Entry Inhibitors

Leah A. Burke and Roy M. Gulick
Division of Infectious Diseases, Weill Cornell
Medicine, New York, NY, USA

Definition

Entry inhibitors are one of the six mechanistic classes of antiretroviral drugs used for the treatment of HIV infection. HIV entry inhibitors

Entry Inhibitors, Fig. 1 Steps in HIV entry and inhibition. †US FDA approved for HIV treatment. *Development for HIV treatment discontinued

interfere with the entry of HIV into its target cell, the human CD4⁺ T-lymphocyte. By inhibiting this step in the HIV life cycle, entry inhibitors and ultimately slow the progression of HIV infection. In targeting the first step in the HIV life cycle before the virus enters the cell, entry inhibitors are distinct from other classes of antiretroviral agents for HIV infection that target HIV after it has entered and infected a CD4⁺ cell. Some HIV entry inhibitors are also distinct in targeting a host-cell receptor, rather than a viral protein.

Introduction

There are three major steps involved in HIV entry into a human CD4⁺ cell: (1) attachment to the CD4 receptor, (2) attachment to the chemokine receptor, and (3) fusion of the viral membrane

with the host-cell membrane. These steps are shown in Fig. 1. Several viral proteins are necessary for this process. The HIV surface protein gp120 binds to the CD4 receptor on the surface of a CD4⁺ cell. This leads to a conformational change in gp120, which increases its affinity for a coreceptor and exposes the HIV envelope protein gp41. HIV gp120 subsequently binds to either the CCR5 or CXCR4 coreceptors on the CD4⁺ cell. gp41 then penetrates the CD4⁺ T cell membrane, which facilitates fusion of the virus and CD4⁺ cell membranes, allowing entry of the virus into the cell. HIV entry inhibitors work by interfering with one aspect of this process. This chapter discusses HIV entry inhibitors that have been approved by the US Food and Drug Administration (FDA) as well as investigational agents that reached clinical trials. A summary of these agents is provided in Table 1.

Entry Inhibitors, Table 1 HIV entry inhibitors

Full name	Abbreviation or alternate name	Mechanism of action	Status	Adult dose for HIV treatment
albuvirtide	ABT, FB006M	Fusion inhibitor	Investigational, Phase 3	320 mg IV weekly
AMD-070	N/A	CXCR4 chemokine receptor antagonist	Development discontinued due to hepatotoxicity	N/A
AMD-3100	N/A	CXCR4 chemokine receptor antagonist	US FDA approved (2008) for stem cell harvesting; development for HIV treatment discontinued due to suboptimal virologic response	Not approved for HIV treatment
aplaviroc	APL, GW 873140	CCR5 chemokine receptor antagonist	Development discontinued due to hepatotoxicity	N/A
BMS-663068	BMS-663068	CD4 attachment inhibitor, binds HIV gp120	Investigational, Phase 3	600 mg PO BID
cenicriviroc	CVC, TAK-652	CCR5 chemokine receptor antagonist	Investigational, Phase 2	100 mg or 200 mg PO daily (dosage adjusted based on coadministered ARVs)
enfuvirtide	ENF, Fuzeon, T-20	Fusion inhibitor	US FDA approved for HIV treatment (2003)	90 mg SQ BID
ibalizumab	N/A	CD4 attachment inhibitor, binds CD4 receptor	Investigational, Phase 3	2,000 mg IV loading dose followed by 800 mg IV every 2 weeks
maraviroc	MVC, Selzentry, Celsentri, UK-427,527	CCR5 chemokine receptor antagonist	US FDA approved for HIV treatment (2007)	150 mg PO BID 300 mg PO BID 600 mg PO BID (dosage adjusted based on coadministered ARVs)
PRO 140	N/A	CCR5 chemokine receptor antagonist	Investigational, Phase 2/3	350 mg SQ weekly
Schering C	SCH-C	CCR5 chemokine receptor antagonist	Development discontinued due to QT prolongation	N/A
10-1074	N/A	CD4 attachment inhibitor, binds HIV gp120	Investigational, Phase 1	30 mg/kg IV (frequency TBD)
3BNC117	N/A	CD4 attachment inhibitor, binds HIV gp120	Investigational, Phase 2	30 mg/kg IV (frequency TBD)
vicriviroc	VCV, SCH 417690, Schering D, SCH-D, MK-4176	CCR5 chemokine receptor antagonist	Development for HIV treatment discontinued due to suboptimal virologic effect; phase 1 for HIV prevention	N/A
VRC01	N/A	CD4 attachment inhibitor, binds HIV gp120	Investigational, Phase 2	40 mg/kg IV (frequency TBD)

Abbreviations: ARVs antiretrovirals, BID twice a day, IV intravenous, PO by mouth, SQ subcutaneous, TBD to be determined

CD4 Attachment Inhibitors

Small-Molecule CD4 Attachment Inhibitors

Fostemsavir as of 10/2016

BMS-663068 is an oral investigational small-molecule HIV CD4 attachment inhibitor. The compound is a methyl phosphate prodrug that is rapidly converted by alkaline phosphatase in the gastrointestinal lumen to the active compound, BMS-626529, that subsequently is rapidly absorbed. The active compound specifically binds to HIV gp120 and inhibits its binding to the CD4 receptor on the cell surface. In vitro, BMS-656529 demonstrated a broad range of virologic activity against a group of clinical HIV isolates.

In phase 1 testing, BMS-663068 demonstrated potent virologic activity over 8 days (Nettles et al. 2012); however, 14% of individuals had decreased baseline susceptibility to the compound due to polymorphisms in the HIV envelope. In a phase 2b study, 251 treatment-experienced individuals who had a prestudy viral isolate with a half maximal inhibitory concentration (IC₅₀) to the prodrug BMS-626529 of less than 100 nM received tenofovir and raltegravir together with BMS-663068 400 mg or 800 mg twice daily, BMS-663068 600 mg or 1,200 mg once daily, or ritonavir-boosted atazanavir (control regimen). At week 24, virologic suppression to <50 copies/ml was seen in the BMS-663068 groups at rates of 80% (400 mg twice daily), 69% (800 mg twice daily), 76% (600 mg once daily), and 72% (1,200 mg once daily) versus 75% in the atazanavir/ritonavir group. Serious adverse events were described in 7% of individuals on BMS-663068 versus 10% on atazanavir/ritonavir, and 2% versus 4%, respectively, discontinued because of adverse events. Individuals continued to be followed and based on 48-week responses, the 1,200 mg daily dose was selected for all BMS-663068 groups and 67% of individuals continued study regimens through 96 weeks (DeJesus et al. 2016). At week 96, HIV RNA was suppressed to <50 copies/ml in 61% (BMS-663068) versus 53% (atazanavir/ritonavir) in a modified intent-to-treat analysis and grade

2–4 related clinical adverse events occurred in 8.5% (BMS-663068) versus 31% (atazanavir/ritonavir), mostly due to atazanavir-associated hyperbilirubinemia.

Ultimately, pharmacokinetic/pharmacodynamic modeling using data from phase 2 studies in HIV-1-infected individuals ($N = 244$, clinical trials.gov identifiers: NCT01009814 and NCT01384734) suggested that BMS-663068 dosed at 600 mg BID would have the optimal risk-benefit profile, and this dose was selected for further investigation. BMS-663068 is now in phase 3 evaluation in heavily treatment-experienced individuals with multidrug resistant HIV (NCT02362503). The US Food and Drug Administration designated BMS-663068 as “breakthrough therapy” in July 2015, a designation for compounds used to treat a serious or life-threatening disease with preliminary clinical data that demonstrate the potential for substantial improvement over existing therapies.

Monoclonal Antibodies

Two to three years after HIV infection, approximately 10–20% of individuals develop serum antibodies that can neutralize a broad spectrum of HIV viral strains. Recent advances have led to the discovery of multiple potent human monoclonal antibodies that are broadly neutralizing across many HIV-1 subtypes. These antibodies target different epitopes on the HIV envelope as shown in Fig. 2. Therapy with broadly neutralizing antibodies (bnAB's) differs from other therapies for HIV infection in that not only is there associated virologic activity but the potential to enhance host immunity to HIV infection. Such compounds are currently being explored in clinical trials for HIV treatment and prevention, both individually and as antibody combinations.

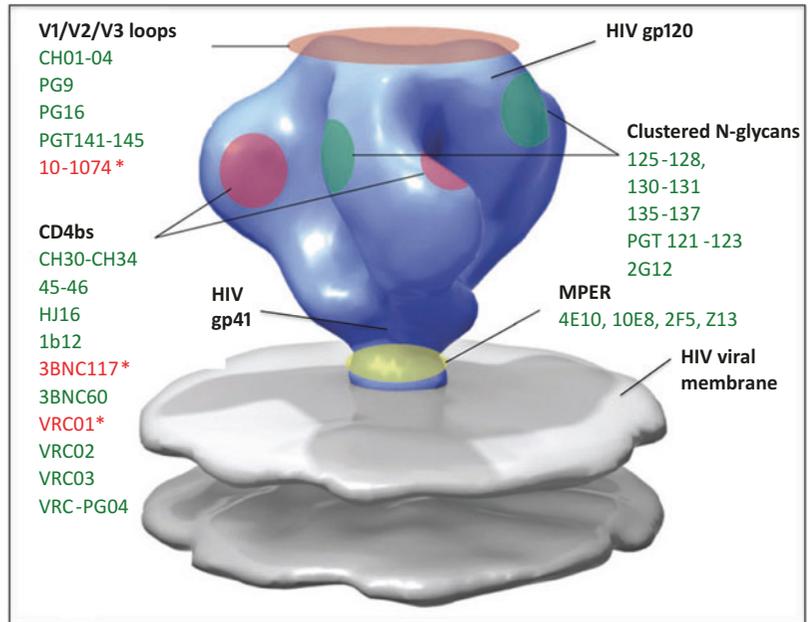

Monoclonal Antibodies that Bind to gp120

10-1074 10-1074 is an investigational broadly neutralizing monoclonal antibody that specifically binds to the base of the V3 loop within HIV-1 envelope gp120. This antibody was originally cloned from a single B cell from an individual infected with clade A HIV-1 with virologic

Entry Inhibitors,

Fig. 2 HIV binding sites for broadly neutralizing monoclonal antibodies.

*Antibodies that are farthest along in clinical development and discussed in the text. *Abbreviations:* *CD4bs* CD4 binding site, *MPER* membrane-proximal external region, *V* variable region

E

control not on antiretroviral therapy. In preclinical trials, while 10-1074 monotherapy did not control HIV-1 infection in an ART-untreated humanized mouse model, administration of 10-1074 alone to mice with virological suppression receiving standard combination antiretroviral therapy was able to sustain HIV suppression. Administration of 10-1074 in combination with other potent human antibodies was able to control established HIV infection in humanized mice as long as antibody remained at target levels (Horwitz et al. 2013).

A phase 1 open-label, dose-escalation study evaluating the safety, tolerability, and pharmacokinetics of 10-1074 at doses of 3 mg/kg, 10 mg/kg, and 30 mg/kg in HIV-infected and uninfected individuals is underway (NCT02511990). Clinical trials are also studying the safety, pharmacokinetics, and antiretroviral activity of the combination of 3BNC117 and 10-1074 in HIV-infected and uninfected individuals as well as the role of 10-1074 in HIV prevention.

3BNC117 3BNC117 is an investigational broadly neutralizing antibody that targets the HIV-1 envelope gp120-CD4 binding site. The antibody was initially cloned from a single

memory B cell isolated from an individual infected with clade B HIV-1 with virologic control not on antiretroviral therapy. 3BNC117 is unique in its potency and breadth and is currently being investigated in clinical trials.

