation and expression of oncoproteins by the infectious agents. Similar to a number of other human malignancies, the role of infectious agents in conjunctival carcinomas is most likely a cofactor to genetic and environmental risk factors (Mikropoulos et al. 2011).

Oncogenes are genes that have the potential to cause cancer through mechanisms including disruption of cell cycle mechanisms or interference with apoptosis. They can either develop from a mutated or dysregulated cellular gene, called a proto-oncogene, or can be encoded by infectious agents. High-risk variants HPV16 and HPV18 may drive carcinogenesis by inactivating tumor suppressor gene products p53 and pRb. HPV-E6 and E7 oncoproteins also increase transforming growth factor beta (TGF- β) promoter activity (Peralta-Zaragoza et al. 2006). Notably, TGF- β controls proliferation, differentiation, and other functions in most cell types. Compared to the high-risk HPV type 16 and type 18, the E6 and E7 oncoproteins of HPV type 6 are seemingly less effective in transforming epithelial cells in vitro (Halbert et al. 1992). This finding correlates with the fact that HPV types 6 and 11 are most frequently associated with the benign conjunctival papilloma, whereas the high-risk HPV types

16 and 18 are most frequently associated with CIN and CSCC (Song et al. 1998).

An additional mechanism whereby infectious agents may be involved in the etiology of conjunctival or other systemic neoplasms is by inducing a state of chronic antigenic stimulation. A systemic example is illustrated by the linkage between infection with *H. pylori* and chronic atrophic gastritis, an inflammatory precursor of gastric adenocarcinoma (Mikropoulos et al. 2011). Also, regression of gastric MALT after eradication of *H. pylori* infection with antibiotics is consistent with this hypothesis (Mikropoulos et al. 2011). Similar regression of disease has been reported in ocular adnexal MALT lymphoma after treatment with antibiotics against *Chlamydomphila psittaci* (Ferreri et al. 2004).

H. pylori is a spiral-shaped gram-negative bacteria that infects a large proportion of the population worldwide (Mikropoulos et al. 2011). In developing countries, up to 70–90% of the population is infected (primarily during childhood), whereas in developed countries the prevalence of infection is lower, at 25–50% (Mikropoulos et al. 2011). In most cases the organism causes no symptoms in the host, yet it has been recognized as the cause of duodenal ulcers and gastric adenocarcinoma and can be found in greater than 90% of gastric mucosa-associated lymphoid tissue (MALT) lymphomas. *H. pylori* has also been identified in conjunctival carcinoma tissues (Ferreri et al. 2004). *H. pylori* evades the host adaptive and innate responses by frequent antigenic variation and host antigen mimicry. Even so, the host immune and inflammatory responses to *H. pylori* can increase cellular damage and turnover, thereby promoting carcinogenesis. Whereas eradication of *H. pylori* leads to regression of early gastric MALT lymphoma in up to 80% of cases, its eradication has not been reported to have a similar effect on conjunctival MALT lymphoma lesions. The only study assessing treatment against this organism on ocular lesions was conducted by Ferreri et al. in Italy to assess rates of *H. pylori* gastric infection in patients with ocular adnexal lymphoma (Ferreri et al. 2006b). Of note, the study did not in fact examine *H. pylori* or

its DNA in conjunctival MALT lymphoma lesions. Out of the 31 patients with ocular adnexal MALT lymphoma, 10 (32%) had gastric *H. pylori*, and 4 were treated solely with *H. pylori*-eradicating antibiotics (erythromycin 500 mg twice a day, omeprazole 20 mg twice a day, and tinidazole 500 mg twice a day, for 7 days) (Ferreri et al. 2006b). The ocular adnexal MALT lymphoma in these patients showed no response. Six additional patients received *H. pylori*-eradicating antibiotics concurrently with other therapies (doxycycline, rituximab, or orbit irradiation), achieving lymphoma regression in all cases. Interestingly, three of the patients who were positive for gastric *H. pylori* infection had *C. psittaci*-positive conjunctival MALT lymphomas. Treatment with *H. pylori*-eradicating antibiotics led to no measurable conjunctival lymphoma regression in these three patients (Ferreri et al. 2006b). Although this may raise doubts about the putative role of *H. pylori* in sustaining the growth of this MALT lymphoma, it may also simply highlight the sensitivity of organisms to the specific antibiotics used. Furthermore, clearance of gastric *H. pylori* may not amount to clearance of conjunctival *H. pylori*, and it is also that previous infection with *H. pylori* may have lingering effects promoting MALT lymphoma of the conjunctiva. Other pathogens that may contribute to various conjunctival tumors include chlamydia and hepatitis C virus (HCV). HCV is a major etiologic agent of hepatocellular carcinoma (► [Hepatocellular Carcinoma in HIV](#)) but has also been linked to B-cell lymphomas. It is possible that different infectious agents in different geographical locations contribute to oncogenesis, with host genetic makeup also playing a role.

Of interest, an increase in OSSN has been observed in the genetic disease xeroderma pigmentosum (XP). OSSN occurs predominantly in the elderly, but in patients with XP, as in patients with HIV infection, it tends to occur at a younger age (6–22 years) (Gupta et al. 2011). OSSN appears to be more aggressive than usual in patients with XP (recurrence rate 64.3%). Patients with XP are unable to repair the DNA

that is damaged by ultraviolet rays. This can lead to somatic mutations and the resulting development of oncogenic cells and cancer. This inherent defect accounts for the increased susceptibility to OSSN and the younger age at presentation (Gupta et al. 2011). Some reports have noted a younger age in intraepithelial cases compared with invasive squamous cell carcinoma (Palazzi et al. 2000). Bilateral involvement is encountered very frequently in patients with XP (Gupta et al. 2011).

In patients with XP, simple excision of conjunctival intraepithelial or invasive neoplasia was reported to be associated with a 24–50% recurrence rate (Gupta et al. 2011). Excision with intraoperative control of the surgical margins and adjunctive cryotherapy have been reported to reduce recurrence rates to 12% (Song et al. 1998; Peralta-Zaragoza et al. 2006). A high overall recurrence rate of 64.3% has been observed; the rate of new or recurrent tumors was 25% for intraepithelial squamous carcinoma and 83% for invasive squamous cell carcinoma. Up to four recurrences were noted in a single patient. There is increased tendency of XP patients with OSSN to develop fresh or recurrent lesions. A majority of these patients develop recurrence of the tumor despite a meticulous tumor excision and adjunctive cryotherapy (Gupta et al. 2011).

Prevention and Treatment

While there is evidence that infectious agents may play a role in CSCC, the use of anti-infectious approaches to prevent or treat this condition has not been extensively studied. An effective vaccine for HPV has now been approved, and it will be interesting to see if the use of this vaccine is associated with a decrease in CSCC; if so, this would support an important role for HPV (Spitzer et al. 2008).

Immunomodulatory agents such as topical interferon alpha and the gastric acid inhibitor oral cimetidine have led to conjunctival papilloma regression. In addition to its apoptotic effect on

tumor cells, interferon alpha exerts its antiviral action by preventing the replication of latent virus in the tissues. While there is evidence that HPV plays some role in a subset of conjunctival papillomas, host immune status likely plays a role in pathogenesis and will likely affect the response to treatment (Manns et al. 2001; Midena et al. 2000; Morgenstern et al. 2003).

Even though conjunctival papilloma may persist for extended periods of time, with reported recurrence rates of 6–27%, spontaneous regression can be seen. Also, cure is possible with current therapies. In cases where large lesions cause symptoms or cosmetic defects and periodic observation would be futile, surgery remains the treatment of choice with double freeze-thaw cryotherapy to the remaining conjunctiva to prevent tumor recurrence. Additionally, topical interferon alpha-2b and mitomycin C have been employed in the treatment of recurrent conjunctival papillomas (Manns et al. 2001; Morgenstern et al. 2003).

A high recurrence rate of CSCC has been seen even after cryotherapy, radiation, and chemotherapeutics. Several treatments have been utilized in an attempt to reduce recurrence rates, including topical mitomycin C, 5-fluorouracil, and interferon alpha (Manns et al. 2001; Morgenstern et al. 2003). There is a need for improved therapies, especially those that can be utilized in resource-limited regions.

Conclusions

CSCC and its precursor lesions are most commonly seen in regions with high sunlight exposure, and their increased incidence with HIV infection suggests an infectious etiology. It is relatively uncommon in the USA and Europe and substantially more common in sub-Saharan Africa, especially in regions near the equator. There is some evidence that certain types of HPV may be involved in the pathogenesis of these tumors, but the evidence is not as robust as for other infection-associated tumors, and more research is needed.

Definition

Host cellular proteins that interact with HIV play critical roles to regulate viral infection and pathogenesis. Cellular proteins can either positively or negatively impact different stages of HIV replication. Restriction factors are host proteins that inhibit virus infections and are considered an integral part of the host's intrinsic cellular defense system. Structural and functional studies of restriction factors and their interactions with viral proteins have not only revealed fundamental mechanisms of HIV replication but have also facilitated the generation of better animal virus models for therapeutic and vaccine development. SAM domain- and HD domain-containing protein 1 (SAMHD1) is the first deoxynucleoside triphosphate triphosphohydrolase (dNTPase) identified in mammalian cells. SAMHD1 acts as an HIV-1 restriction factor in nondividing cells and is counteracted by the retroviral protein X (Vpx). Here the latest advances in understanding the mechanisms of SAMHD1-mediated retroviral restriction and its counteraction by Vpx are summarized. The implications and future directions of SAMHD1 studies are also discussed.

Introduction

Intrinsic cellular immunity against invading pathogens is paramount for the survival of any species.

In the past decade, an elite group of cellular proteins, termed restriction factors, have been identified to autonomously block HIV replication and are now considered part of the cell's intrinsic immune system. Coincidentally, viral countermeasures have also coevolved to antagonize such restriction factors in an ongoing conflict between virus and host. SAMHD1 acts as a potent restriction factor of HIV-1 in nondividing myeloid cells and resting CD4⁺ T cells by starving the virus of cellular deoxynucleotide triphosphates (dNTPs) that are needed for efficient conversion of the viral RNA genome into DNA. However, only HIV-2 has uniquely adapted to overcome SAMHD1-mediated viral restriction by encoding a viral antagonist, Vpx. Intriguingly, HIV-1 does not encode Vpx and thereby lacks the capacity to counteract SAMHD1 but is more pathogenic than HIV-2. Thus, the question arises, does the counteraction of SAMHD1 by Vpx serve to promote or hinder disease pathogenesis? In this entry, the mechanistic details of how Vpx counteracts this novel restriction factor, and our current understanding on the implications it has on HIV-1 that lacks a viral countermeasure against SAMHD1, are discussed.

Vpx and SAMHD1: Genes and Proteins

Vpx Gene and Protein

The *vpx* gene has been identified in HIV-2 and simian immunodeficiency viruses (SIVs) from rhesus macaque (SIVmac), sooty mangabey (SIVsmm), mandrill-2 (SIVmnd-2), red-capped mangabey (SIVrcm), and drill (SIVdrl). It is believed that the *vpx* gene of HIV-2 and SIV evolved from its paralogue, *vpr*, as a result of a gene duplication event that occurred during SIV evolution (Fregoso et al. 2013). The *vpx* gene is 342 base pairs in length and encodes a Vpx protein (12–16 kDa) that is packaged into virion particles similar to Vpr. Its presence in the virion suggested that it played a role during the initial stages of HIV-2 and SIV infection. Early studies revealed that delivery of Vpx via virus-like particles to monocyte-derived dendritic cells was sufficient to relieve the

resistance to HIV-1 infection in myeloid cells. Furthermore, Vpx was found to interact with DNA damage-binding protein 1-and-Cullin-4 associated factor 1 (DCAF1) within a CUL4A-DDB1 E3 ubiquitin ligase complex, which suggested that Vpx might target an unknown host restriction factor in myeloid cells for proteasomal degradation to enhance HIV-2 and SIV infection. The search for the unknown cellular protein targeted by Vpx ended with the identification of SAM domain- and HD domain-containing protein 1 (SAMHD1) as a novel host restriction factor present in myeloid cells capable of potently restricting HIV-1 (Hrecka et al. 2011; Laguetta et al. 2011).

Samhd1 Gene and Its Regulation

Human *samhd1* gene was initially identified in a human dendritic cell complementary DNA (cDNA) library as an orthologue of a mouse interferon gamma (IFN- γ)-induced gene. It is located on chromosome 20 and spans 59.5 kilobases in length and encompasses 16 exons. Mutations in *samhd1* gene are associated in different autoimmune diseases, such as Aicardi-Goutieres syndrome (AGS) and Chilblain lupus. At least 16 mutations in *samhd1* have been identified in people with AGS syndrome that leads to immune system abnormalities and inflammatory damage to the brain and skin. Chilblain lupus 2 is associated with heterozygous mutation in the *samhd1* gene. These findings suggest that SAMHD1 is involved in innate immunity and inflammation. Alternative splicing of *samhd1* gives rise to two splice variants that lack exons 8–9 and 14, respectively, but due to their inherent instability in the cell and lack of dNTPase activity, their physiological roles have not been identified (Welbourn et al. 2012). Different epigenetic mechanisms regulate *samhd1* gene expression. For example, gene promoter methylation, histone deacetylation (de Silva et al. 2013), and microRNA-181 (Jin et al. 2014) can downregulate SAMHD1 expression in certain cell lines.

SAMHD1 Protein

SAMHD1 protein is expressed in human myeloid cells, such as monocytes, dendritic cells, and

macrophages, and also in B and T lymphocytes. SAMHD1 is a 626 amino acid (aa) protein with a molecular weight of 72.2 kDa and is comprised of an N-terminal nuclear localization signal domain (¹¹KRPR¹⁴), a sterile alpha motif (SAM) domain (residues 45–110), a histidine-aspartate (HD) domain (residues 167–311), and a C-terminal variable domain. The nuclear localization signal plays an important role in the nuclear localization of SAMHD1 protein. The SAM domain is one of the most common protein-protein interaction modules and is involved in the interaction with a variety of signaling molecules including kinases, scaffolding proteins, RNA-binding proteins, transcription factors, and GTPases. However, its contribution to HIV restriction remains under scrutiny. The HD domain of SAMHD1 is responsible for the deoxyguanosine triphosphate (dGTP)-regulated dNTPase activity that decreases the cellular levels of dNTPs and is important for the restriction of different viruses. The HD domain is also necessary for SAMHD1 to oligomerize and bind to RNA. The catalytic activity of SAMHD1, residing in the central HD domain, is essential for its ability to inhibit HIV infection in nondividing cells (Laguette et al. 2011).

SAMHD1 protein exists in a dGTP-induced tetrameric form in the cell and the tetramerization is modulated by elements flanking the catalytic core domain within the C-terminal region of the protein. The tetrameric state of SAMHD1 is critical for its catalytic and anti-HIV activities (Yan et al. 2013; Ji et al. 2014). SAMHD1 protein has dGTP-stimulated dNTP triphosphohydrolase activity and nuclease activity against single-stranded DNA and RNA which is associated with its HD domain. This HD domain is responsible for the reverse transcription block to HIV-1 infection observed in myeloid or resting CD4⁺ T cells by limiting the intracellular pool of dNTPs. Phosphorylation of SAMHD1 at threonine 592 (T592) negatively regulates its HIV restriction function but not its dNTPase activity (Cribier et al. 2013, White et al. 2013b), suggesting a dNTPase-independent mechanism of SAMHD1-mediated HIV-1 inhibition.

Physiological Functions of SAMHD1

Regulator of the Cellular dNTP Pool

While the physiological role of SAMHD1 is still being unraveled, mutations in the *SAMHD1* gene have been found to cause AGS in humans, a rare autosomal recessive disorder that mimics congenital viral infection (Rice et al. 2009). Mutations in other genes such as the three prime repair exonuclease 1 (*TREX*) and ribonuclease H2 (*RNaseH2*) also lead to AGS. The common underlying function of these proteins, including SAMHD1, is their ability to prevent the accumulation of abnormal self-nucleic acids in the cytoplasm via their exonuclease or dNTPase activity. AGS is a pro-inflammatory autoimmune disease that is characterized by elevated levels of IFN α in the cerebral spinal fluid. Certain mutations in SAMHD1 associated with AGS patients render the protein defective in its ability to degrade dNTPs. Thus, it is speculated that SAMHD1 functions to suppress type I IFN production in the cell by regulating the overall level of dNTPs and preventing the buildup of nucleic acids in the cytoplasm as a consequence of active endogenous retroelements. SAMHD1 protein levels and its dNTPase activity are regulated during the different phases of the cell cycle where it is maximally expressed during quiescence (G₀) and active during the G₀ and gap 1 (G₁) phases (Franzolin et al. 2013). Conversely, SAMHD1 expression and activity decreases during the synthesis (S) phase of the cell cycle, allowing for high levels of dNTPs to be available to meet the demand for cellular DNA replication to proceed in preparation for mitosis. Hence, SAMHD1 plays a major role as a catabolic enzyme in regulating cellular nucleotide metabolism and works in conjunction with ribonucleotide reductase, which is the key cellular enzyme involved in *de novo* dNTP synthesis, to maintain dNTP homeostasis in the cell.

Maintaining Genomic Stability

Maintaining genomic stability in the cell is critical for proper cellular function and preservation of genetic integrity. Seventeen percent of the human genome is comprised of long interspersed elements 1 (LINE-1) – the only class of active autonomous

retrotransposons that can alter the genomic landscape of the cell unless properly controlled. Through its ability to regulate dNTP levels, SAMHD1 is able to regulate LINE-1 and LINE-1-mediated Alu/SVA retrotransposition in cells by serving as a blockade to the reverse transcription stage of the transposition process (Zhao et al. 2013). Thus, SAMHD1 acts as a cell intrinsic regulator of endogenous retroelements in mammals as a means to preserve genomic integrity. Moreover, somatic mutations of the *samhd1* gene have been reported in chronic lymphocytic leukemia (Clifford et al. 2014). SAMHD1 is associated with DNA repair proteins at sites of DNA damage, suggesting its potential role in DNA double-stranded break repair (Clifford et al. 2014). Given its role in regulating cellular dNTP levels, it is speculated that mutations in *SAMHD1* may play a role in the development and progression of certain types of cancers.

Retroviral Restriction and Regulation of the Innate Immune Response

Another major physiological role of SAMHD1 is to block retroviral infection in nondividing cells, such as myeloid lineage cells and quiescent CD4⁺ T cells, and thereby regulate the innate immune response to retroviral infection. For instance, a hallmark of HIV-1 infection is the ability of the virus to evade immune recognition and clearance. One of the main reasons HIV-1 is able to accomplish such a task is in part due to its reduced capacity to infect antigen-presenting cells, such as dendritic cells and macrophages, that would normally trigger a robust type I IFN response upon pathogen recognition and antigen presentation. If such an innate immune response was mounted, it would lead to an antiviral state and clearance of HIV-1 by a subsequent adaptive immune response. However, due to the restrictive functions of SAMHD1, HIV-1 infection of antigen-presenting cells is blocked, which leads to a lack or attenuated innate and adaptive immune response. Thus, while SAMHD1 limits productive HIV-1 infection of myeloid cells, it inadvertently prevents antigen presentation and immune detection, which enables efficient HIV-1 transmission to CD4⁺ T cells and establishes persistent viral infection.

Mechanisms of SAMHD1-Mediated Retroviral Restriction

Biochemical Basis of HIV-1 Restriction by SAMHD1

Post-entry block to HIV-1 infection in terminally differentiated myeloid lineage cells occurs at the level of reverse transcription, which leads to incomplete synthesis of viral cDNA. Vpx is able to relieve this block to infection by permitting reverse transcription to proceed although the underlying mechanism remained unknown. The identification of SAMHD1 as the cellular protein counteracted by Vpx suggested that SAMHD1 was able to potently block HIV reverse transcription in nondividing cells such as myeloid lineage cells and quiescent CD4⁺ T cells (Hrecka et al. 2011; Laguette et al. 2011; Baldauf et al. 2012). Subsequent studies have characterized SAMHD1 as a dNTPase that is capable of hydrolyzing dNTPs to their constituent deoxynucleosides and inorganic triphosphate in a dGTP-dependent manner (Goldstone et al. 2011). The dNTPase activity of SAMHD1 in nondividing cells reduces the intracellular dNTP pool to levels below that which is required by HIV-1 reverse transcriptase for efficient conversion of viral RNA into complementary DNA (Baldauf et al. 2012; Lahouassa et al. 2012; St Gelais et al. 2012). Mutation of key residues in the catalytic HD domain of SAMHD1 abrogates its restriction activity and ability to hydrolyse dNTPs, suggesting that dNTP regulation is a key mechanism in SAMHD1-mediated retroviral restriction (Fig. 1).

It is likely that the structure of SAMHD1 regulates its biological activity, including its dNTPase function, which could have consequences for retroviral restriction. The crystal structure of recombinant SAMHD1 has revealed that binding of dGTP or GTP to an allosteric site causes SAMHD1 to form catalytically active tetramers (Ji et al. 2014). Mutations of the dGTP binding residues affect tetramer assembly, dNTPase activity, and HIV-1 restriction (Zhu et al. 2013). The C-terminus of SAMHD1 regulates tetramerization of SAMHD1, which is critical for its dNTPase activity and HIV-1 restriction

(Yan et al. 2013; Zhu et al. 2013). Controversially, a separate study suggested that oligomerization and tetramer formation were not required for efficient HIV-1 restriction (Brandariz-Nunez et al. 2013). It is currently unclear whether phosphorylation of SAMHD1 at T592 affects its tetrameric structure and thereby regulates its HIV-1 restriction function.

Mechanisms Independent of the dNTPase Activity of SAMHD1

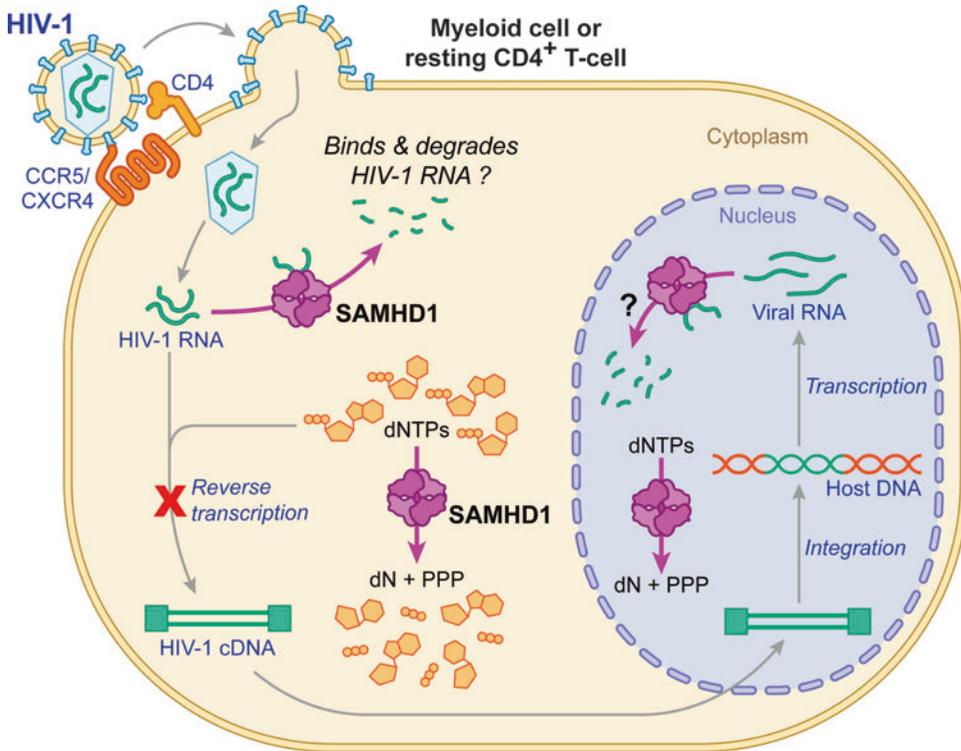

Although there is a strong correlation between SAMHD1's dNTPase function and HIV-1 restriction, the addition of exogenous deoxynucleotides to cells cannot fully rescue HIV-1 infection. This suggests that additional mechanisms, independent of its dNTPase activity, might be involved in SAMHD1-mediated retroviral restriction. Furthermore, the possibility of an alternative mechanism of HIV-1 restriction by SAMHD1 was demonstrated when studies showed that phosphorylation of SAMHD1 at T592 negatively regulates its HIV-1 restriction function. SAMHD1 is phosphorylated in many nonrestrictive cell types but is not phosphorylated in restrictive myeloid or resting CD4⁺ T cells (Cribier et al. 2013; White et al. 2013b). SAMHD1 phosphorylation is mediated through the interaction of SAMHD1 with cellular host factors cyclin A2 and cyclin-dependent kinases 1/2 (CDK1/2), in a cell-type-dependent manner (St Gelais et al. 2014). SAMHD1 functions as a dNTPase independent of the phosphorylation status of the protein, whereas restriction of HIV-1 is abrogated when SAMHD1 is phosphorylated, providing evidence that the dNTPase function of SAMHD1 may not be the sole mechanism of retroviral restriction (White et al. 2013b).

Apart from its role as a dNTPase, new studies have suggested that SAMHD1 may have additional cellular functions that could impact its retroviral restriction and role in innate immune signaling. SAMHD1 has been identified as a nucleic acid binding protein that has a preference for RNA over DNA (Goncalves et al. 2012). The RNA-binding ability of SAMHD1 has been mapped to the HD domain and C-terminus of SAMHD1 (White et al. 2013a). A separate study

also showed that SAMHD1 possesses 3'-5' exonuclease activity against single-stranded DNAs and RNAs in vitro. Further, SAMHD1 is able to bind structured HIV-1 *gag* and *tat* RNA, correlating nucleic acid binding and exonuclease activity with the SAM domain (Beloglazova et al. 2013). Recently, SAMHD1 was found to possess RNase activity in the cell, enabling it to degrade incoming genomic viral RNA during the early stages of infection (Ryoo et al. 2014). Mutational analysis of the allosteric site of SAMHD1 identified mutants that could specifically abrogate either the dNTPase function (D137N) or the RNase function (Q548A). Interestingly, only the RNase-defective mutant, but not the dNTPase-defective mutant, lost its ability to restrict HIV-1, suggesting that the RNase activity of SAMHD1 was more important than the dNTPase activity for HIV restriction. Furthermore, phosphorylation of T592 appears to negatively regulate the RNase activity of SAMHD1 (Ryoo et al. 2014). These results indicate that multiple mechanisms of restriction may occur and vary depending on the target cell type and infecting virus (Fig. 1). How the phosphorylation of SAMHD1 affects its RNase activity and retroviral restriction has not been defined. It remains unknown if SAMHD1 has a broad RNase specificity to restrict other RNA viruses or if this is unique to HIV-1. Moreover, it is also unknown whether SAMHD1 may have RNase activity to degrade newly transcribed HIV-1 mRNA or genomic RNA.

Restriction of Other Viruses by Human SAMHD1

SAMHD1 is able to restrict other retroviruses including feline immunodeficiency virus, bovine immunodeficiency virus, N- and B-tropic murine leukemia virus, and equine infectious anemia virus, through its ability to maintain a low dNTP pool concentration which blocks efficient completion of reverse transcription (White et al. 2013a). Prototype foamy virus (PFV) and human T-cell leukemia virus type 1 (HTLV-1) are not affected by SAMHD1-mediated restriction. PFV reverse transcribes its RNA genome prior to target cell entry and, thus, is not dependent on the intracellular dNTP level in the target cell. HTLV-1, which

Counteraction of SAMHD1 by Vpx, Fig. 1 Mechanisms of SAMHD1-mediated HIV-1 restriction. The figure illustrates the molecular and cellular mechanism underlying SAMHD1-mediated HIV-1 restriction in non-dividing myeloid cells or resting CD4⁺ T cells. SAMHD1 protein localizes in the nucleus and cytoplasm of these cells. Acting as a cellular dNTPase, SAMHD1 decreases

intracellular dNTP levels and thereby limits HIV-1 DNA synthesis during reverse transcription. SAMHD1 has also been proposed to function as an RNase to degrade HIV-1 RNA in the infected cell, which remains to be confirmed. The authors thank Mr. Tim Vojt for the illustration (Reproduced by permission of The Ohio State University)

still undergoes reverse transcription in the cytosol, may have adapted an unknown mechanism to antagonize SAMHD1-mediated restriction (Gramberg et al. 2013). In contrast, abortive HTLV-1 infection in monocytes is linked to SAMHD1 restriction through apoptosis triggered by innate antiviral responses (Sze et al. 2013).

The repertoire of viruses that SAMHD1 can restrict has been further expanded with recent studies finding that DNA viruses, which do not undergo reverse transcription but are dependent on intracellular dNTPs, can also be inhibited by SAMHD1. For example, herpes simplex virus 1 (HSV-1) is restricted in nondividing macrophage cell lines (Kim et al. 2013), vaccinia virus and HSV-1 in nondividing cells (Hollenbaugh et al. 2013), and hepatitis B virus in liver cell lines (Chen et al. 2014).

Counteraction of SAMHD1 by Vpx and Its Implications

Evolutionary Origins of SAMHD1 Counteraction by Vpx

Given its ability to potentially block HIV-1 infection in myeloid cells and quiescent CD4⁺ T cells, it is surprising that HIV-1 lacks Vpx and has not evolved a strategy to counteract SAMHD1. Only two out of the eight primate lentivirus lineages, namely, HIV-2 and SIVsm-derived lineages (SIVsm and SIVrcm), encode the *vpx* gene. Only Vpx in HIV-2 SIVsm, but not SIVrcm, is able to counteract SAMHD1, indicating the species-specific nature of SAMHD1 antagonism by Vpx. HIV-1 and HIV-2 that infect humans have arisen from cross-species transmission of SIV that infects chimpanzees (SIVcpz) and sooty

mangabeys (SIVsm), respectively. One of the key genomic features that distinguish HIV-1 from HIV-2 is its lack of the *vpx* gene, which is also absent in its ancestor, SIVcpz. It is intriguing that HIV-1 and SIVcpz would lack such an important antiviral countermeasure that would enable it to efficiently replicate in myeloid cells and quiescent CD4⁺ T cells and thus increase its pathogenicity. This begs the question whether the lack of *vpx* in HIV-1 is a consequence of the evolutionary selection process and whether it has enabled HIV-1 to be more pathogenic than HIV-2?

Evolutionary analyses have revealed that SAMHD1 underwent a period of strong positive selection during primate evolution where not only Vpx but also Vpr from certain primate lentivirus lineages were able to antagonize SAMHD1 during lentiviral infection (Laguette et al. 2012; Lim et al. 2012). During a genetic conflict between cellular and retroviral genes such as SAMHD1 and Vpx, positive selection occurs in both genes where certain gene mutations that alter the amino acid sequence are rapidly selected in order for one of the genes to overcome the other in the form of an evolutionary arms race. Phylogenetic and functional evidence shows that Vpr was the first lentiviral accessory protein that was able to degrade SAMHD1, which was prior to the “birth” of *vpx* (Lim et al. 2012). It was such an antagonism that initiated an evolutionary arms race between SAMHD1 and Vpr that continued with the advent of Vpx in subsequent lentivirus lineages. It is believed that the birth of *vpx*, which occurred via a gene duplication event of *vpr*, was driven by the need to counteract the restriction imposed by SAMHD1 in certain primate species. Interestingly, as primate lentiviruses evolved under the selective pressure of SAMHD1 restriction, it appears that the *vpx* gene was not inherited by the co-ancestor of SIVcpz and HIV-1 (Zhang et al. 2012), which still enabled these lentiviruses to be pathogenic in their respective hosts. When comparing the pathogenicity of HIV-1 to that of HIV-2, it appears that the lack of Vpx and thereby its inability to counteract SAMHD1 might be one of the reasons why HIV-1 is more pathogenic than HIV-2. However, direct evidence is still lacking to confirm this hypothesis.

Mechanism of SAMHD1 Counteraction by Vpx
HIV-2 and some strains of SIV encode Vpx that is capable of targeting SAMHD1 for proteasomal degradation. This action by Vpx is sufficient to relieve the retroviral restriction posed by SAMHD1 in nondividing cells. Consequently, lentivirus strains that encode Vpx are able to replicate more efficiently in cells that are typically resistant to HIV-1 infection. Virion-incorporated Vpx is released into the cytosol of the infected cell upon viral entry and is able to hijack cellular processes and target cellular SAMHD1 for degradation. The cellular machinery hijacked by Vpx is the DCAF1-E3 ubiquitin ligase complex, which is responsible for the polyubiquitination of cellular proteins. Structure-based analysis of the complex of Vpx with DCAF1 and the C-terminal region of SAMHD1 has provided a molecular mechanism of how Vpx is able to subvert the cell’s normal protein degradation pathway to inactivate the intrinsic immunity against retroviral infection (Schwefel et al. 2014). The precise molecular determinants for the Vpx-SAMHD1 interaction are species dependent, and Vpx from the HIV-2 and SIVmacaque lineages has been mapped to the C-terminus of SAMHD1. The N-terminus of Vpx, which contains a highly conserved motif corresponding to amino acids 24–39 and is present in diverse Vpx and Vpr proteins of primate lentiviruses, interacts with the C-terminus of SAMHD1 and directs it to the DCAF1-E3 ubiquitin ligase complex that targets SAMHD1 for proteasomal degradation (Ahn et al. 2012; Wei et al. 2012). However, the N-terminus of SAMHD1 modulates SAMHD1 interactions with Vpx from SIVmnd-2 and SIVrcm. These molecular variations in the interaction between SAMHD1 and Vpx are not completely elucidated and are likely to have arisen throughout lentiviral evolution and adaptation to the host (Fregoso et al. 2013).

Degradation of SAMHD1 by Vpx occurs in the nucleus (Berger et al. 2012), and Vpx cannot degrade cytoplasmic variants of SAMHD1. Although cytoplasmic SAMHD1 is able to interact with Vpx in the cytoplasm, this complex remains retained in the cytoplasm; thus it is likely that initiation of degradation of SAMHD1

requires nuclear localization of both SAMHD1 and Vpx. Interestingly, although not susceptible to Vpx degradation, cytoplasmic SAMHD1 mutants are capable of effectively restricting lentiviral infection (Brandariz-Nunez et al. 2012; Hofmann et al. 2012).

Counteraction of SAMHD1 by Vpr from SIVs that Lack Vpx

The primate lentiviral protein Vpx counteracts SAMHD1. However, Vpx is unique to only two primate lentivirus lineages, namely, SIVsm and SIVmac. All primate lentiviruses, as well as HIV-2, encode Vpr, a homologue of the HIV-1 Vpr protein. Vpx probably evolved via duplication of its paralogue primate *vpr* gene. Some Vpr proteins from Vpx-lacking lentiviruses also can potentially degrade SAMHD1, often with species specificity. For example, Vpr from HIV-1 and SIV that infects chimpanzee and Old World monkeys cannot degrade human SAMHD1. However, Vpr from SIV that infects De Brazza's monkey can degrade SAMHD1 from all primate species, including human SAMHD1. Similarly, Vpr from SIV that infects mustached monkeys, which is in the same genus as SIV infecting De Brazza's monkey, has broad specificity against primate SAMHD1 proteins. It is likely that positive selection of interacting residues has affected the specificity and sensitivity of binding of Vpx/Vpr protein and degradation of SAMHD1. Evolutionary analysis suggests that *vpr* gained the SAMHD1 degradation function during evolution and indicates that divergent Vpr proteins can functionally degrade SAMHD1 (Lim et al. 2012).

Implications for HIV-1 Due to Lack of Vpx

The presence of Vpx has given HIV-2 an advantage over HIV-1 in the fact that the former is able to replicate more efficiently in myeloid cells that are important for innate immunity. However, incongruously HIV-2 is less pathogenic than HIV-1 and it is speculated that overcoming SAMHD1-mediated restriction in myeloid cells through Vpx triggers an innate immune response by HIV-2 which limits viral replication. Conversely, HIV-1 that lacks such a viral countermeasure against SAMHD1 fails to trigger an innate

immune response due to the lack of productive infection of myeloid cells and is able to evade detection by the immune system. Recent experimental evidence has demonstrated that if SAMHD1-mediated restriction can be overcome in myeloid cells, HIV-1 is then able to trigger an innate immune response and activate myeloid cells, which further confirms the role SAMHD1 plays during HIV-1 infection and in regulating the innate immune response.

Conclusion

The discovery of SAMHD1 as an HIV-1 restriction factor in 2011 and the rapid progress in studying its functions have generated rich information about this novel dNTPase. The focus has been on dissecting the molecular and cellular mechanisms by which SAMHD1 blocks retroviral infections and interacts with the lentiviral protein Vpx and other host proteins. It is clear that SAMHD1 acts as an HIV-1 restriction factor only in nondividing cell types, such as myeloid cells and resting CD4⁺ T cells. However, the molecular basis of the cell-type-specific HIV-1 restriction is not fully understood. Low levels of intracellular dNTPs and expression of unphosphorylated SAMHD1 in these cell types are clearly correlated with HIV-1 restriction. Several cell-cycle regulatory host proteins, including cyclin A2 and CDK1/2, phosphorylate SAMHD1 in cells and may affect cellular dNTP hemostasis. Additional mechanisms, such as RNase activity of SAMHD1, may also contribute to SAMHD1-mediated HIV-1 restriction in nondividing cells.

The future directions of SAMHD1 studies may include at least three major aspects. First is to clearly define the molecular mechanisms underlying SAMHD1-mediated retroviral restriction in primary human myeloid cells and resting CD4⁺ T cells. It is important to dissect the connections between HIV-1 restriction function of SAMHD1 and the regulation of the cell cycle. Second is to translate basic knowledge of SAMHD1 into development of new therapeutic interventions against HIV-1. The key question is how to balance HIV-1 inhibition and nonspecific dNTP

degradation by SAMHD1 in seeking a potential anti-HIV strategy. Third is to explore its physiological functions *in vivo* with a focus of its functions in regulating the innate immunity during viral infections. The success of these three aspects would depend upon further structural and functional analyses of SAMHD1 and its interactions with Vpx and host cofactors.

CRM1

Venkat R. K. Yedavalli

Molecular Virology Section, Laboratory of Molecular Microbiology, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, MD, USA

Definition

CRM1, chromosome *region maintenance* 1 protein also known as exportin-1 (XPO1), mediates the export out of the nucleus of cellular proteins with a leucine-rich nuclear export signal (NES, a short 8–15 amino acid hydrophobic motif), such as the HIV-1 Rev and the HTLV-1 Rex proteins, and the transport of small RNA cargoes. The gene for CRM1 is located on chromosome 2p15. CRM1 is widely conserved and is found in species ranging from candida, yeast, drosophila, xenopus, and mammals.

Organization of CRM1 Protein

The CRM1 protein is 1071 amino acids in length (<http://www.uniprot.org/uniprot/O14980>) (Kudo et al. 1997). It is a member of the karyopherin β family (Moroiianu 1998). This family of proteins is involved in many nucleocytoplasmic transport events; the karyopherin proteins are termed either importins or exportins, depending on the direction that they ferry their cargoes. Human CRM1 shares an N-terminal domain (amino acids 46–112) with homology to karyopherin β 1, β 2, β 3, and β 4 (Fornerod et al. 1997), and it has 10 HEAT repeats (amino acids 217–1039). The HEAT-repeat domain was originally identified in the four proteins that give rise to the name [Huntingtin, elongation factor 3 (EF3), protein phosphatase 2A (PP2A), and yeast kinase TOR1]; the HEAT repeats form a rodlike helical structure that provides a broad surface accessible for interaction with multiple ligands such as GTPase proteins and the FG (phenylalanine-

glycine) sequence repeats, commonly found in many nuclear pore proteins (Denning et al. 2003). Mutagenesis analyses of the CRM1 protein have shown that the region spanning amino acids 1–679 are important for supporting HTLV-1 Rex function while amino acids 327–450 interact with the Ran (*Ras*-related nuclear protein) GTP-binding protein, and amino acids 800–820 bind the HIV-1 Rev protein. Structures have been obtained of CRM1 bound to NES peptides (Guttler et al. 2010); from the structure, it can be deduced that Leptomycin B, a potent antifungal antibiotic, blocks the action of CRM1 via its formation of a covalent bond with the Cys528 residue of human CRM1, which is located in its NES-binding groove (Dong et al. 2009a) Dong et al. 2009b). Leptomycin B, thus, prevents NES proteins from CRM1 binding.

Cargo Transport Functions of CRM1

Karyopherin β proteins are involved in the import or the export of cargoes into or out of the nucleus. The direction of movement is governed by a RanGTP gradient. Thus karyopherin β importins bind their import substrates at low concentrations of RanGTP in the cytoplasm and release them in the high-RanGTP environment in the nucleus (Rexach and Blobel 1995; Jakel and Gorlich 1998) Conversely, karyopherin β exportins bind their export substrates at high-RanGTP concentrations in the nucleus and then move into the cytoplasm (Fornerod et al. 1997) where the cargo is disassembled upon GTP hydrolysis by RanGAP (Ran GTPase-activating protein) and RanBP1 (Ran-binding protein) or RanBP2 (Bischoff and Gorlich 1997; Kutay et al. 1997). The exportin proteins can be re-imported into the nucleus to provide a next round of service.

A major function of CRM1 is its export of NES-containing proteins. A recent survey identified 221 human NES proteins that are substrates of CRM1 (Xu et al. 2012). This list of proteins, which includes several biological important factors such as BRCA1, Cyclin B1, hTERT, I κ B α ,

and NANOG, is available at the <http://prodata.swmed.edu/LRNes> website. Besides its role in the export of NES proteins, CRM1 is also well described to function in the nuclear export of U-rich snRNAs (small nuclear RNAs) and in the intranuclear transport of snoRNAs (small nucleolar RNAs). The U snRNAs (e.g., U1, U2, U4, and U5) act in RNA splicing and are transcribed in the nucleus where they are monomethyl m^7G -capped. Interestingly, m^7G -capped U snRNA complexed with a phosphorylated adaptor for RNA export (PHAX, Ohno et al. (2000)) is then exported into the cytoplasm by CRM1 where it associates with survival of motor neuron (SMN) proteins (Massenet et al. 2002) and becomes hypermethylated (trimethylated) on the G cap by the PIMT protein (see ► [PIMT/TGS1](#)) (Yedavalli and Jeang 2010) to form a mature snRNP (small nuclear ribonucleoprotein) complex. Trimethylated-G-capped snRNPs are then re-imported into the nucleus to participate in mRNA splicing. Another activity of CRM1 is the intranuclear transport of small snoRNAs (e.g., U3, U8, and U13) into and between nuclear compartments such as speckles, Cajal bodies, and nucleoli (Boulon et al. 2002). Interestingly, snoRNAs, like mature snRNAs, have a trimethylated G cap, and it has been raised that this N-terminal trimethylated G cap might in part contribute to the specificity of snRNA and snoRNA recognition by CRM1 (Yedavalli and Jeang 2011). CRM1 has also been suggested to be one of several nuclear export receptors for the 60S ribosomal subunit in yeast (Hung et al. 2008).

Rev Is an Export Substrate of CRM1

The HIV-1 Rev (see ► [HIV-1 Rev Expression and Functions](#)) and the HTLV-1 Rex proteins are now known to be two of the 221 NES-containing proteins that are exported from the nucleus by CRM1 (Xu et al. 2012). Historically, the initial observations were made that the HIV-1 Rev protein competed for nuclear export in a pathway employed by 5S rRNA and U snRNAs (Fischer et al. 1995). Subsequent observations from model experiments

performed in xenopus (Fornerod et al. 1997) and yeast (Neville et al. 1997) cells verified that the export of Rev from the nucleus was dependent on the interaction between Rev's leucine-rich NES signal and the CRM1 nuclear receptor. Rev is a 116 amino acid protein that binds to a ~350 nucleotide stem-loop-rich RRE RNA motif positioned at nucleotides 7709–8063 in the HIV-1 genome. The RRE motif is present in 9 kb (unspliced) and 4 kb (singly spliced), but not 1.8 kb (multiply spliced), viral transcripts. Currently, it is understood that Rev is first imported into the nucleus via interaction between its arginine-rich nuclear localization sequence (NLS) with importin β , and it exits the nucleus via NES engagement with the CRM1 protein. Rev binds RRE-containing HIV-1 RNAs and is instrumental in the egress of unspliced and singly spliced, but not multiply spliced, HIV-1 RNAs from the nucleus (see ► [DDX3, Cofactors, and RNA Export](#); Harris and Hope 2000). Parallel studies have also shown that CRM1 is also the nuclear export receptor for the HTLV-1 Rex protein (Hakata et al. 1998).

Conclusion

Studies on CRM1 have enriched the understanding of pathways employed for the nuclear export of important biomolecules. Moving forward, an emerging area of interest lies with the development of CRM1-specific inhibitory drugs that are potentially useful for blocking protein mislocation (see ► [Cellular Cofactors of HIV as Drug Targets](#)). In cancer cells, tumor suppressor proteins are frequently mislocated from the nucleus into the cytoplasm, rendering them functionally effete. Blocking the nuclear export function of CRM1 in some instances has demonstrated utility in cancer therapy (Turner and Sullivan 2008). An increasingly large number of new CRM1 inhibitors are being developed (Wach et al. 2010; Bonazzi et al. 2010; Monovich et al. 2009; Sakakibara et al. 2011; Ranganathan et al. 2012). They hold promise for future investigation of physiological and/or therapy of pathological CRM1-mediated processes.

Cryptococcosis and HIV

Radha Rajasingham and David R. Boulware
Division of Infectious Diseases and International
Medicine, Department of Medicine, University of
Minnesota, Minneapolis, MN, USA

Definition

Cryptococcus neoformans and *Cryptococcus gattii* are encapsulated yeasts found in the environment. *Cryptococcus neoformans* is classically isolated from the soil and from bird guano.

Cryptococcosis and HIV, Fig. 1 Biology of *Cryptococcus*. *Cryptococcus* lives in the environment (1), usually in association with certain trees or soil around trees. Humans and animals can become infected after inhaling airborne, dehydrated yeast cells or spores (2), which travel through the respiratory tract and enter the lungs of the host (3). The small size of the yeast and/or spores allows them to become lodged deep in the lung tissue. The environment inside the host body signals *Cryptococcus* to transform into its yeast

form, and the cells grow thick capsules to protect themselves (4). The yeasts then divide and multiply by budding. In persons with weaker immune systems, after infecting the lungs, *Cryptococcus* yeasts can travel through the bloodstream (5) – either on their own or within macrophage cells – to infect other areas of the body, typically the central nervous system (6) (Modified from Centers for Disease Control and Prevention www.cdc.gov/fungal/diseases/cryptococcosis-neoformans)

Cryptococcus gattii has been isolated from plants and trees, classically eucalyptus trees. This fungus infrequently causes infection in healthy persons but is also an opportunistic pathogen in persons with defects in cell-mediated immunity, such as HIV. In HIV-infected persons, those with a $CD4 < 100$ cell/ μ L are at particular risk of developing cryptococcal infection. *Cryptococcus* yeasts are acquired through inhalation, with ubiquitous environmental exposure (Fig. 1). As the immune system weakens, from conditions such as HIV infection, organ transplantation, cirrhosis, or corticosteroid use, the fungus can disseminate from the lungs throughout the body, including the brain, skin, and other organs.

Cryptococcus gattii

Although *C. neoformans* causes the predominant burden of disease, *C. gattii* has been identified as

causing disease in immunocompetent persons. Historically, *C. gattii* has been endemic in Australia, with reservoirs in the soil, plants, and trees. The majority of those exposed to *Cryptococcus* remain asymptomatic. If symptoms develop, they are typically mild pulmonary symptoms, and spread to the brain is uncommon but possible. However, in 1999 there was a *Cryptococcus gattii* outbreak in Vancouver Island, British Columbia, Canada, that eventually spread to the United States' Pacific Northwest by 2004. In British Columbia alone, 338 cases were described between 1999 and 2012 (Phillips et al. 2015) and another 100 cases in the Pacific Northwest between 2004 and 2013 (Harris et al. 2013). With respect to this specific epidemic, risk factors for infection include oral steroids, underlying lung conditions, smoking, HIV infection, and underlying malignancy (Phillips et al. 2015). During this

outbreak, only ~20% of persons had an underlying immunocompromising condition. Presentation has typically been with nonsevere pulmonary illness, though approximately one third of persons presented with central nervous system (CNS) disease (Phillips et al. 2015; Smith et al. 2014). During this outbreak, ~25% of persons died within 12 months (Phillips et al. 2015).

Clinical Manifestations

In HIV-infected persons, cryptococcosis typically manifests as meningitis in persons with $CD4 < 100$ cells/ μ L. Other manifestations include pneumonitis and extrapulmonary infections such as cryptococcosis of the skin, eye, or prostate.

Cryptococcal Meningitis

Although the dissemination is widespread, the spread to the brain causes a subacute meningoencephalitis with symptoms developing over several weeks. Typical symptoms include fevers, headache, stiff neck, nausea, vomiting, visual changes, altered mental status, and/or seizures. Cryptococcal meningitis is the most common CNS infection among persons living with AIDS.

Pulmonary Manifestations

As mentioned previously, cryptococcal infection is acquired by inhalation and can colonize the airway without manifestation of symptoms. However, cryptococcosis can cause a range of pulmonary manifestations including pneumonia, pulmonary nodules, cavitary lesions, and hilar adenopathy. In those severely immunosuppressed with a $CD4 < 100$ cells/ μ L, persons are more likely to have symptoms such as fever, cough, and shortness of breath, and there is often quick progression to meningitis. Infectious differential for pneumonia in this patient population includes *Pneumocystis*, bacterial pneumonia, *Nocardia*, mycobacterial infection, and Kaposi sarcoma.

Other Manifestations: Skin, Prostate, and Eye

Skin manifestations are the third most common presentation of cryptococcal infection and can

signify disseminated infection. In HIV-infected persons, cutaneous cryptococcosis resembles molluscum contagiosum, though in immunocompromised hosts it can also present as a cellulitis, ulcers, or abscess. Given the variety in presentations diagnosis is confirmed by a skin biopsy histopathology. Cryptococcal infection of the prostate gland is often asymptomatic and identified during urologic surgery for other reasons. During surgery, infection can spread to the bloodstream. Ocular manifestations of cryptococcal infection are often related to elevated intracranial pressure and compression of the ophthalmic artery. Thus, on ophthalmologic exam, one may find papilledema or cranial nerve palsies. Management of elevated intracranial pressure can prevent blindness in this context. Ocular involvement may manifest during paradoxical immune reconstitution inflammatory syndrome (IRIS) (Boulware et al. 2010a).

Epidemiology

Before the extensive roll out of antiretroviral therapy (ART), the burden of cryptococcal meningitis was estimated in 2008 to be almost 1 million cases annually, causing 624,700 deaths annually (Park et al. 2009). The vast majority of cases (70%) occur in sub-Saharan Africa, where *Cryptococcus* is the most common cause of meningitis in adults (Siddiqi et al. 2014; Durski et al. 2013). Typically, 95% of those with cryptococcal meningitis have a $CD4 < 100$ cells/ μ L in the absence of ART. One multinational study of 501 patients with cryptococcal meningitis observed a median $CD4$ count of 24 cells/ μ L (IQR 10–50 cells/ μ L) (Jarvis et al. 2014). In settings with excellent healthcare access to early ART with retention-to-care, cryptococcal meningitis is relatively rare. However, persons still present late to care worldwide, and in the USA, at least 2400 recognized hospitalizations for HIV-related cryptococcal meningitis occur annually (Pyrgos et al. 2013). The overall incidence rate in the USA is 1.1 per 100,000 total population, making cryptococcal meningitis more common than all causes of bacterial meningitis combined at 0.73 hospitalizations per 100,000

population (Pyrgos et al. 2013; Castelblanco et al. 2014). In resource-limited settings, with limited ART coverage, challenges with retention in care, and lack of virologic monitoring, people still present with opportunistic infections such as cryptococcal meningitis. An increasing proportion (40–50%) of cryptococcal meningitis is occurring among persons on ART, being a mixture of unmasking disease in the first few months of ART or late virologic failure with AIDS progression. In low- and middle-income countries, cryptococcal meningitis accounts for 15–20% of AIDS-related deaths (Park et al. 2009; Liechty et al. 2007).

Diagnosis

Classically, the gold standard for the diagnosis of cryptococcal meningitis is through growing *Cryptococcus* yeasts on CSF culture. While indisputable, this often takes 5–14 days to culture. Practically speaking, given that cryptococcal meningitis is a life-threatening infection that is uniformly fatal without therapy, treatment must be initiated immediately, and more timely diagnosis is essential to avoid starting potentially toxic therapy if not necessary. As a result, surrogate tests such as India ink and especially cryptococcal antigen (CrAg) are often used for presumptive diagnosis while awaiting final culture results.

India ink essentially uses black ink as a negative stain of CSF on a microscope slide. With a light microscope, the thick polysaccharide capsule of the organism remains unstained and lights up over a dark background. This quick test is ~85% sensitive and is often the first test performed in resource-limited settings (Boulware et al. 2014a). Unfortunately, among HIV-infected persons in sub-Saharan Africa, the most common meningitis diagnosis among CSF India ink negative persons often is still cryptococcal meningitis (Boulware et al. 2014a), since for persons with access to medical care presenting early with low burden of infection, the India ink sensitivity is poor (Boulware et al. 2014a; Williams et al. 2015).

A more sensitive diagnostic technique is to detect the CrAg which is the polysaccharide sugar of the capsule of the yeast. CrAg can be detected by enzyme immunoassay, latex agglutination, or lateral flow assay. CrAg assays in the CSF and serum are highly sensitive and specific (>99%). CrAg latex agglutination has been used for many decades; however, the process of latex agglutination requires refrigeration of reagents, heat inactivation of the specimen, lab infrastructure for agglutination testing (e.g., rotator, heat block, electricity), and laboratory labor which although simple is relatively labor intensive (Rajasingham et al. 2012a).

In July 2011, a lateral flow assay was US Food and Drug Administration (FDA) approved and CE marked in Europe for rapid, point-of-care detection of CrAg (Immy Inc. Norman, Oklahoma, USA). This dipstick test requires a drop of CSF, serum, plasma, or urine and produces positive or negative results within 10 min. This is more practical in most settings as it can be done outside of the lab, without additional equipment, and at room temperature. This test has been validated to have a sensitivity and specificity of >99% in CSF and serum and in fact has been found to be more sensitive than culture (Boulware et al. 2014a). Real world end-user costs in low/middle income countries are approximately \$3–4/test, including assay cost, shipping, importation fees, distribution, laboratory supplies, and labor.

The CrAg lateral flow assay has changed the landscape of cryptococcal diagnostics. As a point-of-care test, the test can be used at the bedside at the time of lumbar puncture to test CSF. However, a more useful application, particularly in resource-limited settings, is point-of-care CrAg testing prior to performing a lumbar puncture. The CrAg lateral flow assay can also be used with whole blood, serum, or plasma. If CrAg is positive in blood or by fingerstick testing (Williams et al.), then a manometer can be used during lumbar puncture to measure opening pressure. If no manometer is available, then a large volume (20 mL) lumbar puncture can be performed (Rolfes et al. 2014). The point-of-care nature of this test allows healthcare workers to triage

patients to further intervention after early identification of this fatal illness.

Positive CrAg in blood amongst persons who are symptomatic should always prompt a lumbar puncture for evaluation for cryptococcal meningitis and control of increased intracranial pressure.

Serum CRAG may be a good screening tool for HIV-infected persons with suspected pulmonary cryptococcal infection. However, if positive, one tries to confirm with fungal cultures of the sputum. Given the broad differential for an HIV-infected person with a CD4 < 100 cells/ μ L with pulmonary infiltrates, bronchoscopy is often performed to evaluate for other causes of infection. If a nodule is present, biopsy and histopathology can distinguish cryptococcal infection from malignancy.

Treatment

Treatment of cryptococcal meningitis requires antifungal therapy along with management of elevated intracranial pressure. Intracranial pressure management is an equally important aspect of treatment which is often neglected. Antifungal therapy is generally divided into induction, consolidation, and maintenance therapies. Induction therapy is initiated soon after the diagnosis is made. The preferred induction therapy is 14 days of intravenous amphotericin B 0.7–1.0 mg/kg/day in combination with flucytosine 100 mg/kg/day (Table 1) (Perfect et al. 2010; World Health Organization 2011; Masur et al. 2014). This regimen has been proven to be superior to amphotericin alone with improved survival and sterilization of

Cryptococcosis and HIV, Table 1 Treatment of cryptococcal meningitis

Medication and Daily Dose	~2 weeks ^b	8 weeks	52 weeks
Amphotericin B deoxycholate 0.7 to 1.0 mg/kg + second agent ^a	Continue until CSF is known sterile		
Fluconazole 800-1200mg			
Fluconazole 400mg			
Fluconazole 200mg			
Treatment Phase	Induction	Consolidation	Secondary ^d Prophylaxis

^aFlucytosine (5FC) 100 mg/kg/day preferred where available (Day et al. 2013), otherwise fluconazole at 800–1200 mg/day in divided doses. KCl 40–60 mEq/day should be given with amphotericin (Bahr et al. 2014); Flucytosine is dose reduced with kidney dysfunction with 50% dose reduction at creatinine clearance of <50 mL/min and 25% of dose at <25 mL/min (Perfect et al. 2010; Masur et al. 2014)

^bOptimal duration of initial induction therapy is unknown and likely dependent on the fungal burden of the individual patient. Traditional induction therapy duration is 14 days (Perfect et al. 2010; World Health Organization 2011; Masur et al. 2014). In resource-limited regions, the cost-benefit is likely maximal for 1 week induction with amphotericin B deoxycholate at 1 mg/kg/day coupled with 4–6 weeks of fluconazole 1200 mg/kg/day (Rajasingham et al. 2012b). In settings where electrolytes cannot be actively monitored and managed, no more than 1 week of amphotericin should be given (World Health Organization 2011)

^cContinue fluconazole at 800–1200 mg/day until the CSF culture result is known to be sterile and ART has been initiated. Consider longer duration of enhanced consolidation therapy if CSF culture is positive at 2 weeks. Reverting to 400 mg/day of fluconazole when culture positive is a risk factor for 10-week mortality and paradoxical IRIS (van der Horst et al. 1997; Jarvis et al. 2014; Chang et al. 2013). Continuing 800 mg/day of fluconazole ameliorates this excess risk of 2 week CSF culture positivity (Rolfes et al. 2015)

^dSecondary prophylaxis with fluconazole 200 mg/day should be continued for at least 1 year. IDSA guidelines recommend until CD4 > 100 cells/ μ L and viral suppression for >3 months (Perfect et al. 2010). In the absence of virologic monitoring, WHO recommends continuation for at least 1 year and until two CD4 > 200 cells/ μ L measurements at least 6 months apart (World Health Organization 2011)

CSF cultures (Day et al. 2013; van der Horst et al. 1997). In resource-rich settings liposomal amphotericin is often used due to better tolerability, fewer side effects, and decreased risk of nephrotoxicity.

Side effects from amphotericin are many, most importantly causing renal wasting of potassium and magnesium which can cause life-threatening hypokalemia (Bahr et al. 2014). Up to 30% of persons will have a transient significant rise in their creatinine (Jarvis et al. 2014); however, overt acute kidney failure is uncommon with appropriate care. In older populations and those with preexisting kidney disease, amphotericin-related nephrotoxicity can be expected. Patients receiving amphotericin require at least 1 L of intravenous normal saline prior to each dose and frequent monitoring of serum electrolytes. The WHO now recommends preemptive electrolyte supplementation with potassium and magnesium during amphotericin therapy to prevent life-threatening electrolyte disturbances (World Health Organization 2011; Bahr et al. 2014). Other side effects include phlebitis and infusion reactions including rigors, chills, and fevers secondary to the medication. The vast majority of clinical trials have used amphotericin B deoxycholate. Liposomal amphotericin does not have better efficacy but does have fewer side effects.

Flucytosine is used in combination with amphotericin, at a dose of 25 mg/kg every 6 h in those with normal renal function. Strict dosage adjustment is required in those with reduced renal function, which is common especially when given in combination with amphotericin. Dose reduction is proportional to the decreased creatinine clearance with 50% of dose at creatinine clearance of <50 mL/min and 25% of dose at creatinine clearance of 10–25 mL/min. Side effects include bone marrow toxicity and hepatotoxicity, so drug levels are monitored two hours after dosing, typically after 3–5 days to keep peak levels under 100 µg/mL. Flucytosine is not available in most locales due to its current cost (~\$2000/day in the USA) but is available in Europe. Thus, the majority of patients globally do not receive this medication. Instead, adjunctive

fluconazole is used as an alternative (Perfect et al. 2010; World Health Organization 2011). High dose fluconazole (800–1200 mg daily) is more fungicidal than 400 mg/day without appreciable side effects (Longley et al. 2008). Fluconazole has good penetration into the parenchyma of the brain, whereas amphotericin penetration is more limited. As fluconazole is 90% eliminated by the kidneys, dose adjustments are recommended with declining renal function.

Consolidation therapy, as recommended by the IDSA guidelines, consists of fluconazole at 400–800 mg daily for at least 8 weeks. As the day 14 CSF culture status is typically not known for another 10–14 days, many experts will continue an initial *enhanced* consolidation therapy of fluconazole at 800–1200 mg/day until the CSF is known to be sterile and ART has been started (Rolfes et al. 2015). With doses of fluconazole ≥ 800 mg/day, dividing the dose can decrease nausea. Persons with positive cultures at 2 weeks should have longer consolidation therapy of 10–12 weeks.

Maintenance therapy for secondary prophylaxis is with fluconazole 200 mg daily. IDSA guidelines recommend discontinuing this maintenance after 1 year of antifungal therapy once CD4 > 100 cells/µL and the patient has an undetectable HIV VL for >3 months to prevent cryptococcal relapse. For many individuals, ART is initiated 4–5 weeks after the initial infection with *Cryptococcus*, and the CD4 should have reconstituted by the time the maintenance phase is reached. However, if ART is unavailable, or the patient remains on a failing regimen, fluconazole should be continued while CD4 < 200 cells/µL. In the absence of virologic monitoring, WHO recommends continuation of secondary prophylaxis for at least 1 year and until the CD4 is >200 cells/µL for more than 6 months (World Health Organization 2011).

Management of Intracranial Pressure

A critical part of treatment success in the management of cryptococcal meningitis is controlling intracranial pressure (Rolfes et al. 2014).

Cryptococcal meningitis is unique from other types of meningitis in that the large cryptococcal capsule obstructs the outflow of CSF in the brain's arachnoid villi. This obstruction results in elevated intracranial pressure. An increased pressure reduces local tissue perfusion and function of the brain. Symptoms of elevated intracranial pressure include headache, nausea, vomiting, and vision changes. Signs on exam may include papilledema, cranial nerve palsies, meningismus, acute onset blindness, or reduced level of consciousness. Elevated intracranial pressure in cryptococcal meningitis has been associated with morbidity and mortality when uncontrolled, and lumbar punctures are recommended to therapeutically reduce pressure. Normal CSF opening pressure is <20 cm H₂O when measured with a manometer in the lateral decubitus position. Lumbar punctures to control intracranial pressure are associated with improved survival, regardless of initial intracranial pressure (Rolfes et al. 2014), suggesting potential benefit for all patients with cryptococcal meningitis. Infectious Disease Society of America guidelines recommend when the CSF opening pressure is >25 cm H₂O, CSF is drained until opening pressure is reduced by 50% or to a normal pressure <20 cm H₂O (Perfect et al. 2010). Thereafter, repeat lumbar punctures should be performed daily to remove CSF until pressures are <20 cm H₂O (Perfect et al. 2010). Unfortunately, in resource-constrained settings, where the majority of cryptococcal meningitis occurs, manometers to measure ICP are unavailable. In this situation, one can use a three-way stopcock, IV tubing, and a meter stick to measure opening pressure (Meda et al. 2014). Alternatively, for a diagnostic lumbar puncture in a person with known cryptococcosis (e.g., CrAg positive in blood), empiric removal of 25 mL of CSF is reasonable, as this is the median amount removed in many African cohorts (Rolfes et al. 2014).

If initial lumbar puncture does not demonstrate elevated opening pressure, and daily assessments are negative for classic signs of elevated ICP, a repeat lumbar puncture is still recommended at the end of induction therapy to document sterilization of CSF. Approximately 20% of persons with

normal intracranial pressure at diagnosis will develop increased intracranial within 7 days (Rolfes et al. 2014), thus there should be a low threshold for repeat therapeutic lumbar punctures.

Neither steroids nor acetazolamide are effective at reducing intracranial pressure and both are not recommended (Perfect et al. 2010; Masur et al. 2014). Serial therapeutic lumbar punctures are the management of choice or neurosurgical placement of shunts for those with persistent problems with increased pressure.

Timing of ART Initiation

Earlier ART initiation is generally preferred for other AIDS-related opportunistic infections, which do not involve the central nervous system (CNS) (Zolopa et al. 2009; Blanc et al. 2011). Although earlier immune recovery decreases the risk for developing other new opportunistic infections, early ART also increases the risk of paradoxical immune reconstitution inflammatory syndrome (IRIS) (Blanc et al. 2011). The vast majority of paradoxical IRIS reactions can cause transient morbidity, being severe at times, but rarely mortality. The exception is IRIS events involving the CNS. IRIS within the CNS initiates local inflammation in a confined space within intracranial structures that are neither permissive to inflammation nor to compression. Cryptococcal-related IRIS can result in death, thus earlier ART may have substantial risk. A multicenter randomized clinical trial tested whether earlier ART (1–2 weeks) vs. delayed ART (4–6 weeks after diagnosis) was the optimal strategy. This Cryptococcal Optimal ART Timing (COAT) trial was terminated early due to 15% worse 26-week mortality with earlier ART. Notably, earlier ART had markedly worse survival among those lacking CSF pleocytosis (i.e., <5 WBC/ μ L CSF) (Boulware et al. 2014b), and this subgroup previously has been shown to be at high risk of paradoxical IRIS (Boulware et al. 2010b; Chang et al. 2013). Additionally, those with ongoing altered mental status at 1 week of antifungal treatment also did worse with earlier ART (Boulware et al. 2014b). There

was no subgroup in whom earlier ART was clearly preferred. This trial definitively proved that starting earlier ART during induction therapy does not improve survival. The COAT trial did not prove that the optimal time to initiate ART is at precisely 5 weeks, and physician judgment is necessary. Aiming for a 4–5 week window is reasonable; however, one first needs to verify that the 2-week CSF culture is sterile before decreasing fluconazole dosing and initiating ART.

Immune Reconstitution Inflammatory Syndrome (IRIS)

IRIS occurs after initiating ART with rapid, excessive inflammation in the context of immune restoration in response to alive or dead organisms within the body that may have gone unrecognized prior to initiation of ART. IRIS can occur with any opportunistic infection, but IRIS is more common for infections where antigen is slowly cleared or persists, such as tuberculosis and *Cryptococcus*. There are two distinct immune reconstitution syndrome scenarios, unmasking IRIS and paradoxical IRIS. These are separate, distinct clinical scenarios but often confusingly grouped together simply as IRIS.

Cryptococcal-related **paradoxical IRIS** occurs in 10–30% of persons with cryptococcal meningitis who survive to initiate ART, at a median time of 6–10 weeks after starting ART but can also occur within the first days to weeks of ART (Boulware et al. 2010a; Chang et al. 2013; Bahr et al. 2013). Paradoxical IRIS occurs after a patient with cryptococcal meningitis has been treated with antifungals, clinically improves, starts ART, and then deteriorates with recurrent meningitis symptoms in the setting of successful microbiologic treatment and sterile cultures. Paradoxical IRIS is primarily an immunologic disease where a previously anergic immune system can now generate an effective immune response against persistent antigen from dead, nonviable organisms. The major risk factors for paradoxical IRIS include initial anergy, poor clearance of antigen, and residual CSF fungal burden (Boulware et al. 2010a, b; Jarvis et al. 2014; Chang

et al. 2013). Readily available clinical risk factors include: (1) low initial CSF white cell count at diagnosis (i.e., anergy); (2) persistently positive CSF cultures when beginning fluconazole 400 mg/day consolidation therapy; (3) high pre-ART serum CrAg ($\geq 1:512$ titer); (4) high pre-ART serum C-reactive protein (CRP) (>32 mg/L) indicative of immune dysregulation and/or smoldering ongoing low-grade infection (Boulware et al. 2010a, b; Jarvis et al. 2014; Chang et al. 2013).

Distinguishing between paradoxical IRIS and culture-positive relapse remains clinically impossible, as symptoms are identical. CSF analysis is critical for distinguishing between IRIS and relapse (Haddow et al. 2010). CSF culture ultimately determines whether there is viable *Cryptococcus* growing suggesting relapse. Sterile CSF cultures are typical of IRIS. In the absence of culture data, IRIS typically presents with more inflammation in the CSF, whereas relapse frequently has more of a paucity of CSF inflammation. There is overlap of CSF parameters, and culture remains essential.

The management of IRIS includes controlling intracranial pressure as a first step. While CSF cultures are pending, increasing antifungal therapy with higher dose fluconazole (800–1200 mg/day) and/or short course amphotericin (i.e., 7 days) is also recommended. For severe cases, with signs of cerebral edema, steroids can be given, although no clinical trials have evaluated the benefit of steroids specifically in cryptococcal IRIS. In TB-IRIS, steroids are effective (Meintjes et al. 2010); however, IRIS may commonly recur with tapering of steroids. In most cases, continuation of ART is recommended (Haddow et al. 2010); however, in severe, life-threatening IRIS, ART may be temporarily discontinued. Intraparenchymal inflammation in the brain can commonly cause new onset seizures as a presenting feature of IRIS. Magnetic resonance imaging (MRI) or head computerized tomography (CT) can often demonstrate variable degrees of intraparenchymal inflammation associated with IRIS.

Cryptococcal unmasking IRIS occurs when a person starts ART with unrecognized, subclinical cryptococcal infection. Due to

immunosuppression, early disseminated cryptococcal infection often has minimal or vague symptoms but is detectable by the presence of CrAg in peripheral blood. If untreated, this will progress to overt symptomatic cryptococcal meningitis over weeks to months (French et al. 2002; Letang et al. 2015). With ART-mediated reconstitution of the immune system, the immune system can respond to the cryptococcal organisms in the brain and/or throughout the body. Clinical manifestations of unmasking disease on ART are more diverse than traditional cryptococcosis in ART-naïve persons. Often symptom onset can be more rapid among persons receiving ART. Additionally, the spectrum of clinical manifestations can be more varied with presentations of meningitis, seizures, focal neurologic deficits, pneumonitis, lymphadenopathy, or sepsis. Within the first 6 months of ART among persons with CD4 nadir of <150 cells/ μL , any new onset CNS symptoms occurring should prompt immediate CrAg testing as well as consideration in any ill-defined, unexplained disease process.

Cryptococcal Relapse

Cryptococcal relapse occurs in approximately 5% of persons who survive cryptococcal meningitis and then have a second episode of cryptococcal infection with viable organisms cultured from the CSF. Relapse can occur years later (Katchanov et al. 2015). Primary causes for relapse include: lack of secondary prophylaxis with fluconazole 200 mg/day or interval development of fluconazole resistance (Jarvis et al. 2010).

Persons with cryptococcal meningitis relapse often present with recurrent signs and symptoms such as fever, headache, possible visual changes, and signs of elevated intracranial pressure. Clinically, if the patient has recently started ART, it is difficult to distinguish from paradoxical cryptococcal IRIS. The ultimate diagnosis can only be made by lumbar puncture and CSF culture. If there is *Cryptococcus* growing in CSF culture, this would indicate relapsed cryptococcal infection. If there is inflammation but sterile CSF cultures, this would suggest cryptococcal IRIS. CrAg

in the CSF or in the serum is not helpful, as the CrAg often takes years to fully clear from the body and is qualitatively positive in both IRIS and cryptococcal relapse. India ink may also be positive in both scenarios. Distinguishing between these two complications of cryptococcal meningitis is critical, as management approaches differ. However, IRIS and relapse may not always be distinct and can coexist (Musubire et al. 2013).