In the first-in-man phase 1 clinical trial (Caskey et al. 2015), individuals were administered a single intravenous infusion of 3BNC117 at increasing doses (1 mg/kg, 3 mg/kg, 10 mg/kg, or 30 mg/kg) and were followed for 24 weeks after the last infusion. Pharmacokinetic data from 22 individuals (12 HIV-uninfected, 17 HIV-infected individuals) showed a compound half-life of 17.6 days in HIV-uninfected and 9.6 days in viremic HIV-infected individuals. When administered at 30 mg/kg, 3BNC117 induced rapid decreases in plasma HIV-1 RNA levels, with mean HIV RNA dose-dependent declines of approximately 0.8–2.5 log copies/mL. Peripheral blood mononuclear cells (PBMCs) obtained before and 28 days after antibody infusion in 5 individuals dosed at 30 mg/kg demonstrated emergence of 3BNC117-resistant viral strains in some individuals. At 28 days, high-level resistance (defined as a greater than fivefold reduction in susceptibility to 3BNC117) was seen in 2 out of 5 individuals dosed at 30 mg/kg.

Overall, 3BNC117 was generally safe and well tolerated. Five individuals reported ophthalmic complaints (2 increased lacrimation, 2 conjunctival erythema, and 1 blurry vision); however, a causal relationship with 3BNC117 was not established. No serious adverse events or grade 3 or 4 adverse events deemed to be related to 3BNC117 occurred.

3BNC117 was recently administered to 13 HIV-infected individuals who were virologically suppressed on antiretroviral treatment to determine the delay in the time to viral rebound following a period of treatment interruption. Two or four 30 mg/kg infusions of 3BNC117 given to a total of 13 individuals were generally well tolerated. The infusions were associated with a delay in viral rebound for 5–9 weeks after 2 infusions, and up to 19 weeks after 4 infusions, or an average of 6.7 and 9.7 weeks respectively, compared with 2.6 weeks for historical controls. Rebound viruses arose predominantly from a single genotype. Viruses emerging in the presence of high serum antibody concentrations showed decreased 3BNC117 susceptibility (Scheid et al. 2016). Phase 2 clinical trials are ongoing to determine the safety, pharmacokinetics, and antiretroviral activity of administering multiple doses of this antibody (NCT02588586). In addition, administration of this antibody is being considered for trials of HIV prevention.

VRC01 VRC01 is an investigational broadly neutralizing monoclonal antibody which binds to the CD4 binding site of gp120 on the HIV envelope. In preclinical trials, this antibody neutralized over 90% of 190 diverse strains of HIV. In phase 1 dose-escalation studies of HIV-infected individuals (study VRC 601), a maximal dose of 40 mg/kg IV was administered. Intravenous VRC01 had a half-life of 11 days in HIV-infected individuals (Lynch et al. 2015). A single administration of the antibody lead to a 1.1–1.8 log copies/ml decline in HIV RNA in 6 out of 8 individuals. The 2 individuals with minimal decline in plasma viremia were found to have predominantly VRC01-resistant virus prior to treatment. Adverse events assessed as possibly related to study product administration, including transient localized pruritus at the

subcutaneous injection site and flushing, were mild in severity and resolved with no residual effects. Two pilot studies of VRC01 explored its effect in HIV-infected individuals with virologic suppression on antiretroviral therapy on virologic rebound following a treatment interruption but showed only a modest delay; some individuals developed VRC01-resistant viral strains.

There are several additional ongoing clinical trials involving VRC01. AIDS Clinical Trials Group (ACTG) A5342 is a phase 1 study that administers either intravenous VRC01 or placebo in a crossover design to HIV individuals with suppressed HIV RNA on ART and examines the impact on the HIV latent cell reservoir (NCT02411539). In addition, phase 2 studies are evaluating the safety and efficacy of VRC01 for HIV prevention in reducing HIV acquisition in HIV-uninfected women in Sub-Saharan Africa (study HPTN 081; NCT02568215) and in HIV-uninfected men and transgender persons who have sex with men in North and South America (HPTN 085; NCT02716675). Also, VRC01 has been modified to increase its binding affinity and increase its duration of activity; the safety and pharmacokinetics of this long-acting formulation (VRC01LS) is currently being evaluated in both intravenous and subcutaneous formulations in HIV-uninfected adults (NCT02599896).

Monoclonal Antibodies that Bind to the CD4 Receptor

Ibalizumab (TMB-355, Previously TNX-355)

Ibalizumab is an investigational monoclonal antibody that binds to the CD4 receptor on host CD4+ cells. This antibody provides potent inhibition against a broad range of HIV-1 strains *in vitro*; ibalizumab neutralized 92% of a panel of over 100 HIV-1 pseudoviruses representing multiple clades.

A multicenter phase 2a study was conducted in 82 treatment-experienced HIV-1 infected individuals with multidrug-resistant HIV-1. All individuals received an optimized background antiretroviral regimen based on treatment history and resistance testing and then added either ibalizumab dosed intravenously at 15 mg/kg

every 2 weeks (Arm A) or 10 mg/kg weekly for 9 doses followed by the same dose every 2 weeks (Arm B) or placebo. Reductions in plasma HIV-1 RNA levels at 24 and 48 weeks were 0.95 and 0.71 log copies/ml in Arm A and 1.16 and 0.96 log copies/ml in Arm B, respectively, and were statistically significant greater than those seen in the placebo arm.

A 24-week Phase 2b randomized, double-blinded study was conducted in 113 treatment-experienced HIV-1-infected individuals. Individuals received intravenous ibalizumab dosed at either 800 mg every 2 weeks (Arm A) or 2,000 mg every 4 weeks (Arm B) in combination with an optimized background regimen based on treatment history and resistance testing. A plasma HIV-1 RNA level below detection was achieved after 24 weeks of therapy in 44% of individuals on Arm A and 8% of individuals on Arm B (Bruno and Jacobson 2010).

NCT02475629 is an ongoing phase 3 study of ibalizumab plus an optimized antiretroviral background regimen in treatment-experienced individuals with multidrug resistant HIV-1. In this study, individuals are administered a loading dose of 2,000 mg intravenous ibalizumab on day 7, followed by ibalizumab 800 mg intravenous once every 2 weeks, plus an optimized background regimen beginning on day 14. The primary outcome measures are day 14 HIV RNA level reduction and the proportion of individuals achieving a ≥ 0.5 log copies/ml decrease from day 7/baseline HIV RNA. In February 2015, ibalizumab was designated “breakthrough therapy” from the US Food and Drug Administration, a designation for investigational compounds used to treat serious or life-threatening diseases with preliminary clinical data suggesting the potential for improvement over existing therapies.

Chemokine Receptor Antagonists

CCR5 Antagonists

Aplaviroc (APL, GW 873140)

Aplaviroc was an investigational CCR5 antagonist that demonstrated potent *in vitro* activity

against CCR5-tropic (R5) HIV-1. Aplaviroc was tested in clinical studies in HIV-uninfected and treatment-naive HIV-1-infected individuals, but clinical development was discontinued due to drug-associated idiosyncratic hepatotoxicity (Currier et al. 2008). Study individuals receiving aplaviroc demonstrated increased rates of elevations of hepatic transaminases and bilirubin compared to control arm individuals, and one individual experienced aplaviroc-related severe hepatic cytolysis. The mechanism of drug toxicity is not known but thought to be compound-specific, rather than class-specific.

Cenicriviroc (CVC, TAK-652)

Cenicriviroc is an investigational oral small-molecule CCR5/CCR2 chemokine receptor antagonist. The compound was first developed clinically as an antiretroviral agent for HIV treatment as a CCR5 antagonist and more recently is being explored as an anti-inflammatory drug based on its activity as a CCR2b receptor antagonist. Cenicriviroc does not antagonize binding to other chemokine receptors. Cenicriviroc demonstrates potent activity *in vitro* against CCR5-tropic HIV-1 (R5) and HIV-2 (R5) isolates but has no activity against CXCR4-tropic (X4) HIV-1. Cenicriviroc is active against HIV subtypes A-G. Cenicriviroc is orally bioavailable and demonstrates a long plasma half-life of 3–40 h, allowing once-daily dosing. The compound is metabolized by the liver, is a substrate of CYP3A4 and CYP2C8, and is $>98\%$ bound to plasma proteins.

A phase 1 study demonstrated potent virologic activity over 10 days. A phase 2 study enrolled 143 individuals with CCR5-tropic HIV-1 infection with HIV RNA levels at least 1,000 copies/ml and CD4 cell counts of at least 200 cells/uL (Thompson et al. 2016). Individuals received coformulated tenofovir disoproxil fumarate/emtricitabine and were randomized 2:2:1 to add cenicriviroc 100 or 200 mg or efavirenz 600 mg. The study regimen was a 6-pill twice-daily regimen with cenicriviroc (or placebo) dosed with breakfast and efavirenz (or placebo) dosed fasting at bedtime. HIV RNA was suppressed to <50 copies/ml at week 24, the primary endpoint of the study, in 76% (CVC 100 mg), 73% (CVC 200 mg), and 71%

(efavirenz) and at week 48 in 68%, 64%, and 50%, respectively. Virologic failure was observed in 11% on CVC versus 7% on efavirenz; drug-resistance mutations emerged in 5 CVC individuals versus none on efavirenz, and R5/X4 dual/mixed virus emerged in 1 CVC individual. Treatment-emergent adverse events of at least moderate severity were seen in 9% in each of the CVC groups versus 36% in the efavirenz group ($P = 0.001$). CVC was also associated with an increase in monocyte chemoattractant protein (MCP)-1 levels and a transient decrease in soluble CD14 levels, markers of inflammation. Based on these results, CVC 200 mg daily was selected as the dose for further development and phase 3 studies in treatment-naïve HIV-infected individuals were originally planned but ultimately not begun.

Lenacapavir currently is being studied as a CCR2b antagonist for its anti-inflammatory effects in HIV-infected individuals for neurocognitive impairment (NCT02128828) and arterial inflammation (ACTG 5363) and in HIV-uninfected individuals for nonalcoholic steatohepatitis (NASH), liver fibrosis (NCT02217475), and primary sclerosing cholangitis (NCT02653625).

Maraviroc (MVC, Selzentry, Celsentri, UK-427,527) Maraviroc is the first US Food and Drug Administration-approved chemokine receptor inhibitor and the second approved HIV entry inhibitor (2007). The drug is unique among approved antiretroviral drugs in targeting not HIV itself but the human CCR5 cell-surface receptor. Maraviroc blocks the binding of CCR5-tropic HIV-1 and HIV-2 (also called R5 HIV) to the receptor but has no activity against CXCR4-tropic (X4) HIV. Maraviroc is administered orally at a standard dose of 300 mg twice daily. Potent CYP3A4 inducers decrease maraviroc concentrations, and potent CYP3A4 inhibitors increase maraviroc concentrations, necessitating dose adjustments.

The phase 3 MOTIVATE (*Maraviroc versus Optimized Therapy in Viremic Antiretroviral Treatment-Experienced Patients*) studies were two large, parallel, randomized, double-blind, placebo-controlled multicenter trials in

treatment-experienced HIV-infected individuals with R5 virus that demonstrated the safety and efficacy of maraviroc and supported its approval (Gulick et al. 2008). The studies enrolled 1,049 HIV-infected individuals from Canada and the United States (MOTIVATE 1) and Australia, Europe, and the United States (MOTIVATE 2) with treatment experience or virologic failure with 3 prior classes of HIV drugs (nucleoside analogues, nonnucleoside analogues, and protease inhibitors), and an HIV RNA level of at least 5,000 copies/ml. Individuals underwent genotypic and phenotypic resistance testing that, along with the treatment history, was used to design an optimized background regimen of antiretroviral drugs. Individuals were then randomized 2:2:1 to add maraviroc once daily, maraviroc twice daily, or placebo and were followed for virologic response and safety. At 48 weeks, the primary study endpoint, maraviroc was associated with a significantly greater decrease in HIV RNA level of about 1.0 log copies/ml compared to placebo in both studies. Maraviroc did not demonstrate virologic activity in a study of treatment-experienced individuals with non-R5-HIV (X4 or mixed infection) and demonstrated suboptimal virologic responses in treatment-naïve individuals with R5 virus.

Oral maraviroc was explored for HIV prevention in a phase 2 study of HIV-uninfected at-risk men-who-have-sex-with-men and women as PrEP (*Pre-Exposure Prophylaxis*) either as monotherapy or combined with emtricitabine (FTC) or tenofovir disoproxil fumarate (TDF) versus the control regimen of TDF/FTC and demonstrated comparable safety and tolerability (NCT0105114). Maraviroc also was explored for HIV prevention delivered through a vaginal ring but failed to achieve target drug levels due to decreased elution from the ring.

Side effects with maraviroc are uncommon. The prescribing information contains a boxed warning for hepatotoxicity based on a single case report, but a retrospective review of maraviroc clinical trials did not confirm a risk for hepatotoxicity. Postural hypotension can occur at higher maraviroc doses (typically 600 mg twice daily and higher). Drug resistance

to maraviroc most commonly develops in the setting of ongoing viral replication with the outgrowth of preexisting X4 HIV. With its unique mechanism of action, maraviroc is not cross-resistant to other HIV antiretrovirals.

No dose adjustment is required for individuals with mild-moderate hepatic or renal impairment, but maraviroc is contraindicated in individuals with severe renal impairment (CrCl <30 mL/min) and should not be used in severe hepatic impairment. Maraviroc is pregnancy category B, although there are insufficient data to support its use with only a few case reports in pregnant women.

Maraviroc is not used commonly today for HIV treatment because of its requirement for viral tropism testing (to determine the presence of R5 and/or X4 HIV) and is not recommended in treatment guidelines as initial therapy because of suboptimal virologic responses in studies of treatment-naïve individuals. With its novel mechanism of action, maraviroc is active against multidrug-resistant HIV and can be used as a part of combination regimens in treatment-experienced participants with R5 virus, although typically fewer than 50% of such individuals have R5 virus only.

PRO 140

PRO 140 is an investigational humanized monoclonal antibody that targets the host-cell CCR5 chemokine receptor that has been designated by the Food and Drug Administration for fast-track approval, a designation for a compound to treat a serious or life-threatening condition that fills an unmet medical need. PRO 140 is a non-competitive, allosteric inhibitor and is active against viruses resistant to small-molecule antagonists of CCR5 such as maraviroc.

PRO 140 demonstrated virologic activity both in vitro against R5 viruses and in vivo in HIV-1-infected individuals with CCR5-tropic virus. A phase 2a study was conducted to evaluate the antiviral activity, tolerability, and pharmacokinetics of weekly or biweekly subcutaneous doses of PRO 140 in HIV-1 infected individuals with R5-tropic HIV-1 (Jacobson et al. 2010). Individuals were dosed with placebo, 162 mg, or 324 mg

of PRO 140 at days 1, 8, and 15. A fourth study arm dosed 324 mg of PRO 140 on days 1 and 15 and placebo on day 8. Pharmacokinetic studies revealed terminal half-lives of 3.4 and 3.7 days with 162 and 324 mg dosed weekly, respectively. Subcutaneous PRO 140 demonstrated mean log reductions in HIV-1 RNA level of 0.15, 0.75, 1.20, and 1.51 for the placebo, 162 mg weekly, 324 mg biweekly, and 324 mg weekly dose groups, respectively, by day 22. HIV RNA levels remained suppressed between successive doses. Treatment was generally well tolerated with no drug-related serious adverse events. Administration-site reactions, including induration (20%), pain (9%), and irritation (7%), were infrequent, mild, and transient. Low titers of anti-PRO 140 antibodies were detected in 7 (5%) individuals; however, there was no clear effect on pharmacokinetic profiles or virologic activity. All viruses were susceptible to PRO 140 before and after therapy, and the maximum percentage inhibition of R5 viruses was 98–100%.

PRO 140 is undergoing phase 2 trials evaluating weekly subcutaneous injections for maintenance of virologic suppression in individuals suppressed on ART (NCT02175680) as well as those with poor ART adherence (NCT01272258) and a phase 3 trial evaluating the safety and tolerability of weekly injections in individuals with limited treatment options (NCT02483078).

Vicriviroc (VCV, SCH 417690, Schering D, SCH-D, MK-4176) and Schering C

Vicriviroc is an investigational small-molecule CCR5 antagonist that was first developed clinically as an antiretroviral agent for HIV treatment and received US FDA fast-track status for clinical development in 2005. Vicriviroc demonstrates potent activity in vitro against CCR5-tropic HIV-1 (R5) isolates but has no activity against CXCR4-tropic (X4) HIV-1. Vicriviroc is metabolized by the CYP3A4 hepatic enzyme system and plasma levels are enhanced by coadministration with ritonavir, the potent CYP3A4 inhibitor.

A phase 2 study in treatment-naïve individuals enrolled 92 individuals with R5 HIV and randomized them to receive one of 3 doses of vicriviroc (25, 50, 75 mg once daily) for 14 days and then

added zidovudine/lamivudine or to the standard-of-care 3-drug regimen zidovudine/lamivudine and efavirenz. This study was stopped early because of increased virologic failure rates in the 25 and 50 mg vicriviroc arms.

Phase 2 studies in treatment-experienced individuals demonstrated significant virologic activity of vicriviroc. In parallel identically designed phase 3 studies, VICTOR-E3 and VICTOR-E4, 857 treatment-experienced HIV-infected individuals with documented resistance to at least two prior antiretroviral drug classes had their antiretroviral regimen optimized on the basis of treatment history and drug-resistance testing to include at least two fully active antiretroviral drugs, and then were randomized 2:1 to receive vicriviroc or matching placebo (Casiero et al. 2012). The primary study endpoint, the proportion of individuals with HIV RNA suppressed to <50 copies/ml, was 64% in the vicriviroc arm versus 62% in the placebo arm ($p = 0.6$).

Based on the increased virologic failure rates in the treatment-naïve study and the lack of a significant virologic benefit in the large treatment-experienced studies, further clinical development of vicriviroc for HIV treatment was discontinued in 2010. Vicriviroc currently is being explored for HIV prevention in phase 1 studies using the compound in an intravaginal ring, either alone or in combination with a second agent, MK-2048, an investigational HIV integrase inhibitor (Microbicide Trials Network [MTN] study 027 [NCT02356302], NCT02419456.)

A related compound, SCH-351125 (SCH-C, Schering C), a CCR5 antagonist that is structurally distinct, was discontinued from clinical development due to QT interval prolongation.

CXCR4 Antagonists

AMD-3100 (JM-3100, Plerixafor, Mozobil) and AMD-070 (AMD-11070)

AMD-3100 is an investigational bicyclam CXCR4 antagonist that interferes with HIV binding to the host-cell CXCR4 chemokine receptor. AMD-3100 demonstrates potent activity in vitro against CXCR4-tropic HIV-1 and HIV-2 (X4) isolates but has no activity against CCR5-

tropic (R5) HIV-1. A phase 1 study of AMD-3100 administered at escalating doses by continuous intravenous for 10 days to 40 HIV-infected individuals with HIV RNA at least 5,000 copies/ml demonstrated dose-proportional concentrations, up to 3.4-fold increases in white blood cell counts, but no significant change in HIV RNA – although the one enrolled individual with X4-virus only demonstrated a decrease in HIV RNA of 0.9 log copies/ml (Hendrix et al. 2004). Based on these results, further development of AMD-3100 for HIV infection was discontinued.

The notable leukocytosis was found to be due to AMD-3100 interfering with the binding of SDF-1, the natural ligand of the CXCR4 receptor, that functions to retain hematopoietic stem cells in the bone marrow and clinical studies ensued. AMD-3100, renamed plerixafor, was ultimately approved by the US Food and Drug Administration in 2008 for use in stem cell mobilization for bone marrow transplantation in individuals with hematologic malignancies (non-Hodgkin's lymphoma and multiple myeloma).

A follow-on compound, AMD-070, an orally bioavailable investigational CXCR4 antagonist, was tested in pilot studies of HIV-uninfected and HIV-infected individuals, but development was ultimately abandoned due to hepatotoxicity in laboratory assays and animal studies.

Fusion Inhibitors

Albuvirtide (ABT, FB006M)

Albuvirtide is an investigational HIV fusion inhibitor that is a peptide analogue of enfuvirtide, modified with 3-maleimimidopropionic acid (MPA). Albuvirtide demonstrates potent activity in vitro against HIV-1 of different subtypes, including variants resistant to enfuvirtide. The compound is administered parenterally and can irreversibly conjugate to serum albumin, conferring a long plasma half-life that could allow weekly (or less frequent) dosing.

The first clinical study of albuvirtide was a phase 1 trial that enrolled 55 HIV-infected individuals who received single intravenous doses escalating from 20 to 640 mg (or placebo).

Albuvirtide was generally safe and well tolerated and demonstrated a half-life of 11 days with virologic activity demonstrated over 6–10 days following dosing. A phase 2a study enrolled 12 HIV-infected individuals who received albuvirtide 160 or 320 mg given intravenously once daily for 3 days, followed by 2 weekly administrations. The compound was generally safe and well tolerated and associated with dose-dependent HIV RNA reductions of 0.7 (160 mg) and 1.0 (320 mg) log copies/ml.

A follow-up study enrolled 20 HIV-infected individuals who were randomized to receive albuvirtide 160 or 320 mg given intravenously weekly with standard-dose lopinavir/ritonavir twice daily for 7 weeks (Zhang et al. 2016). At week 7, HIV RNA decreased 1.9 (160 mg) and 2.2 (320 mg) log copies/ml, HIV RNA was suppressed to <50 copies/ml in 11% (160 mg) and 56% (320 mg), and there were no serious adverse events.

Albuvirtide currently is under study in a phase 3 trial of a target 420 HIV-infected individuals experiencing virologic failure of their first antiretroviral regimen in which all individuals receive standard-dose lopinavir/ritonavir and are randomized to add either albuvirtide 320 mg given intravenously once weekly or standard daily doses of tenofovir disoproxil fumarate and lamivudine (NCT02369965).

Enfuvirtide (ENF, Fuzeon, T-20)

Enfuvirtide was the first US Food and Drug Administration-approved HIV entry inhibitor (2003). The drug is a linear synthetic 36-amino acid peptide that has a structure analogous to the heptad repeat region (HR2) of HIV-1 membrane glycoprotein 41 (gp41). As part of viral-CD4 cell membrane fusion, the heptad repeat (HR) regions of HIV gp41 (HR1 and HR2) fold in on and bind to one another. Enfuvirtide, as an analogue of HR2, inhibits this binding and acts as a viral-cell membrane fusion inhibitor. As a peptide, enfuvirtide requires parenteral administration and with its short half-life of about 4 h, enfuvirtide requires dosing every 12 h. The US FDA-approved dose of enfuvirtide is 90 mg every 12 h by subcutaneous injection.

The TORO (*T-20 vs. Optimized Regimen Only*) studies were two large, parallel, randomized, controlled, open-label, multicenter phase 3 trials in treatment-experienced HIV-infected individuals that demonstrated the safety and efficacy of enfuvirtide and supported its approval. The studies enrolled 1,013 HIV-infected individuals from the Americas (TORO 1, Lalezari et al. 2003) and from Europe and Australia (TORO 2, Lazzarin et al. 2003) with treatment experience or virologic failure with 3 prior classes of HIV drugs (nucleoside analogues, non-nucleoside analogues, and protease inhibitors) and an HIV RNA level of at least 5,000 copies/ml. Individuals underwent genotypic and phenotypic resistance testing that, along with the treatment history, was used to design an optimized background regimen of 3–5 antiretroviral drugs. Individuals were then randomized 2:1 to add enfuvirtide (or not) and were followed for virologic response and safety. At 24 weeks, the primary study endpoint, enfuvirtide was associated with a significantly greater decrease in HIV RNA level of about 0.8–0.9 log copies/ml in both studies.