Cryptococcal relapse is distinct from initial treatment failure. In treatment failure, the CSF is never sterilized after the initial episode of meningitis, whereas in relapse, the CSF is sterilized and then subsequently re-infected. Treatment failure suggests an inadequate treatment regimen or fluconazole resistance. Optimal induction therapy for cryptococcal meningitis consists of an amphotericin-based regimen with flucytosine or fluconazole if flucytosine is unavailable. Many resource-limited settings use fluconazole monotherapy, and treatment failure is mainly seen in this context. There is also the possibility of fluconazole resistance if low dose fluconazole is used alone. Amphotericin resistance has not been described with respect to cryptococcal infection. IDSA guidelines recommend induction therapy for 4–10 weeks, using high dose amphotericin at 1 mg/kg/day.

Management of relapse is similar to management of the initial cryptococcal meningitis episode. That is, induction therapy with amphotericin (0.7–1 mg/kg/day) with flucytosine, or fluconazole if flucytosine is unavailable, along with management of elevated intracranial pressure with serial lumbar punctures. Thereafter, one should reinstitute consolidation therapy with high dose fluconazole. If ART has already been initiated, it is important to ensure that persons with relapse are on a fully active regimen, and in the process of reconstituting the CD4 cells, as this will ultimately prevent future infection.

Prevention and Preemptive Therapy

Given the substantial morbidity and mortality from cryptococcal meningitis, especially in low income countries with a high burden of AIDS, an

effective prevention strategy would be highly valuable to health systems, not to mention life saving. Universal fluconazole prophylaxis for all those with a CD4 < 200 cells/ μ L has been evaluated in a randomized controlled trial (Parkes-Ratanshi et al. 2011). Although fluconazole prophylaxis decreased cryptococcal meningitis, overall mortality did not differ between those who received fluconazole prophylaxis and those who did not. Thus, universal prophylaxis has not been recommended, as persons living with AIDS require prompt ART initiation, whereby immune recovery is the most effective long-term prevention.

Screening for cryptococcal infection using serum or plasma CrAg testing prior to initiation of ART among persons with CD4 < 100 cells/ μ L is a cost-effective method to identify subclinical infection that can reduce morbidity and mortality (Mfinanga et al. 2015; Meya et al. 2010). Prevention via screening is possible as CrAg can be detected in the blood weeks to months prior to the development of fulminant meningitis, when people are asymptomatic. CrAg + prevalence amongst asymptomatic HIV-infected persons has been evaluated in multiple settings across sub-Saharan Africa and Asia with a prevalence averaging 7% amongst persons with a CD4 < 100 cells/ μ L (Rajasingham et al. 2012a). Those with detectable CrAg in their blood, despite not having meningitis, have a higher mortality, compared to those who are CrAg negative (Liechty et al. 2007; Mfinanga et al. 2015; Meya et al. 2010). Being CrAg + is 100% sensitive for predicting the development of meningitis within 1 year of ART initiation (Jarvis et al. 2009). Conversely, if one is CrAg negative when initiating ART, the risk of developing cryptococcal meningitis is near zero (Jarvis et al. 2009; Pongsai et al. 2010). Subclinical cryptococcal infection also occurs among persons with CD4 100–200 cells/ μ L; however, the prevalence is lower (approximately 2%). Most of these persons will have an uneventful immune recovery with ART; and the cost-effectiveness is less favorable (Rajasingham et al. 2012a). How best to conduct the screening may vary by structure of the healthcare system; however, many sites are using reflex CrAg lateral flow assay testing of the

leftover plasma sample whenever the CD4 < 100 cells/ μ L.

Those who are asymptomatic but CrAg + derive significant benefit from fluconazole preemptive therapy (Mfinanga et al. 2015; Meya et al. 2010). In 2011, the WHO recommended CrAg screening of those HIV infected with a CD4 < 100 cells/ μ L and preemptive therapy for those CrAg+ with high dose fluconazole (800 mg/day for 2 weeks, followed by 400 mg/day for 8 weeks) (World Health Organization 2011). This may not be optimal preemptive therapy, as the mortality rate is still 30% among CrAg + persons preemptively treated (Mfinanga et al. 2015). Studies are underway evaluating optimal dose and duration of preemptive therapy in this population. The benefit of secondary prophylaxis with fluconazole 200 mg/day in this CrAg + population is also unclear. Coupled with the point-of-care, affordable CrAg lateral flow assay, pre-ART CrAg screening is now recommended in an increasing number of national HIV program guidelines, with various degrees of implementation.

Conclusion

In summary, cryptococcal meningitis is the most common cause of adult meningitis in sub-Saharan Africa, affecting HIV-infected persons predominantly with a CD4 < 100 cells/ μ L. Due to challenges in accessing and retaining persons in HIV care, cryptococcal meningitis continues to occur among marginalized populations and accounts for approximately 20% of AIDS-related deaths in some areas. Cryptococcal meningitis remains a neglected disease with poor outcomes even among optimally treated persons. A novel point-of-care CrAg lateral flow assay has changed the landscape of cryptococcal prevention and diagnostics. Treatment requires management of elevated intracranial pressure by serial lumbar punctures coupled with antifungals. Optimal antifungal therapy of amphotericin and flucytosine is rarely available in resource-limited settings, where the majority of cryptococcal infection occurs. Initiation of ART is unique from other

opportunistic infections as in those with cryptococcal meningitis waiting for approximately 4–5 weeks after diagnosis and treatment of meningitis results in improved outcomes. Paradoxical IRIS can occur after ART initiation, and IRIS can be fatal in cryptococcal infection. Finally, prevention with pre-ART CrAg screening and preemptive treatment of CrAg + persons is a promising, cost-effective public health intervention to decrease the development of cryptococcal meningitis once persons enter into HIV care.

Definition

Cryptosporidiosis is a gastrointestinal infection presenting as diarrhea due to infection with

various species of *Cryptosporidium*, an Apicomplexan parasite.

Introduction

Cryptosporidium is an intestinal parasite of the phylum Apicomplexa, which causes diarrheal disease in humans and animals worldwide (Tzipori and Ward 2002). Initially thought to be a coccidian (subclass Coccidiasina), recent phylogenetic studies indicate that *Cryptosporidium* is more closely related to gregarines (subclass Gregarinasina). Although *Cryptosporidium* was discovered in 1907, it was not until 1976 that the first human cases of cryptosporidiosis were reported and not until the onset of the AIDS epidemic in the 1980s that this parasite was recognized as a significant human pathogen (O'Connor et al. 2011). Cryptosporidiosis was one of the original AIDS-defining illnesses and was associated with an increased risk of death compared to other AIDS-defining illnesses (Shikani and Weiss 2014).

In addition to AIDS patients, other immune-compromised populations at risk for cryptosporidiosis include those on immunosuppressive therapy such as transplant recipients, patients with severe combined immunodeficiency, and X-linked hyperimmunoglobulin M syndrome. Children under the age of 5 years in resource-limited settings, particularly those who are malnourished, are also vulnerable to moderate to severe diarrhea caused by *Cryptosporidium*. In these young children, immaturity of the immune system combined with malnutrition may contribute to immune compromise.

Species and Life Cycle

Twenty-seven species of *Cryptosporidium* have been described (Leav et al. 2003). However, two major species most commonly infect humans; *C. parvum* infects humans and animals while *C. hominis* almost exclusively infects humans. Other species including *C. meleagridis*, *C. muris*, *C. canis*, *C. felis*, *C. suis*, *C. muris*, and *C. andersoni* are also known to infect humans. *Cryptosporidium* exists in several

intracellular and extracellular developmental stages, and the life cycle is completed within a single host. The infective stage of the parasite is the environmentally resistant oocyst which can survive in water for months. The infective dose of oocysts is extremely low but varies by the infecting species or isolate. As few as 10 oocysts have been reported to be sufficient to cause infection.

Infection is initiated by ingestion of oocysts which excyst in the upper small intestine to release four motile sporozoites. Sporozoites attach to and invade the brush border membrane of intestinal epithelial cells and are engulfed by the microvilli. Intracellular replication occurs within a parasitophorous vacuole, in a unique intracellular but extracytoplasmic niche. Small villi-like folds of the parasite cytoplasm extend into the host cell to form a structure called the feeder organelle which is thought to serve as a route of transport between the parasite and host. Within the parasitophorous vacuole, *Cryptosporidium* replicates via asexual and sexual cycles. During the asexual cycle, sporozoites develop into trophozoites which differentiate into Type I meronts. Merozoites, which are morphologically indistinguishable from sporozoites, are released from meronts into the lumen and rapidly invade adjacent cells where they perpetuate the asexual cycle or differentiate into Type II meronts. Merozoites from these meronts initiate the sexual cycle by forming microgamonts and macrogamonts. Microgametes released from microgamonts fertilize macrogamonts and form zygotes which mature into either thick-walled oocysts that are released into the external environment via the feces or thin-walled oocysts that rupture in the intestinal lumen releasing sporozoites that initiate a new round of replication. These thin-walled auto-infective oocysts are thought to contribute to perpetuation of the infection in patients with HIV/AIDS.

Epidemiology

Cryptosporidiosis is found worldwide, but infection prevalence varies widely among different regions and populations at risk (Collinet-Adler and Ward 2010; Checkley et al. 2015). Prevalence rates range from as low as 1% in industrialized

countries to as high as 30% in developing countries. In the USA, the incidence of *Cryptosporidium* was reported to be 2.5–2.7/100,000 for 2009 and 2010 respectively. Seroprevalence rates are higher than those estimated by microscopic examination of stools and range from 30% to 89% depending on geographic region. The widespread use of combination antiretroviral therapy (cART) for HIV/AIDS in developed countries has drastically reduced the prevalence of cryptosporidiosis in these countries. Although cART is available in some developing countries it is not widely available or affordable in some areas where the burden of HIV/AIDS is high. In these countries, *Cryptosporidium spp.* remain a major cause of diarrheal disease in untreated AIDS patients, with prevalence rates as high as 80% reported.

In the general population those at increased risk of acquiring cryptosporidiosis include children in day care centers and their caregivers, travelers to endemic areas, backpackers, campers or hikers who drink unfiltered water from streams or rivers, those who drink unfiltered water from wells, and those who handle infected dairy or farm animals. The risk of acquiring cryptosporidiosis in patients with HIV/AIDS is associated with the degree of immunosuppression as measured by CD4 T cell counts. Other risk factors for cryptosporidiosis in these patients include male gender, younger age, and sexual practices involving oral-anal contact.

Cryptosporidium spp. are one of the most frequent causes of waterborne disease outbreaks. In the USA and other developed countries, most infections are caused by waterborne outbreaks, mostly in drinking water but more recently in recreational water sources such as swimming pools or water parks. The largest ever documented outbreak of waterborne disease in the USA was caused by *Cryptosporidium* in Milwaukee, WI, in the USA and affected an estimated 400,000 people with over 100 deaths in immune-compromised and elderly individuals.

Clinical Manifestations

The clinical features of cryptosporidiosis vary widely depending on the immune status of the

host (Shikani and Weiss 2014). In immune-competent individuals most *Cryptosporidium* infections are asymptomatic. The incubation period for symptomatic cryptosporidiosis is 1–2 weeks. Young children and the elderly are at greater risk for symptomatic infections. Watery diarrhea is the commonest symptom, but abdominal cramps or pain, nausea, vomiting, fever, anorexia, and weight loss may also occur. Diarrhea generally lasts for 1–3 weeks but may persist for a month. In immune-competent individuals, infection is self-limited, and spontaneous recovery is the rule. Recurrence of symptoms may also occur. For example, 30% of those infected during the Milwaukee outbreak reported recurrence of symptoms.

Oocyst shedding may occur in the absence of symptoms. In symptomatic infections, oocyst shedding occurs for 1–2 weeks after symptoms subside but may occasionally continue for up to 2 months. The intensity and duration of oocyst shedding may also depend on the infecting species. The oocyst burden in stools is reported to be greater and oocyst shedding longer in *C. hominis* than in *C. parvum* infections.

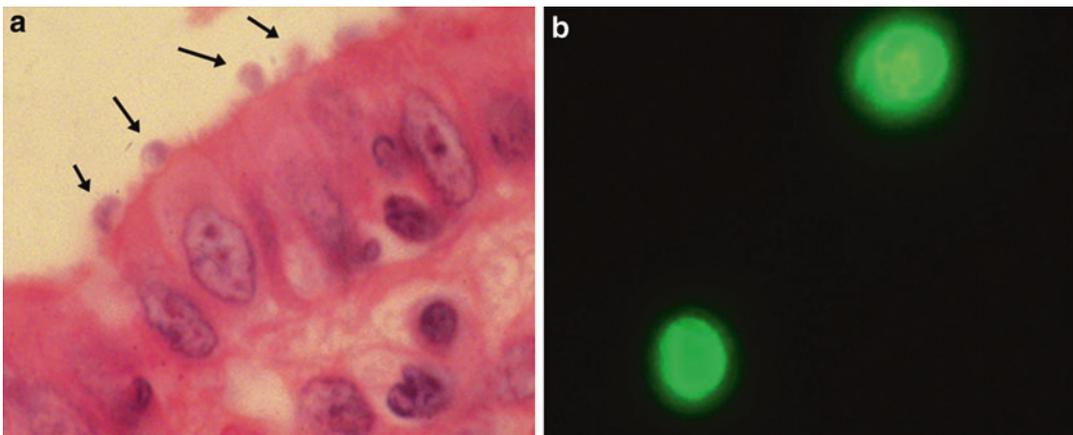

In immune-compromised hosts such as AIDS patients, severity of clinical symptoms is generally related to the degree of immune compromise, with those with CD4 T cell counts less than 200 cells/mm³ being at risk for more severe

clinical disease. Most patients with fulminant cryptosporidiosis have CD4 T cell counts less than 50 cells/mm³. However, some patients with CD4 T cell counts less than 200 cells/mm³ are reported to have asymptomatic infection or mild illness, while others experience severe, debilitating, and chronic diarrhea and wasting which may be ultimately be fatal. The reason for this variability is unknown but may be related to coinfection with other enteric pathogens which exacerbate or suppress symptoms of cryptosporidiosis.

In immune-competent individuals, infection is generally limited to the small intestine (Fig. 1a). However, in AIDS patients, particularly those with low CD4+ T cell counts, other parts of the gastrointestinal tract may be involved including the pharynx, esophagus, stomach, colon, and rectum. Extraintestinal infection involving the gallbladder, biliary tract, pancreatic duct, and respiratory tract have also been reported. Cryptosporidiosis has also been associated with autoimmune conditions such as reactive arthritis and Reiter's syndrome.

Diagnosis

Diagnosis is typically made by microscopic examination of stool samples using acid fast staining or immunofluorescence with

Cryptosporidiosis, Fig. 1 (a) Intestinal biopsy stained with hematoxylin and eosin showing intracellular stages of *Cryptosporidium* (arrows). (b) Immunofluorescence assay

of *Cryptosporidium* oocysts with a monoclonal antibody to the oocyst wall

Cryptosporidium-specific antibodies (Fig. 1b) (Checkley et al. 2015). Acid fast staining has a ~70% sensitivity compared to immunofluorescence. Microscopy with immunofluorescence staining is currently considered the gold standard for clinical diagnosis. Antigen detection methods by ELISA or immunochromatography have higher throughput, but sensitivities vary from 70% to 100%.

Molecular methods including conventional and real-time PCR targeting the 18S ribosomal RNA gene or other genes are much more sensitive than microscopy or antigen detection but are mainly used for research purposes. Real-time PCR quantitation can be multiplexed for detection and quantitation of multiple pathogens and has been adapted to the Luminex platform. Targeting the 18S rRNA gene detects both major species as well as other species that infect humans. Serological assays are used for epidemiological studies and can be indicative of past or current infection. *Cryptosporidium*-specific fecal IgA is associated with recent infection (within 1 month), whereas serum IgG can persist for months to years.

Treatment and Prevention

Management of dehydration caused by diarrhea, particularly in AIDS patients and young children in developing countries, is the mainstay of treatment for cryptosporidiosis and includes oral or intravenous replacement of fluid and electrolytes (Checkley et al. 2015; Leav et al. 2003). Antimotility agents such as opiates or loperamide may also be used. Tincture of opium may be more effective than loperamide. Total parenteral nutrition might be indicated in some patients. Since cryptosporidiosis may be associated with lactase deficiency which may persist into the recovery phase, milk products should be restricted and/or lactase used.

In AIDS patients the mainstay of treatment is restoration of immune function. Antiretroviral (cART) therapy significantly improves diarrheal symptoms in AIDS patients with

cryptosporidiosis. Unfortunately, in spite of extensive testing of various agents, there is no consistently effective antiparasitic drug for cryptosporidiosis in immune-compromised patients (Checkley et al. 2015; Shikani and Weiss 2014). Nitazoxanide and Paromomycin have shown limited efficacy in some trials. Nitazoxanide, a broad spectrum thiazole-containing antiparasitic agent, has been approved by the US Food and Drug Administration for treatment of cryptosporidiosis in immune-competent children and adults. This drug has demonstrated efficacy in reducing the severity and duration of diarrhea in these individuals. However, regardless of dosage or duration of treatment, Nitazoxanide has not been shown to be very effective as primary therapy in immune-compromised patients. In these patients, particularly those with advanced AIDS, Nitazoxanide (500–1,000 mg twice daily for 14 days) or Paromomycin (500 mg four times a day for 14–21 days) in conjunction with cART (but never without cART) may be used.

HIV-infected individuals should be counseled about the different modes of transmission of *Cryptosporidium* and advised to practice scrupulous hand washing after potential contact with human feces, to avoid drinking water from lakes or streams, and to avoid swimming in water that may be contaminated.

Conclusion

Cryptosporidiosis is an important cause of diarrhea in AIDS patients and can be associated with chronic infections as an AIDS defining illness. Infection is associated with higher mortality rates. There are currently no highly effective anti-cryptosporidial drugs for patients with immune dysfunction. Immune restoration and supportive care are the cornerstones of current treatment. Research into effective therapy has been limited due to the absence of long-term culture system, the absence of genetic systems for experimental studies, and the unique cellular niche in which this organism lives.

CXCR4, Coreceptors

Ester Ballana and José A. Esté
IrsiCaixa, Hospital Universitari Germans Trias i Pujol, Universitat Autònoma de Barcelona, Badalona, Spain

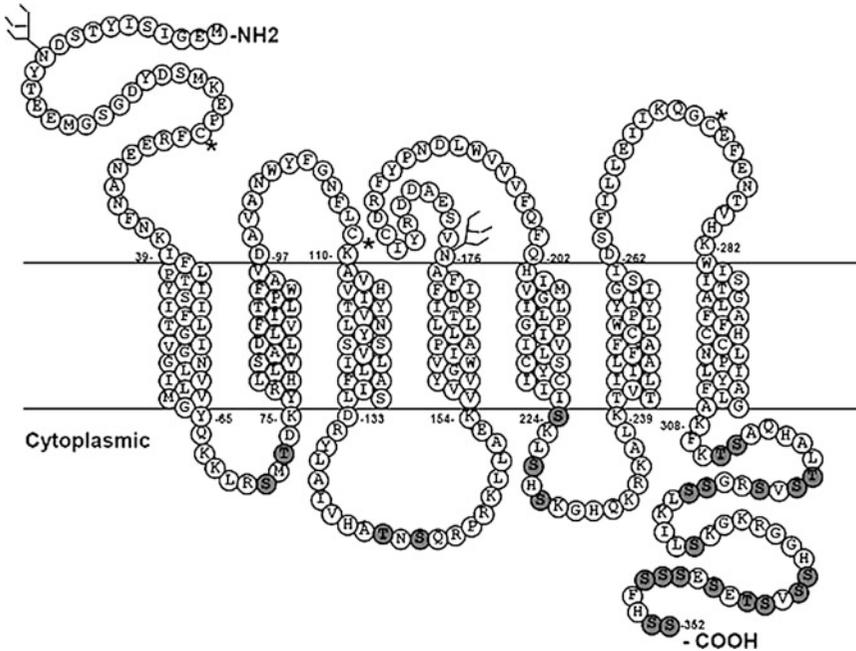

Definition

C-X-C chemokine receptor type 4 (CXCR4) is a G-protein-coupled receptor (GPCR) for the

chemoattractant cytokine (chemokine) CXCL12 (or stromal cell-derived factor-1alpha, SDF-1 α). Along with the CC chemokine receptor 5 (CCR5), CXCR4 is a major coreceptor for the human immunodeficiency virus (HIV) on the surface of CD4⁺ cells. Attachment of the HIV envelope glycoprotein to CXCR4 allows for efficient fusion, entry, and replication of HIV (Su et al. 1999). Amino acid changes in the HIV gp120 glycoprotein, particularly in the V3 loop region, induce HIV to switch coreceptors from CCR5 to CXCR4 which is often associated to a late stage of disease progression or as a mechanism of virus resistance to drugs targeting CCR5. Drugs that block CXCR4 are potent inhibitors of CXCR4-using HIV strains in cell culture and in pilot drug efficacy studies. However, development of such agents has been halted due to adverse drug effects. The CXCR4 antagonist plerixafor (AMD3100, Mozobil[®]) has been approved for clinical use as a hematopoietic stem cell mobilizer as it potently blocks the CXCL12-induced homing of stem cell to the bone marrow. New generation inhibitors and new gene therapy approaches are being developed to block CXCR4 function as a HIV coreceptor.

History of CXCR4 as HIV Coreceptor

CXCR4 (previously known as leukocyte-derived seven-transmembrane domain receptor, LESTR) was first identified as an orphan receptor after isolation of a cDNA clone encoding a 352 amino acid protein (Fig. 1) with roughly 93% homology with that of bovine neuropeptide Y (NPY) receptor and similar to the receptor for interleukin-8 (IL-8) known in the early 1980s to activate and attract leukocytes toward the interleukin gradient (chemotaxis) (Vaddi et al. 1997). However, LESTR expressed in cells after mRNA transfection did not bind or react to other identified chemokines, including NPY, IL-8, NAP-2, GRO alpha, PF4, IP10, MCP-1, MCP-3, MIP-1 alpha, HC14, I309, RANTES, C3a, or LTB4. The close identity of LESTR to the IL-8 receptor was indicative of its function as a chemokine receptor. LESTR, however, was an orphan receptor.

CXCR4, Coreceptors, Fig. 1 Amino acid sequence of CXCR4. Membrane orientation of the seven-transmembrane segments of the receptor and the N- and C-terminal regions in the extracellular and intracellular

regions, respectively. (*) marks the cysteine residues involved in disulfide bonding. Shaded residues represent potential phosphorylation sites. N-glycosylation sites are also indicated

In 1996, the group of Edward Berger discovered fusin, a G-protein-coupled receptor with seven-transmembrane segments that allowed efficient HIV entry when recombinant fusin was transfected into CD4-expressing nonhuman cell types. Antibodies directed to fusin blocked HIV-1-induced cell fusion and infection with normal CD4-positive human target cells and fusin messenger RNA levels correlated with HIV-1 permissiveness in diverse human cell types (Feng et al. 1996).

The CC chemokines MIP-1 alpha and MIP-1 beta and RANTES (renamed CCL3, CCL4, and CCL5, respectively) had been shown to prevent infection with primary, monocyte-tropic viruses but were inactive against T-cell-tropic HIV. These findings were a clear indication that chemokines and their receptors played a major role in the initial steps of HIV infection and set the stage for the identification of stromal cell-derived factor-1alpha (SDF-1 α) or CXCR4 ligand 12 (CXCL12, as it is known now), as the ligand for fusin/LESTR/CXCR4. In 1996, two independent

groups showed that CXCL12 activated nonhuman cells transfected with CXCR4 cDNA as well as blood leukocytes and lymphocytes. In cell lines expressing both CXCR4 and CD4 and in blood lymphocytes, CXCL12 was shown to be a powerful inhibitor of infection by lymphocyte-tropic HIV-1 strains.

Function and Regulation of CXCR4

CXCR4 is one of 19 known human chemokine receptors, belongs to the superfamily of seven-transmembrane G-protein-coupled receptors, and is activated exclusively by the isoforms of chemokine CXCL12. Chemokine binding to CXCR4 induces a change in conformation of the receptor that is transmitted to the cytoplasm domains of the protein, enabling it to couple with an intracellular heterotrimeric G protein that acts as an intracellular signal (Alkhatib 2009).

CXCR4 is functionally expressed on the cell surface of human blood monocytes, neutrophils,

lymphocytes, and phytohemagglutinin (PHA)-activated T-cell lymphoblasts. CXCR4 is also expressed in various cancer cells and plays a role in cell proliferation and migration of these cells, being associated with more than 23 types of cancer, where it promotes metastasis, angiogenesis, and tumor growth or survival. Deletion of CXCR4 or CXCL12 in mice confers embryonic lethality and leads to defects in vascular and central nervous system development, hematopoiesis, and cardiogenesis, indicating a monogamous relation between CXCL12 and CXCR4. The CXCR4-CXCL12 axis is functional in evolutionarily distant organisms such as zebrafish and mice, in which CXCR4 expression is a prerequisite for germ cell migration to CXCL12-expressing gonads during development (Este and Lederman 2009).

CXCL12 induces internalization of CXCR4 molecules leading to downregulation of receptor sites at the cell surface, desensitizing cells from further chemokine stimulus and contributing to the chemokine-mediated inhibition of HIV-1 entry by making the cell invisible to CXCR4-using virus. Downregulated receptors are endocytosed and either recycled back to the plasma membrane or sorted into the degradative pathway. For CXCR4, this process is controlled by a protein called E3 ubiquitin ligase AIP4 that is required for degradation of CXCR4 and a cytokine-independent survival kinase (CISK) that blocks AIP4 activity, inhibits endosomal sorting, and favors recycling of the receptor (Alkhatib 2009).

The Structure of CXCR4

The limited crystallography data on chemokine receptors was mainly due to the fact that such proteins are highly hydrophobic and cannot be readily purified. However, in 2010, the crystal structures of human CXCR4 were resolved in complex with a small-molecule antagonist (IT1t, Fig. 4) at 2.5 Å resolution and with a cyclic peptide inhibitor at 2.9 Å resolution. The final model included 293 residues (27–319) of the 352 residues of CXCR4 (Wu et al. 2010). The main fold of CXCR4 consists of the canonical

bundle of seven-transmembrane helices (Fig. 2), which shows about the same level of structural divergence from seven-transmembrane helical bundles of previously solved GPCR structures as the rhodopsin receptor, the β_2 -adrenergic receptor, and the adenosine receptor A_{2A} .

The extracellular interface of CXCR4 consists of 34 N-terminal residues, extracellular loop 1 (ECL1, residues 100–104) linking the transmembranes helices II and III, ECL2 (residues 174–192) linking helices IV and V, and ECL3 (residues 267–273) linking helices VI and VII (Fig. 2). The intracellular side of CXCR4 contains the intracellular loop 1 (ICL1, residues 65–71) linking helices I and II, ICL2 (residues 140–144) linking helices III and IV, ICL3 (residues 225–230) linking helices V and VI, and the C terminus. There are two disulfide links in CXCR4 formed between cysteine (Cys) residues 28 and 274 and 109 and 186, both in the extracellular part of the receptor. The disulfide link between Cys109 and Cys186 is critical for ligand binding and functions by constraining ECL2 and the N-terminal segment (residues 27–34), which shapes the entrance to the ligand-binding pocket (Wu et al. 2010).

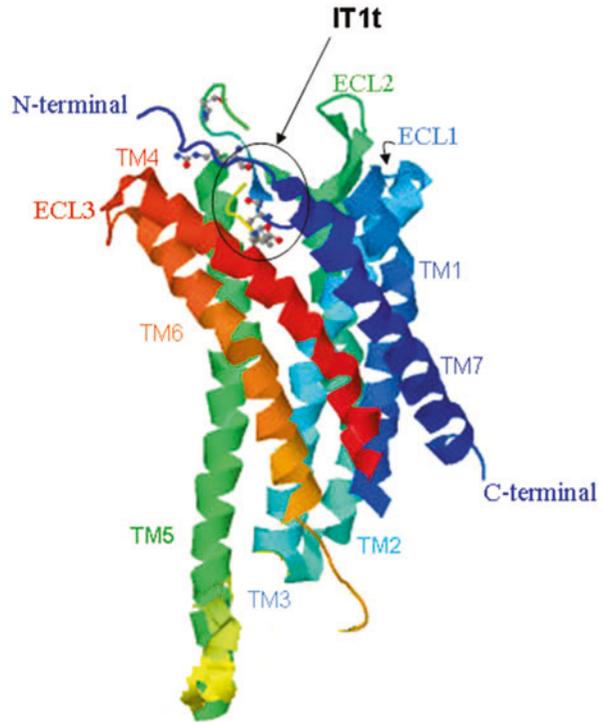

CXCR4 has been shown to form homo- and heterodimers, constitutively and upon binding to CXCL12. Receptor dimerization is important for *in vivo* pharmacological effects. For example, warts, hypogammaglobulinemia, infections, and myelokathexis syndrome (WHIM syndrome) has been linked to mutations in the C terminus of CXCR4 and results in truncated variants that exhibit enhanced signaling and fail to desensitize and internalize upon CXCL12 stimulation.

CXCR4 Interaction with HIV-1

HIV binds to the cell surface of CD4-positive cells through the virus envelope complex formed by two glycoproteins: gp120 and gp41. HIV-1 gp120 mediates the initial contact with the cell surface, binds the CD4 receptor, and interacts with the coreceptors CCR5 and CXCR4. The viral surface protein gp120 is characterized by a high degree of genetic variability among HIV-1

CXCR4, Coreceptors,

Fig. 2 Crystal structure of CXCR4 bound to the small molecular weight inhibitor IT1t. The helices that form each of the seven-transmembrane (TM) segments are depicted, linked by three extracellular (ECL) regions, two intracellular regions (not shown), and the extracellular N-terminal and intracellular C-terminal regions. Note that only one subunit is shown in each case – the receptor normally functions as a dimer of two subunits. The *circle* highlights the site of interaction of IT1t

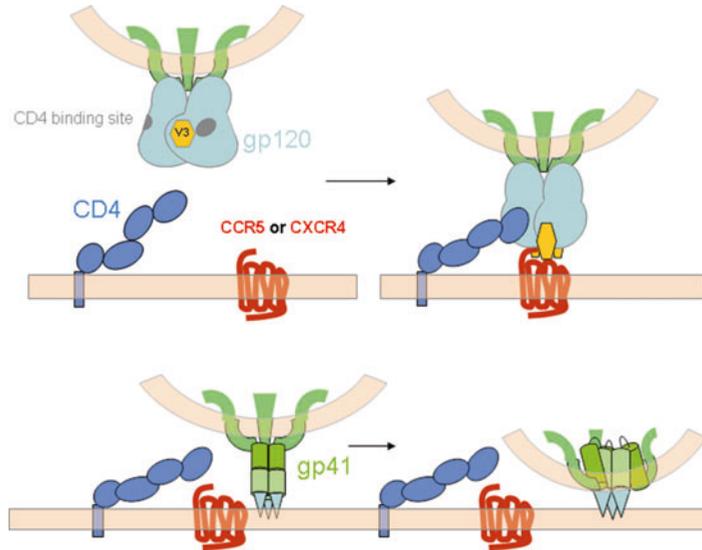

isolates. Evaluation of the amino acid sequence of different HIV-1 strains led to the identification of five variable (V1–V5) and 4 constant (C1–C4) regions in gp120. The region of gp120 that binds the coreceptor has been revealed by the crystal structure of gp120. The residues involved are located within the conserved stem of the V1/V2 structure, near the base of the V3 loop, and in other regions folded into proximity. The V3 sequence usually contains 34–36 amino acids arranged in a disulfide loop involving cysteine residues at position 296 and 331. This domain plays an important role in governing several biological properties of the virus including cell tropism, cytopathicity, fusogenicity, and coreceptor use. Although the actual sequence between the two cysteines seems not to be of importance for processing and binding to CD4, it is important for the CXCR4-using property of some virus strains.

The sulfotyrosine-containing N-terminal region of CXCR4 serves as the initial site of interaction with the V3 loop, analogous to CXCL12 recognition. This interaction results in a conformational change of the V3 loop, the

subsequent interactions of the rearranged V3 loop with the CXCR4 extracellular loops, and the ligand-binding pocket of the coreceptor. The structural details of CXCR4 revealed in Wu et al. (2010) and its implications for the binding of CXCL12 and gp120 of HIV-1 to CXCR4 are of great value for understanding the signal transduction via the receptor and for the design of new strategies targeting the viral fusion of HIV-1.

The HIV Entry Process and Coreceptor Use

The simplest model of coreceptor use suggests that CCR5 and CXCR4 are the main coreceptors used by HIV (Fig. 3). The expression of CCR5 or CXCR4 on different CD4+ target cells determines their permissiveness to infection by the corresponding CCR5-using (R5) or CXCR4-using (X4) HIV-1 strain. In addition, there are HIV-1 strains that may use both CCR5 and CXCR4, referred to as dual tropic (D) R5/X4 strains, and there are patients that have mixtures

CXCR4, Coreceptors, Fig. 3 HIV entry into target cells is a sequential process that begins with attachment of the virus to host cell surface, followed by binding of the envelope gp120 (glycoprotein) to the CD4 receptor. This binding promotes conformational changes that expose the gp120 coreceptor-binding site. Then, the CD4-envelope

glycoprotein complex interacts with the appropriate chemokine, mainly CCR5 (R5 virus) or CXCR4 (X4 virus), used as a coreceptor. In response to such coreceptor binding, there are additional conformational changes that allow gp41-mediated fusion of virus and cell membranes

(M) of R5 and X4 HIV-1 isolates. D or M isolates are indistinguishable in HIV coreceptor phenotype assays (Este and Telenti 2007).

After CD4 virus attachment and coreceptor engagement, a series of conformational changes in gp120 allow gp41 to reorient parallel to the viral and cellular membranes and promote the events leading to virus and cell membrane fusion.

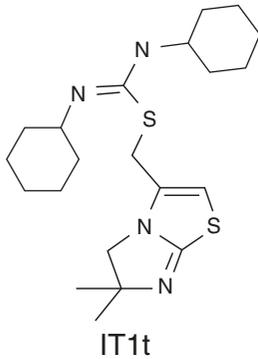

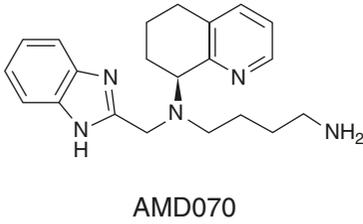

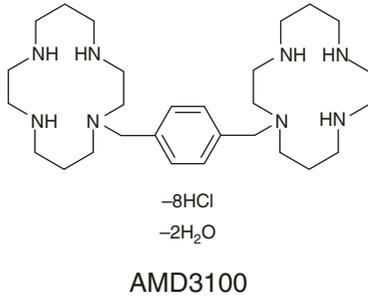

R5 viruses are preferentially transmitted over X4 viruses and are almost exclusively associated with acute infection, irrespective of the route of transmission. The basis of this preferential selection is unclear but multiple barriers to infection by X4 viruses have been proposed.

R5 viruses also predominate during most of the chronic stage of the disease. Eventually, X4 variants emerge in 40–60% of HIV-1-positive individuals. X4 variants have been associated to expanded cell tropism, increased virus replication rate, and a faster disease progression. However, the emergence of X4 virus is not a prerequisite for the development of AIDS. Whether emergence of CXCR4-using strains is a marker for disease progression rather than the cause is not known.

Inhibition of CXCR4 as an Antiviral Strategy

The various steps in virus entry have long been considered a relevant target for anti-HIV intervention, and a large number of agents have been tested and are developed as promising anti-HIV drugs. At least one agent targeting the CCR5 coreceptor (maraviroc, Selzentry[®]) has been approved for the treatment of HIV infection.

Although no CXCR4 antagonists are in active clinical trials for the treatment of HIV-1 infection, several are in development and have demonstrated potent inhibitory effects on X4-tropic strains (Tilton and Doms 2010). The first low molecular weight anti-HIV agents targeting a coreceptor was the bicyclam AMD3100 (Fig. 4), a potent antagonist of CXCR4. Since then, a number of agents have been tested, and some have advanced to clinical trials, but most of them have failed. The latest AMD11070 was evaluated in a pilot monotherapy study (eight and two patients receiving 200 and 100 mg b.i.d., respectively) in patients with X4-tropic or dual/mixed-tropic

CXCR4, Coreceptors, Fig. 4 Chemical structure of CXCR4 antagonists

HIV. No significant changes in HIV-1 viral load or CD4 cell count were noted. Four of nine patients evaluated achieved a reduction in X4 virus population. The median change in X4 virus population at the end of treatment was $-0.22 \log_{10}$ relative units. Three of four patients who responded to therapy showed a tropism shift from dual/mixed-tropic viruses to exclusively R5 virus by day 10. These results demonstrate the activity of AMD11070. However, development of AMD11070 was suspended because of liver histology changes and animal hepatotoxicity (Este 2010).

Despite the apparent lack of success of CXCR4 antagonists as anti-HIV agents, the clinical

evaluation of AMD3100 helped to recognize these agents as potent hematopoietic stem cell mobilizers. AMD3100 (plerixafor, Mozobil[®]) is now indicated in combination with granulocyte colony-stimulating factor (G-CSF) to mobilize hematopoietic stem cells to the peripheral blood for collection and subsequent autologous transplantation in patients with non-Hodgkin's lymphoma and multiple myeloma.

Several polypeptide mimics of CXCL12 have been evaluated. These compounds, including T-22 and its analogues T-134, T-140, and ALX40-4C, act by binding specifically to the CXCR4 receptor and preventing gp120 binding. ALX40-4C was tested in humans prior to the identification of CXCR4 as a coreceptor for HIV and despite being well tolerated did not have a significant effect on reduction of HIV viral loads. However, the majority of patients in this study were later found to have R5 strains of HIV.

Other Approaches to Inhibiting CXCR4 Use

Alternative methods have been evaluated to block CXCR4. Zinc finger nucleases (ZFNs) are a class of engineered DNA-binding proteins that facilitate targeted editing of the genome by creating double-strand breaks in DNA at user-specified locations. The *CCR5* gene was efficiently disrupted through ZFNs in human CD4⁺ T cells or hematopoietic stem cells and found to confer protection in vitro and in humanized mice to infection by HIV-1 isolates that require CCR5 (but not CXCR4) providing an important proof of concept. ZFNs targeting *CXCR4* have also been employed rendering human CD4⁺ T cells permanently resistant to X4 HIV-1 strains. It has been demonstrated that *CXCR4* can be safely and efficiently disrupted in CD4⁺ T cells obtained from CCR5D32 homozygotes resulting in cells resistant to all strains of HIV-1 tested. This suggests that combined treatment of mature CD4⁺ T cells with X4-ZFNs and R5-ZFNs can provide permanent protection against HIV-1 infection (Wilens et al. 2011).

Resistance to CXCR4 Inhibitors

The driving force behind the numerous HIV variants is the combination of an error-prone reverse transcriptase, the viral enzyme transcribing the viral RNA genome into DNA on the one hand, and the human immune system on the other hand. This puts a constant selection pressure on the HIV population leading to the emergence of escape mutants.

The development of resistance to agents targeting CXCR4 has mostly been studied in cell culture experiments. An AMD3100-resistant strain derived from HIV-1 NL4-3 was obtained after long-term passaging in lymphoid cells in the presence of progressively increasing concentrations of the compound. The AMD3100-resistant strain proved 300-fold resistant to AMD3100 and cross-resistant to other bicyclam analogues with similar or lower anti-HIV activity indicating that all bicyclam analogues share a common mode of action. This AMD3100-resistant strain is cross-resistant to CXCR4 agents such as CXCL12 or peptidic CXCR4 antagonists such as Allelix-40-4C. However, T134, an analogue of the CXCR4 antagonist T22, has been shown active against the AMD3100-resistant strain.

If CXCR4 agents can effectively block CXCR4 for use as HIV coreceptor, then HIV resistance may emerge only by two possible alternatives: HIV-1 can utilize the drug-bound conformation of CXCR4 by the antagonist or it may change coreceptor use. The selection of the AMD3100-resistant strain was done in the lymphoid cell MT-4. This cell line can be easily infected by X4, laboratory adapted strains of HIV, and express CXCR4; but, MT-4 cells cannot be effectively infected with R5 strains such as HIV-1 BaL and do not express CCR5. Therefore, HIV-1 in the absence of coreceptors other than CXCR4 and under selective pressure by a CXCR4 antagonist will develop into a strain that continues to use CXCR4 differently and retains the X4 phenotype. Conversely, selection of resistant variants using clinical isolates of HIV-1 leads to coreceptor switch from CXCR4 to CCR5. Within a patient, the circulating virus population is composed of various mixtures of closely related

but genetically distinct viruses that may comprise a pure population sharing the same coreceptor use or a mixed population. Therefore, selective antiviral activity toward the X4 component leads to the emergence of minority R5 strains and the switch in coreceptor phenotype.

CXCR4 Use as a Mechanism of CCR5 Drug Resistance

Similar to CXCR4 agents, there are two possible pathways of viral escape from CCR5 antagonists: the selection of viruses that can use CXCR4 as their entry coreceptor and the selection of viruses that continue to use CCR5 but can recognize the drug bound for of the coreceptor. Maraviroc, the only approved antiretroviral drug targeting a coreceptor, demonstrated potent and selective antiviral activity against all CCR5-tropic HIV-1 viruses tested, including primary isolates and virus resistant to other existing drug classes. However, screening for clinical trials with maraviroc demonstrated that roughly 60% of the patients for whom at least two antiretroviral regimens failed were infected with R5 HIV-1 only. That is, the majority of patients failing treatment with maraviroc had a change in tropism to dual tropic/mix (R5/X4) or X4 at time of failure, drawing attention to the propensity of virus isolates from patients to switch coreceptor preference. Therefore, HIV-1 may escape from CCR5 drug treatment by utilizing CXCR4.

Methods for Identifying CXCR4-Using HIV Variants

Numerous studies have associated different regions in the HIV-1 envelope as determinants of CCR5 and CXCR4 tropism. For example, the X4 phenotype seems to be determined by the presence of a positively charged V3 region of the envelope protein gp120, particularly amino acids in positions 11 and/or 25 in the 35 amino acid coding sequence. On the other hand, regions outside the V3 loop have been shown to be involved with R5, X4, or R5/X4 phenotypes. Amino acid substitutions in other env hypervariable regions

(V1, V2, V4, and V5), the entire C1-V4 region, and even the gp41 transmembrane unit may also play a role in HIV-1 tropism. As a consequence, HIV-1 coreceptor usage and its implication on disease progression, antiretroviral therapy, and even on vaccine strategies have led to the development of multiple tools aimed at determining the ability of HIV-1 to use coreceptors to infect target cells (Rose et al. 2009). Importantly, evaluation of virus coreceptor use is required prior to the initiation of antiretroviral therapy containing a CCR5 inhibitor.

Viral tropism can be assessed with either genotypic or phenotypic approaches. Coreceptor genotype testing is based on amplification and population sequence analysis of patient-derived V3 region. Two different sequencing approaches, population-based and pyrosequencing, have been used, the latter with improved sensitivity to detect minority X4 variants. Then, bioinformatic interpretation techniques are used to predict coreceptor use from a consensus sequence. Phenotypic tests include the coculture of patient-derived cells with lymphoid cells expressing CXCR4 (MT-2 cells) or infection of reporter cell lines with recombinant or pseudoviruses containing *env* genes derived from the virus population in a given patient (Vandekerckhove et al. 2011). A widely used phenotypic assay, Trofile™, is a single-cycle, recombinant virus assay. The entire patient-derived *env* gene is amplified by polymerase chain reaction (PCR) and inserted into an expression vector containing a luciferase reporter gene that is transfected into cells to produce a pseudovirus population subsequently used to infect CD4⁺ cells expressing either the X4 or R5 receptor on their surface. Trofile™ has been utilized in the characterization and clinical development of several HIV-1 CCR5 inhibitors, and it is currently used to identify patients with X4 viruses as exclusion criteria for treatment with CCR5-targeting strategies.

Conclusion

CXCR4 is one of the two major coreceptors used by HIV to enter cells. Viruses that use CCR5 are commonly transmitted and persist throughout the

course of infection, but CXCR4-using viruses may emerge at later stages and dominate the virus population. Importantly, CXCR4 use is strongly associated to treatment failure of CCR5 drugs, with CD4 T-cell decline and the onset of AIDS. There are no drugs targeting CXCR4 currently approved for the treatment of HIV infection, but novel strategies are envisioned to simultaneously block CCR5 and CXCR4 to prevent HIV infection.

Cyclophilin A and HIV-1 Replication

Jeremy Luban

Program in Molecular Medicine, Department of Biochemistry and Molecular Pharmacology, University of Massachusetts Medical School, Worcester, MA, USA

Definition

Cyclophilin A (CypA) is the founding member of the large cyclophilin family of proteins. It is encoded by the 5 exon *PPIA* gene on chromosome 7p13. CypA is a globular protein with a hydrophobic pocket that is expressed constitutively at high level. There are roughly 20 genes that encode proteins with a CypA domain, as well as many nonfunctional CypA pseudogenes. The owl monkey TRIM5-CypA fusion gene is a textbook example of how new exons are generated by LINE-1-catalyzed retrotransposition of abundant cDNAs, in this case the CypA cDNA. Orthologues of CypA are found in most species, from eubacteria through mammals. The only species that do not have orthologues are extremophile archaeobacteria. The hydrophobic pocket of CypA binds to proline-containing peptides, as best exemplified by proline 90 on the external face of the HIV-1 capsid. CypA is thought to carry out a global function in protein folding by catalyzing the *cis-trans* interconversion of peptide bonds that contain proline.

Introduction: Retrovirus *gag*-Encoded Proteins as Multitaskers

The *gag* gene of HIV-1 and other retroviruses encodes a polyprotein that is sufficient to direct

the assembly of virions (► [Life Cycle Overview](#); ► [Virus Assembly](#); Franke et al. 1994). The Gag polyprotein is targeted to the plasma membrane where it buds out of the cell. Concurrent with virion budding, the viral protease is activated. This cleaves the Gag polyprotein into at least six mature, *gag*-encoded, virion-associated proteins, among which is the matrix protein (MA), which associates with the inner face of the virion membrane, and the highly basic, zinc-finger-containing nucleocapsid protein (NC), which coats the viral genomic RNA. The capsid protein (CA) undergoes a large conformational transformation upon proteolytic cleavage and collapses to form the protein lattice that encases the viral genome at the core of the virion (► [HIV-1 Virion Structure](#)).

Following membrane fusion with a susceptible target cell, the CA core is released into the cytoplasm where it regulates ► [reverse transcription](#) (Braaten et al. 1996a). What happens to the CA core lattice at this stage of the virus replication cycle is frankly unclear. It may crumble into monomers of CA or small CA multimers, or it might disassemble in a more complex, directed fashion. Some believe that the CA lattice core persists in the cytoplasm and docks to the nuclear pore – perhaps via interaction with discrete nucleoporins like Nup358 (► [Nuclear Import: HIV-1 Goes NUPs](#)), while others have provided evidence that CA multimers traffic to the nucleus with the preintegration complex (► [Integration](#)).

Discovery of CA Interaction with Cyclophilin A

The wide-ranging functions of the *gag*-encoded proteins suggest that multiple host factors (► [Identification and Validation of Cofactors](#)) assist the structural transformations and functional changes described above. Host factors are undoubtedly also required to propel CA on its wide-ranging journey through the various subcellular compartments. Additionally, host cells elaborate restriction factors that hinder retrovirus progression through the replication cycle.

As a step toward the identification of host factors of functional relevance for *gag*-encoded

proteins, host proteins were sought that interact with the Gag polyprotein or with each of the Gag proteolytic products (Luban et al. 1993). cDNAs encoding HIV-1 Gag-interacting proteins were screened in the yeast two-hybrid system. Cyclophilin A came out of these initial screens with the HIV-1 Gag polyprotein, as well as in subsequent screens with CA (Luban et al. 1993). It is now clear that CypA binds to HIV-1 CA and the CA of a large subset of lentiviruses, including some HIV-2 isolates and FIV, but not the CA of all retroviruses (Braaten et al. 1996a; Franke et al. 1994; Gamble et al. 1996; Goldstone et al. 2010). CypA set the stage for the more extensive functional investigation of *gag*-interacting proteins that followed.

CypA and Protein Folding

The ubiquitous cellular protein cyclophilin A (CypA) was first discovered as a high-affinity cellular binding protein for the immunosuppressive drug cyclosporine (Handschumacher et al. 1984). CypA was then shown to possess an enzymatic activity. It catalyzes the rate of interconversion between *cis* and *trans* isoforms of peptide bonds that possess proline (Fischer et al. 1989). CypA is a small globular protein that has a hydrophobic pocket that binds to proline-containing peptides. It is believed to have subtle yet global effects on protein folding within cells. As a complex with the immunosuppressive drug cyclosporine, it is a potent inhibitor of the CA-dependent phosphatase calcineurin in T cells (Colgan et al. 2005; Liu et al. 1991). Among the specific cellular functions of CypA, it regulates the nuclear export of Zpr1 (zinc finger protein 1) in yeast (Ansari et al. 2002), the kinase activity of Itk (inducible T-cell kinase) in CD4⁺ T cells (Colgan et al. 2004), and the nuclear translocation of apoptosis-inducing factor in neurons after cerebral hypoxia-ischemia (Zhu et al. 2007).

It thus is reasonable to propose that HIV-1 Gag is a catalytic folding substrate for CypA and that the conformational changes necessary for the function of *gag*-encoded proteins would be aided

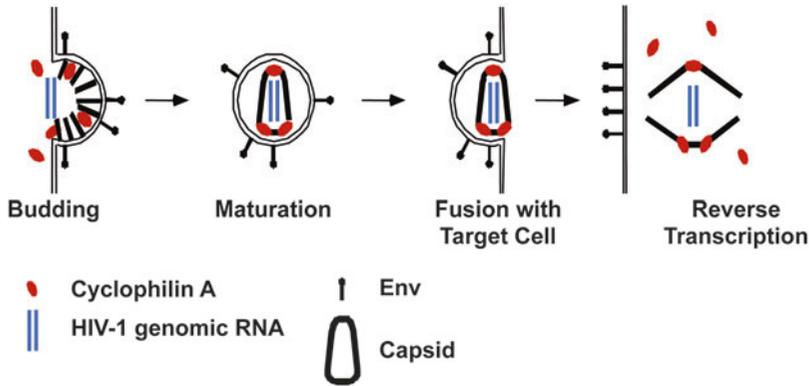

by CypA. HIV-1 CA interaction with CypA involves the insertion of a critical proline residue, P90, into the catalytic pocket of CypA (Franke et al. 1994; Gamble et al. 1996). Binding of CypA indeed catalyzes a conformational change in CA that is detectable by NMR (Bosco et al. 2002). To this date, though, the functional significance of this modest conformational change in CA structure remains undetermined.

CypA and HIV-1 Assembly

CypA interacts with the HIV-1 Gag polyprotein and with the mature HIV-1 CA via the same local contact points, with similar micromolar affinities (Colgan et al. 1996; Gamble et al. 1996; Luban et al. 1993). In some assays using recombinant protein *in vitro* or with viral protein in cells, interaction with the Gag polyprotein is more readily detectable than interaction with CA, perhaps because of greater avidity provided by Gag polyprotein multimerization.

CypA is incorporated into HIV-1 virions in a specific manner (Fig. 1), via interaction with a critical proline and adjacent amino acid residues within the Gag polyprotein (proline residue 222 with respect to the Gag polyprotein – proline 90 with respect to capsid – consensus clade B strain) (Braaten et al. 1996a; Franke et al. 1994). The stoichiometry is on the order of one CypA molecule to five Gag molecules. The CypA protein is protected within the virion membrane envelope from digestion by exogenous protease (Ott et al. 1995).

CypA interaction with the Gag polyprotein can be disrupted by several different means. It has been disrupted by knockout and by knockdown of CypA within virion producer cells (Braaten and Luban 2001; Sokolskaja et al. 2004). Mutation of critical amino acid residues in the Gag polyprotein blocks CypA interaction with Gag and incorporation of CypA into virions (Braaten et al. 1996a; Franke et al. 1994). The Gag-CypA interaction can also be disrupted by cyclosporine or non-immunosuppressive analogues of this drug (Luban et al. 1993; Thali et al. 1994). Each of these experimental tools has been used to examine

Cyclophilin A and HIV-1 Replication, Fig. 1 Cyclophilin A (red ovals) is stoichiometrically incorporated into HIV-1 virions during virion budding, via interaction with Gag polyprotein. Virion-associated cyclophilin A is likely associated with the CA in the core of the virion, where it is protected by the virion membrane from protease digestion.

The function of cyclophilin A during virion assembly is unknown. When a virion fuses with a susceptible target cell, the virion CA protein interacts with the target cell cyclophilin A protein. The latter interaction has functional consequences; it promotes HIV-1 reverse transcription and nuclear entry

CypA function during ► **virion assembly**. None of them disrupt rates of Gag polyprotein synthesis, kinetics of Gag polyprotein cleavage by viral protease, virion assembly kinetics, particle yield, virion infectivity, virion protein content, or virion morphology by electron microscopy or cryo-EM. To date no convincing data has been obtained demonstrating a role for CypA in HIV-1 virion assembly, or within the virion. Given the specific interaction of CypA with the Gag polyprotein, it is surprising that the interaction has no influence on replication. Perhaps the right assay has not been performed. Or, maybe CypA plays a role in virion assembly in vivo that is not detectable in tissue culture. Finally, it might be that CypA interaction with Gag is selected for because it influences how the immune system detects virion-producing cells (Manel et al. 2010).

The Role of CypA During the Early Steps of HIV-1 Replication

In contrast to the lack of effect on the late steps of the HIV-1 replication cycle, CypA has clear effects on the efficiency of HIV-1 transduction (Fig. 1). Disruption of CypA in the target cell by knockdown, knockout, or cyclosporine reduces

the ability of HIV-1 to reverse transcribe within, and infect, a target cell (Braaten et al. 1996a; Franke et al. 1994; Hatzioannou et al. 2005; Sokolskaja et al. 2004). Similar reduction in infectivity is observed with Gag mutants that do not bind CypA. This effect is usually modest, somewhere between two and fivefold. How CypA promotes reverse transcription is not known, but it seems related to effects on CA.

CypA and CA-Dependent Restriction

In some cases, in particular cell lines, for example, CypA has paradoxical effects on HIV-1 replication. While CypA knockdown was associated with a reduction in HIV-1 replication in primary T cells, an increase in HIV-1 infectivity was observed with CypA knockdown in HeLa cells. As compared with wild-type HIV-1 CA, this increase in infectivity is greatly pronounced with particular CA mutants, including A92E and G94D (Braaten et al. 1996b; Yin et al. 1998). Whatever the explanation for this cell-type-specific, CypA-dependent inhibition of HIV-1, heterokaryon experiments have demonstrated that it acts in a dominant fashion (Song and Aiken 2007). The identity of this dominant-acting, CypA-dependent

inhibitor is unknown. Some have reported elevated CypA protein levels in the cell lines in which CypA KD increases HIV-1 infectivity. This suggests that CypA interaction with HIV-1 CA is intrinsically inhibitory of CA function, at least under conditions of heightened CypA expression. Others failed to detect this increase in CypA level.

CypA and TRIM5

Soon after the discovery of HIV-1, it was clear that this virus is unable to infect certain monkey species. Over subsequent years it was shown that HIV-1 CA conferred sensitivity to the block, that the block was dominant, and that the block occurred soon after virus entry into the cell cytoplasm. Ultimately, expression screens identified TRIM5 α in macaques, and the TRIM5-CypA fusion gene in owl monkeys, as responsible for the block (Sayah et al. 2004; Stremlau et al. 2004). In the latter case, the CypA was fused directly to TRIM5, thus targeting the restriction factor to the HIV-1 CA. In the former case, CypA, as a protein acting in trans, is required for TRIM5 α recognition of the HIV-1 CA (Berthoux et al. 2005).

Conclusion

Studies on CypA led to the discovery of TRIM5 as a capsid-specific restriction factor (Sayah et al. 2004; Towers et al. 2003). Further assessment of the effects of CypA on CA recognition may lead to the identification of additional host factors that regulate HIV-1 replication. With improved understanding of the HIV-1 CA lattice structure may come further information about how CypA regulates CA conformation and accessibility of antiviral factors such as TRIM5. It should also be pointed out that cyclophilin A-binding, non-immunosuppressive analogues of cyclosporine have been shown to inhibit HIV-1 in infected people (Flisiak et al. 2008); such drugs (► [Cellular Factors as Drug Targets](#)) may one day have a role in the clinic.

Definition

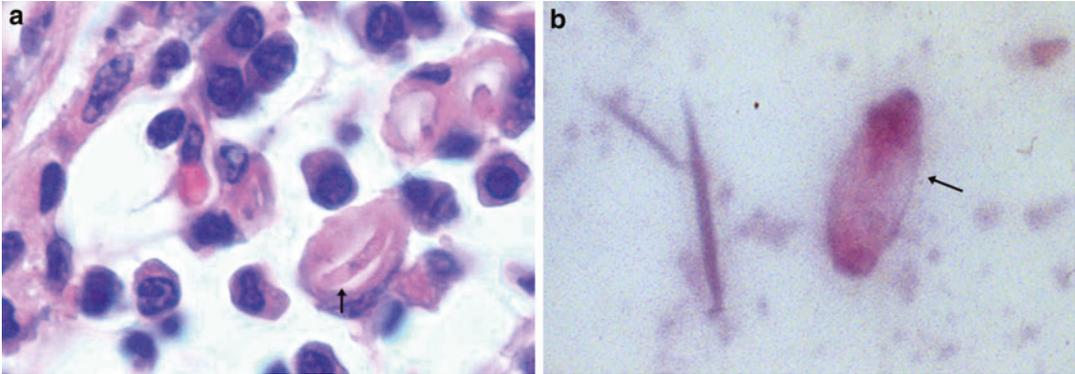

Cystoisosporiasis, also known as isosporidiasis, is caused by *Cystoisospora belli* and is a gastrointestinal infection that presents as diarrhea without associated fever.

Introduction

Cystoisospora belli is a member of the Phylum Apicomplexa in the Subclass Coccidiasina and Family Sarcocystidae (Lindsay and weiss 2015). While previously referred to as *Isospora belli*, and occasionally as *I. hominis* (some of these reported cases may also have been due to misidentified *Sarcocystis* species), both the life cycle of this human pathogen and molecular phylogeny indicate that this organism should be a member of genus *Cystoisospora*, which contains over 200 species.

Species and Life Cycle

Cystoisospora belli causes diarrhea in humans and is the only member of this genus that commonly causes human infection. There are a few reports from South Africa, in the literature prior to 1955, of a second species, *C. natalensis*, causing infections; however, these have not been subsequently confirmed (Lindsay and Weiss 2015). *C. belli* infections accounted for 2–3% of AIDS-

Cystoisosporiasis, Fig. 1 (a) Tissue section of intestine demonstrating tissue cyst of *Cystoisospora belli* (arrow). (b). Acid fast stain of stool demonstrating *Cystoisospora*

belli oocyst in stool (arrow). Charcot leyden crystals are also demonstrated in this specimen

defining conditions in the 1980s (Pape et al. 1989), but with the widespread use of trimethoprim-sulfamethoxazole (TMP-SMX) prophylaxis for *Pneumocystis pneumonia* this decreased to 0.1% in the late 1990s. In reports of groups of patients with AIDS and chronic diarrhea, prior to widespread use of combination antiretroviral therapy (cART), this infection accounted for up to 25% of cases; however, with cART the prevalence of this infection as a cause of chronic diarrhea has decreased.

Infection with *C. belli* is more commonly found in tropical, subtropical, and warm temperate regions (Pape et al. 1989); however, indigenous infection has been reported from temperate regions. Transmission is due to fecal oral spread, usually by ingestion of sporulated oocysts, and foodborne outbreaks have occurred. Sexual practices that permit fecal oral spread are also associated with infection. It is possible that transmission may also occur by the ingestion of raw or undercooked tissues from paratenic (i.e., transport) hosts, although this mechanism has not been definitively proven to occur. As with most fecal oral pathogens improved sanitation and water quality decreases the risk of transmission.

The life cycle of *C. belli* generally occurs in a single host, with the formation of oocysts occurring 9–17 days following infection which are passed in feces; however, there is evidence that this organism can be facultatively heteroxenous

(use two hosts) and that it forms tissue cysts following the initial infection (Lindsay et al. 1997). In fact, these tissue cysts are probably the source of relapsing infections seen in immunocompromised hosts. Oocysts are generally non-infectious when passed in the feces and complete sporulation within 1–5 days depending upon the environmental conditions. Shedding of oocysts usually lasts for 30–50 days; however, in immune-suppressed patients shedding may be prolonged lasting over 6 months and in such patients recrudescence of oocyst shedding occurs. This prolonged shedding is presumably due to activation of dormant tissue resident monozytic tissue cysts (Fig. 1a). Cysts can be found in a variety of tissues, including lamina propria, mesenteric lymph nodes, liver, and spleen. These cysts are thick walled and measure $12\text{--}22 \times 8\text{--}10 \mu\text{m}$ in size, each containing a single dormant sporozoite/merozoite about $8\text{--}10 \times 5 \mu\text{m}$. These tissue cysts are suggestive that a paratenic host could be involved in the life cycle of *C. belli*, as this has been shown to occur in the *Cystoisospora* species that infect cats and dogs.

Clinical Manifestations

In immune-competent hosts 1 week following the ingestion of oocysts a self-limiting diarrheal illness results that lasts 2–3 weeks and is associated with

malaise, weight loss, cramps, watery diarrhea, steatorrhea, headache, low-grade fever, abdominal pain, vomiting, dehydration, and weight loss (Lindsay and Weiss 2015). Infection can result in a very severe illness and fatalities have occurred. Blood is not usually present in the feces. Eosinophilia is observed in many patients. Oocysts can be present in the feces or biopsies for several months to years. Recurrences occur and have been reported as long as 10 years after initial infection.

In general, clinical disease is more severe in infants, young children, and in immunocompromised host. In the patient with HIV infection with low CD4 counts, infection results in severe watery, secretory-like diarrhea that often leads to dehydration requiring hospitalization. This can be associated with fever and weight loss. In patients with AIDS infection tends to be chronic and recrudescence is common if the CD4 count is under 200. Hemorrhagic colitis as well as extraintestinal infection has been described in this setting. Coinfection with other pathogens can occur. In addition to patients with AIDS, *C. belli* infection has been reported in patients on systemic corticosteroids being treated for eosinophilic gastroenteritis, in patients with renal transplants, liver transplants, Hodgkin's disease, non-Hodgkin's lymphoproliferative disease, human T-cell leukemia virus type I-associated adult T-cell leukemia, acute lymphoblastic leukemia, and human T-cell-leukemia-virus-1-associated T-cell lymphoma. In general, these immune-suppressed hosts respond to TMP-SMX and other anti-*C. belli* treatments. In addition to the intestine, *C. belli* has been found in gallbladder epithelium, endometrial epithelium, and in bile samples. Clinical signs in patients with parasites in these locations are not specific for coccidiosis; however, biliary track infection with cholangitis was the presenting manifestation of this AIDS defining infection in a case report.

Diagnosis

Diagnosis of infection is best accomplished by examination of stool specimens, usually three

specimens collected on different days, for oocysts. Concentration techniques like formalin-ethyl acetate (rarely formalin-ether) sedimentation or sucrose centrifugal floatation are helpful when few oocysts are present. *C. belli* oocysts stain red with the modified Kinyoun's acid-fast stain (Fig. 1b); however, this staining can be variable and some oocysts do not stain. Autofluorescence is seen with *C. belli* oocysts and can be a useful tool for finding this organism in stool samples using UV fluorescent microscopes. There are no commercial monoclonal antibodies available for the detection of this pathogen in stool. There are no FDA-approved molecular techniques for the diagnosis of *C. belli*; however, PCR assays using primers based on ITS and ssRNA have been described and three genotypes of *C. belli* can be identified using PCR and RFLP using MboII digestion; PCR has been able to identify stool negative infections that were confirmed by finding developmental life cycle stages in tissue samples. This organism has not been cultured in vitro and no serological or antigen diagnostic tests are available for this pathogen.

Treatment and Prevention

The drug of choice for the treatment of *C. belli* is trimethoprim-sulfamethoxazole (TMP-SMX) (Pape et al. 1989). A dose of TMP 160 mg-SMX 800 mg two to four times a day for 10–14 days results in rapid (within 2–3 days) clearance of parasites and diarrhea. In patients with HIV-1 infection and CD4+ cell counts less than 200 secondary prophylaxes with TMX 320 mg/SMX 1600 once daily or three times a week prevent relapses. In general, secondary prophylaxis can be stopped if the CD4+ count exceeds 200; however, there are case reports of chronic infection with relapse still occurring despite patients having CD4+ counts above 200 and having received primary therapy with TMP/SMX (Boyles et al. 2012). In patients unable to tolerate sulfonamides due to allergy or intolerance there is no standard treatment. Pyrimethamine at a dose of 50–75 mg/day is an effective alternative treatment

in patients with sulfonamide allergies and secondary prophylaxis can be performed with pyrimethamine 25 mg/d (Weiss et al. 1988). When pyrimethamine is administered it should be given with folic acid (5–10 mg/day) to minimize bone marrow suppression. Ciprofloxacin can be used as an alternative treatment, although it is less effective than either TMP/SMX or pyrimethamine (Verdier et al. 2000). In a randomized study of 22 patients with cystoisosporiasis and HIV infection, 10/10 patients on TMP/SMX had cessation of diarrhea within 2 days and 10/12 on ciprofloxacin (500 mg BID) had a cessation of diarrhea within 4.5 days. All three patients (two with diarrhea and one without) who had persistent *C. belli* oocysts in their stools responded to treatment with TMP/SMX with clearance of the parasite. In patients who responded to ciprofloxacin continued prophylaxis with ciprofloxacin prevented recurrence of disease. Nitazoxanide has also been used to treat *C. belli* infections (Fox and Saravolatz 2005). Two patients on 500 mg nitazoxanide twice daily for 3 days were oocyst negative after treatment; a patient treated with 500 mg nitazoxanide twice daily for 7 days became oocyst negative by day 14 after treatment. However, in another case report treatment failure occurred in a patient with biliary cystoisosporiasis and malabsorption on 2 g nitazoxanide twice daily, perhaps due to poor absorption of this drug as indicated by low serum drug levels. A study of eight AIDS patients with *C. belli* enteritis treated with diclazuril 200 mg/day for 7 days demonstrated resolution of diarrhea in half of the treated patients. A patient with allergy to both TMP/SMX and pyrimethamine was successfully treated with diclazuril 300 mg twice a day; however, when the drug was reduced to once a day the infection recurred. Treatment with metronidazole, tinidazole, quinacrine, or furazolidone is not effective for this pathogen.

Conclusion

Cystoisospora belli causes diarrhea in humans and is found in immune-competent and immune-

deficient patients. This diarrheal syndrome, however, is often chronic in patients with AIDS and more frequently seen in these patients. Infection responds rapidly to therapy with trimethoprim-sulfamethoxazole unlike other causes of chronic diarrhea patients with AIDS. While cystoisosporiasis can be acquired in any country, it is more common in tropical environments.

Cytomegalovirus Infection and HIV

Paul Griffiths and Isobel Ramsay
Centre for Virology, Institute for Immunity
and Transplantation, UCL Medical School,
London, UK

Definition

Cytomegalovirus (CMV) is a herpesvirus that infects most individuals worldwide. It establishes latency and persists for the life of the individual usually only producing overt disease in individuals with immature immune systems (e.g., fetuses following stem cell transplant) or the immunocompromised (solid organ transplant, AIDS). Detection of active CMV infection in a patient is thus an indicator of functional suppression of cell-mediated immunity (CMI) as well as a harbinger of serious end-organ disease.

Introduction

CMV is first acquired in developing countries early in childhood where seroprevalence in adults may be over 90%. In developed countries, primary infection is delayed into adulthood in many people (adult seroprevalence rates are 50–60% although seroprevalence is higher in those at risk of HIV infection including MSMs and intravenous drug users.) Infection is spread within families through contact with saliva and urine of young children, particularly as viral shedding tends to persist longer in children than in immunocompetent adults. It is also spread in communities through sexual contact (Staras et al. 2008). Additional routes of transmission include in utero acquisition from an infected mother or perinatally acquired infection from maternal secretions or via breast milk, from a donor organ to a recipient during solid organ transplantation, by semen during in vitro fertilization, or by blood transfusion (now rare).

In HIV-positive adults, CMV seroprevalence is typically high. Before the use of highly active

antiretroviral therapy (HAART), CMV end-organ disease was a major cause of morbidity and mortality in HIV-infected patients. With the advent of potent antiretroviral therapy, cases of CMV end-organ disease including retinitis, encephalitis, colitis, and pneumonitis are seen less frequently. Diagnostic difficulties lie in distinguishing whether CMV despite being detectable by PCR is the sole causative agent of disease as it may coexist with other pathogens, e.g., *P. jirovecii*. Management of CMV disease includes the use of HAART and antiviral medication against CMV including ganciclovir, foscarnet, and cidofovir. Several new drugs with activity against CMV are in development.

Pathogenesis

CMV is a member of the *Betaherpesvirinae* subfamily. It contains a double-stranded DNA genome that encodes approximately 165 named proteins. Every protein is recognized by CMI and by humoral immunity which act to keep the virus suppressed into latency in most individuals so that they usually remain asymptomatic. However, reactivation from latency produces active CMV infection that can disseminate within the body and also spread to others. People with active infection can cause primary infection in contacts who are CMV seronegative or reinfect people who are CMV seropositive. Thus, natural immunity against CMV provides substantial protection against disease but is less effective at preventing acquisition of new strains of CMV.

If natural immunity is compromised, CMV replication continues in an individual. Over weeks or months, the viral load in the blood (termed viremia or DNAemia because the quantity of virus is measured by polymerase chain reaction (PCR) amplification of viral DNA) increases. A high viral load is a prerequisite for CMV crossing the blood-organ barrier to cause end-organ disease. In allograft recipients, about 1% of patients with CMV end-organ disease have retinitis, whereas the corresponding figure for AIDS patients is 85%. The reason for this

remarkable difference in localization of CMV to one body site in these two groups of immunocompromised hosts is not known. Other organs affected by viremic spread of CMV include the gastrointestinal tract (about 10%), central nervous system, and lungs. The processes that lead to viremia and an increasing viral load are typically found once HIV has damaged the immune system so that the CD4 count declines below 100/ μ L. Thus, natural immunity, as measured by the CD4 count, has to decline approximately 90% (from 1000 to 100) before CMV becomes a clinical problem. Suppressing HIV replication so that the CD4 count increases back above 100 restores natural immunity to CMV so that viremia is no longer detectable.

As well as causing overt end-organ disease, CMV has the potential to interact with HIV to hasten progression to AIDS and death (Griffiths 1998). Cohort studies report that adults or children with perinatally acquired HIV have increased clinical endpoints of death and morbidity if coinfecting with CMV (Kovacs et al. 1999; Deayton et al. 2004). One nonrandomized clinical intervention study also reports a survival benefit from systemic treatment of CMV in patients with retinitis (Kempen et al. 2003). The mechanisms for this so-called cofactor relationship between CMV and HIV are not well defined, but studies looking at direct interactions between the two viruses have not consistently shown that CMV increases the viral load of HIV. Like HIV, CMV also affects the immune system, so this might explain some of the phenomena. Over decades, CMV increases the proportion of T cells in normal individuals with markers of differentiation (CD57+, CD28-) and thereby contributes to the laboratory definition of immunosenescence. This phenomenon is also seen in AIDS patients, where the abundance of these T cells was reduced by placebo-controlled administration of valganciclovir (Hunt et al. 2011). Finally, now that CMV positive serostatus has been shown to increase the mortality of patients in large cohorts of normal individuals followed long term (Simanek et al. 2011; Gkrania-Klotsas et al. 2013), the cofactor phenomenon might simply be the recognition of this effect in AIDS patients.

Irrespective of the final explanation, these data should encourage physicians to keep HIV suppressed so that it does not allow CMV to reactivate.