The main side effect of enfuvirtide is injection site reactions characterized by pain, erythema, induration, and subcutaneous nodules, and these are seen in nearly all individuals. Drug resistance to enfuvirtide is conferred by substitutions in the HR1 region of gp41 at positions 36–40, 42, and 43 that decrease binding of the drug; these substitutions develop commonly in the presence of ongoing viremia; enfuvirtide is considered to have a low barrier to resistance. With its unique mechanism of action, enfuvirtide is not cross-resistant to other HIV antiretrovirals. As a peptide, enfuvirtide does not have significant interactions with other drugs. No dose adjustment is required for renal or hepatic impairment.

There are limited efficacy data in pediatric individuals aged 6–16. Enfuvirtide is pregnancy category B, although there are insufficient data to support its use in pregnant women. Enfuvirtide is not used commonly today because of its requirement for twice-daily subcutaneous dosing. With its novel mechanism of action, enfuvirtide is active against multidrug-resistant HIV and may

be used in heavily treatment-experienced individuals with few or no remaining HIV treatment options.

Conclusions

In summary, entry inhibitors are antiretroviral drugs that prevent HIV from entering target cells. Entry inhibitors interfere with the one of three major steps involved in the HIV life cycle: (1) CD4 receptor attachment, (2) chemokine receptor attachment, or (3) viral-cell membrane fusion. There currently are only two entry inhibitors that are US FDA approved for HIV treatment (enfuvirtide, maraviroc), but a number of agents under investigation hold promise for both HIV treatment and prevention.

Epidemic Kaposi Sarcoma, Pathogenesis and Presentation

Corey Casper

Vaccine and Infectious Disease, Public Health Sciences and Clinical Research Divisions, Departments of Medicine, Epidemiology and Global Health, Fred Hutchinson Cancer Research Center and the University of Washington, Seattle, WA, USA

Definition

Kaposi sarcoma (KS) is a vascular neoplasm caused by infection with human herpesvirus 8 (HHV-8, also known as Kaposi sarcoma-associated herpesvirus) which may involve the

skin, mucous membranes or viscera. Epidemic KS is the form of the disease found among persons with HIV infection; it is the most common malignancy in persons with HIV worldwide.

Introduction

Kaposi sarcoma (KS) remains among the most common cancers seen in persons with human immunodeficiency virus (HIV) infection more than three decades after it was initially described as a key-presenting manifestation of the acquired immunodeficiency syndrome (AIDS) in 1981. While new cases of KS have decreased dramatically in the United States with the widespread availability of combination antiretroviral therapy (cART), the incidence remains threefold higher than prior to the HIV pandemic, and the cancer (► [Cancers Related to HIV](#)) is the most common in the entire male population of several countries in sub-Saharan Africa. Much has been learned about the pathogenesis of KS and its clinical manifestations in HIV-infected persons, and many of these discoveries have led to effective therapies for the disease. However, KS remains a cancer that infrequently responds completely to therapy, and continued research into the biology of the malignancy will likely lead to more effective, safer, and less expensive therapies that may be used in the coming years.

Pathogenesis

The dramatically increased incidence of KS among persons with severe CD4 T-cell deficiencies (► [Central Memory CD4+ T cells](#)) led investigators to seek an infectious etiology of the tumor. In 1994, a novel human herpesvirus (human herpesvirus 8, HHV-8, or Kaposi sarcoma-associated herpesvirus) was shown to be the cause of KS (Chang et al. 1994). Subsequently, it has been observed that infection with HHV-8 is necessary, but not sufficient, for the development of KS. In the pre-cART era, only half of severely immunosuppressed individuals with HHV-8 infection developed KS (Martin

et al. 1998), and in some regions of sub-Saharan Africa, the majority of the general population is infected with HHV-8 but few go on to develop KS (Dollard et al. 2010). Although many aspects of the pathway to tumorigenesis have been worked out for KS, a number of gaps in the understanding of the pathogenesis remain.

Several epidemiologic patterns of KS have been recognized; these include classic KS (arising in elderly men in regions surrounding the Mediterranean Sea), endemic KS (arising in individuals in Africa before the AIDS epidemic or who are not infected with HIV), epidemic KS (associated with HIV infection), and transplantation-associated KS. It is now recognized that these are all forms of the same disease.

Acquisition and Dissemination of HHV-8

Behavioral, seroepidemiologic, and virologic studies have consistently underscored the importance of salivary transmission and acquisition of HHV-8 (Pauk et al. 2000). In areas where KS is not endemic, HHV-8 is most often acquired as a sexually transmitted infection after the time of sexual debut. In regions of the world where KS is endemic, HHV-8 is most often acquired in childhood with persistent acquisition into adulthood. The timing of primary acquisition of HHV-8 may play an important role in determining whether the infection will remain asymptomatic or progress to KS. Precedent with other viral infections, such as hepatitis B virus, shows that infection earlier in life may be associated with immune tolerance that is permissive of viral replication. HHV-8 replication is associated with a higher risk of developing KS (Engels et al. 2003) and therefore may explain why one of the two peaks in KS incidence in endemic regions occurs shortly after the time that HHV-8 is acquired.

Primary infection with HHV-8 likely occurs in oral epithelial cells (Pauk et al. 2000), and dissemination to other anatomic sites is thought to be an important next step in the progression to KS. Infection of circulating B lymphocytes may then lead to wider anatomic dissemination, which may in turn allow for infection of circulating endothelial cells. Endothelial cells are almost certainly the primary origin of the pathognomonic

cell of KS tumor, the “spindle cell,” though the absence of an animal model which completely recapitulates all of the features of the progression from primary viral infection to tumorigenesis makes definitive conclusions about the process challenging.

KS is an unusual tumor, in that it does not share some of the key characteristics of almost all other malignant tumors. First, while the spindle cell is central to the pathogenesis of the malignancy, it comprises the minority of many KS lesions, and the neoplasm is always a heterogeneous mix of cell types. Inflammatory cells (B and T lymphocytes as well as monocytes) and vascular proliferations predominate. Spindle cells tend not to be clonal and cannot proliferate in culture in the absence of growth factors or in nude mice, and KS tumors are dependent on persistent HHV-8 replication for survival.

The development and maintenance of KS tumors is clearly therefore reliant on host, viral, and environmental factors, as summarized below.

Viral Factors

Like all herpesviruses, HHV-8 (► [Kaposi's Sarcoma Associated Herpesvirus](#)) has two genetic programs: the lytic stage, in which viral replication occurs, and the latent stage, in which the virus persists with expression of an extremely restricted number of gene programs. Latency is maintained through a tethering of the HHV-8 episome to the host chromosomes by the latency-associated nuclear antigen (LANA or ORF73). In addition to maintaining the viral genome through cell division, LANA and other viral latency genes play a clear role in carcinogenesis. LANA also inhibits traditional tumor suppressors (p53 and Rb) and upregulates the expression of proto-oncogenes. The viral FLICE-like inhibitory protein (v-FLIP) is antiapoptotic, and v-cyclin and the kaposins may contribute to neovascularization, disruption of the cell cycle, and inflammation. During lytic infection a larger number of viral genes are expressed. Key among the lytic viral genes for the initiation and propagation of the KS tumor includes the viral interleukin 6 analogue (v-IL6) and the viral G protein-coupled receptor (v-GPCR) which each increases angiogenesis in

a number of different ways and the viral ORFK15 that incites a proinflammatory cytokine and chemokine response permissive to KS tumors.

Genomic Heterogeneity

Human herpesviruses exact efficient and accurate replication of their DNA genome due in part to the presence of a proofreading DNA polymerase. However, the large size of the genome and the number of viruses produced in some portions of the lytic life cycle can lead to genomic heterogeneity (Zong et al. 2002). Distinct “strains” of HHV-8 can be detected between individuals that tend to cluster by geographic region, though within an individual are stable over time. These strains are determined based on sequencing small regions of one or a limited number of genes that are thought to be hypervariable. It is unclear as to how these genetic variations affect the clinical manifestations of disease, and this will be an interesting area for future research.

Coinfection

In the field of cancer biology, increasing attention is being paid to the microbial community in a given anatomic compartment and how that may alter the susceptibility to cancer within an individual. Both in vitro models and data from clinical cohorts support a role for coinfections to potentiate HHV-8 replication, which may in turn increase the odds of developing KS from asymptomatic infection. The HIV *Tat* protein (► [Tat Expression and Function](#)) increases the production of HHV-8 in culture (Aoki and Tosato 2004), and relationships have been established between the detection of HIV in the plasma and both the frequency of detection of HHV-8 at mucosal sites (Johnston et al. 2009) and the risk for development of KS over time. Taken together with epidemiologic evidence that HIV infection increases the risk of developing KS over that seen in immunocompromised transplant recipients (Grulich et al. 2007), the data are compelling that HIV coinfection strongly potentiates the development of KS. Similarly, cytomegalovirus coinfection (► [Immunopathogenesis of HIV Co-infections](#)) increases HHV-8 replication (Vieira et al. 2001), though the clinical relevance of this interaction

has not been established. Observations that HHV-8 lytic replication may be triggered by the engagement of toll-like receptors 7 and 8 (TLR 7/TLR8) (Gregory et al. 2009), whose ligands are typically single- or double-stranded RNA, raise the possibility that RNA viruses inhabiting the human virome could also play a role in KS tumorigenesis. No data to date has evaluated the role of the gut microbiome and predisposition to KS, but with the understood importance of the oral cavity in HHV-8 acquisition and dissemination, the preliminary evidence that oral inflammation is associated with HHV-8 oral replication, and increasing appreciation of the role of the oral microbiome in oral inflammation, further research is necessary to determine if there is an association between the microbiome and the susceptibility to KS.

Host Factors

Cellular Immunity

The inverse association between the incidence of KS and the quantity of CD4 T lymphocytes in HIV-infected individuals highlights the importance of T cells in the biology of KS, but to date, the exact mechanisms by which T-cell deficiencies predispose to KS are not clear. Early studies were mixed but overall found either a weak or no association between the absolute number of T lymphocytes and the risk of classic or endemic KS. In the setting of HIV infection, weak CD4 T-cell responses to latent HHV-8 antigens can be detected, but have not been correlated with risk of developing KS (Sabbah et al. 2012). CD8 T-cell responses have been identified to both latent and lytic (Ribechini et al. 2006) HHV-8 antigens, with a suggestion that the LANA protein is immunodominant. Observations from small numbers of patients with KS show that cytotoxic T-cell responses in patients with KS are most robust after immune reconstitution with cART (► [Immunological Responses to Antiretroviral Therapy](#)) and that an inverse relationship exists between robustness of cytotoxic T-cell response and the presence of HHV-8 in the peripheral blood (Bihl et al. 2009). Taken together, it is clear that while T-cell immunity is important in the pathogenesis of KS, other immunologic factors must also contribute.

Fewer studies have examined the role of B lymphocytes or NK cells in the development of KS. Reduced numbers of NK cells and impaired function have been observed with classic KS, and deficits in NK cell function are restored after cART.

Humoral Immunity

Given the importance of HHV-8 replication in the development of KS, it is possible that control of viral replication with neutralizing antibodies could reduce the progression to KS. Reduced levels of neutralizing antibodies to HHV-8 are found in the peripheral blood of persons with KS compared with asymptotically infected controls. Neutralizing epitopes have not been identified.

Inflammation

The development of KS at sites of surgical incisions or trauma (the “Koebner phenomenon”) has been held out as an example of the importance of inflammation in the development of KS. Worsening or newly emergent KS lesions have been described as a complication cART initiation, often attributed to “immune reconstitution inflammatory syndrome” (► [Immunological Response to ART](#)) (Achenbach et al. 2012). The detection of higher quantities of leukocyte esterase in the oral mucosa (traditionally a marker for the presence of inflammatory white blood cells from clinical specimens) was associated with high quantities of HHV-8 detected in that compartment (Casper et al. 2004).