Clinical Presentations

Eye Disease

Retinitis, either unilateral or bilateral (up to half of patients), is the major clinical presentation of CMV infection in AIDS patients, particularly in those with CD4 counts less than 50/ μ L. It is the most common cause of retinitis in HIV infection, ahead of toxoplasmosis, cryptococcal retinitis, and varicella zoster virus (VZV) infection. Prior to the use of HAART, CMV retinitis was seen in 30–40% of all patients with AIDS leading to significant decreases in visual acuity and loss of visual field. Development of successful antiretroviral therapy has led to a dramatic decline in the incidence of CMV retinitis of around 80%, and it is now usually limited to those who are not taking antiretroviral therapy or have failed to respond.

The patient may complain of visual disturbance or “floaters,” flashing lights (photopsia), or visual field defects including scotomata. Depending on the area of the retina affected, the retinitis may be asymptomatic and found incidentally on clinical examination. CMV retinitis is described in terms of its stage and the zone of the retina affected (zone 1 closest to the optic nerve and fovea and zone 3 in the periphery). Retinitis may begin in the peripheral retina (zones 2–3) and often progresses slowly over weeks but ultimately has a major effect on vision if left untreated. This may be because the spreading lesion involves the macula and/or because the scarring of the retina impairs attachment to the underlying choroid layer leading to retinal detachment, particularly in those with large peripheral lesions.

Immune Recovery Uveitis

Recovering immune responses to CMV induced by antiretroviral therapy may lead to immune recovery uveitis within weeks after starting antiretroviral therapy. This may occur in patients with

subclinical retinitis who start antiretroviral therapy as unmasking immune reconstitution inflammatory syndrome (IRIS). Therefore, it is important to perform an ophthalmological examination before starting antiretroviral therapy in all patients who are CMV seropositive and have CD4 counts $<100/\mu\text{L}$.

Immune recovery uveitis is also seen in patients who are treated for CMV retinitis and thereafter start antiretroviral therapy (paradoxical IRIS). In these patients, after an initial recovery of retinitis, vision may worsen again. Paradoxically, this inflammatory reaction may affect the patient's vision more severely than did the initial CMV retinitis with the potential for cataract formation, vitreous hemorrhage, and glaucoma. Perseverance with treatment for both HIV and CMV is indicated, because long-term visual acuity reflects the degree of control of progression of the underlying retinitis (Thorne et al. 2011).

The diagnosis of CMV retinitis and its complications is through dilated ophthalmoscopy performed by an experienced ophthalmologist.

Typically, lesions are irregular and yellow-white close to retinal blood vessels with accompanying hemorrhage or present a "brushfire" appearance with a border of advancing retinitis surrounding the atrophic retina. More rarely, retinitis may take on a granular form in the periphery without coexistent hemorrhage. All of these may progress to retinal necrosis if left untreated.

On histological examination, full-thickness retinal necrosis and edema may be present with accompanying vasculitis and choroiditis. Infected cells may show intranuclear or intracytoplasmic "owl's eye" inclusion bodies.

Diagnosis of CMV retinitis is usually based on clinical findings. However, vitreous/aqueous sampling and PCR for CMV DNA may be performed in those cases where the diagnosis remains unclear or retinitis is unresponsive to therapy.

Gastrointestinal Tract

As with retinitis, the incidence of gastrointestinal manifestations of CMV infection in AIDS patient has decreased with the use of HAART. CMV may present with ulcerations in the esophagus, causing odynophagia, dysphagia, and nausea and should

be considered in the differential for esophagitis in HIV infection which also includes candida and herpes simplex virus (HSV) infection. Ulcers are usually grouped near the lower esophageal sphincter but may be more widespread. More commonly, CMV may have similar effects on the colon leading to diarrhea with or without blood in the feces, weight loss, and abdominal pain. CMV colitis may result in massive hemorrhage or perforation. Rarely, ulceration may occur in the mouth or anus.

In both clinical presentations, endoscopy and biopsy are required for diagnosis. Macroscopically, large shallow ulcers are seen in the upper GI tract; in the lower GI tract, appearances range from more superficial erosions to necrotizing colitis. Microscopically, mucosal inflammation and tissue necrosis may be present with intranuclear and intracytoplasmic inclusions.

CMV DNA PCR of the biopsied tissue may be positive but is not definitively diagnostic of end-organ disease and should be interpreted together with clinical findings and the presence of other potential pathogens or inflammatory processes.

Central Nervous System Disease

CMV infection in the CNS results in a variety of clinical presentations.

CMV encephalitis may present with acute ventriculitis, which can include cranial nerve involvement, or subacute encephalitis, which resembles dementia caused by HIV, and CMV DNA may be detectable on cerebrospinal fluid (CSF) PCR.

CMV may cause myelitis, presenting with leg weakness and hyperreflexia or polyradiculopathy where the patient develops urinary retention and/or difficulty in walking. CMV can also affect peripheral nerves resulting in a mononeuritis multiplex picture, involving the peripheral or cranial nerves, in particular the laryngeal nerves.

Diagnostic tools include imaging which may show periventricular or meningeal enhancement in encephalitis or cord enhancement on spinal MRI in CMV myelitis. CMV DNA may be detectable on CSF PCR in cases of encephalitis, myelitis, and polyradiculopathy. In the setting of

Cytomegalovirus Infection and HIV, Table 1 Dosing of antivirals in the treatment of CMV end-organ disease

Medication	Standard treatment dosing in end-organ disease	Standard maintenance dosing
Valganciclovir (oral tablet)	900 mg twice daily	900 mg once daily
Ganciclovir (intravenous)	5 mg/kg twice daily	5 mg/kg daily
Ganciclovir (intravitreal injection – retinitis only)	Single 2 mg injection or 1–4 doses over 7–10 days with systemic therapy If no systemic therapy available, 2 mg twice weekly without systemic therapy	Only if systemic therapy is not available
Foscarnet (intravenous)	60 mg/kg three times daily or 90 mg/kg twice daily	60–120 mg/kg daily
Foscarnet (intravitreal injection – retinitis only)	Single 2.4 mg injection or 1–4 doses over 7–10 days with systemic therapy If no systemic therapy available, 2.4 mg twice weekly	Only if systemic therapy is not available
Cidofovir (intravenous)	5 mg/kg once weekly with prehydration and probenecid for 2 weeks	5 mg/kg every 2 weeks

polyradiculopathy, the CSF contains an abundance of polymorphonuclear leucocytes, whereas cell counts may remain normal in myelitis.

Lung Disease

In advanced HIV infection, CMV may cause very rarely pneumonitis, presenting with a dry cough and shortness of breath on exertion. Auscultation may be unremarkable but imaging may show diffuse interstitial infiltrates. CMV DNA can be detected by PCR on bronchoalveolar lavage samples, and CMV inclusion bodies are found in lung biopsies or cytology.

Positive CMV PCR is not specific for CMV pneumonitis, and CMV DNA is often detectable in bronchoalveolar lavage samples in cases of pneumonia due to other pathogens including *Pneumocystis jirovecii*. Specific treatment against CMV is not required in most of these cases but should be considered if multiple CMV inclusion bodies are found in lung tissue or cytology.

Treatment

The mainstay of treatment is to keep HIV replication under control with HAART so that natural immunity to CMV can, in turn, keep CMV suppressed into latency.

Drugs with activity against CMV include ganciclovir and its oral prodrug valganciclovir,

foscarnet and cidofovir. Standard doses for these medications are shown in Table 1.

Ganciclovir

Ganciclovir is a guanosine analogue which, once activated to its monophosphate by the viral enzyme encoded within the 97th gene of the unique long region (UL 97), is converted to its triphosphate by cellular enzymes. Ganciclovir triphosphate is a potent inhibitor of the CMV-encoded DNA polymerase (UL 54). It is available for intravenous administration, as a topical gel or for intravitreal use (discussed below). The main toxicity of ganciclovir is bone marrow suppression, in particular causing neutropenia, leading to discontinuation or interruption of therapy in around 30% of patients. This effect may be augmented by the coadministration of other myelosuppressive agents including zidovudine. Neutropenia often responds to granulocyte colony-stimulating factor (G-CSF), and these effects may resolve once ganciclovir is stopped. Regular full-blood-count monitoring is therefore advised. Dose adjustment is necessary for those with renal impairment.

Valganciclovir is an oral prodrug of ganciclovir with relatively stable bioavailability of 55–65% as compared to IV ganciclovir. The proposed dosage in Table 1 therefore leads to similar pharmacokinetic curves as in patients with IV ganciclovir (Martin et al. 2002). Side

effects are the same as those with ganciclovir although phlebitis is avoided by oral administration.

Cidofovir

Cidofovir is a phosphonate (structurally equivalent to a monophosphate) which bypasses the UL97 step to be converted by cellular enzymes to its diphosphate form. Cidofovir's main dose-limiting side effect is nephrotoxicity and its use is contraindicated in preexisting renal impairment or with other nephrotoxic agents. This may manifest as a dose-dependent Fanconi-like syndrome. Renal impairment may be seen after only a single dose. It should be given with adequate prehydration and probenecid to reduce tubular secretion. Side effects of probenecid include nausea, fever, and rash. As with ganciclovir, cidofovir may also cause neutropenia, rarely neuropathy. In animal models, cidofovir is teratogenic. Dosing must be reduced or drug discontinued if renal dysfunction or proteinuria develops depending on its severity. Unlike ganciclovir and foscarnet, cidofovir has minimal CSF penetration.

Foscarnet

Foscarnet is different; it does not require anabolism and occupies the pyrophosphate binding site of UL54 to block DNA replication. It is available as a solution for infusion and may be administered IV or via the intravitreal route.

Its predominant toxicity is renal affecting around a third of patients, and dosage must be adjusted for renal function. It may cause proteinuria and nephrogenic diabetes insipidus. It is known to affect electrolyte balance in particular leading to hypokalemia, hypomagnesemia, and hypocalcemia. These effects may be enhanced by the use of other nephrotoxic drugs, e.g., aminoglycosides, amphotericin B, and pentamidine so that close monitoring is required. These effects may be minimized by good hydration.

Direct skin contact with urine containing foscarnet may lead to skin ulceration – a differential for ulceration around the genital area in AIDS patients.

Specific Treatment of Retinitis

In patients who present with first-episode retinitis, immediate treatment with ganciclovir or valganciclovir is indicated. If the ophthalmologist is concerned about a lesion that is immediately sight threatening, he/she may give intravitreal treatment with ganciclovir or foscarnet as well. Note that cidofovir is contraindicated by the intravitreal route.

First-episode lesions usually respond to treatment, but constant vigilance is required to identify when progression occurs and to alter treatment. In some cases, progression is due to resistance to ganciclovir and/or foscarnet. CMV DNA sequenced from the blood of first-episode cases matches that of CMV sequenced from the vitreal fluid. In case of doubt, a vitreal sample (conveniently taken when intravitreal therapy is needed) can be amplified to detect mutations in UL97 and/or UL54.

Close coordination is required between the ophthalmologist and HIV physician to optimize the clinical outcome of patients with retinitis. Specifically, the former may be focused on local treatment for the eye with retinitis plus complications, while the latter will want to monitor for viremia and give systemic treatment to prevent CMV spreading to the currently unaffected eye. Following initial therapy, if the patient's CD4 count remains under 100, maintenance therapy may be considered until the CD4 count has been above 100 for at least 3 months to allow development of a successful lymphocyte response. This decision must be made taking into account the likelihood of treatment adherence (both ART and CMV therapy), the potential for development of resistance or side effects and the risk to sight in both the affected and the unaffected eye.

Management of Immune Recovery Uveitis

Immune recovery uveitis should be managed in coordination with the ophthalmologist.

Treatment is dependent on the site and severity of disease including the presence of complications such as cystoid macular edema and epiretinal membrane formation.

Corticosteroids are often used for treatment and may be administered topically to the eye, by

periocular or intraocular injection (e.g., into the sub-Tenon space) or systemically although evidence from controlled trials for this is lacking. There is no proven benefit of intensification of anti-CMV therapy in IRU.

In severe cases with features such as epiretinal membrane formation, surgery (e.g., vitrectomy) may be warranted.

Three new drugs active against CMV (maribavir, brincidofovir, and letermovir) are currently in phase 3 clinical trials in transplant patients. If licensed, they may provide additional options for managing patients in the near future.

Treatment of Other CMV Manifestations

Colitis

Patients with CMV colitis should receive at least 3 weeks of therapy and until clinical resolution. Failure to respond after 6 weeks of adequate therapy should lead to consideration of an alternative diagnosis. The intravenous route may be preferred, at least initially, unless the disease is mild and there are no concerns over oral absorption. Ganciclovir is the first-line agent but foscarnet may also be used. The efficacy of cidofovir in GI disease is unknown.

CNS Disease

There is an absence of clinical trial data to support specific medications in the treatment of CNS infection. In practice, both ganciclovir and foscarnet are used either alone or as proposed by many experts in combination to achieve an additive inhibition of CMV replication. Despite this combination treatment, the clinical outcome is often poor.

Resistance Development

CMV resistance is sometimes seen in AIDS patients with previous antiviral exposure. Resistance to ganciclovir can occur through mutation in the UL97 kinase or via mutation in the CMV DNA polymerase which may also confer resistance to cidofovir and foscarnet. Genotypic resistance testing should be performed if resistance is suspected.

Prevention

Patients with HIV should be counseled to avoid CMV where possible by using the same safe sex guidelines that are given for HIV. This applies to the uncommon cases who are CMV seronegative, with the intention of preventing primary CMV infection, and to the majority of seropositives, with the intention of preventing reinfection.

Vaccines against CMV have reached phase 2 clinical trials in women of childbearing age and in candidates for solid organ transplantation or stem cell transplantation (Pass et al. 2009; Griffiths et al. 2011; Kharfan-Dabaja et al. 2012). Even if they become licensed and are recommended for universal immunization, it will take decades to bring CMV under control even in developed countries (Griffiths 2012). However, the same vaccines have also shown promise when used immunotherapeutically to boost the immunity of seropositives, so this mode of administration could be evaluated in HIV-positive patients in the future.

Conclusions

CMV is a ubiquitous virus that can act as an opportunist in patients whose CMI is suppressed by HIV. Knowledge of the complex natural history of this virus and the treatments currently available for both HIV and CMV has helped bring about a massive reduction in CMV retinitis and morbidity for AIDS patients.

D

DDX3, Cofactors, and RNA Export

Venkat R. K. Yedavalli
Molecular Virology Section, Laboratory of
Molecular Microbiology, National Institute of
Allergy and Infectious Diseases, National
Institutes of Health, Bethesda, MD, USA

Definition

RNA helicases are enzymes that bind to RNA, hydrolyze ATP in an RNA-binding-dependent manner, and separate two annealed RNA duplex strands. Based on sequencing data, there are approximately 85 deduced RNA helicases in the human genome. They have been postulated to have many different functions inside cells. DDX3 is a DEAD (Asp-Glu-Ala-Asp) box RNA helicase protein. There are two forms of the protein. DDX3X is encoded on the X chromosome at position Xp11.3-p11.23 while DDX3Y is located at Yq11. The X-encoded protein and the Y-encoded protein are 91% identical. The DDX3 helicase has attributed roles in pre-mRNA splicing, RNA export, and translation of mRNAs, among other functions.

Organization of DDX3 Protein

There are five superfamilies of helicases, SF1–5 (Kwong et al. 2005). DDX3 is a member of the

SF2 family of helicases. Helicases are operationally defined by whether they can bind single- or double-stranded nucleic acids, unwind RNA or DNA, or both, in either 5' to 3' or 3' to 5' directions. They generally, albeit not invariably, contain certain conserved signature motifs (Kwong et al. 2005). The two major superfamilies of helicases, SF1 and SF2, share at least seven conserved protein motifs. These include domains that specify for nucleic acid binding, ATP hydrolysis, and core helicase activity. The conserved motifs in DDX3 and the demonstration of its RNA unwinding activity have been previously outlined (Yedavalli et al. 2004).

Pleiotropic Functions Attributed to DDX3

Several different functions have been attributed to DDX3. For example, it has been reported that DDX3 has a cell proliferative function through enhancing the translation of cyclin E1 (Lai et al. 2010) and that DDX3 can influence the progression of some cancers through increasing the expressing of the SNAIL transcription factor (Sun et al. 2011). On the other hand, DDX3 has also been reported to act as a tumor suppressor through its transcriptional upregulation of p21waf1/cip1 (Chao et al. 2006), and in settings of environmental insult, DDX3 was reported to inhibit eIF4e (eukaryotic initiation factor 4E), leading to a repression of translation accompanied

by an increase in stress granule formation (Shih et al. 2012). DDX3's inhibitory effect on eIF4e-mediated translation appears to correlate with its described tumor-suppressing function, but interestingly, these activities apparently do not require intact ATPase or helicase functions (Shih et al. 2008). DDX3 also has been reported to play roles in neuronal RNA granules and RNA transport (Kanai et al. 2004), in spliceosomes and RNA splicing (Zhou et al. 2002), in innate antiviral immunity to virus infections (Schroder 2011), as well as in interactions with HCV (Ariumi et al. 2007; Angus et al. 2010) and HIV (Yedavalli et al. 2004; Chen et al. 2012).

Interactions of DDX3 with HIV

Several viruses encode RNA helicases. Herpes virus UL5 and UL9, alphavirus nsP2, rubella virus p70, SARS coronavirus nsp13, hepatitis E virus ORF1, and flavivirus NS3 are some examples of virus-encoded helicases (Jeang and Yedavalli 2006). HIV-1 does not encode an RNA helicase, but there is growing evidence that it interacts with several RNA helicases for replication (Chen et al. 2012). First, cDNA microarray analyses have found that the expression of RNA helicases DHX9, DDX11, DDX18, DDX21, and DDX24 are changed in human cells by HIV-1 infection (Krishnan and Zeichner 2004). Second, a recent mass spectrometric proteomic study found that HIV-1 Gag complexes with DHX9, DDX18, DDX21, DDX24, HIV-1 Vpr interact with DDX20, and Env gp120 binds DDX6 (Jager et al. 2012). In a separate study, Rev, in the presence of RNA, was reported to bind DDX1, DDX3, DDX5, DHX9, DDX17, DDX24, DHX36, and DDX47 (Naji et al. 2012); and DDX24 and DHX30 were described to be involved in Rev-influenced packaging of HIV-1 RNA (Ma et al. 2008; Zhou et al. 2008a).

The role of DDX3 in HIV-1 biology was first broached by Yedavalli et al. (2004). They reported that DDX3 is a nucleocytoplasmic shuttling protein that binds CRM1 (see ► [CRM1](#)), a nuclear export factor, and also that DDX3 is involved in the egress from the nucleus of Rev/RRE-

dependent unspliced and partially spliced HIV-1 RNAs (see ► [HIV-1 Rev Expression and Functions](#)) (Yedavalli et al. 2004). Another RNA helicase, DDX1, was found to also provide a similar nuclear-to-cytoplasmic transport of HIV-1 RNAs (Fang et al. 2004). However, among all the RNA helicases postulated to be important for HIV-1, in three recent siRNA-based genome-wide screens for HIV-1 dependency factors, DDX3 was the only RNA helicase found in all three studies to be required for HIV-1 propagation in human cells (Brass et al. 2008; Konig et al. 2008; Zhou et al. 2008b). In addition to DDX3's role in HIV-1 RNA transport, there is emerging evidence that DDX3 can also contribute to the translation of viral RNAs (Liu et al. 2011; Lee et al. 2008). More investigation is needed to parse the mechanistic distinctions between DDX3 activity needed for RNA transport versus RNA translation.

Conclusion

Extant data suggest that the DDX3 RNA helicase plays roles in cell proliferation, tumor progression, and virus infection of human cells. Above, the contributions of DDX3 to several pathological processes are outlined, arguing that this helicase could be an important drug target. It is thus encouraging that progress has been made in the development of small molecule compounds that target DDX3 (see ► [Cellular Cofactors of HIV as Drug Targets](#)) (Yedavalli et al. 2008; Maga et al. 2011; Radi et al. 2012). Going forward, these candidates should help investigators to further dissect the mechanism(s) and function(s) of DDX3.

Delayed Sexual Debut

Erin Smith

Lydia O'Donnell, Ed.D., Education Development Center, Inc., Waltham, MA, USA

Definition

Early sexual debut, often defined as first sexual intercourse at age 13 or younger, is associated with multiple negative health outcomes, including subsequent sexual risk taking, unintentional pregnancy, and sexually transmitted infections (STI). Evidence-based behavioral interventions (EBI)

aimed at delaying first sex can be delivered to youth as well as parents and are part of a comprehensive HIV prevention strategy, especially when implemented by communities where the prevalence of HIV is high and many young teens are sexually active.

Why Delay Early Sexual Debut?

According to data from the 2011 Youth Risk Behavior Survey, 6% of teens in the USA report they first had sexual intercourse before they were 13 years of age; by 9th grade, 38% of males and 28% of females say they have had sex (Centers for Disease Control 2012). Compared to peers who delay initiation until they are older, young adolescent females are less likely to use condoms or other contraception not only the first time they have sex but throughout their teens (Centers for Disease Control 2006). Among males, even a relatively small difference in age of initiation (12–13 years vs. 14 years) may influence subsequent condom use (Moore et al. 2001). A longitudinal study that followed youth from middle school through young adulthood found that early initiating males and females had a greater number of lifetime sex partners; they also reported higher levels of intimate partner violence, teen pregnancy, and lifetime STI (O'Donnell et al. 2001). Moreover, those who engage in early sexual activity are more likely to be involved in other problem behaviors linked to HIV risk, including alcohol use and bingeing, experimenting with marijuana and other drugs, and substance use before sex.

Ethnic and cultural differences in early sexual debut and sexual activity contribute to disparities in STI and HIV transmission throughout the teen and young adult years. Over three times as many black high school students report having sex before the age of 13 as white teens (14% vs. 4%), and about twice as many have had four or more lifetime sex partners (25% compared to 13%). Differences between whites and Latinos are not as striking: 7% of Latinos report intercourse before they were 13 and 15% have had four or more sex partners. However, over the last decade,

the proportions of black teens and white teens that are sexually active have decreased, while this has not been the case among Latinos. Further, Latinos are less likely to use condoms or other contraceptives at first or subsequent sex: 41% of Latina teens reported using no method of contraception during their last sexual experience, compared with 25% of black females and 10% of white females. While many behavioral interventions – and especially those delivered in schools – are designed to address the needs and risks of both genders, a consistent finding across population groups is the higher level of early initiation reported by males. Overall, males are more than three times as likely to report early initiation as females; 21% of black males and 11% of Latinos report having sex before they are 13 (Centers for Disease Control 2012).

Although the need to intervene early to delay sexual debut is evident, many behavioral interventions are geared toward older teens and may not address the developmental stage, circumstances, or risk contexts of younger adolescents. As Kirby and others point out, interventions to delay sexual debut have often delivered too late to be effective, especially in communities where early initiation, teen pregnancies, and STI and HIV infection are prevalent (Kirby 2007). With studies indicating the onset of puberty among both males and females is now happening at younger ages (Herman-Giddens et al. 2012), the need to provide developmentally appropriate interventions to pre- and early adolescents is likely to become even more pressing. In the USA, this is especially the case for minority and economically disadvantaged youth, for whom disproportionately high levels of early sexual initiation are reflected in ongoing disparities in rates of unintended pregnancy, gonorrhea, chlamydia, HIV, and AIDS. In the USA and globally, early sexual initiation and patterns of subsequent sexual risks also have long-term implications for social as well as physical health, by impeding youths' school completion and economic viability. Indeed, efforts to increase age at first sex have been singled out as a contributing factor in declines in HIV prevalence among youth in sub-Saharan countries with generalized HIV epidemics (Kirby et al. 2005). Thus,

decreasing age at sexual debut is a health priority for multiple reasons, not least of which is the potential impact on reducing HIV transmission and other health disparities.

Behavioral Intervention Approaches: School, Parent, and Community Approaches

Most behavioral interventions that aim to delay sexual initiation target youth directly, primarily through school health and sexuality education programs. In addition, parent education, community-based youth development programs and workshops, and media campaigns have shown promise for reducing sexual risk taking during early and mid-adolescence, especially when targeted to populations and communities where the need is greatest. Across these different types of interventions, however, there is strikingly limited information on what strategies are specifically effective in helping youth postpone sexual initiation and stay abstinent. For example, as part of federal efforts to address unintended teen pregnancies and STI, Mathematica (2012) has identified 31 interventions with moderate to high ratings of effectiveness based on a standardized set of evaluation criteria. However, only five have demonstrated impact on delaying sexual debut or promoting abstinence, even though 17 have been used with adolescents 13 years of age and younger. This underscores a twofold need, first for intervention approaches that target youth before they become sexually active and second for more rigorous evaluations of what programs work to delay initiation until later in adolescence when teens are better prepared to deal with physical, emotional, and social aspects of sexual relationships.

School-Based Approaches to HIV Prevention and Sexuality Education

In 2006, 61% of states required schools to teach students about HIV prevention beginning in elementary school, and 74% required instruction in

middle school; these figures were slightly lower for sex education overall, 49% and 59%, respectively. School district policies were often more restrictive, with only 48% requiring instruction on sexual health and 39% on HIV prevention prior to middle school (Centers for Disease Control 2007). While school-based sex education has the potential to reach youth before they are sexually initiated, the timing and content of lessons have been controversial. Abstinence-only federal and state funding as well as legislation and school policies restricted discussion of condoms and contraception, as well as alternatives to abstinence until marriage (Santelli et al. 2006). Given controversies about the appropriateness of content for older teens, choices for younger teens may be more constrained by disagreements over comprehensive versus abstinence-only or abstinence until marriage sex education.

Multiple literature reviews and several meta-analyses support the benefits of sex education delivered during pre- and early adolescence on sexual risk behaviors. Importantly, studies have consistently shown that sex education neither encourages teens to begin having sex nor increases their sexual activity. The Institute of Medicine has compiled evidence showing that comprehensive sex education programs, which combine abstinence messages with safer sex education and condom availability, are most effective in reducing risks during adolescence (IOM 2000). These programs typically provide youth with information about the benefits of delaying sexual initiation as well as interactive opportunities for developing skills, such as practicing refusal skills, setting personal goals, and considering how peer norms, gender roles, and attitudes influence their behaviors. They are distinguished from abstinence-only or abstinence until marriage curricula because they not only include information about the benefits of abstinence but also address strategies for reducing sexual risks and the use of condoms and other contraception for disease and pregnancy prevention.

As part of the Mathematica review (2012), several sexuality education curricula for use in middle schools have been identified as having moderate to high effectiveness. In general, these

integrate sexual health topics with broader life skills and youth development goals. Examples include the Aban Aya Youth Project for African American youth, Draw the Line/Respect, It's Your Game, and one abstinence-based program, Heritage Keepers. These have been delivered either by teachers or by specially trained health educators and require a minimum of 10–20 classroom sessions. In addition to variation in the amount of information provided on sexual risk reduction, condoms, and other contraception, they differ in whether they are targeted to specific at-risk population groups as well in the extent to which they address gender differences in risks, such as girls who become involved with older boyfriends, or address topics such as dating violence and sexual coercion.

A growing number of public health and national organizations have advocated for the inclusion of comprehensive sex education in elementary as well as middle and high schools (Eisenberg et al. 2008). This support is mirrored by results of multiple surveys that indicate parents, too, overwhelmingly support sex education in school, including provision of age-appropriate medically accurate information on abstinence, contraception, and disease prevention (Kaiser 2004). Yet, in addition to ongoing disagreements about the content of lessons, other barriers to the diffusion of evidence-based school interventions have been identified. For example, time-to-learning requirements and “high-stakes” standardized academic testing have limited classroom opportunities not only for sexuality and HIV education but for health education more broadly. These barriers underscore the importance of more rigorous assessment of the duration and amount of classroom time needed for school-based programs to be effective, either for delaying early initiation or for addressing the needs of youth who are sexually experienced. Other challenging issues include strategies for addressing the needs of sexual minority youth as well as how to address potentially sensitive topics such as dating violence and sexual coercion in general classroom settings.

In addition to providing youth with health and sexuality education, several other school-based

intervention approaches have shown promise, including two programs aimed at younger students, the Good Behavior Game and the Raising Healthy Children Program. The Good Behavior Game is a classroom-management intervention that rewards first and second grade children for displaying on-task behaviors. Delivered by trained classroom teachers, a longitudinal study has demonstrated long-term impact on reducing high risk sexual behaviors as well as drug use into young adulthood (Kellam et al. 2014). This is one of the few programs that have shown such long-term impact. The Raising Healthy Children program for elementary schools as well the middle-school program, Adult Identity Mentoring, are examples of evidence-based youth development programs delivered in schools. These emphasize the connections and social ties that reinforce the importance of avoiding sexual as well as other risks, overlapping content with comprehensive health education programs that also emphasize life skills such as goal-setting, decision making, and maintaining healthy relationship as well as reducing sexual risks.

In sum, school-based programs have the potential to reach youth before they become sexually active, if the timing of delivery and content matches the behavioral risks of youth in diverse communities. In addition, the availability of guidance and health services in the school setting provide opportunities for linking youth to counseling and sexual and reproductive health care.

Parent and Parent-Teen Approaches

Parents are a primary and critical source of information and support for youth undergoing the physical, emotional, and social changes that come with puberty. Research shows not only that positive parent–child communication about sexuality helps teens make good choices but also that teens want their parents' guidance and support (Hacker 2000). Parents can supplement and reinforce school-based sex education by providing information and reinforcing family values and reasons for delaying sexual initiation and risk.

However, many parents report feeling unprepared to address issues of sexuality and sexual health. As a result, studies show that their advice, on reasons for abstinence or on the use of condoms or other contraception, often comes after youth are already sexually active (Kaiser Family 2002). One of the strongest deterrents to positive parenting practices during early adolescence is parents' underestimation of the risks to which their young adolescents are exposed, which may lead to inappropriate or ineffective parenting practices. For example, if mothers discussed condom use with teens before they had sex, their teens were more likely to use condoms at first sex, which is related to more consistent condom use over time; however, this conversation was less helpful if youth were already sexually active (Miller et al. 1998). In addition, parents may underestimate the extent to which their children want to learn from them, and not only from teachers, peers, media, and other sex education channels. Even if they want to play a role in sex education and helping their sons and daughters delay sex until they are older, many parents do not feel they have adequate or accurate information about sexual and reproductive health; this discomfort may be compounded in cultural contexts and communities where family talk about sex has traditionally been limited.

To address these gaps, a number of behavioral interventions have been developed to promote positive parent-child communication. These focus on making parents more comfortable and efficacious when discussing sexual and reproductive health topics with their children. Some have been tailored to address culturally influenced attitudes and beliefs about sexuality and family interactions as well as the increased unintended pregnancy, STI, and HIV risks of at-risk populations of African American and Latino youth. As described in compilations provided by Advocates for Youth (2011) and other clearinghouses, these interventions take a variety of approaches. They include multi-session groups for parents, such as Talking Parents, Healthy Teens; parent-teen (mother-daughter; father-son) workshops, such as Parents Matter! and Keepin' It R.E.A.L.: Mother-Adolescent HIV Prevention Program; multimedia parenting education, such

as Saving Sex for Later's audio-based role model stories that supporting positive parenting practices; parent supplements to school curricula, such as homework assignments for Safer Choices and Youth AIDS Prevention Program; and parent-to-parent networking and support strategies, such as Plain Talk. Other programs, such as Safer Choices and Reducing the Risk have been developed and primarily tested with parents of older teens.

In general, evaluations of these interventions show they are effective in preparing parents to support of their sons and daughters as they make the transition from childhood to adolescence. Parents generally welcome these learning opportunities and report they have benefit from their participation. However, difficulties of community recruitment (as opposed, say, to reaching almost all young teens when they are a captive audience in their middle school classrooms) as well as participation demands may limit their reaching broad audiences. Workshops only reach a segment of the target population of parents who may be sufficiently motivated to attend. Homework assignments may be difficult in households where school attachment or literacy levels are low. Despite the limitations, across different strategies, a number of benefits for youth have been identified, including teens' reports of increased communication and perceptions of greater parental support as well as reductions in sexual and related risk behaviors, like alcohol and drug use. As with many school-based programs, however, there is limited information on the extent to which they specifically help young teens delay sexual initiation and little on long-term impact on sexual health over an extended time.

Community Approaches

Community interventions also can play a role in efforts to reduce early sexual debut, especially as a compliment to what is offered by school and provided by parents. These include youth development programs, strategies aimed at primary care and reproductive health providers, and social marketing campaigns. An advantage of out-of

school programs is that content can be tailored to address levels of risk, gender differences, and sensitive issues such as coercion and relationship violence.

Youth development programs aim to help teens develop assets and resiliencies that are associated with positive behaviors and reduced risks. A review of nine studies found that involving at-risk youth in community service can be effective in reducing sexual risks, including age of initiation, number of sex partners, and related behaviors such as violence and substance use (Guide to Community Preventive Services 2007). In addition to targeting specific youth risks, these facilitate community connectedness—a protective factor for multiple problem behaviors.

Primary care providers can play a unique role in providing youth with access to safe and accurate reproductive health resources but often lack the resources and time. Interventions focused on improving provider-patient relationships in adolescent health care settings have the potential to influence adolescent attitudes and behaviors prior to sexual debut (McKee et al. 2004). In particular, vulnerable urban youth can benefit from improved access to personalized, supportive care from providers in settings where they perceive their privacy is protected. However, like teens' communication with parents, adolescent-provider communications about sexuality can be challenging and often happen only after youth have initiated sexual activity. Six programs identified in the Mathematic review were evaluated when delivered in clinic settings; only two – Sisters Saving Sisters and Safer Sex, both targeted to black teens – included youth under 14 in their evaluation studies and only Safer Sex is noted for having a measurable impact on delay of sexual initiation or abstinence (Mathematica 2012).

Media campaigns based on health communication theory have underscored the role parents play in sex and drug education and keeping teens from engaging in risk. Relationships between parent-child communication and adolescent sexual behavior are well documented in the literature. In addition, HIV/AIDS prevention media campaigns targeting youth directly in the USA and

globally have also found increases in condom use initiation, decisions to be abstinent, and a reduction in number of partners (Noar et al. 2009). While studies have found that in communities where accessibility, availability, and acceptability of condoms are greatest, there are lower incidences of new HIV infections, strategies that support condom distribution programs have not focused on delays in sexual initiation and are not typically targeted to youth under the age of 15. Globally, there has been support for structural interventions that address underlying factors that contribute to early sexual initiation, including poverty, lack of educational opportunities, gender inequity, power imbalances, and forced sex. These most often have been implemented in Africa and other regions with the highest prevalence of HIV. Many of these efforts have been directed to girls around the time of puberty; they address social and economic barriers to school attendance and completion and other strategies that promote gender equality and empowerment (Family Health International 2010).

Limitations

Despite the potential of evidence-based behavioral interventions to help youth delay sexual initiation, there are numerous barriers to their effective dissemination and use by communities where they could have the greatest impact. First, there are relatively few programs that have been specifically targeted to support youth in the transition from middle childhood into adolescence, and relatively few evaluation studies have specifically examined program impact on the timing of sexual initiation. Second, to have the biggest impact on HIV prevention, programs must be directed to the most at-risk populations and highest prevalence communities, yet finding the resources to support programs in these resource-limited settings can be challenging. Across settings, schools have encountered problems devoting classroom time for sex education, the major strategy for reaching almost all youth; it has been difficult to engage parents or youth in voluntary,

afterschool programs. While a growing body of evidence demonstrates that comprehensive sex education can have a positive impact on reducing youths' reports of sexual risk taking, many evaluations are limited by weak study designs and small samples, and youth have not been followed over time to measure impact on pregnancy or STI/HIV rates (Mathematica 2012; Kirby et al. 2005). Comparative information on what works best for what populations is not available, despite sizeable cultural and community differences in age at sexual debut. We also do not know which components of interventions most directly address delay of initiation or how school, parent, and community approaches can be integrated to achieve the greatest impact. Political will and public controversies continue to shape how and when some HIV prevention topics and strategies are addressed, such as information about and access to condoms or other contraception or linkages to sexual health services, especially prior to first sex. There is also little information about patterns of early adolescent risk behaviors and effective prevention strategies for non-heterosexual youth and, especially, young males who may be at risk for early initiation and experimentation. This is especially troubling given the elevated HIV risks of young men who have sex with men and the young age at which many become infected. Despite these limitations, however, the fact is that schools and communities nationwide are selecting and implementing behavioral interventions that seek to reduce early and risky sex, and most surveys have shown that youth, parents, and the public are, in general, highly supportive of these efforts.