While no studies to date have definitively characterized the inflammatory cytokines or “milieu” that may predispose to KS in vivo, careful study of HHV-8 has allowed a greater understanding of how inflammation may lead to KS. While the virus acts aggressively to downregulate certain specific immune responses that could result in its elimination (i.e., Th1 responses) (Th1 & Th2 Cells), several viral proteins act to increase the Th2 response (Th1 & Th2 Cells) (chemokine ligands), recruit T lymphocytes to areas of HHV-8 replication, and subsequently produce inflammatory cytokines such as TNF-alpha, IL-6, etc. which may allow for the rapid development of the KS tumor. Additional research is

needed to understand how differences in the inflammatory response to HHV-8 may lead to differential rates of progression to KS.

Environmental Factors

Given the widespread geographic and demographic variations in KS incidence, it is tempting to speculate that environmental factors may also modify the risk of developing KS from HHV-8 infection. However, epidemiologic studies to investigate these associations are challenging due to the relative rarity of the disease, the difficulty in finding comparable controls for cases in case-control studies, and even the absence of biologically plausible environmental factors to examine in such studies. There are few similarities in the environments of the diverse populations where KS is endemic, such as East Africa, Southern Italy, and Western China. However, exposure to iron-rich soil, plants which produce phorbol esters, or arthropods have all been proposed as environmental risk factors for KS in at least one study. Perhaps more consistent is the strong association between the use of amyl nitrates (“poppers”) and the risk of KS among the community of men who have sex with men in resource-rich regions. Again the biologic plausibility of this association has not been established, and it remains possible that the use of amyl nitrates is a surrogate for another exposure that is the true cause of increased risk for KS.

Exploiting Knowledge of KS Pathogenesis for Clinical Therapeutics

The mainstay of treatment for KS (► [Management of AIDS-related Kaposi's Sarcoma](#)) currently is cytoreductive chemotherapy. While this treatment in many is highly effective, even in resource-rich settings, the combination of chemotherapy and cART may leave residual disease in more than half of patients treated (Nguyen et al. 2008). Thus, the knowledge gained from understanding the pathogenesis of KS can inform more effective and less toxic therapies for the disease. Strategies aimed at inhibiting HHV-8 replication have been ineffective in treating KS, likely because the current antiviral drugs are only moderately effective in reducing HHV-8 replication, the possibility that

these DNA synthesis inhibitors may still allow production of early viral gene products, and the fact that only the minority of cells in KS tumors contain lytically replicating virus. Inhibition of angiogenesis was thought to be a promising target for these extremely vascular tumors, but results to date have been disappointing. Modulation of the inflammatory response has shown some evidence of success; interferon administration results in modest tumor response, interleukin-12 has shown activity in pilot studies, and more promise has been seen with the immunomodulatory drugs thalidomide and lenalidomide. Finally, drugs that inhibit specific pathways important for tumorigenesis such as matrix metalloproteinases and tyrosine kinases have limited activity in small clinical trials. It is clear that due to the complexity of the disease process, the optimal therapy for KS will likely entail drugs that inhibit multiple targets, and future studies will need to define optimal treatment strategies.

Presentation

KS is a disease with diverse clinical manifestations. An HHV-8 “primary infection syndrome” has been described in African children, transplant recipients, and HIV-negative men who have sex with men, typically consisting of fever, cytopenias, and cutaneous manifestations (rash or even KS), but it is thought that the majority of cases of incident KS occur sometime after primary infection. In resource-rich regions where the HIV epidemic has matured, KS often presents in patients who have either been marginalized from HIV care or who are not able to adhere to HIV therapy, though occasionally is identified as the AIDS-defining illness. In resource-poor areas, KS often is the diagnosis which prompts HIV testing, but may also be identified among patients participating in HIV care programs. In resource-rich regions, KS most commonly presents at low CD4 T-cell counts (Biggar et al. 2007), though the disease is increasingly being identified in persons with higher CD4 counts and suppressed HIV replication. In places where the tumor was endemic prior to the HIV pandemic, the range of CD4 counts for persons

presenting for care appears to be wider than what has been reported in the United States and Europe. In the United States, Europe, and Australia, epidemic KS is predominantly a disease of men, whereas in sub-Saharan Africa, epidemic KS cases in women are beginning to approximate the number seen in men.

Patients typically present with mucocutaneous disease, though many may have coexisting visceral disease, most typically involving the lungs or gastrointestinal tract. cART has modified the presenting manifestations of KS from what was initially described in the early HIV epidemic (Nasti et al. 2003).

Mucocutaneous KS

The morphotypes and distribution of mucocutaneous KS appear to vary by demographic and geographic populations. In the United States, Europe, and Australia, epidemic KS classically presents as an erythematous patch, progressing to a violaceous plaque or macule, and often on to a larger nodule. These lesions can be distributed virtually anywhere on the body. The oropharynx is the most common mucosal surface involved, and the tumor typically involves the hard palate and less commonly the soft palate, gingiva, and tongue. Especially in sub-Saharan Africa, additional morphotypes of KS are seen, including fungating and infiltrative disease. Perhaps due to the tendency to present with more advanced disease or the challenges of diagnosing the disease among persons with darkly pigmented skin, the patch morphology is infrequently observed as a presenting manifestation of KS in the region, but may come to predominate following treatment. Also of note in sub-Saharan Africa are the differences in clinical presentations between women and men, with women more often having disease which involves the face and less commonly involving the lower extremities.

Although the diagnosis of mucocutaneous KS is often made clinically, even astute clinicians may incorrectly ascribe a different disease process to KS. Definitive diagnosis is rendered through biopsy, where histopathology reveals the classic spindle cells and, where available, in resource-rich regions in situ hybridization for HHV-8

proteins (most often LANA) can provide confirmation to the visual histology.

Visceral KS

Up to 40% of HIV patients presenting with KS had visceral disease identified in the early HIV pandemic in the United States, but this number has decreased substantially in the era of cART (Nasti et al. 2003). Visceral disease is not routinely or exhaustively sought in the workup of patients with cutaneous KS in either resource-rich or resource-poor regions, so the true prevalence of disease is not known. Presenting manifestations of visceral KS are most commonly hemoptysis or hematochezia, representing pulmonary and gastrointestinal disease, respectively. Early staging systems for KS, which were subsequently validated later in the HIV pandemic, confirm that visceral disease portends a poorer prognosis (Krown et al. 1997). Diagnosis of pulmonary KS is established by bronchoscopy – because biopsy of lesions may be associated with hemorrhage, the detection of HHV-8 by polymerase chain reaction has been proposed as both a sensitive and specific alternative. Conversely, diagnosis of gastrointestinal KS is best established through biopsy or reliance on morphologic appearance in the appropriate clinical setting. Involvement of lymph nodes is also common, and KS in inguinal lymph nodes is often associated with substantial edema of the lower extremities.

Pediatric KS

Epidemic KS among children is uniquely described in sub-Saharan Africa. Interestingly, disease in HIV-positive children (► [Children, Care and Treatment](#)) most commonly presents with lymphadenopathic involvement, and mucosal disease is less common (Gantt et al. 2010). The median presenting CD4 T-cell count is substantially higher than what has been reported in adults, and outcomes tend to be poor.

KS as a Manifestation of IRIS

The exacerbation or novel presentation of KS among persons initiating cART has now been well described in both the United States and sub-Saharan Africa, with the incidence ranging

from ~4% of persons in the United States (Achenbach et al. 2012) to one-third of persons in Uganda (Martin et al. 2009). The predictors of developing KS-IRIS and the complete clinical manifestations are still being identified, though cases of fatal KS-IRIS complicated by systemic inflammatory syndrome, multiorgan system failure, and death have been reported.

Associated Comorbidities

KS represents one of several HHV-8-associated diseases, including ► [multicentric Castleman disease \(MCD\)](#), ► [primary effusion lymphoma \(PEL\)](#), and the recently described Kaposi sarcoma-associated herpesvirus inflammatory cytokine syndrome (KICS) (Uldrick et al. 2010). Not surprisingly, immunocompromised patients with HIV may present with more than one of these illnesses. KS accompanies up to one-third of cases of MCD, and although PEL and KICS are too rare to develop accurate estimates of the frequency of co-presentation with KS, clinical reports suggest it commonly occurs.

Outcomes After Diagnosis of KS

KS is a disease that when treated early and aggressively is infrequently fatal, but as noted above responses to therapy are uncommonly complete, and advanced disease still is associated with a poor prognosis. In the current cART era in the United States, a diagnosis of mucocutaneous KS is associated with a 2-year overall survival of 85%, but visceral disease reduces the 2-year overall survival to 64% (Achenbach et al. 2011). In the pre-cART era in Uganda, less than 10% of patients with HIV-associated KS survived 5 years (Gondos et al. 2005), though more recent data suggests that survival approximates what has been described in the United States.

Conclusions

More than three decades after the resurgence of KS accompanied the HIV pandemic, the disease remains a common complication of HIV infection worldwide. Years of steady research have led to great leaps in the understanding of KS

pathobiology and facilitated better treatments for the disease, but significant gaps in knowledge preclude the development of highly effective and implementable prevention and treatment strategies. Continued efforts are needed to comprehensively reduce the morbidity of KS.

Epidemiology of AIDS-Defining Malignancies

William A. Blattner and Rebecca G. Nowak
Division of Epidemiology and Prevention,
Institute of Human Virology, University of
Maryland School of Medicine, Baltimore, USA

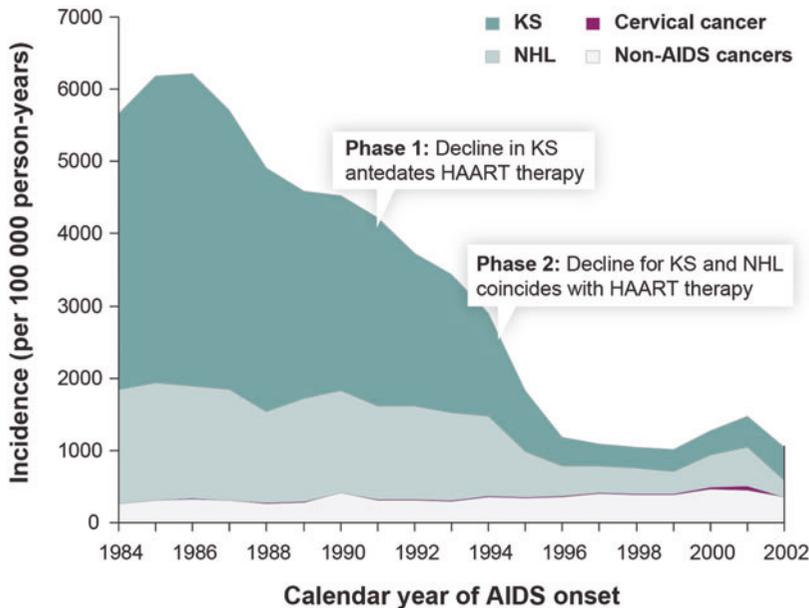

Definition

AIDS-defining malignancies are a subset of HIV-associated malignancies that include Kaposi

sarcoma, some forms of non-Hodgkin lymphoma, and invasive cervical cancer. KS along with PCP are among the first diseases that comprised the original definition of AIDS “in the United States.” Subsequently, non-Hodgkin lymphoma (1985) and invasive cervical cancer were added (CDC 1992). Compared to non-AIDS-defining malignancies, Kaposi sarcoma and non-Hodgkin lymphoma demonstrated the highest incidence in the early AIDS epidemic. As shown in Fig. 1, with the introduction of highly active antiretroviral therapy (HAART) in 1996, the incidence patterns of these cancers with the exception of cervical cancer dropped significantly. It is hypothesized that HAART restores immune function and delays progression to AIDS. However, even with the improved clinical outcome, HAART has not eliminated the risk of AIDS-defining malignancies. HIV-positive persons still remain at a substantially increased risk of developing these cancers as compared to the general population, and AIDS-related and non-AIDS-related cancers combined are the most frequent underlying causes of death in AIDS in the United States.