Conclusion

Preventing early sexual debut is an important target for HIV prevention programs as well as for broader efforts to address disparities in sexual and reproductive health, including STI, unintended pregnancies, and sexual violence. Program planners can choose from a variety of evidence-based interventions that address the

sexual risks and contexts of younger teens, are appropriate for the communities they serve, and matched to their local opportunities and resources.

Dendritic Cell Interactions with HIV-1 Envelope Glycoprotein: Implications for Preventing Transmission

Kerrie J. Sandgren^{1,2}, Frank Liang², Anna Smed-Sörensen² and Karin Loré²

¹Centre for Virus Research, Westmead Millennium Institute, Sydney, Australia

²Department of Medicine, Clinical Immunology and Allergy Unit, Karolinska Institutet and University Hospital, Stockholm, Sweden

Definition

Dendritic cells (DCs) are critical sentinels of the immune system and potent antigen-presenting cells. They patrol peripheral tissues including the blood, skin, and mucosal surfaces, poised to sense and respond to incoming microbes. Upon encountering a microbe, DCs engulf it and are triggered to migrate to the lymph nodes. Along the way they degrade the microbe and undergo a process of maturation that includes upregulation of molecules associated with antigen presentation. In the lymph node, DCs present their antigen on major histocompatibility complex (MHC) class I and II molecules to T cells and thus activate an adaptive immune response specific to the microbe. DCs can be one of the first cell types to encounter HIV. The virus has evolved to exploit the natural function of DCs, which includes avoiding degradation in order to gain access to its primary target – the CD4⁺ T cells. DCs are therefore a key target to investigate for strategies to prevent HIV transmission. In this entry we will introduce the reported interactions of different subsets of DCs and HIV, particularly the envelope glycoprotein expressed on the virus surface, as well as strategies to interfere with these interactions to inhibit HIV acquisition.

Introduction

Accumulating data from HIV vaccine clinical trials (► [Prevention Clinical Trials Highlights of](#)

Evidence and Research) and preclinical research suggests that the HIV envelope glycoprotein spike (Env) is likely to be an essential component of a prophylactic vaccine. Env is a heterodimer of the highly glycosylated gp120 and gp41 subunits (► **HIV virion structure**) that form trimers on the virion surface. The trimer mediates attachment and fusion of HIV into host cells and is the sole target for neutralizing antibodies (nAbs). Env is therefore an important focus for HIV prevention strategies in the form of vaccines designed to elicit nAbs and microbicides that directly block infection.

Dendritic cells (DCs) are the most potent antigen-presenting cells and are essential for priming naïve T cells and establishing effective adaptive immune responses. DCs in the genital mucosa are among the first cells to encounter HIV (► **HIV-1 Transmission; Cell-Types Associated with**) and other sexually transmitted infections (► **HIV-1 Sexual Transmission**). They can be infected with HIV, and more importantly, by virtue of their close interactions with CD4⁺ T cells in the lymph nodes, DCs can also transfer virus from the mucosa to these primary HIV target cells with high efficiency. Thus, DCs represent an important link in the chain of HIV transmission and immunity. They play a role in HIV dissemination and seeding of a viral reservoir but they are also critical in governing immune responses to vaccines. Targeting DCs with prevention strategies may be an effective approach to inhibit the establishment of HIV infection.

Dendritic Cells

DCs Prime Adaptive Immune Responses

Human DCs have evolved into multiple distinct and functionally specialized subsets, tailored to handle the microbes associated with their location (Teunissen et al. 2012; Smed-Sorensen and Lore 2013). DCs constantly sample their environment for antigen and can sense the invasion of a pathogen through pattern recognition receptors including C-type lectin receptors (CLRs), toll-like receptors (TLRs), and an array of DNA and RNA sensors. Upon detecting and internalizing a

pathogen, DCs become activated, maturing into potent antigen-presenting cells, and migrate from the peripheral tissue to the draining lymph nodes. Here they present their antigen on MHC class I and II molecules and activate naïve CD8⁺ and CD4⁺ T cells to become cytotoxic or helper T (Th) cells, respectively. CD4⁺ Th cells support the development of cytotoxic CD8⁺ T cells and the production of antibodies (Ab) by B cells. DCs also regulate the magnitude and quality of the ensuing adaptive immune response through the release of cytokines.

DC Subsets Are Functionally Specialized

There are two main subtypes of human DCs – myeloid and plasmacytoid DCs (Table 1). CD123⁺ plasmacytoid DCs (PDCs) are localized primarily in the lymph nodes, secondary lymphoid organs (e.g., spleen, tonsils, mucosal-associated lymphoid tissues), and blood, but migrate into tissues upon inflammation or pathogen exposure. PDCs are uniquely potent producers of interferon- α (IFN α), which plays a key role in the antiviral response, but they can also take up and present antigens to T cells. CD11c⁺ myeloid DCs (MDCs) exist as three major subsets in the blood and multiple subsets in the tissues (Fig. 1). CD1c (BDCA-1)⁺ blood MDCs are superior at antigen uptake and stimulating naïve CD4⁺ T cell responses and are the predominant producers of IL-12p70. CD141 (BDCA-3)⁺ blood MDCs are a very rare subset that are competent at cross-presentation and stimulating naïve CD8⁺ T cell responses and produce large amounts of IFN- λ (Nizzoli et al. 2013; Smed-Sorensen and Lore 2013). CD1c⁺ MDCs can also efficiently cross-prime cytotoxic CD8⁺ T cells although the signaling requirements for optimal priming by the two DC subsets differ (Cohn et al. 2013; Nizzoli et al. 2013; Segura et al. 2013) and may reflect their specialization for different pathogens. The third subset, CD16⁺ MDCs, is relatively poor antigen presenters but are potent secretors of pro-inflammatory cytokines (Smed-Sorensen and Lore 2013).

The skin and mucosa (► **Mucosal Immunity**) are composed of two main compartments – the epidermis and dermis in skin, or stratified

Dendritic Cell Interactions with HIV-1 Envelope Glycoprotein: Implications for Preventing Transmission, Table 1 Specialization of DC subsets

Location	DC subset	Key phenotypic markers	Key cytokine produced	Specialty
Blood, LNs	Plasmacytoid DCs (PDCs)	CD123	IFN α	Innate antiviral response
		BDCA-4		
Blood, tissues	Myeloid DCs (MDCs)	CD11c	IL-12p70	Prime naïve CD4 ⁺ Th cells
		CD1c (BDCA-1)		
		CD11c	IFN- λ	Cross-prime CTLs
		CD141 (BDCA-3)		
		CD11c	TNF	Proinflammatory
		CD16		
Skin – epidermis Mucosa – stratified squamous epithelium	Langerhans cells (myeloid)	CD11c	IL-15	Peripheral tolerance
		CD1a		Support development of CTLs
		Langerin		
Skin – dermis, Mucosa – lamina propria	Dermal DCs (myeloid)	CD11c	Low IL-15	Support development of CTLs
		CD1a		
		MR		
		CD11c	IL-10	Support Ab production
		CD14		
		DC-SIGN		
		MR		
		CD11c	Not determined	Not determined
		CD141		

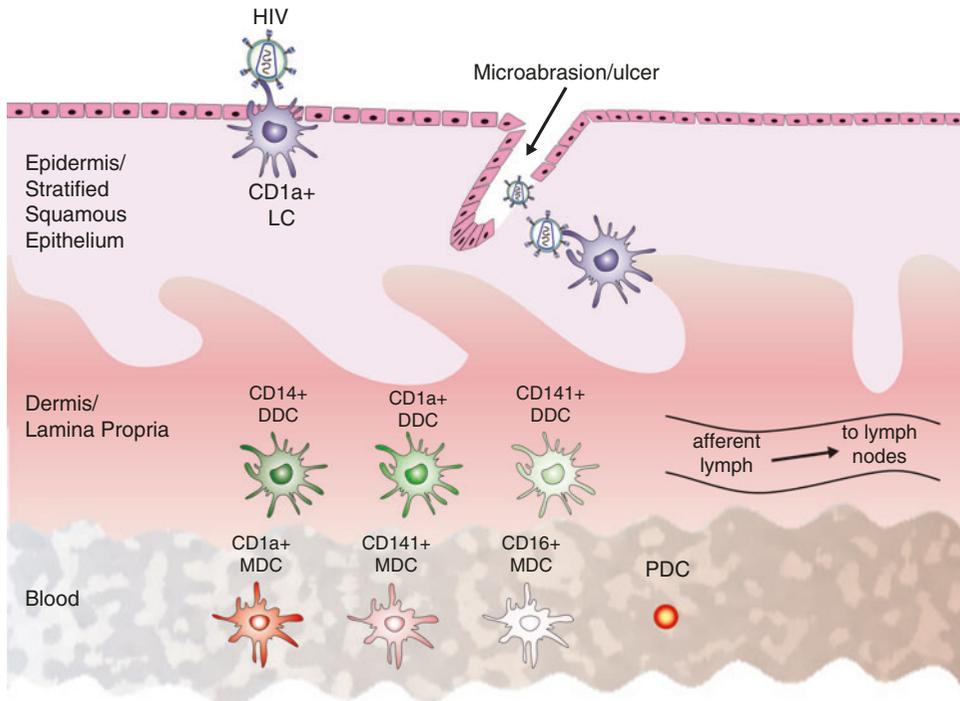

squamous epithelium and lamina propria in mucosa. Langerhans cells (LCs) are the major DC subset found near the surface, in the epidermis/epithelium. Several subsets of dermal or interstitial DC subsets reside deeper in the dermis/lamina propria (Fig. 1), including CD1a⁺CD14⁻, CD1a⁻CD14⁺, and CD141⁺ subsets (Harman et al. 2013b). In the skin, LCs play a dual role, maintaining epidermal tolerance by stimulating skin-resident regulatory T cells but also responding in an immunostimulatory fashion to pathogens and efficiently priming cytotoxic T cells and CD4⁺ Th cells that support their development. In contrast, CD14⁺ DDCs primarily prime CD4⁺ Th cells that support the proliferation and differentiation of B cells into Ab-producing cells (Teunissen et al. 2012). These differential roles are governed by the distinct cytokine profiles of the two subsets with the specialized production of IL-15 by LCs and IL-10 by DDCs (Banchereau et al. 2012). Due to the low frequency of DCs in vivo, DCs are commonly derived from monocytes in vitro as a reliable way of generating high numbers of DCs.

These model monocyte-derived DCs (MDDCs) most closely resemble dermal DCs in terms of gene expression (Harman et al. 2013a).

DC Interactions with HIV Env

DC Binding and Uptake of HIV/Env

In the infection process, HIV first anchors to the host cell via Env binding to the high-affinity receptor CD4. Env binding is followed by interactions with the co-receptor CCR5 or CXCR4 that allows fusion with the plasma membrane and entry of the virus. In DCs (► [HIV-1 Transmission; Cell-Types Associated with](#)) this may result in a low level of productive infection (*cis* infection). As DCs are nonproliferating cells, the replication of HIV is generally low and is also restricted by host factors such as SAMHD1 (Vicenzi and Poli 2013). A more significant and unique feature of DCs is that they can capture and transfer virus to closely associated CD4⁺ T cells without becoming infected themselves, in a process termed *trans*

D

Dendritic Cell Interactions with HIV-1 Envelope Glycoprotein: Implications for Preventing Transmission, Fig. 1 Skin and mucosal DC subsets interact with HIV at the point of entry. Genital skin and mucosal surfaces represent a portal of entry for HIV. Multiple phenotypically and

functionally distinct DC subsets interact with HIV in these tissue as the virus enters through breaches in the epidermis/epithelium or is actively transported across the luminal wall by Langerhans cells. DCs contribute to virus dissemination as well as the initiation of anti-HIV immune responses

infection. DCs efficiently capture and endocytose HIV via pattern recognition receptors, including CLR that have affinity for the high mannose glycans on Env. The normal function of CLR is to facilitate antigen uptake for efficient processing and presentation to T cells, but HIV has evolved to subvert this pathway and can be routed to intracellular compartments where the virus remains intact (see section “[The Role of DCs in HIV Dissemination](#)”).

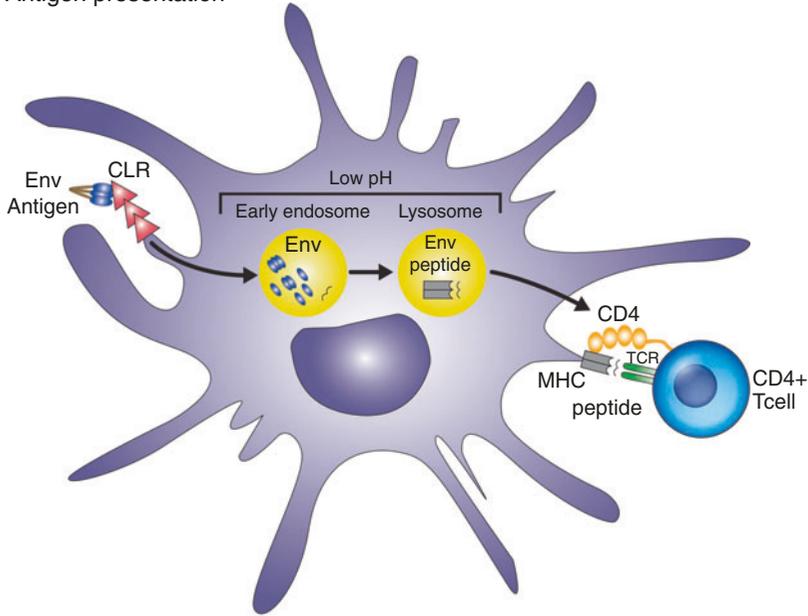

The different DC subsets express unique repertoires of CLR, enabling the DCs to capture a variety of pathogens via their glycosylated surface proteins. In relation to HIV binding, LCs uniquely express high levels of langerin. The various dermal DCs express combinations of dendritic cell-specific ICAM-3 grabbing non-integrin (DC-SIGN), mannose receptor (MR), dendritic cell immunoreceptor (DCIR), and DEC-205 (Harman et al. 2013a; Sandgren et al. 2013). The

expression patterns of CLR on lamina propria DCs are currently less well defined. Blood DCs express a more restricted CLR repertoire including DCIR, DEC-205, and BDCA-2 (the latter on PDCs only) and tend to rely on CD4 for Env binding. In the context of soluble Env protein alone, this is a functional pathway for internalization and antigen presentation (Sandgren et al. 2013). HIV also exploits non-glycan dependent binding to other DC-expressed pattern recognition receptors, including siglec-1 and syndecan-3, for capture and transfer to CD4⁺ T cells (Tsegaye and Pohlmann 2010).

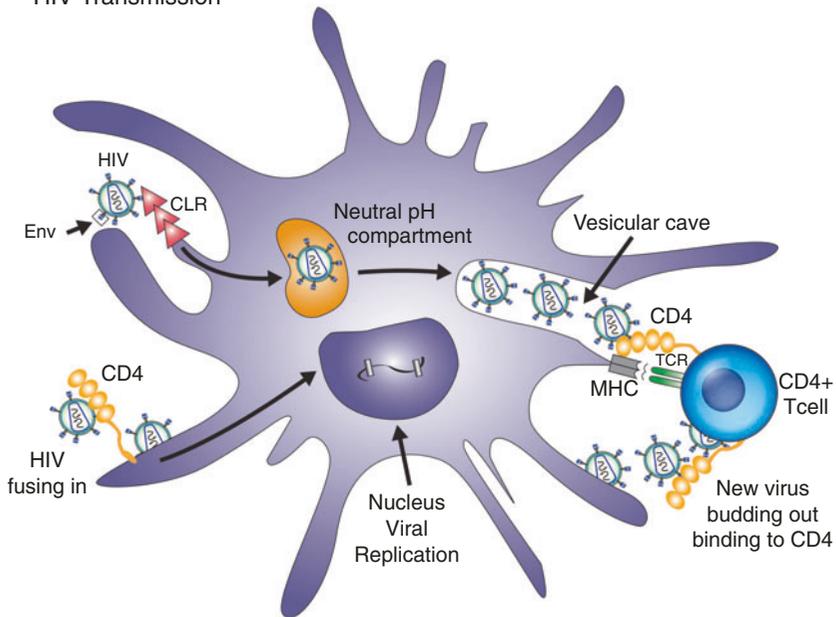

The Role of DCs in HIV Dissemination

As mentioned above, Env binding to certain CLR triggers endocytosis of HIV leading to two outcomes (Fig. 2). The virus can be degraded and subsequently presented to T cells. Alternatively, approximately 5–10% of the virus subverts

a Antigen presentation

b HIV Transmission

Dendritic Cell Interactions with HIV-1 Envelope Glycoprotein: Implications for Preventing Transmission, Fig. 2 HIV subverts antigen presentation pathways in DCs to gain access to its target cell, CD4+ T cells. (a) DCs utilise CLR to bind and take up pathogens, which it processes and then presents to T cells to stimulate

an immune response. (b) HIV can also be taken up via this route without being destroyed and transferred directly to CD4+ T cells interacting with the DC. At later times, newly synthesised virus in an infected DC buds out in close proximity to CD4+ T cells for efficient spread

endolysosomal trafficking and is preserved in pH-neutral compartments or deep plasma membrane invaginations continuous with the cell surface, referred to as vesicular caves (Cunningham et al. 2013). Upon contact with a CD4⁺ T cell, the virus recycles rapidly to the interface between the two cells and is transferred directly to the T cell where it can replicate explosively. The latter is a very efficient route of infection for T cells – much more efficient than direct infection by cell-free virus (► [Inhibition of HIV-1 Spread: Cell-Free Versus Cell-Cell](#)). Furthermore, DCs have been shown to preferentially transfer virus to responding antigen-specific CD4⁺ T cells that cluster with them (Lore et al. 2005), and the simultaneous activation of these T cells by antigen recognition enhances HIV transmission (Rodriguez-Plata et al. 2013).

The result of these interactions between HIV and different DC receptors is that DCs can transfer HIV to CD4⁺ T cells in two waves. The first phase of virus transfer occurs within 24 h and results from transfer of virus to bystander CD4⁺ T cells in the absence of DC infection. The second wave begins 48–72 h after infection and is a result of de novo virus production in infected DCs (Cunningham et al. 2013). DCs thus play a critical role in the capture and transfer of HIV from the portals of entry to the regional lymph nodes, dissemination of the virus to T cells, and the seeding of a viral reservoir.

Mucosal DCs are especially relevant to sexual transmission of HIV and dissemination to the draining lymph nodes. Mucosal LCs have been observed to extend their dendrites between the tight junctions of the epithelial cells, or even to migrate across the epithelium right into the lumen, to sample antigen. In fact, HIV attracts DCs in the gut (Selection of CCR5 Using Viruses; Transmission) and exploits their migratory capacity to hitch a ride across the mucosa to the T cell-rich areas in the gut and in the lymph nodes (Harman et al. 2013b).

Immunosuppressive Effects of Env

DC Dysfunction in HIV Infection

DC-mediated immune responses are subverted by HIV and are insufficient to control dissemination

of the virus (Smed-Sorensen and Lore 2011; Miller and Bhardwaj 2013). For example, not all the virus taken up by DCs is degraded and DCs do not fully mature in response to HIV, which may lead to suboptimal antigen presentation and T cell activation in the lymph nodes. HIV Env is also able to shut down autophagy in DCs, which compounds this dysfunction by decreasing MHC class II antigen presentation and stimulation of HIV-specific CD4⁺ T cells. This concomitantly allows accumulation of virus and enhanced transmission to T cells (Blanchet et al. 2010). DCs, both in vitro and in simian AIDS models, have also been shown to become sensitized by Env to undergo apoptosis upon exposure to activation stimuli (Wijewardana et al. 2010; Chen et al. 2013). The result is significant DC depletion occurring early in acute infection and dysfunction, which may lead to defective or skewed Th cell responses. The DCs that do remain are hyperfunctional in response to TLR7/8 agonists (HIV also triggers TLR7/8) in terms of maturation, and cytokine and chemokine secretion, which may contribute to the systemic immune activation (► [Chronic Immune Activation](#)) observed in chronic HIV (Miller and Bhardwaj 2013).

Env-Mediated Immunosuppression

While the factors governing the fate of HIV inside a DC (transfer vs. degradation) are unclear, the glycan composition of Env (Virus Structure), which varies from strain to strain, may play an important role. It has been shown that virus modified to have an oligomannose-enriched envelope was captured more efficiently by DCs and was routed more efficiently into the endolysosomal pathway and degraded, resulting in reduced viral transfer to T cells. It was also presented to Env-specific CD4⁺ T cells more efficiently (van Montfort et al. 2011). The glycan composition of Env determines the binding affinity of the glycoprotein for different CLRs that can subsequently target it to different compartments in the endolysosomal pathway. These results may have promising implications for Env-based protein subunit vaccines, but Env has also been associated with immunosuppressive effects through its interactions with mannose-binding CLRs.

Echoing what has been observed in HIV-infected patients, multiple *in vitro* studies have shown that Env glycoproteins can impair critical DC functions including maturation, cytokine production, and activation of T and B cells and can induce DC apoptosis. Exposure to certain strains of Env results in defective maturation of DCs in response to classical maturation stimuli (Shan et al. 2007), as well as impaired production of effector cytokines such as TNF, IL-12, and IFN α (Fantuzzi et al. 2004; Martinelli et al. 2007; Chung et al. 2012) and the induction of anti-inflammatory IL-10 (Shan et al. 2007; Sarkar et al. 2013). Furthermore, Env exposure can lead to a decreased capacity to stimulate T cell proliferation (Fantuzzi et al. 2004; Fernando et al. 2007; Shan et al. 2007; Hu et al. 2008) and B cell activation (Chung et al. 2012). As mentioned above, exposure to Env also sensitized DCs to undergo extensive apoptosis upon activation by various stimuli that would normally promote DC function, including CD40 ligand, TLR ligands, and proinflammatory cytokines both *in vitro* and *in vivo* (Chen et al. 2013). These immunosuppressive effects have all been shown to be dependent on Env interactions with mannose-binding CLRs, such as DC-SIGN and MR (Shan et al. 2007; Chung et al. 2012; Chen et al. 2013). In line with these observations, immunization of humanized mice with Env glycoproteins where the mannose moieties were occluded or removed, thus preventing binding to CLRs and presumably circumventing this route of DC dysfunction, resulted in enhanced Env-specific Ab titers and T cell responses (Banerjee et al. 2009, 2012). As mentioned above, the position and type of N-linked glycans on Env may again play a critical role in these negative effects on DC function (Shan et al. 2007). Using different strains of Env or HIV, other studies have not observed any impairment of maturation in MDDCs or primary MDCs and PDCs in response to various TLR ligands or inflammatory stimuli (Lore et al. 2005; Harman et al. 2009; Vani et al. 2012a, b). Env exposure in these instances also did not inhibit DC antigen presentation or stimulation of T cell proliferative responses (Lore et al. 2005; Vani et al. 2012a). Importantly,

MDCs and PDCs do not express the main culprit receptors DC-SIGN and MR, but these are highly expressed on MDDCs. The presence or absence of distinctive glycosylation sites on Env is known to facilitate mother-to-child transmission of HIV and be associated with disease progression, confirming that this phenomenon likely plays a role *in vivo* (Baan et al. 2012, 2013).

Preventing HIV Transmission

Microbicide Strategies

HIV is most commonly transmitted via heterosexual intercourse (► [HIV-1 Sexual Transmission](#)); thus, preventative strategies need to operate at the genital mucosal surfaces. Two such strategies include microbicides (► [HIV-1 Transmission Blocking Microbicides](#)) (topical applications that can be formulated to block HIV infection) and mucosal Abs (that can be elicited by vaccination (► [HIV-1 Transmission Blocking Vaccines; How Feasible Are They?](#))). Given the critical role that Env plays in attracting and infecting DCs and subsequent HIV transmission to T cells, it is a primary target for blocking strategies to interrupt these events and prevent the establishment of HIV infection. A number of compounds have been identified that can block Env interactions with host cells, namely, via DC-SIGN and CD4 binding, that have the potential to be developed into microbicides (Table 2). These include sugars found in human breast milk and other subsequently developed multimeric glycomimetics (structural mimics of mannose and fucose polysaccharides) (Anderluh et al. 2012), as well as purpose-designed CD4-binding proteins, e.g., designed ankyrin repeat proteins (DARPs) (Schweizer et al. 2008).

Compounds that target the actual virus may be preferable over agents that bind directly to cell-surface receptors such as DC-SIGN and CD4 as they are less likely to influence the natural functions of these receptors in immunity. It has not yet been fully validated whether DC-SIGN (which acts as an adhesion molecule and pathogen capture receptor) or CD4 (which binds to MHC II to stabilize the immune synapse and amplify the T cell receptor signal) can be targeted by inhibitors

Dendritic Cell Interactions with HIV-1 Envelope Glycoprotein: Implications for Preventing Transmission,**Table 2** Compounds that can inhibit Env/DC interactions

Agent	Function
Lewis-X motif containing sugars	Compete with HIV for binding to CLRs, e.g., DC-SIGN
Glycomimetics	Compete with HIV for binding to CLRs, e.g., DC-SIGN
DARPinS	Compete with HIV for binding to CD4
Soluble CD4/DC-SIGN/langerin	Bind to HIV Env and thus block HIV binding to cellular receptor
Small-molecule CD4 mimics	Bind to HIV Env and thus block HIV binding to CD4
Algal lectins	Bind to HIV Env and thus block HIV binding to DC-SIGN and DC-mediated transfer to T cells
Dendrimers	Bind to HIV Env and thus block HIV binding to cellular receptor
Env-specific nAbs	Bind to HIV Env and thus block HIV binding to CD4 and DC-mediated transfer to T cells. Opsonize virus for degradation

in vivo without unwanted effects. To this end, various soluble HIV receptors have been tested including soluble CD4 and small-molecule CD4 mimics (Teixeira et al. 2011), DC-SIGN, and langerin. However, such soluble HIV receptors have so far demonstrated limited success. For instance, although soluble CD4 was found to be effective at blocking binding of cell-free virus, it actually enhanced infection with cell-associated virus (Haim et al. 2009), and during natural transmission via semen, vaginal secretions, breast milk, or blood, a significant proportion of virus is expected to be cell associated (► [Inhibition of HIV-1 Spread: Cell-Free Versus Cell-Cell](#)). A number of lectins have been isolated from algae and cyanobacteria that bind to Env and block HIV binding to DC-SIGN in vitro. Compounds including griffithsin, cyanovirin-N, and scytovirin were even more potent at inhibiting DC-SIGN-mediated HIV transfer to T cells and are being investigated for their microbicide potential (Huskens and Schols 2012). Dendrimers are synthetic, highly branched nanoparticles that, by virtue of their highly charged surface, can exhibit antiviral activity by binding to and blocking the

entry of a virus. SPL7013 (Starpharma) is a dendrimer that has been developed as the active ingredient in VivaGel, which is now in clinical trials as a HIV and herpes simplex virus microbicide (Parboosing et al. 2012).

A novel therapeutic strategy may be to develop a mechanism for inhibiting Env-induced DC migration through tissues, to inhibit dissemination of the virus from the mucosa. A signaling pathway via CCR5 was recently identified, whereby Env enhances filopodium formation and trans-endothelial migration of DCs. As described above, these processes are central for initial DC homing to and uptake of HIV as well as migration to the lymph nodes and virus transfer to CD4⁺ T cells in vivo. An active fragment of the protein Slit2 was used to inhibit filopodium formation and DC migration, which could contribute to a potential protective strategy (Prasad et al. 2012).

Env-Based Protein Subunit Vaccines

As previously mentioned, Env represents the sole target on HIV for nAbs and as such is considered to be a critical component of a prophylactic HIV vaccine (► [HIV-1 Transmission Blocking Vaccines; How Feasible Are They?](#)). The early Env-based protein subunit vaccine (AIDSVax by VaxGen), based on Env monomers, was unsuccessful at eliciting broadly nAbs against primary HIV strains. However, a more recent trial (RV144) combining a modified canarypox vector (ALVAC) with AIDSVax in a prime-boost strategy resulted in a reduction in susceptibility to HIV infection and the detection of HIV-specific Ab responses, albeit non-neutralizing, in some vaccinees. This trial demonstrated that vaccination can be effective at conferring a degree of protection against HIV acquisition (► [Preventing HIV-1 Transmission Through Vaccine-Induced Immune Responses](#)) and provides the benchmark for the development of more potent vaccine regimens. Areas for optimization include primarily the design of stable trimeric Env immunogens (► [HIV-1 Transmission Blocking Vaccines; New Designed Immunogens](#)) to elicit broadly nAbs but also the mode of antigen delivery, such as the site of injection and cell types targeted, and the activation of cells receiving the vaccine, usually

achieved through coadministration of an adjuvant. Finally, it may not be enough to elicit Env-specific broadly nAbs systemically. It is likely that they will need to be present at the mucosal surfaces in order to effectively block HIV transmission.

Broadly nAbs (► [Role of Antibodies in HIV Transmission](#)) directed toward the gp120 surface unit of Env, as well as the gp41 transmembrane unit of Env, have been detected in sera from HIV-infected individuals. Such nAbs have also been proven to block transmission of HIV in macaques. nAbs directed toward the membrane proximal region of Env may be particularly successful at blocking transfer of HIV from DCs to T cells (Sagar et al. 2012). However, trials testing Env immunogens have to date been unsuccessful at eliciting such nAbs. Consequently, efforts are currently underway to map the broadly nAb response to understand both the physical characteristics of these Abs and their cognate epitopes on Env, as well as how they evolved, in terms of their germline sequence and degree of somatic hypermutation. The hope is that this information will inform the rational design of new Env immunogens (Burton et al. 2012).

Targeting DCs to Enhance Vaccination

One of the critical factors in the establishment of an effective humoral response is the provision of appropriate CD4⁺ T cell-mediated help. T follicular helper (Tfh) cells that are specialized for B cell help and are essential for the formation of germinal centers may be of particular importance. As DCs are critical for priming and polarizing CD4⁺ Th cells, the potency with which they do this following vaccination is likely to influence the quality of a vaccine-induced B cell response. Specifically, the efficiency with which DCs take up vaccine antigens, their degree of maturation, and their mode of antigen processing and presentation to CD4⁺ T cells, especially Tfh, are likely to be central in this process.

Extensive efforts have been directed toward targeting vaccine Ags to DCs via specific CLRs, including DC-SIGN, DEC-205, and DCIR, to improve Ag uptake and presentation. This strategy can augment T and B cell responses and reduce the dose of Ag required in a vaccine

setting; however, none of these targeting antibodies have yet been tested with HIV Env. Given the functional specialization of the DC subsets, the choice of targeting receptor and the expression pattern of that receptor on the DC subsets will likely influence the immunological outcome. Uptake of antigen via different CLRs leads to different efficiencies and modes of antigen presentation (Delamarre and Mellman 2011). For example, targeting DEC-205 enhances cross-presentation of exogenous antigen on MHC I to CD8⁺ T cells, whereas DC-SIGN targeting results in efficient MHC II presentation to CD4⁺ T cells. In the case of Env, its high glycosylation naturally targets it to DCs via certain CLRs, including DC-SIGN. Additionally, in blood DCs, including PDCs, that display restricted CLR repertoires, the high-affinity interaction between Env and CD4 also enables efficient uptake and presentation of Env to CD4⁺ T cells (Sandgren et al. 2013).

Another receptor that appears attractive for antigen targeting is CD40. Although it is not a CLR, it is expressed on all DC subsets and also on other APCs including B cells and monocytes. Stabilized Env trimers fused to CD40 ligand (normally expressed on CD4⁺ Th cells) induced activation of DCs via CD40 signaling and licensed them for naive CD4⁺ T cell priming (Melchers et al. 2011). As CD40 ligand also promotes proliferation of B cells and Ab production, this targeting approach may enhance anti-Env responses from two angles.

In terms of targeting DCs, another critical aspect may be the site of vaccine delivery. Most vaccines to date are administered intramuscularly; however, the muscle is poorly populated with immune cells. Generally DCs and other innate immune cells are recruited into the muscle to take up the vaccine and transfer it to the lymph nodes where an adaptive immune response is triggered. The skin, in contrast, has a well-developed immune network with multiple DC subsets as described above and may thus represent a more potent site for vaccine delivery. In fact, intradermal vaccination that delivers antigens to the direct vicinity of the DC network has allowed for large dose sparing without compromising adaptive immune responses (Fehres et al. 2013).

For a successful prophylactic HIV vaccine, it may be critical to combine targeting of antigen to specific DC subsets along with potent, targeted activation of these same cells (Smed-Sorensen and Lore 2013). Protein subunit vaccines are usually poorly immunogenic and require coadministration with an adjuvant to activate immune cells. Adjuvants are used to enhance the immune response and can be used to tailor the type of immune response generated. A major mechanism of adjuvant action is thought to be the recruitment and activation of APCs, such as DCs, to the site of vaccination. The activation, or maturation, of DCs involves upregulation of key molecules associated with antigen presentation such as MHC class II and co-stimulatory molecules CD40, CD80, and CD86, as well as chemokine receptors such as CCR7 that direct the DC to migrate from the periphery to the lymph nodes, all of which endow the DC with a potent capacity to prime T cells.

The most commonly used adjuvant in humans is alum, which consists of aluminum phosphate or hydroxide salts, to which vaccine antigens are adsorbed. Despite being in use for over 80 years, the mechanism of action of alum has only recently been elucidated and includes stimulation of the innate immune system, which is in part dependent on activation of the NALP3 inflammasome. Alum also renders antigens particulate and enhances Ag uptake by DCs (Garçon et al. 2011).

A distinctly different class of adjuvants is emulsion adjuvants, including MF59 (Novartis) and AS03 (GlaxoSmithKline) which are licensed for use in influenza vaccines. It is proposed that these adjuvants act by creating an immunocompetent environment at the site of injection, recruiting critical innate immune cells including neutrophils, monocytes, and DCs, although their effects on DC maturation and capacity to prime T cells remain to be defined (Garçon et al. 2011).

A more targeted approach can be achieved using defined TLR ligands as adjuvants (Duthie et al. 2011). TLR ligands efficiently induce cytokine production and maturation of DCs which collectively augment their ability to present antigens on MHC I and MHC II to stimulate antigen-specific T cell responses. TLR signaling also

enhances migration of DCs to the lymph nodes. The various DC subsets express unique repertoires of TLRs and this offers opportunities to target specific subsets and fine-tune the DC response (Smed-Sorensen and Lore 2013). For example, it was recently shown that DC subsets require specific combinatorial TLR stimulation to enable optimum priming of T cell responses (Matthews et al. 2012; Nizzoli et al. 2013).

Conclusion

The interactions between HIV Env and DCs are complex and depend on the glycosylation of Env and the type of DC, among other things. This impacts on the initial transmission of the virus at mucosal surfaces, the dissemination of the virus from the site of exposure throughout the body, the widespread infection of CD4⁺ T cells, and finally the generation of anti-HIV immune responses. Env can, in some contexts, have a negative effect on DC function, yet it is also considered to be an essential component in a prophylactic HIV vaccine. In the future, the cumulative knowledge of the interactions between Env and DCs can hopefully be used in the development of potent microbicides and/or optimized vaccine formulations to stimulate appropriate DC subsets while overcoming Env-induced immune subversion and thus allow the generation of effective protection against HIV acquisition.

Differential Diagnosis of HIV-Associated Neurocognitive Disorders

Justin Y. Garber¹ and Bruce J. Brew^{1,2}

¹Neurology and HIV Departments Sydney, St. Vincent's Hospital, Sydney, NSW, Australia

²Peter Duncan Neurosciences Unit, St. Vincent's Centre for Applied Medical Research, Sydney, NSW, Australia

Definition

Cognitive dysfunction in human immunodeficiency virus (HIV)-infected patients is common and can be a difficult diagnosis for the treating physician in the face of multiple potential causes.

Cognitive dysfunction persists in up to 50% of HIV-infected patients in the post-highly active antiretroviral therapy (post-HAART) era, with milder forms predominating (Cysique et al. 2004; Cohen and Gongvatana 2010). The differential diagnoses are divided into those relevant to virally suppressed patients and those that are not, with HIV-associated neurocognitive disorder (HAND) common to both groups.

In patients who are virally suppressed, the diagnoses more commonly encountered, apart from HAND, are substance abuse, psychiatric illness, and hepatitis C, both through its direct effects on cognition and through hepatic encephalopathy. The clinical significance of ageing and neurodegenerative diseases such as Alzheimer's and vascular cognitive impairment is not presently clear though the risk factors for degenerative diseases are common in HIV disease raising the possibility of increased significance in the future. In patients who are not virally suppressed, cognitive dysfunction is more commonly related to HAND, but central nervous system (CNS) opportunistic infection and malignancy such as primary CNS lymphoma are also important considerations. Cognitive dysfunction after the recent commencement of HAART suggests an immune reconstitution inflammatory syndrome (IRIS) related to a previously subclinical opportunistic infection, most commonly progressive multifocal leukoencephalopathy, but HAND as an IRIS phenomenon directly related to HIV is also a possibility.

Virally Suppressed or Early HIV Disease (CD4+ Count >500/ μ L)

Substance Abuse

Drug use is a major problem for a subset of the HIV population, as a contributor to cognitive dysfunction as well as being a vector of transmission through high-risk behaviors, such as sharing of unclean needles and high-risk sexual activity (Foley et al. 2008). It also contributes to increased morbidity and mortality through higher risk of complications such as infective endocarditis and coinfection with hepatitis C, which in itself is a

risk factor for cognitive dysfunction directly and through hepatic encephalopathy, often even in mild forms.

Cognitive impairment from long-term substance abuse is well studied. Long-term stimulant abuse for instance leads to lasting generalized cognitive impairment, rather than in specific cognitive domains (Spronk et al. 2013). In studies focused on the HIV population, substance abuse was additive to the effects of HIV on cognition, leading to greater declines in attention, psychomotor function, and executive abilities (Foley et al. 2008). Substance abuse is also a major factor that negatively affects engagement and response to medical services, such that these patients are at increased for HIV disease progression and mortality (Margolin et al. 2002).

The effects of acute drug intoxication and withdrawal can have significant overlap with the clinical manifestations of HIV. Drug intoxication in common with HAND may present with apathy, disorientation, and poor concentration. Similarly drug withdrawal features such as agitation, altered consciousness, and seizures may also be present in CNS infections.

Treatment of substance abuse disorders in conjunction with HIV can improve outcomes for both conditions. The treating physician should be aware of potential interactions between HAART and treatments for substance abuse, as well as engaging a multidisciplinary team to address all issues (Gourevitch and Friedland 2000).

Psychiatric Illness

Psychiatric illness especially major depression is more common in the HIV population due to direct damage to subcortical brain areas but also due to psychiatric factors such as stress related to chronic illness and social aspects, for example, isolation and stigma. Depression is underdiagnosed in the HIV population, and its prevalence increases as HIV disease progresses (Asch et al. 2003). Patients with depression in turn are at increased risk of progression of HIV disease and mortality.

Depression may also be a side effect of medications used to treat HIV and its complications. For example, efavirenz is a non-nucleoside reverse transcriptase inhibitor with prominent

neuropsychiatric side effects that can exacerbate or cause depressive symptoms. These usually respond to the removal of the drug.

Several clinical symptoms and signs are common to HAND and depression. Mood symptoms in HAND are common including apathy, irritability, insomnia, and anxiety, while cognitive deficits may also occur in major depression especially impaired concentration and memory. HAND is associated with apathy rather than sadness and anhedonia, critical features that distinguish between major depression and HAND. Major depression may also present with nonspecific somatic symptoms such as headache, lethargy, and gastrointestinal symptoms, all of which have a wide differential in the HIV-infected patient. Psychiatric illness needs to be firmly at the forefront of the physician in order to make accurate diagnoses.

Successful management of depression improves the adherence to HIV and psychiatric treatment. Pharmacotherapy must be cautiously chosen as there can be considerable risk of interaction with HAART, and side effect profiles should be individualized to the patient.

Hepatitis C Virus

Hepatitis C virus (HCV) infection is known to be a cause of cognitive impairment as a direct manifestation and also indirectly through hepatic encephalopathy. Up to 30% of HIV-infected patients are coinfecting with HCV (Letendre et al. 2005) though there is a wide variability, and up to two thirds of coinfecting patients have cognitive impairment to some degree (Hinkin et al. 2008). It is curious that it seems to be independent of HCV viral load in the plasma (Garvey et al. 2010). Apart from hepatic encephalopathy which in its mild form can be difficult to diagnose, HCV can cause cognitive impairment probably through direct brain infection. Indeed, there are data supporting HCV infection of macrophages, microglia, and astrocytes (Wilkinson et al. 2009), the same brain cell types implicated in HAND pathogenesis. Treatment of HCV can lead to improvement in cognition (Thein et al. 2007), though the frequency and degree of improvement require further definitive data.

Moreover, the efficacy of the new non-interferon-based therapies in relation to cognition also needs further study.

Ageing

The life expectancy of HIV-infected patients has steadily improved over the last decade and is now on par for many subsets of the HIV population with their non-HIV-infected counterparts (Hogg et al. 2013). This means that more and more patients are living to the age in which they will suffer from the effects of normal ageing. Given that the prevalence of HAND has not decreased with effective virological control, there is a concern that the longer duration of HIV infection together with age may have a compounding detrimental effect on cognitive function (Brew et al. 2009).

HAND has some interesting similarities with the cognitive dysfunction seen in ageing. The neuropsychological parameters of processing speed, working memory, and effortful memory retrieval are deficient in both ageing and HAND, while semantic knowledge, language, and visuospatial abilities are relatively preserved (Brew et al. 2009). Additionally, there is intersection between the neuropathology found in HIV and ageing particularly in relation to the frontal lobes and hippocampus, as well as impairment of the blood-brain barrier and disturbances in the cellular disposal of toxins (Brew et al. 2009). Functional brain imaging studies have shown that HIV infection is equivalent to a 21-year increase in brain age (Ances et al. 2010).

As can be appreciated, ageing and HAND may act in concert to increase the cognitive deficits that are common to both, with potential acceleration and worsened severity of the ultimate cognitive deficit. Definitive prospective data, however, are needed.

Neurodegenerative Diseases and Mechanisms in HIV

There are several areas of similarity in the mechanisms of HAND and neurodegenerative disease. Inflammation, highlighted by elevated levels of tumor necrosis factor α (TNF α), interleukin 6 (IL-6), monocyte chemotactic protein

1 (MCP-1), and quinolinic acid in the cerebrospinal fluid (CSF) and serum, is seen in HAND as well as neurodegenerative diseases (Brew et al. 2009). Chronic inflammation, through interferon γ (IFN γ) and TNF α , leads to changes in the ubiquitin-proteasome system to the immune-proteasome system, switching its function from degrading large proteins to cleaving antigenic proteins for MHC-1 presentation. This exerts a potentially harmful slowing of protein turnover leading to accumulation of misfolded ubiquitinated proteins of pathological ageing, which is a hallmark neuropathological change in neurodegenerative diseases (Nguyen et al. 2010). HIV provides a chronic long-term substrate of inflammation due to its persistent long-term carriage in the CNS.

Normal neuronal autophagy has a protective function in the CNS to maintain homeostasis; however, neuronal autophagy is both inhibited by HIV and is disrupted in neurodegenerative diseases. Furthermore, P-glycoprotein expression is deliberately inhibited in some HIV therapies through the use of ritonavir in order to enhance antiretroviral activity of protease inhibitors. However, the P-glycoprotein system is thought to play a role in the normal clearance of amyloid from the brain and has been implicated in neurodegenerative disease as well as HIV-infected patients on HAART (Brew et al. 2009).

These pathogenetic mechanisms, that are common between HIV and neurodegenerative diseases, can be seen to provide evidence that some patients may develop cognitive impairment as a consequence of premature ageing and accelerated expression of the diseases of ageing, the neurodegenerative diseases (Brew and Cysique 2010).

Alzheimer's Disease

There exists significant overlap in HAND and Alzheimer's disease (AD) in terms of similar pathogenic mechanisms as shown above, common risk factors, neuropathology, measurable biomarkers, and potential response to pharmacological agents. In AD, the brain tissue is notable for the presence of extracellular deposits of beta amyloid, especially 1–42 (A β 42), in the form of plaques and aggregations of microtubule-

associated, tau-forming, neurofibrillary tangles. The CSF contains low levels of A β 42 and elevated total tau (t-tau) as well as phosphorylated tau (p-tau) (Brew and Cysique 2010). In HIV, there is evidence for increased amyloid deposition in the brains of patients at autopsy even in those treated with HAART, and there is evidence for reduced levels of A β 42 in the CSF of patients with HAND. As described above in mechanisms related to P-glycoprotein inhibition, HAART especially ritonavir may be associated itself with abnormal A β 42 deposition in the brain (Becker et al. 2009).

Interestingly, risk factors that are known to be associated with AD, such as insulin resistance, midlife raised lipids, lowered leptin levels, APOE4 status, and elevated CD69 monocytes have also been shown to be associated with the development of HAND (Brew and Cysique 2010).

HIV and AD also share a common anatomical substrate of the brain, namely, the hippocampus (Brew et al. 2009), while there is preliminary evidence that AD treatment in the form of cholinesterase inhibitors is beneficial in HAND (Simioni et al. 2013).

Clinically it can on occasion be difficult to distinguish HAND from AD especially in mild cases. Careful neuropsychological testing can be helpful in identifying the “subcortical” cognitive domains of processing speed, working memory, attention, and executive functioning (Schouten et al. 2011) characteristic of HAND as opposed to the “cortical” deficits of AD such as episodic memory, language disturbances, and loss of visuospatial skills. Motor symptoms also appear earlier in the course of HAND but are unlikely to be the presenting complaint. Motor disturbances such as unsteady gait and tremor are relatively early manifestations, while impaired saccadic eye movements, bradykinesia, hyperreflexia especially of the legs, and frontal signs occur later (Brew 2001). This is in direct contrast to AD which is unlikely to cause significant motor disturbances until a late stage.

While both diseases can be progressive, HAND can have a fluctuating course over time not usually seen with other neurodegenerative diseases.

In addition to these clinical differences, neuroimaging can also be a useful diagnostic tool. While focal or diffuse cerebral atrophy and white matter changes shown on MRI are nonspecific, more advanced techniques of MR spectroscopy, functional MRI, single-photon emission computed tomography (SPECT), and positron emission tomography (PET) with amyloid PET tracers are promising to be potential discriminators between HAND and other neurodegenerative diseases (Ances et al. 2012).

Vascular Cognitive Impairment

HIV infection and the use of HAART, especially protease inhibitors, are well known to cause changes to fat distribution as well cause metabolic abnormalities including dyslipidemia, diabetes mellitus, insulin resistance, and hepatic steatosis. Hypertension has also been linked to HIV infection and in particular HAART (Becker et al. 2009). This induction of the metabolic syndrome leads to an increased incidence in cardiovascular disease such as stroke and myocardial infarction in the HIV population (Currier et al. 2008). The metabolic syndrome is also a risk factor for dementia and vascular cognitive impairment. Even though the traditional cardiovascular risk factors have an increased prevalence in the HIV population, studies correcting for these traditional risk factors still show higher rates of cardiovascular disease. The pathogenesis of vascular disease in HIV is most likely related to inflammation and immune dysregulation affecting endothelial function and coagulation (Fedele et al. 2011). Clinically, vascular cognitive impairment has a very similar presentation to HAND, characterized by cognitive slowing and impaired executive function. It may not be clearly related to stroke events, and imaging may only show white matter disease indicative of microangiopathic changes of small cerebral vessels. On the other hand, the clinical presentation of vascular dementia (VaD) is broad, reflecting the variety of vascular territories that can be involved. Features that would be suggestive of vascular dementia in an HIV-infected patient would be localizing cortical syndromes, a stepwise progression reflecting

cumulative vascular incidents, history of stroke, and neuroimaging consistent with previous large or small vessel ischemia. VaD can be diagnosed in isolation but also commonly in conjunction with neurodegenerative diseases such as Alzheimer's disease.

Studies on the relative risk of traditional cardiovascular risk factors and HIV serostatus, CD4+ counts, and viral replication on cognitive function in older HIV-infected patients show a much higher association with traditional risk factors than HIV factors. This suggests that close attention to traditional cardiovascular and metabolic risk profiles is mandatory to limit cognitive dysfunction in the HIV population (Becker et al. 2009).

Not Virally Suppressed with Advanced HIV Disease (CD4+ Count <200 μ L)

Central Nervous System Opportunistic Infections

CNS infections have the potential to cause cognitive dysfunction; however, most are easily distinguished from HAND by the systemic features, acuity of the illness, headache, and the progression of cognitive dysfunction to confusion to stupor with advancing severity. In general the opportunistic infections that infect the CNS occur when CD4+ counts are low and profound immunosuppression is present. Deficits occur over days to weeks with the slowest of progressing infections and over months with HAND. Systemic features such as fever are not commonly present, even in diseases such as cryptococcal meningitis, tuberculosis, or toxoplasmosis. Headache, a common symptom of CNS infection, can be a feature of HAND, or indeed a prodrome to it, but is usually less severe than in CNS infection. The focal features of presentation with tuberculosis and toxoplasmosis are also out of keeping with HAND, which is a nonfocal disorder (Brew 2001). However, there are two infectious diseases in the HIV context that warrant special mention, as they have the potential, at least early on, to mimic a presentation of HAND.

Differential Diagnosis of HIV-Associated Neurocognitive Disorders, Table 1 Differential diagnosis for cognitive impairment in HIV infected patients

	Cognitive impairment	Associated signs	Patient profile	Neuropathology	Neuroimaging	
HIV-associated neurocognitive disorder (HAND)	Attention		Prior AIDS defining illness	Impaired BBB	Frontal, hippocampal, and basal ganglia atrophy	
	Working memory		Longer duration of HIV infection	Disturbed toxin removal	Symmetric white matter lesions	
	Executive function		Low CD4+ count	Impaired autophagy	Distinct patterns on MRS, SPECT, and PET scans	
	Processing speed			Disturbed ubiquitin-proteasome complex		
Asymptomatic neurocognitive impairment (ANI)	Asymptomatic or symptomatic impairment defined by $\geq -1 \sigma$ from the mean in two cognitive areas as above	Depressive symptoms				
		Insomnia				
Mild neurocognitive disorder (MND)		Lethargy				
		Apathy				
HIV-associated dementia (HAD)	Severely affected impairment defined by $\geq -2 \sigma$ from the mean in two cognitive areas as above	Unsteady gait				
		Tremor				
Ageing	Processing speed	Impaired saccadic eye movements				
		Bradykinesia				
	Working memory	Hyperreflexia				
		Frontal signs				
	Memory retrieval	Psychosis or mania		Age > 70	Decreased myelination	Frontal and hippocampal atrophy
					Impaired BBB	
					Disturbed toxin removal	
Alzheimer's disease	Declarative memory		Age > 70	Impaired autophagy	Frontal and hippocampal atrophy (beyond that seen in ageing)	
				Amyloid (A β 42) plaques		White matter lesions
	Language		APOE4 status	Neurofibrillary tangles	Distinct patterns on fMRI, SPECT, FDG-PET	
	Visuospatial skills		Family history			Amyloid PET tracer uptake increased

Vascular cognitive impairment and dementia	Executive function	Stepwise progression	Hypertension Diabetes Metabolic syndrome Smoking IVDU Coinfection HCV End-organ damage of long-term substance abuse	Infarcted brain tissue	Large vessel cortical and subcortical infarction
	Psychomotor retardation	Cortical Syndromes Gait disturbance (falls) Urinary symptoms			Small vessel ischemia and lacunar infarction White matter lesions
	Generalized impairment Working memory (esp. alcohol) Attention				Ventricular and sulcal enlargement (esp. alcohol)
Substance abuse	Concentration	Depressive symptoms			Normal
	Memory	Sadness			
	Executive Function	Anxiety Insomnia Mania Psychosis Self harm			
CNS opportunistic infections	Generalized impairment	Progression to confusion and stupor	Low CD4+ count (<200/μL)	Meningitis or encephalitis	<i>Numerous depending on specific infection</i>
		Fever	No prophylactic antimicrobials	Demyelination (PML)	
		Meningism	IRIS	Abscess	
		Focal neurological deficits		SOL	
		Seizures			

AIDS acquired immunodeficiency syndrome, *HIV* human immunodeficiency virus, *BBB* blood-brain barrier, *MRS* magnetic resonance spectroscopy, *SPECT* single-photon emission computed tomography, *PET* positron emission tomography, *FDG-PET* fludeoxyglucose-PET, σ standard deviation, *fMRI* functional magnetic resonance imaging, *IVDU* intravenous drug user, *HCV* hepatitis C virus, *CNS* central nervous system, *IRIS* immune reconstitution inflammatory syndrome, *PML* progressive multifocal leukoencephalopathy, *SOL* space-occupying lesion

Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy (PML) is a subacute demyelinating condition resulting from the infection of oligodendrocytes and astrocytes by the polyomavirus JC. It was relatively common before the advent of HAART in patients with depressed CD4+ counts. PML onset is gradually progressive over several weeks and develops in the absence of fever. Classic PML presents with cortical signs, hemiparesis, speech disturbances, headache, ataxia, and cognitive dysfunction; however, atypical forms are increasingly being recognized (Koralnik 2006). CSF examination for JC virus DNA by polymerase chain reaction (PCR) is the usual method of diagnosis, but its sensitivity is significantly diminished in HAART-treated patients. MRI features of PML occasionally can be similar to those seen in HAND and include bilateral non-enhancing subcortically localized white matter changes. More typically, PML lesions tend to be more asymmetric and more demarcated than those seen in HAND (Brew 2001). PML may also occur in the context of rapid immune reconstitution after the commencement of HAART. In this immune reconstitution inflammatory syndrome (IRIS), enhancement of demyelinating plaques can be seen on neuroimaging (Gheuens et al. 2013).

Cytomegalovirus Encephalitis

Cytomegalovirus (CMV) is a herpesvirus that can cause an encephalitis most commonly in immunosuppression related to HIV infection. The mean CD4+ count of patients with CMV encephalitis is 13 cells/ μ L. The clinical features include fluctuating confusion and apathy, with evidence of poor memory, headache, and ataxia, a not dissimilar picture to the more severe forms of HAND. Symptoms develop over an average of 3.5 weeks but with a range up to 3 months (Brew 2001). Some patients however have evidence on examination of brainstem involvement with nystagmus, ophthalmoplegia, and cranial neuropathies that do not occur in HAND. It is common also for patients with CMV encephalitis to have or have had CMV infection elsewhere,

usually in the retina (Brew 2001). MRI can show ventriculoencephalitis with periventricular enhancement and increased signal on T-2-weighted images or diffuse multifocal scattered micronodules. CSF PCR for CMV DNA is the usual method of diagnosis, keeping in mind that it may be positive in the absence of symptoms.

Conclusion

Cognitive dysfunction in HIV-infected patients is common and has a variety of causes. HIV not only directly infects brain tissue, it also increasingly appears able to overlap with and possibly mimic some neurodegenerative processes. It contributes to vascular risk factors as well as causing the immunosuppression that leads to opportunistic infections. As outlined above, the cognitive impairment of HAND differs from other causes of cognitive impairment, but at times the clinical distinction can be challenging. The physician confronted with such patients needs to work methodically through all potential causes, utilizing discriminating tests where possible while understanding at all times the likelihood and potential additive effects of two or more pathologies occurring concurrently.

Diffuse Large B-Cell Lymphoma

Neel K. Gupta and Lawrence D. Kaplan
Department of Medicine, Division of
Hematology/Oncology, University of California,
San Francisco, CA, USA

Definition

Diffuse large B-cell lymphoma (DLBCL) is an AIDS-defining, aggressive lymphoid neoplasm in which normal lymph node architecture is replaced by sheets of large, atypical lymphoid cells. It is thought to arise from mature B cells and is comprised of large, noncleaved centroblasts and immunoblasts with abundant cytoplasm and prominent nucleoli. As the most common form of non-Hodgkin lymphoma (NHL) in both HIV-positive and HIV-negative individuals, there is an increasing appreciation of its morphologic, genetic, and biologic heterogeneity.

Epidemiology and Risk Factors

DLBCL accounts for roughly 30% of all NHLs in the HIV-negative population. By comparison, up to 75% of systemic NHL subtypes in HIV-seropositive individuals are comprised of DLBCL or variants thereof (Cote et al. 1997). As a whole, standardized incident ratios for NHL in HIV-positive individuals have decreased over the last two decades from over 1,000 in the early 1990s to below 200 in the mid-2000s due to the advent and widespread use of combination antiretroviral therapy or cART (Patel et al. 2008). Primary central nervous system (PCNS) lymphomas account for approximately 15% of AIDS-related lymphomas (ARL) and are morphologically classified as DLBCL; however, given recent insights into the tumor micro-environment and unique biology of this disease, PCNS lymphoma likely represents a distinct ARL entity and will not be further addressed in this section.

Risk factors for DLBCL and ARLs in general are linked to the degree of host immune-suppression and viral activity. In the pre-cART era, a CD4 count less than 50 and plasma HIV RNA levels greater than 100,000 were strongly linked to the development of ARL; however, in the era of cART, most patients with newly diagnosed ARLs will have CD4 counts greater than 200 (Kaplan et al. 2012).

Pathogenesis

The mechanisms by which HIV exerts its oncogenic effects in human lymphoid tissue are complex and not yet fully elucidated. While B cells are not considered a direct target of HIV, it has been proposed that immune dysregulation as a consequence of HIV viremia results in aberrant somatic hypermutation and loss of T-cell immunity against pathogenic viruses such as Epstein-Barr virus (EBV) or human herpesvirus 8 (HHV8, also known as Kaposi's sarcoma-associated herpesvirus or KSHV) (Kaplan et al. 2012). The loss of regulation leads to hypergammaglobulinemia and polyclonal B-cell hyperplasia in milieu of constant antigenic stimulation. In addition, myeloid dendritic cells (mDC) play a pivotal role in propagating HIV-related B-cell disease states via increased expression of B lymphocyte stimulator (BLyS) surface expression, which is in turn correlated with disease progression (Fontaine et al. 2011).

Presentation, Diagnosis, and Staging

Patients with ARLs typically present with advanced-stage disease, constitutional symptoms, marrow involvement, and extranodal distribution in unusual sites such as the gingiva, rectum, and biliary tree. DLBCL in particular involves the gastrointestinal tract in many cases, with patients reporting abdominal pain, bleeding, diarrhea, or severe nausea.

Definitive diagnosis requires tissue biopsy with sufficient material to correlate morphologic, immunohistochemical, and immunophenotypic characteristics. Excisional biopsy is the preferred

method for obtaining tissue for subtype classification. Core needle biopsy may be utilized for sampling otherwise inaccessible or high-risk areas, although fine-needle aspiration should be avoided due to the potential for sampling error and lack of cytological architecture. Biopsy material should be processed for standard B-cell immunohistochemical and flow cytometric markers in addition to a comprehensive morphologic assessment by an experienced hematopathologist. Evaluation of the proliferative index using Ki-67 or MIB-1 staining helps to distinguish aggressive from very aggressive subtypes, which in turn may influence the choice of chemotherapeutic regimens. In addition to adequate peripheral tissue sampling, unilateral bone marrow aspirate and core biopsy should be obtained to evaluate for lymphomatous involvement. Central nervous system (CNS) evaluation is not routinely indicated unless there are greater than two areas of extranodal involvement in the context of elevated LDH, marrow involvement, epidural disease, paranasal sinus disease, or testicular involvement.

Along with pretreatment assessment of renal and hepatic function, serum lactate dehydrogenase (LDH), phosphorus, and calcium should be obtained to evaluate potential tumor lysis, especially in the presence of bulky or rapidly progressive disease. If not already known, hepatitis B serologies should be obtained, and in patients with a positive core antibody, positive surface antigen, or circulating levels of hepatitis B DNA, appropriate antiviral therapy should be initiated due to the risk of reactivation or exacerbation with rituximab-containing regimens.

Contrast computed tomography (CT) of the chest, abdomen, and pelvis is recommended as a baseline assessment of disease distribution as per the Cotswold-modified Ann Arbor staging system. In contrast to the HIV-negative population, interpretation of positron emission tomography with [18F] fluorodeoxyglucose (FDG-PET or PET hereafter) in HIV-positive individuals can be confounded by persistent generalized lymphadenopathy related to viral load and opportunistic infections secondary to immune suppression. As such, its role in staging, interim scanning, and

risk-adapted therapy for HIV-related DLBCL remains an area of active investigation. However, end-of-treatment response assessment carries a similarly high negative predictive value (NPV) as seen in the HIV-negative population, suggesting a possible role for response assessment in individuals with limited disease without suspected coinfection (Hentrich et al. 2011).

Prognosis

The previously poor prognosis of patients with HIV-associated DLBCL in the pre-cART era stemmed from a variety of factors including the presence of concomitant opportunistic infections, aggressive and advanced-stage disease at presentation, and toxicities associated with the use of multiagent chemotherapy in a severely immunocompromised population. By contrast, prognosis in the era of cART has improved to the point that outcomes now approach those of the HIV-negative population. In one study relatively early in the cART era, improvement was limited to individuals demonstrating a virological response to cART (Antinori et al. 2001), highlighting the importance of a functional or recovering immune system through the course of therapy. This improved immunocompetency of HIV-positive patients has resulted in lymphoma-specific factors playing a more important role in predicting clinical outcome than was previously the case. The International Prognostic Index (IPI) is a well-validated model incorporating disease stage, patient age, presence of extranodal involvement in two or greater areas, performance status, and serum LDH into a prognostic index with high discriminatory power in HIV-negative individuals. Several studies have examined its utility in ARLs and HIV-associated DLBCL specifically, demonstrating a similar ability to risk-stratify patients at diagnosis. The lowest-risk individuals with either none or one of the aforementioned risk factors appear to maintain an overall survival approaching 70% at 5 years, nearly identical to the comparable HIV-negative population (Lim et al. 2005; Bower et al. 2005). In addition,

multivariate analyses have shown a CD4-positive lymphocyte count less than 100 as being associated with significantly worse outcomes, though it is unclear if this has retained prognostic significance in the era of cART.

The use of gene expression profiling (GEP) has identified distinct cell of origin (COO) signatures in DLBCL. Lymphomas with a post-germinal center (non-GC), also called activated B cell (ABC), subtype are associated with a markedly worse prognosis compared to lymphomas with a germinal center (GC) signature in HIV-negative lymphomas. The data in HIV-associated DLBCL are less clear. Retrospective data from two trials of the US AIDS Malignancy Consortium (AMC) suggest no difference in lymphoma-specific nor overall survival. Conversely, a planned subset analysis of patients with HIV-associated DLBCL receiving dose-dense rituximab and the infusional regimen EPOCH (etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin) at the National Cancer Institute (NCI) reported a substantial difference in PFS between GC and non-GC subtypes (95% vs. 44%).

The true prognostic relevance of COO in HIV-related DLBCL notwithstanding routine incorporation of GEP into clinical decision making remains a work in progress due to the expense and limited availability of testing outside academic centers. Attempts at correlating GEP with immunohistochemistry have been complicated by a lack of reproducibility or standardization of diagnostic algorithms. Despite these challenges, however, the unique biology and disparate prognosis of non-GC subtypes in the HIV-negative population have spurred investigation into targeted agents and novel multiagent regimens. For example, constitutive activation of nuclear factor kappa-light-chain-enhancer of activated B cells (NFkB) in these tumors is a potential target for proteasome inhibition, and this is supported by preliminary studies indicating increased activity of the drug bortezomib in relapsed non-GC DLBCL compared with GC DLBCL in HIV-negative patients. Recently, inhibitors of Bruton's tyrosine kinase (BTK) have been shown to induce responses in relapsed HIV-negative non-GC DLBCL and are currently undergoing further testing in clinical trials.

Clinical Management and Initial Treatment

Early attempts at treatment of ARL in general were limited by the baseline immunodeficiency and cytopenias commonly found in HIV-positive individuals at presentation. Administration of cytotoxic therapy compounded these deficiencies, thereby increasing the risk of opportunistic infections that further compromised delivery of adequate treatment. Through the bolstering immunologic effects of cART and improved supportive care, clinicians are now able to administer even high-dose therapy with a manageable side effect profile.

The standard-of-care treatment for DLBCL in HIV-negative individuals combines the anti-CD20 monoclonal antibody rituximab (R) with a multiagent chemotherapy regimen including cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) administered every 21 days for six to eight cycles. This regimen has produced five-year OS rates of approximately 60% in randomized phase III trials, averaged over all risk groups. Historically, CHOP and CHOP-like regimens had not achieved anywhere near this degree of success in HIV-positive individuals treated in the pre-cART era, with two-year OS no better than 20% (Kaplan et al. 2012). Given these dismal outcomes and concern for hypogammaglobulinemia in already immunocompromised hosts, prospective trials sought to evaluate the role of rituximab in combination with chemotherapy in the HIV-positive population.

A prospective multicenter German trial evaluated 72 patients, risk-stratified by World Health Organization (WHO) performance status >3 , CD4 count less than 50, and prior opportunistic infection. The 48 patients with zero or one risk factor were considered "standard risk" and achieved a CR rate of 79% with median survival not reached at 47 months' follow-up. This was in contrast to the 29% CR rate obtained in the 24 "high-risk" patients with 2 or more risk factors. A phase II trial of 61 patients with one or no risk factors including CD4 < 100 , prior AIDS, or Eastern Cooperative Oncology Group (ECOG) performance score >2 produced two-year OS rates of 75%.

The AMC conducted the only randomized, phase III prospective trial comparing standard dose CHOP with R-CHOP in patients with HIV-related DLBCL. One hundred fifty patients were administered CHOP or R-CHOP in a 2:1 fashion while receiving cART, growth factor support, and prophylaxis against *Pneumocystis jiroveci*. Patients randomized to rituximab had a statistically nonsignificant improvement in CR rate from 47% to 58% and a median OS of 2.6 years compared to 2.1 years in the CHOP cohort. However, 14% of the patients in the R-CHOP group suffered infection-related deaths compared to two percent in the CHOP group. While majority of these deaths occurred in patients with a CD4 count less than 50/ μ l, and neutropenic antibiotic prophylaxis was not administered in the study, these findings initially raised concerns over the use of rituximab in HIV-positive individuals with severe immunodeficiency.

Subsequent studies evaluating the combination of rituximab and infusional chemotherapy firmly established rituximab as not only safe given the proper supportive care but also highly effective in the treatment of HIV-related DLBCL. The infusional regimen EPOCH was developed intramurally at the National Cancer Institute on the basis of in vitro studies suggesting greater tumor kill as a result of continuous – rather than bolus or episodic – exposure to multiagent cytotoxic therapy. Importantly, this regimen adapted a pharmacodynamic approach to dosing, with subsequent dose increases or reductions based on nadir CD4 counts in preceding cycles. A modified, dose-adjusted (da) EPOCH regimen was employed in another multicenter AMC phase II trial whereby patients were randomized to receive rituximab either concurrently with chemotherapy or sequentially after each cycle. Although the study was not designed to evaluate overall survival, 73% of patients receiving rituximab concurrently achieved a CR, compared with 55% in the sequential arm. Deaths related to sepsis were uncommon due to the routine use of neutropenic antibiotic prophylaxis with fluoroquinolones.

A phase II intramural NCI trial evaluating daEPOCH with dose-dense rituximab delivered one cycle of chemotherapy beyond

documentation of complete response for a minimum of three cycles. The five-year PFS and OS were 84% and 68%, respectively, and there were no treatment-related deaths. As stated above, along with CD4 count, cell of origin was an independent predictor of outcome.

In summary, several trials have demonstrated both efficacy and safety of this infusional approach. An ongoing phase III, multicenter randomized controlled trial comparing R-CHOP with daEPOCH-R for the treatment of DLBCL in HIV-negative patients may further inform the choice of treatment for DLBCL in HIV-positive individuals.

Treatment of Relapsed/Refractory Disease

As is the case for HIV-negative individuals, the goal of treatment for relapsed/refractory HIV-associated DLBCL is to achieve a response sufficient enough to proceed with high-dose chemotherapy followed by autologous stem cell rescue (ASCT). The PARMA study was the first multicenter randomized trial to establish the superior event-free and overall survival benefit of this approach for chemosensitive relapsed/refractory DLBCL in HIV-negative patients. Though such an approach would have been impractical in the pre-cART era, it is now considered the standard of care for fit HIV-positive patients with chemosensitive disease at relapse.

The largest prospective trial evaluating the efficacy of ASCT in HIV-positive lymphomas looked at a total of 50 patients, 22 of whom had DLBCL. Thirteen of the 22 patients received transplant, with 11 of those (42%) in continuous CR at the data cutoff time point. For the DLBCL subset, the overall and progression-free survival post-transplant was 81.5% and 83%, respectively, at 44 months (Re et al. 2009). Importantly, there were no treatment-related deaths, and median time to neutrophil and platelet engraftment was 10 and 12 days, respectively, similar to that observed in the HIV-negative population. Although somewhat smaller in sample size, other prospective and retrospective studies have

confirmed the efficacy and safety of ASCT in HIV-associated, relapsed/refractory DLBCL with chemosensitive disease. Predictably, long-term survival seen in these studies was largely confined to patients with well-controlled viral loads. As this is a population with significant pretransplant treatment exposure, CD4 counts are generally low prior to ASCT and therefore not a reliable index for prediction of outcomes or toxicities.

The role of allogeneic stem cell transplantation remains an area of active investigation. An ongoing multicenter trial conducted by the US Bone Marrow Transplant Clinical Trials Network and the AMC is intended to provide the first prospective data on efficacy and transplant-related toxicities; however, until completion of this study with sufficient follow-up, it is recommended that allogeneic transplantation for HIV-positive patients occur within the context of a clinical trial at an academic institution.

Management of cART and Supportive Care

The optimal point at which cART should be incorporated during treatment has been evaluated in several studies but remains an unresolved issue. Given the previously discussed importance of sustained virological suppression on outcomes, the prospect of uncontrolled HIV replication during cytotoxic and lymphocyte-depleting therapy argues for the continuation of cART during treatment. Conversely, potential pharmacokinetic and pharmacodynamic interactions may lead to lower effective chemotherapeutic drug exposure or, importantly, increased toxicities. In particular, the CYP 3A inhibition associated with protease inhibitors (PIs) has been associated with increased myelosuppression without an increased rate of infectious complications. As shown by the NCI EPOCH study, high response rates can be seen without the concomitant use of cART. At the same time, concerns over cART noncompliance – and therefore suboptimal viral control and subsequent emergence of viral resistance – due to nausea or vomiting are increasingly unfounded given the highly effective antiemetics and supportive care

currently available. If there are concerns over excess toxicity or specific drug interactions, consideration may be given to raltegravir-based regimens, which are less frequently associated with these potential interactions. Ultimately, in the absence of prospective, randomized controlled data, the decision to incorporate cART during chemotherapy must be made on a case-by-case basis, taking into account the above considerations and individual risk/benefit ratio. However, in general, most physicians with expertise in this field now feel that it is preferable to continue antiretroviral therapy through the course of chemotherapy when possible. Should toxicities necessitate discontinuation of cART, it is best to continue to hold these agents until after the completion of all chemotherapy.

Use of pegylated granulocyte colony-stimulating factor (G-CSF) ameliorates chemotherapy-induced neutropenia, and infectious complications are minimized by the use of prophylactic fluoroquinolone antibiotics and azoles during periods of protracted neutropenia. All patients should receive *Pneumocystis jiroveci* prophylaxis (e.g., dapsone, inhaled pentamidine, atovaquone) regardless of initial CD4⁺ cell count. Caution should be exercised when using trimethoprim-sulfamethoxazole given its potential to exacerbate myelosuppression with concurrent chemotherapy.

Conclusion

The prognosis and treatment of DLBCL in HIV-positive individuals has improved dramatically in the era of cART. As a result of improved immunocompetency secondary to antiviral therapy, supportive care, and evolving treatment strategies, remission rates for individuals with at least certain types of DLBCL rival those of the HIV-negative population, and patients with good-risk features can reasonably expect to be cured of their disease. Results of ongoing trials examining the role of gene expression profiling, allogeneic stem cell transplantation, and novel targeted therapies will clarify the optimal strategy for treatment of relapsed or otherwise poor-prognosis disease.