Epidemiology of Kaposi Sarcoma Before HAART

Prior to the AIDS epidemic, Kaposi sarcoma (KS) was a cancer with an incidence in white males of 0.3 per 100,000 in the United States (1973–1978) (Mbulaiteye et al. 2003). With the advent of the AIDS epidemic in 1981, a new form of KS, classified as “epidemic” or AIDS-associated KS, was identified. In the initial definition of AIDS, it was considered an AIDS-defining illness because epidemiologically these cases (characterized by young age at onset, high prevalence among men who have sex with men (MSM), and association with unexplained immunodeficiency) were distinct from the other three recognized patterns of KS (classic KS, elderly Mediterranean men; endemic KS, sub-Saharan Africa; and iatrogenic KS, associated with therapeutic immunosuppression) and they tended to occur in individuals with other manifestations of this new syndrome. Beginning with the first report

Epidemiology of AIDS-Defining Malignancies, Fig. 1 Cancer incidence among people with AIDS in the United States (1984–2002). Incidence is shown as a function of calendar year of AIDS onset for Kaposi sarcoma (KS), non-Hodgkin lymphoma (NHL), cervical cancer, and non-AIDS-defining cancers. Incidence estimates for each cancer are stacked on top of each other to depict the

proportion of total cancer incidence contributed by each cancer type. Analysis was restricted to the 2-year period 4–27 months after AIDS onset (Engels EA, et al., Trends in cancer risk among people with AIDS in the United States 1980–2002, *AIDS*, 2006, 20:1645–1654, pending permission from Wolters Kluwer Health through RightsLink)

of KS among MSM in 1981, incidence rapidly increased and peaked in 1985–1986. By 1989–1991, incidence was 8.9 per 100,000 with nearly 40–50% of men who have sex with men (MSM) presenting with KS as their AIDS-defining illness (Fig. 1; Mbulaiteye et al. 2003). KS became the most common AIDS-associated cancer in the United States in 1990–1995, and it was associated with a 53,000-fold higher risk compared to the general population (Engels et al. 2006). AIDS-associated KS generally presented with purple or black cutaneous lesions but also frequently with organ involvement, especially among those with advanced immunodeficiency. Survival prior to antiretroviral treatment was at most 12–18 months (Bower et al. 2006) and for the cases with extensive involvement of internal organs and concurrent opportunistic infections, prognosis was particularly poor.

Epidemiological studies documented an association of epidemic KS with high rates of sexual partner exchange, coincident sexually transmitted

infections (particularly oral gonorrhea), anal intercourse, fecal-oral exposure [particularly oral anal insertive sex (rimming)], fisting (insertion of the hand into the partners rectum), usage of nitrite (a smooth muscle relaxant used to facilitate anal sex), and contact of KS cases with a sex partner from the New York and San Francisco epicenter. These associations, plus a discordance in KS rates between MSM compared to those who acquired AIDS through parenteral [transfusion (4%) and injection drug use (10%)] and perinatally (3%) (Mbulaiteye et al. 2003), supported the hypothesis that a sexually transmitted factor independent of HIV was responsible.

Human herpesvirus 8 (HHV-8), also known as Kaposi sarcoma-associated herpesvirus (KSHV), was discovered by Chang and Moore in KS lesions, and this virus is now established as the causative agent of KS. Epidemiological analyses established that HHV-8 is a necessary but not sufficient cause of KS, based on cross-sectional and longitudinal studies of MSM that documented

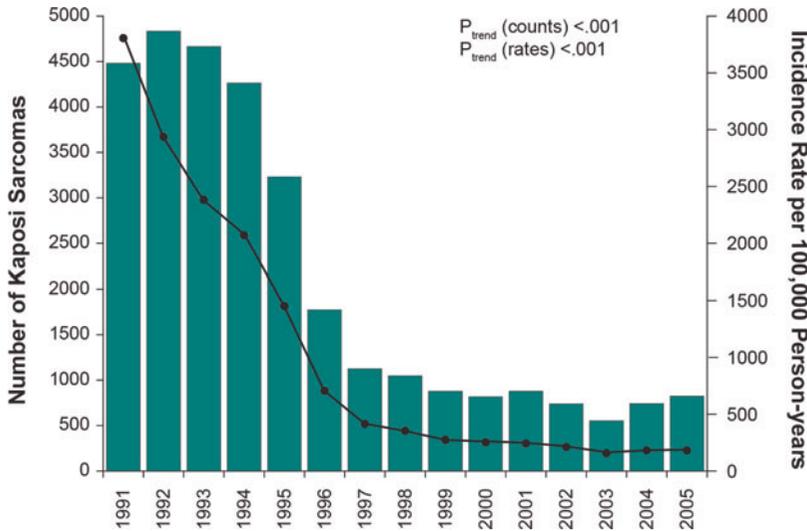

that all AIDS-associated KS cases were HHV-8 positive. Also, these studies revealed that a substantial fraction of MSM, especially in the New York and San Francisco epicenters, were carriers of the virus. Seroepidemiological studies further documented that not only was HHV-8 linked to AIDS-associated KS but that HHV-8 is also detected in cases with classic, endemic, and iatrogenic KS. By contrast, the prevalence of HHV-8 infection was low in blood donors in the United States. To better understand the complex epidemiological relationship between HIV and HHV-8, several epidemiological studies documented that anal-related sexual activities were independent risk factors for the acquisition of both viruses, confirming the hypothesis that co-epidemics of HIV and HHV-8 accounted for the emergence of AIDS-associated KS. These co-epidemics were most prominent in the New York and San Francisco epicenters, and this pattern explained the association with sexual contact with someone from New York or San Francisco as a risk factor for KS in populations outside of the New York and San Francisco areas. In summary, both HIV and HHV-8 share some overlapping risk factors, particularly fecal-oral exposure for HHV-8 and the closely related penile-anal exposure for HIV.

The AIDS-associated KS epidemic in Africa has a different epidemiological pattern, essentially reflecting the superimposition of HIV upon an existing endemic pattern of HHV-8 infection that drives the occurrence of endemic KS. Epidemiological data suggest that in this setting, HHV-8 was highly prevalent before the AIDS epidemic and like other herpesviruses is associated with oral exposure resulting from poor hygiene and practices such as pre-mastication of food during infant feeding common in the African setting. The sexual risk factors detected in the African KS setting (e.g., high rates of sexual partner exchange, commercial sex worker exposure, etc.) are associated with the acquisition of HIV infection rather than with the acquisition of HHV-8. This superinfection with HIV in an HHV-8-infected person and its attendant HIV-induced immunosuppression accelerates and amplifies the imposition of epidemic KS on a background of endemic KS.

Epidemiology of Kaposi Sarcoma After HAART

As shown in Fig. 1, the phase 1 decline in KS incidence commencing in 1986 likely represented the rapid expansion of AIDS beyond the original epicenters with high rates of HHV-8, changes in sexual behaviors, and modest impacts of early mono and dual antiretroviral HIV therapy. A more dramatic declination occurred in 1994–1996 (Fig. 1) in the United States coincident with the introduction of the highly active antiretroviral therapy (HAART), a pattern observed in other populations when effective treatment was implemented. In the Multicenter AIDS Cohort Study (MACS) of MSM, the incidence of KS declined by 87% in the post-HAART era (1996–2007) as compared to the pre-HAART era (1984–1995) (Seaberg et al. 2010). In the Swiss HIV Cohort study, the standardized incidence rates of KS declined from 1375 to 67 per 100,000 in 1985–1996 and 2002–2006 periods, respectively (Franceschi et al. 2010). Similarly, the incidence rate of KS declined significantly from 15.2 to 4.9 per 1,000 person-years in the 1992–1996 and 1997–1999 periods, in a collaborative study of 23 prospective studies from North America, Europe, and Australia (International Collaboration on HIV and Cancer 2000). HAART was also associated with improved survival of KS. The mortality rate from KS decreased fourfold for persons with AIDS and nearly 70% of persons survived up to 3 years (Simard et al. 2010; Spagnuolo et al. 2012).

Regardless of these improvements, individuals continue to present with AIDS-associated KS (Fig. 2). KS is currently associated with a 3,640-fold higher risk in HIV-infected individuals compared to the general population (Engels et al. 2006). KS has been documented in individuals with failing HAART, individuals with immune reconstitution inflammatory syndrome after initiating HAART for the first time, and those who have steady suppressed HIV viral loads and relatively high CD4⁺ T cells. Children diagnosed with AIDS before the age of 14 years have significantly elevated risk of developing KS in the post-HAART era as compared to the general

Epidemiology of AIDS-Defining Malignancies, Fig. 2 Cancer burden of Kaposi sarcoma among people living with AIDS in the United States during 1991–2005. **Bars** depict estimated counts (i.e., number of cancers) and **points connected by lines** depict the incidence rates standardized to the 2000 US AIDS population by age group,

race, and sex. Trends in cancer counts and rates were estimated with linear regression. Two-sided *P* values were calculated using the χ^2 test (Shiels MS, et al., Cancer Burden in the HIV-Infected Population in the United States, *J Natl Cancer Inst*, 2011, 103(9):753–762, by permission of Oxford University Press)

population. The current risk of AIDS-associated KS remains elevated, even though the risk has decreased significantly since the pre-HAART era.

Risk factors associated with KS in the post-HAART era primarily include low CD4 cell counts and high plasma HIV RNA levels. In particular, low CD4⁺ T cell counts (<50 cells/ μ l) were associated with an increased risk of KS for those taking HAART in the Swiss HIV Cohort (Franceschi et al. 2008). Additional risk factors specific to the post-HAART era include older age and immune reconstitution inflammatory syndrome (IRIS). HIV-infected individuals may be surviving longer and becoming at risk of KS independent of restored immunity from HAART. With IRIS, there is a transient increased incidence of KS after initiation of therapy independent of current CD4 counts. Starting HAART in a proportion of treatment-naïve individuals may stimulate a heightened inflammatory response that induces KS, perhaps in part, by provoking HHV-8 activation from latent to active gene expression. The relationship between HIV-related immune suppression and HHV-8 activation is dynamic, and understanding the relevance of the current risk

factors, such as age and IRIS, may be better understood at a molecular rather than population level.

More recently, host and viral cofactors are emerging as recognized factors in the development of KS. Molecular epidemiological studies suggest that polymorphisms in host genes involved with inflammation or immune responses are associated with a slightly increased risk of KS. Host factors include a positive association between KS and substitution of phenylalanine for glycine at position 13 in the HLA-DRB1 locus, suggesting a role for immunogenetic factors. Also, a specific polymorphism in the IL-8 promoter (TT is protective versus AT) is associated with both the occurrence and severity of KS. Additional host factors include a decrease in NK cells and immune activation measured by elevated cytokine levels.

A number of HHV-8 genes have functions that can promote tumorigenesis. Like other herpesviruses, HHV-8 has “picked up” host genes that encode for key cell cycle regulatory genes (e.g., human complement-binding protein, IL-6, BCL-2, cyclin-D, FLICE inhibitory protein

(FLIP)) and some DNA altering genes (e.g., dihydrofolate reductase, thymidine kinase, thymidylate synthetase, and DNA polymerase). These “accessory” genes are thought to be integral to KS oncogenesis on the molecular level. HIV-1 itself has a viral protein, Tat (trans-activating factor) that may synergize with HHV-8 to foster angiogenesis and disease progression and promote tumor survival. The potential synergistic effect of host and viral cofactors on KS progression may further disrupt immune control of HHV-8 and explain the more advanced clinical state of KS among HIV-1-infected individuals as compared to immunosuppressed organ transplant recipients.