E

Eastern Europe and Central Asia, Specific Characteristics of HIV/AIDS Epidemic

Jack DeHovitz¹, Anneli Uuskula² and Nabila El-Bassel³

¹Department of Medicine, Division of Infectious Disease, SUNY Downstate Medical Center, Brooklyn, NY, USA

²Department of Family Medicine and Public Health, University of Tartu, Tartu, Estonia

³Social Intervention Group, Columbia University School of Social Work, NY, USA

Introduction

While there is increasing evidence that HIV incidence is in decline among general populations worldwide, Eastern Europe and Central Asia are notable exceptions. There, HIV infections have increased 13% since 2006 (World AIDS Day Report 2012).

Several factors contribute to these rising rates. First, the political transition in the early 1990s led to dramatic economic dislocations as well as an expansion of criminal economies. Second, a highly structured public health system rooted in the Soviet tradition has been unable to effectively transition to meet post-Soviet challenges. These changes resulted in a dramatic increase in

injection drug use (IDU), associated with an increase in opiate smuggling from the Central Asian state of Afghanistan.

Initially the HIV epidemic in the region was driven by people who inject drugs (PWIDs). However, while risk factor profiles vary substantially between countries of the region (Gouws and Cuchi 2012), surveillance data suggest heterosexual transmission has now become the leading mode of HIV transmission in this region (World AIDS Day Report 2012).

Nonetheless, substance use remains an important driver of new infections. Implementation of known interventions to reduce transmission in IDUs has been impeded by challenges in scaling up opioid substitution therapy (OST) as well as other harm reduction efforts such as needle exchange. The use of OST is illegal in Russia and access to these services is limited in other countries. Antiretroviral therapy in the region became widely (but not universally) available after 2002. However, as noted below, access to therapy may be reduced in the setting of substance use. Complicating control of HIV has been the emergence of different non-injection drugs such as stimulants. These can lead to an elevated rate of HIV transmission due to their association with high-risk sexual behaviors (Platt et al. 2013).

The epidemic varies between Eastern Europe and Central Asia. For the purposes of this chapter, Eastern Europe is defined as the countries of

Belarus, Estonia, Latvia, Lithuania, Moldova, Russia, and Ukraine, and Central Asia represents the countries of Kazakhstan, Kyrgyzstan, Uzbekistan, Tajikistan, and Turkmenistan.

Eastern Europe

Epidemiology

The rate of diagnosed cases of HIV infection per 100,000 population in Eastern Europe has increased from 11.7 in 2004 to 22.3 in 2014 (ECDC and WHO Regional Office for Europe 2014). The highest rates of new HIV infections are in Russia, Ukraine, and Estonia. Notably, the epidemic continues to rise in the most populous countries of the region. For example, in 2012, Russia reported a 12% increase in the number of new HIV cases. In 2014, AIDS diagnoses per 100 000 population: 23 in Ukraine, 8.5 Latvia, 6.6 Georgia, 5.7 Moldova and Armenia, 5.0 Belarus, and 1.4 Estonia (ECDC and WHO Regional Office for Europe 2014- ref: Table 15).

HIV Prevention and Care

Needle and syringe programs (NSPs) are present in nearly all countries in Eastern Europe. However, coverage of NSPs is variable across and generally low, largely because of low levels of needle-syringe provision by NSPs in Russia, although in Russia and in other countries PWIDs can purchase needles in pharmacies. High NSP coverage is present in Estonia and Lithuania (Uusküla et al. 2011).

Most countries have implemented OST programs (with Russia a notable exception); however, overall, the scale of programs was very limited with one person receiving OST for every 100 PWIDs (Mathers et al. 2010). One of the success stories has been the launching opioid substitution therapy in Ukraine in 2004 (initially limited to the buprenorphine use and methadone since 2007). The number of people in Ukraine receiving OST has increased threefold from 2009 to mid-2012. However, even given its success there is less than 3% OST coverage among PWID in Ukraine (Bojko et al. 2015).

HIV Care and Treatment (ART)

Limited data is available on the characteristics of people accessing HIV care in Eastern European countries. The most common HIV-associated opportunistic infections diagnosed in 2011 were pulmonary tuberculosis (36%), wasting syndrome (25%), and esophageal candidiasis (23%). The status of TB in the setting of HIV is remarkable for the region. In 2011, tuberculosis notification rates per 100,000 ranged from 25.4 in Estonia to 150.7 in Moldova, and the estimated proportion of new cases of TB (including relapses) who were HIV positive varied from 0.9% in Lithuania to 20% in Ukraine (ECDC and WHO Regional Office for Europe 2013).

Additionally, access to care for patients with TB/HIV patients is worse compared to Western Europe. Initial TB therapy in Eastern Europe is suboptimal, with less than two-thirds of patients receiving at least three active drugs (Efsen et al. 2014). Highest rates of resistance to at least one anti-TB drug was reported in Estonia, Latvia, and Lithuania (34–41%). Multidrug resistant (MDR) TB was also most frequently observed in these same countries, occurring in 11–23% of all new cases and 29–58% among previously treated cases (ECDC and WHO Regional Office for Europe 2013). Mortality is high among HIV-infected patients with MDR, and they were more likely to die than the other group of those with HIV disease.

A high proportion of patients present late for care. For example, it has been documented that 57.9% of those in HIV care in Eastern European sites were late presenters (defined as HIV diagnosis with a CD4 count $<350/\text{mm}^3$ or an AIDS diagnosis within 6 months of HIV diagnosis) (Mocroft et al. 2013; ECDC and WHO Regional Office for Europe 2014- ref: Table 14). Officially, HIV care and ART is universally available for those in need in the region. However, studies have revealed multiple barriers to obtaining HAART. These barriers include a labyrinthine bureaucracy controlling access to ART, limitations created by an expectation that access to ART was conditional on treated drug use in a setting of limited drug treatment opportunity, and the lack of integration across HIV,

tuberculosis, and drug treatment programs (Pecoraro et al. 2014).

An additional significant coinfection given the burden of IDU is hepatitis C (HCV). This region has high rates of HIV/HCV coinfection – currently up to 80% among people living with HIV and seeking treatment in Estonia and Ukraine and over 90% in Russia (Central and Eastern European Harm Reduction Network 2007). Access to pegylated interferon-based therapies remains a challenge given the high cost of a 48-week treatment course which exceeds 14,000 USD with even lower access to new, oral direct-acting agents.

In addition to the structural level barriers, stigma toward HIV-infected people operating at multiple levels has been documented. In Russia, many people living with HIV (PLH) had been refused general health care, and negative attitude toward treating HIV-positive patients has been noted among medical students. These barriers may to some degree explain the high proportion of late presentations for HIV care and the low acceptance of ARV. ART has relatively low penetration in Eastern Europe. The percentage of adults (aged 15+) living with HIV accessing antiretroviral therapy in Eastern Europe and central Asia is only approximately 20% [19–22%] (UNAIDS 2016).

Special Populations

There is little data defining HIV risk among female sex workers in the region. The highest rates of HIV prevalence among female CSWs is in Moldova. Not surprisingly, IDU has been associated with HIV seropositivity in many CSW studies.

High rates of HIV disease have also been documented in prisons. Specifically, studies have found rates higher than 10% in Estonia and Ukraine (Dolan et al. 2007). A recent review suggested that regionally, the prevalence of HIV in prisons was approximately 4% (95% CI 1.4–8.0). Little information is available on the implementation and efficacy of HIV prevention programs within the correctional institutions in the region.

Eastern Europe has been experiencing increasing rates of both internal and external migration. Typically, this is due to economic, political, or

social factors. Low socioeconomic status, lack of access to services, separation from family, and limited risk awareness all contribute to migrants' HIV vulnerability.

Central Asia

Epidemiology of HIV

As with Eastern Europe, HIV rates are rising in Central Asia (CA). As with Eastern Europe, new HIV infections in Central Asia (CA) have risen primarily among people who inject drugs (PWIDs), female sex partners of PWID, men who have sex with men (MSM), female sex workers (FSWs), and migrant workers. While it is estimated that 1% of adults inject drugs in CA, the number exceeds 10% in areas along major drug trafficking routes, representing one of the highest rates of injection drug use in the world. As a result, high rates of HIV infection have been noted in various seroprevalence studies. Regional studies have shown that HIV prevalence among PWID varies from 0% to over 13% in different regions in Kazakhstan. Similar variation has been shown in Kyrgyzstan, Tajikistan, and Uzbekistan. Supporting this, additional data showed that 33% of Uzbekistan's cumulative registered cases and 72% of those in Kazakhstan were transmitted through the use of shared injection equipment (Thorne et al. 2010).

In the past 3 years, there has also been a steady rise in the incidence of sexual transmission of HIV as PWID in CA have infected their sexual partners (Boltaev et al. 2013). For example, data from Kazakhstan in 2011 showed heterosexual activity as the primary mode of transmission, which represented 50.7% of new cases surpassing IDU. The rise in sexual HIV transmission, particularly to the sexual partners of PWID, has been reported in each of the Central Asian countries except Turkmenistan. Another key population affected by HIV in CA is MSM. National reports estimate HIV prevalence among MSM to range from 1% to 2% in Kazakhstan, Kyrgyzstan, Tajikistan, and Uzbekistan in 2011 and as high as 6.8% in Tashkent, Uzbekistan.

HCV

While robust data on the magnitude of HIV/HCV coinfection are lacking, HCV prevalence is high in PWID, as noted above. Given the known potential for HIV transmission through sharing contaminated injection equipment, studies suggest that the majority of PWID infected with HIV will also be coinfecting with HCV. In a recent study with 364 couples (728 individuals) from Almaty, Kazakhstan, where at least one member of the dyad reported recent injection drug use, 90.2% of PWID were HCV positive (El-Bassel et al. 2013).

Prisoners have high rates of injection drug use and blood-borne infections. In Kyrgyzstan, 38% of inmates in one study test are positive for HCV, while in Kazakhstan, 91% of HIV-infected prisoners are HCV positive (Larney et al. 2013).

TB

Tuberculosis incidence rates in Kazakhstan, Uzbekistan, Tajikistan, and Kyrgyzstan are extremely high, and the percentage of both new cases and previously treated cases of TB that demonstrate multidrug resistance in Kazakhstan, Uzbekistan, Tajikistan, and Kyrgyzstan are among the highest in the world (Schluger et al. 2013). According to WHO, the percentage of TB cases with HIV coinfection is 2% in Kazakhstan and Tajikistan and 3% in Uzbekistan (WHO 2012). This situation requires substantial effort and improvement in diagnosis and treatment to control CA's staggering TB epidemic, especially that of MDR-TB. Furthermore, there is limited attention to adherence to TB treatment protocols for people who use drugs. Effective programs have been created in a number of regions around the world, and these models should be adopted in CA.

HIV Testing and Counseling

The WHO European Action Plan for 2012–2015 released in 2011 calls for reducing the number of undiagnosed people by increasing early uptake of HIV testing and counseling services, especially those most at risk (WHO 2011). Despite notable progress in scaling up HIV testing in CA, the number of key populations (such as PWID, MSM, and FSWs who inject drugs) who have been tested remains well below WHO's recommended

coverage of more than 90%. Coverage of PWID with recent testing has increased in Kazakhstan and in Tajikistan from 2009 through 2011; however, these numbers have declined in Kyrgyzstan and Uzbekistan. Highlighting some of the challenges, a study in Kazakhstan with 580 PWID found that 25% of the study sample had never been tested for HIV (El-Bassel et al. 2013). Nonetheless, coverage of PWID with a recent HIV test is higher than coverage among MSM with an HIV test in most countries of the region. There is unquestionably an urgent need to increase HIV testing among these key populations in CA.

HIV Treatment and Care

Currently, the Ministries of Health in CA countries recommend ART for HIV-infected individuals with CD4+ count <350 or WHO clinical stage III/IV which is analogous with the 2010 WHO guidelines. As of January 2013, the proportion of estimated ART-eligible PWID on treatment among those who were enrolled in HIV care in Kazakhstan, Kyrgyzstan, and Tajikistan ranged between 51% and 88% (Kazakhstan RAC 2012; Kyrgyzstan RNC 2013; Tajikistan RAC 2011). However, these statistics must be considered with caution because a large number of PWID are not enrolled in care, and ART coverage may actually be much lower. Solid data on ART among other key populations is limited, and access to ART treatment is limited by multiple barriers.

Conclusion

The region has a growing HIV epidemic in the world occurring in a setting of multiple gaps of translation of evidence into policy and programs. To meet the needs of key populations especially PWID, their sexual partners, MSMs, sex workers, and their social networks, it is critical to establish comprehensive programs and measure their impact. Additionally, it is critical to identify and address structural barriers in order to enhance access to needed services. This process must involve overcoming all the barriers noted above, as well as addressing discriminatory practices and laws and

transforming the health system through increased awareness that health is indeed a human right.

Definition

The introduction of highly active antiretroviral therapy in the mid-1990s, along with new infections in adults over the age of 50, has resulted in increasing numbers of adults over 50 living with

HIV and surviving into the later stages of life. These adults face a new set of challenges and threats to their health from cardiovascular disease and cancer as well as neurocognitive disease, bone disease, and frailty. In this chapter we describe the epidemiology of common chronic illnesses in the aging HIV population, as well as their relation to the HIV virus and traditional risk factors. Means to prevent, predict, and treat these conditions in the HIV-positive population are an area of ongoing study by HIV clinicians and researchers.

Introduction

Biologically, aging is a consequence of the rate at which an organism accumulates random damage and its ability to subsequently perform repairs in responding to these insults (Brothers and Rockwood 2014). The aging process is more pronounced – occurring more rapidly and at younger ages – in individuals infected with human immunodeficiency virus (HIV). Accelerated aging in HIV is caused by a combination of accumulated random damage and a reduced ability to mitigate these insults. Longstanding HIV infection produces vulnerability to various biological insults, while the virus causes inflammation and immune suppression that reduces physiological response to damage.

Aging among HIV-infected individuals is also associated with growth in the availability of life-saving medications. Highly active antiretroviral therapies (HAART) that reduce viral loads and immune suppression have led to dramatic improvements in life expectancy of HIV-infected individuals, while fundamentally altering the landscape of the disease. The incidence of once-feared complications of HIV infection and AIDS, including opportunistic infections and AIDS-related cancers, is dramatically reduced in the post-HAART era. However, noncommunicable, age-associated illnesses have increased in parallel, in part a result of increased longevity and, in part, a consequence of viral and behavioral factors. As such, HIV-infected adults experience at least some

shorter lifespan, high levels of comorbid disease, and earlier age-associated functional decline than their uninfected counterparts. Despite improvements in immune function in the setting of HAART, HIV-infected individuals still have elevated inflammatory biomarkers (Interleukin-6 or IL-6), altered coagulation (D-dimer), monocyte activation (soluble CD14 or sCD14), and at least somewhat suppressed immune systems that all contribute to age-associated complications (Brothers and Rockwood 2014). These virus-related factors interact with behavioral and social factors like smoking rates more than double that of the uninfected population and high rates of diabetes, cardiovascular, and renal disease in HIV-infected persons. Long-term HAART exposure has itself been linked to metabolic, cardiovascular, and bone diseases and acts to potentiate the effects of aging (Deeks 2009).

This chapter covers the epidemiology of aging in the HIV population and explores common causes of illness and death in this group. Therapy for HIV has curbed rates of death from infection and cancers related to abnormal immune function so that diseases most affecting the elderly HIV population today mirror those affecting the HIV-negative population, for whom heart disease and cancer remain the leading causes of death. Such is the case for cardiovascular disease, bone disease, non-AIDS-related cancers, cognitive dysfunction, and frailty – each profiled here. Each, however, also presents with unique characteristics in the HIV population as a result of interactions with virologic factors, medications, and comorbid medical illnesses that often result in accelerated or altered progression of disease and higher levels of disability and death. These discrepancies pose new challenges in the care of the aging and elderly HIV patient while models for predicting disease occurrence and progression continue to be studied.

Epidemiology

Median life expectancy among HIV-infected persons in high-income countries has risen steadily

since HAART was introduced (mid-1990s) from 55 years of age in 1996 to 70 years in 2005, while the rate of new infections has remained constant in this time (Pathai et al. 2014; Rubinstein et al. 2014). Previous projections estimated that by 2015, 50% of the HIV-positive population in the United States would be over the age of 50 (Effros et al. 2008). Even in lower-income settings such as KwaZulu-Natal, South Africa – the country with the highest prevalence of HIV and highest incidence of new infections (AIDSInfo) – the overall life expectancy increased from 49.2 years in 2003 to 60.5 years in 2011 (Sabin 2013). Between 2005 and 2013, moreover, while the number of adults and children living with HIV infection worldwide grew from 32.1 million to 35 million, the number of deaths due to AIDS fell by nearly 1 million, from 2.4 million to 1.5 million (AIDSInfo 2015).

Two distinct epidemiologic phenomena are responsible for the establishment and growth of the elderly HIV-positive population. First, immune reconstitution using HAART has led to decreased rates of AIDS-related morbidity and mortality, resulting in increased survival into older age of individuals infected at a young age. Effective therapy with HAART has meant a narrowing of the gap in life expectancy between HIV-positive and HIV-negative populations and a changing epidemiology of disease and illness in the aging HIV-infected population globally. However, such gains in life expectancy have been unevenly distributed and are mediated by socio-demographic, lifestyle, and disease-related factors, including markers of severity of disease prior to initiation of HAART (Sabin 2013). In some populations, life expectancies can range from 10 to 30 years less in infected individuals than uninfected counterparts and come closest to approaching normal life expectancy among individuals who have remained on therapy for several years and successfully achieved near normal CD4+ counts (defined as $CD4 > 500$) (Deeks 2009). There is evidence of higher rates of non-AIDS conditions linked with aging and chronic inflammation, such as cardiovascular disease, cancers, bone disease and fractures, kidney and liver

failure, and cognitive dysfunction in HIV-positive individuals (Deeks 2009). The cumulative effect of this multi-organ decline is a syndrome of increased frailty, polypharmacy, and falls – all occurring at earlier ages than observed in the HIV-negative population (Deeks 2009; Pathai et al. 2014).

Second, new infections in individuals above the age of 50 continue to occur as a result of low levels of knowledge regarding HIV infection and its transmission, increased rates of sexual activity among middle- and older-age individuals, low utilization of condoms, and physiologic changes postmenopause that cumulatively increase vulnerability to infection. In the United States, 10.8% of all new HIV infections annually are in adults aged 50 and older (Althoff et al. 2014). Risk factors for infection and modes of transmission mirror those in younger age groups, with most cases transmitted by male-to-male sexual contact in men and heterosexual contact for women ([HIV among older Americans](#)). Newly infected individuals over the age of 50 are often uniquely disadvantaged, however, as they are more likely than younger individuals to be diagnosed late in the course of infection and are twice as likely to progress from HIV infection to AIDS within the first year after diagnosis. This trend is evident in data from the Centers for Disease Control and Prevention (CDC); in 2011, elderly HIV-positive Americans represented nearly a quarter of all new AIDS diagnoses, and in 2010 more than half of all deaths in HIV-infected adults ([HIV among older Americans](#)). Late diagnosis is itself a consequence of a failure to recognize and seek care for symptoms of HIV and of decreased routine HIV testing and other prevention efforts by healthcare providers.

Frailty

The changing demographic of the HIV-infected population, from young to older ages has created demand for a better understanding of aging and frailty in this group. Frailty, as a medical condition, refers to the relative difference in

vulnerability among individuals of the same age to physiological and pathological stressors (Brothers and Rockwood 2014). Some decline in function is expected with aging. However, being frail entails an increased likelihood of poor outcomes and comorbid conditions as compared to others of the same age. To be considered frail, it has been suggested that at least three of five clinical findings must be met: the person must exhibit weakness, slowness, unintentional weight loss, low energy, and low physical activity (Brothers and Rockwood 2014). Together, frailty is associated with greater risk of disability, hospitalization, and death than persons of the same age that are not frail.

Frailty is common among older HIV-infected persons. Estimates of its prevalence range from as low as 5% in women enrolled in the Women's Interagency HIV Study to as high as 19% of HIV-infected participants in South Africa (Althoff et al. 2014). A US-based cohort of men who have sex with men in the Multicenter AIDS Cohort Study (MACS) estimated the prevalence at 12% among HIV-positive men compared to 9% in their uninfected comparison group (Althoff et al. 2014). In both infected and uninfected populations, the condition is associated with lower levels of education and income, unemployment, and comorbid medical and psychiatric disease. However, additional risk factors related to HIV disease and higher levels of comorbid conditions, including diabetes, cardiovascular disease, and dyslipidemia, contribute to elevated levels and accelerated progression of frailty. HIV-positive individuals with poorly controlled diseases – defined as having low CD4+ cell counts, detectable viral loads, past AIDS diagnoses, and high-risk factors like injection drug use – appear to experience increased frailty compared to HIV-negative populations, whereas their low-risk, well-controlled HIV-positive counterparts do not (Womack et al. 2013).

Current knowledge on means to effectively prevent frailty and the decline it heralds is theoretical only, suggesting the need for further research. Clinical approaches are geared toward earlier initiation of HAART along with aggressive management of known comorbidities like the use

of statins and aspirin for secondary prevention of cardiovascular disease.

Bone Disease

Osteopenia (defined by low bone mineral density) and osteoporosis (low bone mineral density in conjunction with diminished bone strength and abnormal bone architecture) are the most prevalent metabolic complications of HIV infection, affecting as many as 50–60% and 15% – respectively – of HIV-positive adults in high-income settings (Ali et al. 2014; Bhavan et al. 2008). The increased risk of fragility fractures corresponds to significant morbidity and mortality in this population. In the United States, HIV-positive adults experienced 60% more fractures of the spine, hip, and wrist than their HIV-negative counterparts in one study period (Walker Harris and Brown 2012). Similar trends have been observed in low- and middle-income settings as well, where the development of fractures has been demonstrated at higher rates and younger ages than in comparable uninfected populations (Ali et al. 2014).

The mechanisms leading to osteopenia, osteoporosis, and fractures are multifactorial and linked to chronic immune activation by HIV infection and HAART exposure. Other common factors and mechanisms include comorbid renal disease, vitamin D deficiency, and related bone resorption, as well as typical behavioral risk factors, including high rates of smoking, alcohol consumption, and physical inactivity. In studies, osteoporosis in HIV-infected adults was most closely associated with older age, lower body mass index (BMI), longer duration since HIV diagnosis and more advanced disease (Bhavan et al. 2008). Exposure to HAART is associated with bone resorption of approximately 2–6% loss of bone mineral density (BMD) after therapy for 48–96 weeks – an effect well beyond that expected with normal aging (Walker Harris and Brown 2012).

Osteoporosis is diagnosed using a combination of dual-energy, x-ray absorptiometry (DXA)-measured BMD and clinical evidence of fragility fractures (Walker Harris and Brown 2012).

Workup in the HIV-positive patient involves searching for and treatment of secondary causes of low BMD common to this group, including vitamin D deficiency, secondary hyperparathyroidism, and BMI less than 20 kg/m² (Bhavan et al. 2008). Traditional therapy for osteoporosis includes bisphosphonates. However, the use of these agents can be limited by side effects and can be associated with increased risk of atypical femoral fractures after use for more than 5 years (Ali et al. 2014). Just as in the non-HIV population, suggestions for HIV-infected individuals are to take vitamin D and calcium supplementation and adjust the HAART regimens to reduce bone mineral effects (Ali et al. 2014; Walker Harris and Brown 2012). Lifestyle modifications recommended for the non-HIV population, including increased physical activity with weight-bearing and muscle-strengthening exercise, smoking and alcohol cessation, and measures to reduce fall risk, are recommended for HIV-infected persons as well (Walker Harris and Brown 2012).

Cardiovascular Disease

In the post-HAART era, cardiovascular diseases (CVD) have emerged as a leading cause of morbidity and mortality in HIV-infected adults, with effects most pronounced among elderly HIV-positive individuals (Bhavan et al. 2008). CVD in this population includes coronary artery disease (CAD) – the most common cause of cardiovascular death in both infected and uninfected adults – stroke, heart failure, peripheral vascular disease, and cardiomyopathy, among other less common diagnoses. Estimates of the prevalence of all CVD in this population approach 10%, with rates increasing with age (Esser et al. 2013). The full extent of the virus's role in the development of CVD is incompletely understood, but CVD in HIV is likely mediated by a combination of three pathways: (1) HIV-infected individuals are at high risk for CVD through other mechanisms related to a high propensity toward certain behaviors including tobacco and alcohol abuse; (2) HIV or HAART may increase the development of

traditional cardiovascular risk factors, including diabetes, hyperlipidemia, and obesity and lipodystrophy; and (3) HIV or HAART – via inflammation, endothelial dysfunction, or other yet undiscovered means – acts to increase cardiovascular risk independent of traditional risk factors for disease (Currier et al. 2008). Emphasis will be placed here on the development of atherosclerotic cardiovascular disease (ASCVD), as it represents the most common cardiovascular risk in elderly HIV-positive adults.

Direct comparisons of groups of HIV-positive and HIV-negative adults have revealed significant differences in the rate of development of ASCVD and resulting myocardial infarction (MI) and stroke – in this case a result of virus-mediated vascular damage or elevated rates of traditional risk factors. HIV-infected adults are 1.5–2 times as likely to suffer from an MI than HIV-negative adults of similar age and risk profile (Currier et al. 2008). Other studies have shown up to a sixfold increased rate of ischemic cardiomyopathy and CAD-associated hospitalization in the HIV population. CAD is the primary risk factor for MI, ischemic stroke, and cardiovascular death and occurs at increasing rates as we age. In HIV, the pattern of normal risk progression with age is accelerated.

In an effort to disentangle the contributions of various risk factors in the development of ASCVD and predict the risk of MI, researchers have developed risk models incorporating both traditional risk factors (diabetes, hypertension, age) and HIV-specific risk factors (protease inhibitor exposure, viral load, total years infected, and markers of inflammation) that mirror models used in the uninfected population (e.g., the Framingham Risk Equation). One of the largest of these is derived from the Data Collection on Adverse Events of Anti-HIV Drugs (D:A:D) study, a longitudinal cohort composed of more than 30,000 HIV-positive adults in Europe, Australia, and the United States (Friis-Moller et al. 2010). When tested against the Framingham Risk Score – the gold standard in predicting MI in the uninfected population – the D:A:D model was better able to predict the development of MI events.

In addition to risk models to predict disease, tests aimed at accurately measuring surrogates of

atherosclerotic disease as it develops (carotid intima-media thickness) and more aggressive strategies for preventing and treating ASCVD have been designed and implemented. Studies using carotid intima-media thickness (CIMT) have helped to elucidate additional mechanisms of increased stroke and MI risk in this population, including findings of relatively higher rates of unstable coronary artery plaque in HIV-positive persons compared to matched HIV-negative controls (Hulten et al. 2009). Increasingly, aggressive therapy and prevention strategies for HIV populations have been advocated including empiric therapy with statins, even in persons without elevated lipid levels. An ongoing investigation, the Randomized Study to Prevent Vascular Events in HIV (REPRIEVE) trial, will help clinicians understand the utility of such a strategy. REPRIEVE randomizes HIV-positive persons without an ASCVD history to receive either a low-dose statin or placebo (Release MGHN 2014). As the relationship between HIV and ASCVD is better characterized through studies such as REPRIEVE, clinicians' abilities to prevent and treat ASCVD in the aging HIV-positive population will be augmented.

Non-AIDS Cancer

Following the introduction of HAART, rates of AIDS-defining cancers (ADC) – including Kaposi sarcoma, primary CNS lymphoma (PCNSL), and non-Hodgkin lymphoma (NHL) – have decreased by more than 70%, while non-AIDS-defining cancers (NADC) such as lung, anal, and oropharyngeal malignancies common to the uninfected population increased in prevalence more than threefold (Rubinstein et al. 2014). In the post-HAART era, oncogenic viruses and chronic malignancies related to behavioral risk factors like smoking account for the majority of malignancies occurring in the HIV-positive population (Rubinstein et al. 2014). Smoking rates in the HIV-positive population have been estimated to be as high as 50% in the United States, compared to just 18% in the general adult population, and these individuals are subsequently at an elevated

risk of developing and dying from lung and oropharyngeal cancers, for example. High levels of alcohol consumption – as much as double the rate seen in the HIV-negative population – can also be tied to an elevated risk of NADC.

Still, the increase in NADC exceeds that expected based on age alone and remains elevated despite controlling for smoking (Rubinstein et al. 2014). Together, ADC and NADC annually account for 26–30% of deaths among HIV-infected individuals in the United States and more than 4000 new cases of cancer each year. Today, rates of ADC remain highest in resource-poor settings with low access to HAART, and NADC rates have been observed in low- and high-income settings alike.

Oncogenic viruses have long been known to contribute to ADC. This relationship is exhibited most notoriously in the link between human herpes virus 8 (HHV-8) and Kaposi sarcoma, which at its peak in the early 1990s affected nearly one in every two HIV-positive Americans (Society AC). Epstein-Barr virus was similarly implicated in HIV-associated lymphomas, including Burkitt's lymphoma, immunoblastic B-cell lymphoma, and primary central nervous system (CNS) lymphoma (Rubinstein et al. 2014). NADC too exhibit links with oncogenic viruses: human papillomavirus (HPV) has been linked to nearly all cases of anal and cervical carcinoma and many cases of head and neck carcinoma, while hepatitis B and C viruses that occur commonly in the HIV-infected population greatly increase the risk of development of hepatocellular carcinoma. Each of these viruses is believed to promote cancerous replication by disrupting normal cell cycle regulation and by inhibiting the expression of naturally present tumor suppressor genes. These changes are thought to interact with pro-oncogenic properties of HIV in creating increased susceptibility to cancerous states, though the exact mechanism of this transformation is poorly understood.

CD4+ cell counts in isolation are often ineffective indicators of malignant potential as ADCs and NADCs have been detected in patients with depleted and elevated CD4 counts alike. Patients on HAART are often candidates for the same chemotherapy offered to uninfected patients as

treatment for NADC, though attention must be paid to interactions between chemotherapeutic agents and HAART drugs.

Neurocognitive Dysfunction

Aging and HIV infection have each been shown to contribute to progressive cognitive changes manifested in dysfunctions in learning, mood, attention, memory, perception, and problem solving. Whether this decline is a result of the HIV virus's effect on the CNS, normal aging, or an interaction of the two remains unclear, however. Early epidemiologic studies prior to HAART demonstrated higher prevalence of HIV dementia in the elderly compared to HIV-positive young adults suggesting some interaction between the virus and age-related changes in the brain (Bhavan et al. 2008). These findings were supported by a decrease in rates of the most severe form of cognitive dysfunction, HIV-associated dementia (from 16% to 5%), and CNS infections after the rollout of HAART (Heaton et al. 2011). Still, estimates of the prevalence of all HIV-associated neurocognitive disease (HAND) remain as high as 50%, and neurocognitive deficits continue to be more common in HIV-positive than HIV-negative individuals often regardless of treatment status, severity of disease, or age (Gannon et al. 2011).

HAND today represents a group of syndromes differentiated by the degree of impairment and disability each produces. From least to most impairment, the syndrome includes asymptomatic neuropsychological impairment (ANI), HIV-associated mild neurocognitive disorder (MND), and HIV-associated dementia (HAD) (Gannon et al. 2011). Increasingly, cases of HAND represent ANI and MND, characterized by psychomotor retardation and tremor, as opposed to the more severe HAD, which presents with a combination of neuropsychiatric abnormalities including trouble with attention, concentration, learning, memory, psychomotor skills, and processing severe enough to affect the performance of activities of daily living.

Multiple theories have emerged to try to explain neurocognitive deficits detected among

HIV-positive persons. First, HIV increases rates of cardiovascular disease via three separate mechanisms, detailed above, leading to a form of vascular dementia which may manifest as neurocognitive dysfunction. Second, chronic viral infection – even at low levels of replication – leads to smoldering inflammation, which has been demonstrated to cause glial damage in the frontal white matter of the brain leading to cognitive changes (Gannon et al. 2011). This theory was supported by a study after the advent of HAART that demonstrated twice the rate of cognitive impairment in elderly HIV-positive persons with detectable viral loads in cerebrospinal fluid (CSF) compared to those without detectable CSF viral loads (Cherner et al. 2004). Other groups have shown that insulin resistance associated with HAART may itself induce cognitive dysfunction (Bhavan et al. 2008). And while HAART has decreased rates of virus-related CNS damage, it too may have neurotoxic effects independent of the HIV virus (Gannon et al. 2011). Finally, comorbid social factors more prevalent in the HIV-positive population such as drug and alcohol abuse, low socioeconomic status, and unemployment may influence cognitive function.

The tenants of HAND treatment remain effective treatment of HIV with HAART, with emphasis on use of agents that can penetrate and lower viral loads in the CNS, along with investigation and treatment of curable causes of neurocognitive dysfunction including infections (syphilis), metabolic derangements (vitamin B12 deficiency, hypothyroidism), and comorbid psychiatric disease, common in elderly adults (Bhavan et al. 2008). Investigations of other drugs to target processes of neuronal damage and CNS inflammation, as well as strategies for the prevention of HAND, remain under study.

Health Maintenance and General Considerations for the Care of the Elderly HIV Patient

Given the changing demographics of the HIV-infected population, clinicians will begin to encounter a changing face to the virus. Improved

access to HAART and continuing levels of new infections among adults over the age of 50 contribute to an elderly HIV-positive population with unique comorbidities and treatment challenges requiring specialized care. HIV infection increases the risk for and interacts with comorbid aging-related diseases in order to cause accelerated disease progression and an increased likelihood of disability and death in the elderly HIV-positive person. HIV clinicians, while specialists, are frequently the primary care provider for the HIV-infected person and thus should be familiar with the health maintenance recommendations for this group (Aberg et al. 2014). Particular attention should be given to the use of screening tools for cardiovascular, neurocognitive, bone, and malignant disease and emphasis on risk factor modification to decrease rates of tobacco and alcohol abuse and improve early management of hyperlipidemia, diabetes, and hypertension to prevent disease progression.

Due to the high rates of comorbid medical illness in the elderly HIV patient, issues of polypharmacy, medication side effects, and interactions can pose an additional challenge to care. Physiologic differences in immune function between the elderly and young adults contribute to differing responses to HAART as well. Elderly HIV patients demonstrate more successful viral suppression than younger patients, likely a result of better medication compliance, improved access to HIV medications and fewer high-risk behaviors within the older population (Bhavan et al. 2008). Despite improved viral suppression, however, markers of immune reconstitution suggest the elderly lack robust immune activity even in the presence of an undetectable HIV viral load. Increased rates of renal and liver disease in elderly HIV-infected adults contribute to problems metabolizing drugs and exacerbate interactions between medications. Further research is needed to better understand the mechanisms behind viral suppression, age, and immune function, as well as the long-term safety and efficacy of HAART for the elderly.

Geriatric HIV care, like geriatric care for the uninfected patient, requires a nuanced approach to a clinic visit. Clinicians must be able to effectively communicate with patients, and integrating social

support systems into the broader care plan may prove beneficial (Bhavan et al. 2008). In addition to HIV-specific primary care recommendations (referenced above), the HIV clinician should incorporate standard geriatric screening for other problems such as elder abuse, financial difficulties, safe driving practices, and end-of-life preferences into the care plan of this unique population. A systematic approach to the care of HIV-positive elderly adult can be integrated into a multi-disciplinary team's daily practices to improve the care of elderly patients and their quality of life.

Conclusions

Elderly HIV-infected adults, like the uninfected elderly, face a number of health challenges as a consequence of increasing age and comorbidity. These problems are often potentiated among HIV-infected individuals by viral effects on immune suppression, chronic inflammation, and medication side effects and interactions. Cardiovascular disease and non-AIDS cancers are today among the largest contributors to disease and death in HIV-infected elderly, along with neurocognitive disease, bone disease, and frailty. Other common comorbidities, including chronic kidney disease and liver disease, are not described here but contribute to deaths from cardiovascular and other causes and further exacerbate issues of frailty. Ongoing study in the field aims to elucidate the mechanisms of increased risk of these diseases in HIV-infected adults compared to uninfected adults as well as means to predict, prevent, and treat disease. Care for the HIV elderly, meanwhile, follows the same principles as care for the uninfected geriatric adult and should aim to eliminate polypharmacy, reduce risk of falls, and intervene on preventable and reversible causes of injury and death.