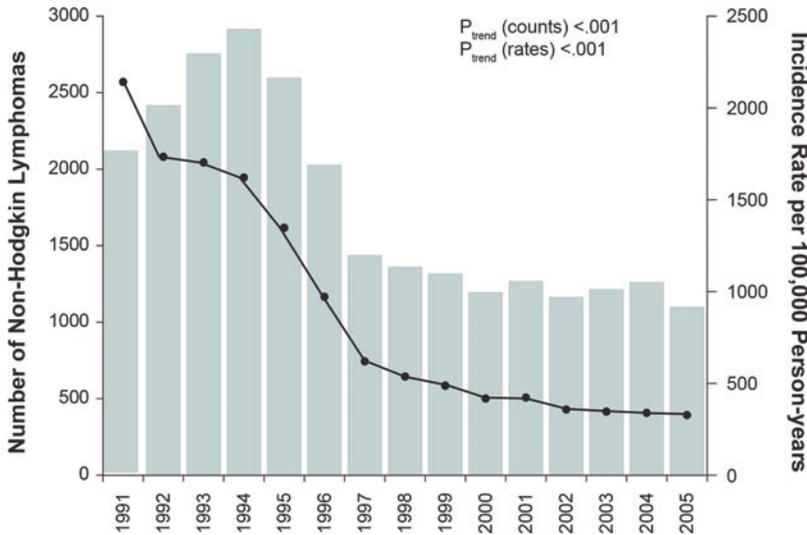

An emerging risk factor in the post-HAART era is ineffective treatment. Ineffective HAART may be the result of poor adherence resulting in insufficient immune restoration and the development of drug resistant strains. Ineffective therapy may also be associated with interrupted treatment. In the Swiss HIV Cohort study, the absence of antiretroviral therapy (ART) for 3 months was associated with an eightfold increased risk of KS (Franceschi et al. 2008). In a randomized clinical trial, KS incidence was higher among those with intermittent therapy as compared to those on continuous therapy (Silverberg et al. 2007). These relapses in HIV viremia may have a direct effect on viral and host interactions, ultimately altering host susceptibility to KS disease progression.

Epidemiology of Non-Hodgkin Lymphoma (NHL) Before HAART

NHL was the second most common cancer early in the AIDS epidemic and it was included as an AIDS-defining illness by the Centers of Disease Control (CDC) in 1985. The background prevalence of NHL in the United States prior to the AIDS epidemic was much higher than KS, so incidence trends were not as striking. In a period analysis, the incidence of NHL from 11 regions in the United States in the Surveillance, Epidemiology, and End Results (SEER) Program was 21.1 per 100,000 white men in 1995 as compared to

10.4 per 100,000 white men in 1973 (Mbulaiteye et al. 2003). For those with HIV infection, the incidence of NHL was 60–200 times higher as compared to HIV-negative individuals (Bower et al. 2006). 5–10% of all HIV-infected individuals were expected to develop lymphoma as either the first or subsequent AIDS-defining malignancy (Hamilton-Dutoit et al. 1991). Overall survival from NHL was worse than KS, less than a year (Bower et al. 2006).

AIDS-related lymphomas (ARL) are cancers of the lymphatic system. These NHL are predominantly of B-cell origin and intermediate- to high-grade malignancies and often have extensive extranodal involvement, such as the central nervous system. The prevalence of high-grade malignancy is much higher among AIDS patients (80–90%) as compared to HIV-uninfected individuals (10–15%) (Levine 1993). They occur late in HIV infection, and in general, their incidence is not affected by a transmission group or geographic region in the United States. Women have a slightly lower incidence of ARL, but that is similar to the gender distributions of lymphomas in HIV-uninfected individuals. The strongest risk factors are duration of HIV infection, low CD4⁺ T cell counts at lymphoma diagnosis, and having a prior AIDS-defining illness. Of the 35 different histological types of NHL, four are associated with AIDS-defining malignancies by the 1985 definition of the Centers for Disease Control: ► **Diffuse Large B-cell Lymphoma (DLBCL)** with centroblastic features; DLBCL with immunoblastic features; primary central nervous system lymphoma (PCNS); and Burkitt’s lymphoma (BL). The nomenclature for lymphomas has changed since then, and while it is hard to map the DLBCL in the 1985 nomenclature to the current lymphoma types, it is generally accepted that DLBCL of either the germinal center subtype or activated B-cell subtype can be considered AIDS defining. Three additional lymphomas that rarely occur in immunocompetent patients but are more specific to HIV infection are ► **primary effusion lymphoma (PEL)**, ► **plasmablastic lymphoma** (often of the oral cavity), and large B-cell lymphoma arising in HHV-8-associated ► **multi-centric Castleman’s disease**. About 70% of the

Epidemiology of AIDS-Defining Malignancies, Fig. 3 Cancer burden of non-Hodgkin lymphoma among people living with AIDS in the United States during 1991–2005. Bars depict estimated counts (i.e., number of cancers) and points connected by lines depict the incidence rates standardized to the 2000 US AIDS population by age

group, race, and sex. Trends in cancer counts and rates were estimated with linear regression. Two-sided P values were calculated using the χ^2 test (Shiels MS, et al., Cancer Burden in the HIV-Infected Population in the United States, *J Natl Cancer Inst*, 2011, 103(9):753–762, by permission of Oxford University Press)

ARL are of the DLBCL histological type which also includes variants or subtypes such as PCNS, PEL, and plasmablastic lymphoma.

► **Epstein-Barr virus (EBV)**, which had previously been identified as an etiologic agent of certain lymphomas, is a major contributor to AIDS-related lymphoma. EBV is ubiquitous in the general population and it has been associated with transplant-related lymphomas and primary immunodeficiency-associated lymphoma. Another oncogenic virus more recently linked to NHL is HHV-8, which like EBV, is specifically associated with a subset of AIDS-associated lymphomas. EBV occurs in 30% of centroblastic DLBCL, 90% of immunoblastic DLBCL, 100% of PCNS, 30–50% of Burkitt-like lymphoma, and 50% of plasmablastic lymphoma (Carbone 2003). Primary effusion lymphoma is associated with both EBV (about 80%) and HHV-8 (100%) (Carbone 2003). With varying prevalence of oncogenic viruses, no clear transmission patterns, and a multitude of host and viral risk factors, the only common risk among the ARL is HIV-related immunosuppression. Fortunately, for those who

were most susceptible to NHL, HAART significantly changed the incidence of the disease.

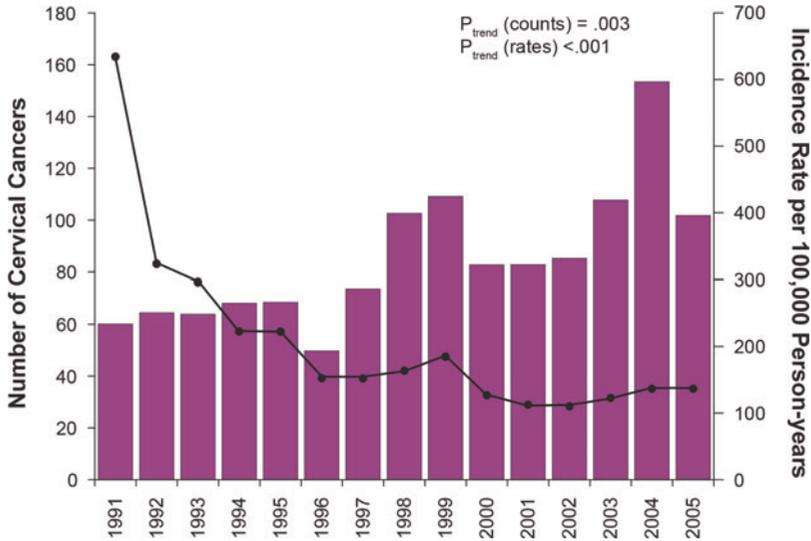

Epidemiology of Non-Hodgkin Lymphoma After HAART

Upon the introduction of HAART, the incidence of NHL declined in the United States, but not as dramatically as KS (Fig. 1). Further, unlike KS, which showed a biphasic decline, the decline for ARL was only observed during the 1994–1996 period when HAART was introduced (Fig. 3). In the Multicenter AIDS Cohort Study (MACS) of MSM, the incidence of NHL declined by 77% in the post-HAART era (1996–2007) as compared to the pre-HAART era (1984–1995) (Seaberg et al. 2010). In the Swiss HIV Cohort study, the standardized incidence rates of NHL declined from 952 to 98.4 per 100,000 in the 1985–1996 and 2002–2006 periods, respectively (Franceschi et al. 2010). Similarly, the incidence rate of NHL declined from 6.2 to 3.6 per 1,000 person-years in the 1992–1996 and 1997–1999 periods,

respectively, based on a collaborative study of 23 prospective studies from North America, Europe, and Australia (International Collaboration on HIV and Cancer 2000). In looking more specifically at the histological types that comprise ARL, HAART has been particularly effective at reducing the incidence of PCNS and immunoblastic DLBCL, but it appears to have less impact on the incidence of Burkitt's lymphoma. Both mortality and survival improved for NHL in the post-HAART era, but the changes were more gradual. NHL mortality rate decreased twofold for persons with AIDS and about 56% had an overall survival of 3 years with HAART and improved lymphoma therapies (Simard et al. 2010; Spagnuolo et al. 2012). HIV-positive individuals continue to present with NHL (Fig. 3) and are at a 23-fold increased risk compared to the general population (Engels et al. 2006). In several recent studies in the United States and Europe, NHL has emerged as the most common AIDS-associated malignancy. For example, in a record linkage study that evaluated the cumulative incidence of all cancers across the pre- and post-HAART eras, NHL surpassed KS as the most prevalent cancer in the post-HAART era (Simard et al. 2011). One risk factor in the post-HAART era driving this increase is a larger and aging AIDS population. The AIDS population has grown fourfold and is comprised of a higher proportion of individuals aged 40 years or older (Shiels et al. 2011). For those on HAART, older age (45 years+) is independently associated with a threefold increased risk of NHL (Polesel et al. 2008). Cases currently present with the same stages of disease as seen early in the epidemic, but they are older, less likely to have a prior AIDS diagnosis, and have a higher CD4⁺ T cell count at NHL diagnosis. As a result, current epidemiological studies have focused less on markers of immune suppression and more on the molecular markers of pathogenesis to better understand the risk factors in the post-HAART era.

Studies of archived pre-lymphoma samples from the Multicenter AIDS Cohort Study (MACS) document that several markers of immune function are altered years before the

AIDS-associated lymphoma development. CXCL13 (a chemokine promoting B-cell chemotaxis) is significantly elevated particularly among EBV-negative compared to EBV-positive cases (Husain et al. 2010). CD23 (a B-cell stimulatory factor), IgE, IL-6, CD27, and IL-10 as well as the IL-10 promoter 592 C/C genotype are all elevated a year or more before lymphoma development compared to age and immune status matched controls, demonstrating underlying markers of immune activation associated with future risk for HIV-associated lymphoma (Breen et al. 2011). An emerging risk factor in the post-HAART era is HIV viral replication as measured by cumulative or intermittent viremia (linked to treatment interruption) (Silverberg et al. 2007; Zoufaly et al. 2009). Recent epidemiological studies have found that HIV may upregulate activation-induced cytidine deaminase (AID) prior to NHL diagnosis. AID's normal function is to promote hypermutation of immunoglobulin genes associated with increasing affinity of the antibody during the normal development of memory B cells and to promote class switching of antibody isotypes (i.e., IgM to IgG). The genetic modifications induced by AID sometimes lead to mistakes, such as chromosomal translocations or point mutations in immunoglobulin and/or oncogenes. The chromosomal translocations of the c-MYC gene common in HIV-associated Burkitt's lymphoma may be related to this upregulation of AID. Other early genetic modifications in HIV-related lymphomas include alterations of the BCL-6, a transcription repressor gene, and point mutations or deletions in proto-oncogenes (Ras) and tumor suppressor genes (P53) (Carbone 2003). The decreased functionality of EBV-specific CD4⁺ and CD8⁺ T lymphocyte cells affects the cell-mediated responses necessary to control reactivation and replication of EBV-associated lymphomas. Any combination of these risk factors may have a multiplicative effect on developing NHL. While the pattern of HIV-associated lymphomas has changed in the post-HAART era (Fig. 3), there remains the paradox of emerging lymphoma risk particularly for some histological types not previously linked to HIV, such as certain T-cell

Epidemiology of AIDS-Defining Malignancies, Fig. 4 Cancer burden of cervical cancer among people living with AIDS in the United States during 1991–2005. **Bars** depict estimated counts (i.e., number of cancers) and **points connected by lines** depict the incidence rates standardized to the 2000 US AIDS population by age group,

race, and sex. Trends in cancer counts and rates were estimated with linear regression. Two-sided P values were calculated using the χ^2 test (Shiels MS, et al., Cancer Burden in the HIV-Infected Population in the United States, *J Natl Cancer Inst*, 2011, 103(9):753–762, by permission of Oxford University Press)

lymphomas. In summary, lymphoma remains a major cause of mortality among HIV-infected patients even in the HAART era.

Epidemiology of Cervical Cancer Before and After HAART

Invasive cervical cancer occurring in HIV-infected women was added as an AIDS-defining condition in 1993. Its inclusion at that time was somewhat controversial, as the incidence of cervical cancer was not substantially increased in AIDS patients. However, the increase in cervical cancer in HIV-infected patients has since become more apparent. It takes approximately 10–15 years for a cervical abnormality to become invasive, and during those years, it progresses through the stages of cervical intraepithelial neoplasia (CIN 1,2,3). The benefit of HAART in delaying the progression of HPV disease in HIV-infected women remains unclear. As seen in Fig. 4, the pattern of HIV-associated cervical cancer differs from the patterns for KS and NHL where in the

pre-HAART era, rates were exceptionally high and declined after the introduction of HAART. In the case of HIV-associated cervical cancer, the initially high incidence rate in the early 1990s may be attributed to a lack of regular screening and management of abnormal Pap smears in HIV-infected women. As screening and treatment of precursor lesions improved, the incidence rate stabilized. HIV-infected women compared to the general population maintained a similar risk of cervical cancer through the introduction of HAART (1990–1995, SIR:4.2; 1996–2002, SIR:5.3) (Engels et al. 2006). The 5-year cumulative incidence of cervical cancer in the post-HAART era (0.64%, 1996–2006) is similar to the pre-HAART era (0.63%, 1980–1989; 0.73%, 1990–1995) among those living with AIDS (Simard et al. 2011). Additionally, a collaborative study of 23 prospective studies from North America, Europe, and Australia found no change in the incidence of cervical cancer in the post-HAART era (International Collaboration on HIV and Cancer 2000). HAART appears to have had little or no impact on the incidence of cervical cancer so far,

and HIV-infected women remain at an elevated risk of developing the disease. However, it is possible that HAART may in the future be found to have effects on cervical cancer after a number of years.

For HIV-infected women who do develop cervical cancer, the disease is more aggressive, develops at a younger age with more advanced disease that relapses after treatment (Pantanowitz and Michelow 2010). AIDS-defining cervical cancer progresses more rapidly and has a worse median survival compared to cervical cancers among HIV-negative women (Bower et al. 2006). The aggressive nature of cervical cancer in HIV-infected individuals would suggest that HIV-related immunosuppression may play a role in disease progression. However, HAART has had little impact on the incidence or progression rates of cervical lesions (Bratcher and Sahasrabudde 2010). Declining levels of CD4⁺ counts have not been shown to be a strong risk factor for disease progression. This is further supported by the observation that there is no difference in the severity of neoplasia in women with asymptomatic HIV as compared to women with AIDS (Clarke and Chetty 2002). It is possible that oncogenic changes that result in genetically unstable precancerous lesions determine progression rates independent of any restored immunity from HAART. There is also the possibility that the inconsistent findings in the prior research have been biased by the variability in cervical detection methods, follow-up time, duration of HAART, and small numbers of incident cases of cervical cancer.

The strongest risk factor for cervical cancer is the persistent infection of high-risk types of the sexually transmitted virus, human papillomavirus (HPV). Human papillomavirus is comprised of at least 40 different genotypes that infect the genital tract, 15 of which are considered high oncogenic risk. Genotypes HPV 16 and HPV 18 carry the highest risk and account for nearly 70% of cervical cancers in the United States. HPV is highly transmissible particularly among younger women at sexual debut where an immunologically naïve host first experiences viral exposure. Risk factors associated with HPV acquisition include a lifetime number of sexual partners, frequency of sex, partner's sexual history and behavior, parity, hormonal

contraception, smoking, HIV, and other sexually transmitted infections. For most women, nearly 90% of the infections are cleared by cell-mediated immunity within 2 years. For those coinfecting with HIV, the course of HPV disease differs significantly.

HIV-infected women have a higher incidence, prevalence, and number of concurrent HPV infections than HIV-negative women, and this is compounded by the sexual risk factors shared between HIV and HPV. Cervical HPV infection persists longer in HIV-infected women and has a higher probability of progressing from low- to high-grade lesions. The regression rates of low-grade cervical lesions decrease from 60% in uninfected women to 27% in HIV-infected women (Clarke and Chetty 2002). The burden of HPV infections increases as CD4 counts decline and HIV-1 viral loads increase. It is believed that selective depletion of effective CD4⁺ T cells results in poor responses by local CD8⁺ T cells in promoting clearance or regression of HPV (Clarke and Chetty 2002). A decrease in Langerhans cells in the cervical epithelium where HPV resides results in fewer numbers of antigen-presenting cells needed to activate a cell-mediated response (Clarke and Chetty 2002). HIV may also release viral proteins, such as Tat, in the local environment that can enter cells and interfere with the repair of DNA double-strand breaks resulting in mutations and genetic instability (Nunnari et al. 2008). Tat may also activate gene transcription which may not be specific to the host or virus. Tat has been found to increase expression of early HPV genes that promote cell cycle progression (Clarke and Chetty 2002). Further studies of novel cofactors, such as HIV viral proteins, are needed to understand malignant transformation and development of cervical cancer. Any restored immunity from HAART may be too late depending on when therapy is initiated relative to the oncogenic events occurring with HPV.

Central to HPV's oncogenic potential are two viral gene products, viral proteins termed E6 and E7 that increase cell proliferation, immortalization, and transformation. The E6 protein, particularly from HPV 16 and HPV 18, is efficient at binding the tumor suppressor protein p53, leading to degradation. Loss of p53 prevents DNA repair

and apoptosis and allows cell cycle progression regardless of any DNA damage. The E6 protein also increases telomerase activity and promotes cell immortalization. The E7 protein binds and inactivates another tumor suppressor, retinoblastoma gene protein (pRB), resulting in activation of gene transcription and cell cycle progression. Unlike low-risk HPV types that are not associated with precancerous lesions, high-risk types are more likely to integrate HPV's episomal chromosome into the host DNA. This disrupts a regulatory gene, viral E2, resulting in overexpression of E6 and E7 proteins. Viral integration confers an advantage of cell cycle progression, but it is not in itself sufficient for malignant transformation. The majority of invasive cancers, particularly for HPV 18, have integrated HPV genomes, but there are still a proportion of invasive cervical cancers with episomal genomes. Recently, HPV DNA methylation has been described as a potential biomarker that may be able to distinguish the HPV infections that will progress to precancerous lesions (Clarke et al. 2012). HPV has conserved sites of CpG that when methylated by the host cell's DNA methyltransferase may, by mechanisms that are not completely understood, promote pathogenesis. Increased methylation in the capsid genes, L1 and L2, has been associated with increased risk of CIN2+ lesions (Clarke et al. 2012). However, methylation of the promoter and enhancer regions upstream of E6 is mixed, and further studies are needed (Clarke et al. 2012). As more studies explore the epigenetic changes in precancerous lesions, the role of HIV and the host's genetic background in enhancing HPV infection will be better understood. In summary, HIV is a strong risk factor for more aggressive cases of cervical cancer, but widespread use of HAART so far appears to have little effect on the incidence, progression, or mortality rates of cervical cancer.

Conclusion

Most studies evaluating the changes in morbidity and mortality of AIDS-defining malignancies across calendar time rely on record linkage studies. This is an effective way to evaluate the cumulative effect of changing treatment strategies on cancer

risk, given the power of the large sample sizes. A number of studies have shown that HAART on a population level has significantly decreased the rates of KS and NHL but has had little impact on cervical cancer. However, cancer is a leading cause of death "in the United States" among HIV-infected individuals. Further studies that evaluate HAART on the level of the individual are needed to identify molecular factors involved with the pathogenesis of these different malignancies. More specifically, studies need to evaluate the role of HIV and its viral proteins in driving lytic replication in KS, somatic hypermutations and chromosomal translocations in NHL, or early gene expression in cervical cancer. A common theme across all these malignancies is that they often present with more aggressive cases during HIV infection. Therefore, cohort studies that dive deeper into the molecular interactions will offer new insights into the continued burden of AIDS-defining malignancies and potentially lead to new therapies and prevention measures in the current era of HAART.

Definition

HIV-2 is mainly prevalent in West Africa, where an estimated 1–2 million people are infected. It is a rare infection elsewhere. From the eight known HIV-2 groups, only group A and B have established themselves as ongoing endemics in

populations. Guinea-Bissau is thought to be the nucleus of the HIV-2 epidemic. HIV-2 has been able to spread there, probably through iatrogenic spread and increased sexual risk behavior between 1950 and 1970. Few studies have investigated risk factors for acquiring HIV-2 infection, but sexual behavior and increased mobility have been associated with HIV-2 infection. In most populations, the highest HIV-2 prevalence is observed in women older than 45 years. Mortality is lower for HIV-2 than for HIV-1 infection, because many infected individuals have low viral loads. The Unusually low viral load is also the reason for the lower transmission rates compared to HIV-1. The HIV-2 epidemic in West Africa has been declining since the mid-1980s, while HIV-1 prevalence increased. The rise of HIV-1 may have impacted on the decline of HIV-2. HIV-2 remains a public health problem in West Africa, and understanding this virus may also help us to increase our understanding of both HIV-2 and HIV-1.

Introduction

In 1986, three years after HIV-1 was first isolated, a very similar virus was isolated from two AIDS patients from Guinea-Bissau and Cape Verde. This virus was found to be approximately 40% genetically homologous to HIV-1 (Guyader et al. 1987) and therefore was assigned a different name: HIV-2. The source of HIV-2 was the simian immunodeficiency virus (SIV) from sooty mangabeys, small monkeys that are indigenous to West Africa.

The most important difference between HIV-1 and HIV-2 is that a large proportion, perhaps around 50%, of HIV-2-infected persons controls the virus and remains asymptomatic, while an untreated HIV-1 infection almost always leads to AIDS. Those with HIV-2 who do experience disease progression develop similar symptomatology as HIV-1-infected people. The highest prevalence of HIV-2 has been reported in Guinea-Bissau in the 1980s: 8% in the adult population. By 2007 this had declined to 4% (van Tienen et al. 2010). Substantial declines in HIV-2 prevalence have

been observed in all countries with HIV-2 epidemics, so HIV-2 is an epidemic in decline. Yet, HIV-2 remains an important public health problem. Based on the reported adult prevalence by country and the adult population size of these countries, an estimated 1 to 2 million adults are infected (based on the highest published prevalence data from countries and World Bank data on population size by country). Thus, HIV-2 has caused and still causes a sizeable burden of morbidity and mortality. By studying the natural course of HIV-2 infections in individuals and of HIV-2 epidemics in populations, we may increase our understanding of the pathogenesis of HIV in general and find new ways of preventing and controlling these infections.

HIV-2 Groups

HIV-2 can be divided into eight groups (formerly referred to as subtypes) based on phylogenetic studies based on the genetic differences between the strains: group A to group H (Damond et al. 2004). Each group represents a separate cross-species transmission. HIV-2 group A is most prevalent in the western part of West Africa (e.g., the Gambia, Senegal, and Guinea-Bissau) and group B in the eastern part of West Africa (e.g., Cote d'Ivoire and Nigeria). HIV-2 groups C to H have not established themselves in populations, and only sporadic cases of these HIV-2 groups have been described in individuals from Liberia, Sierra Leone, and Cote d'Ivoire. The groups C, D, E, F, and H viruses were isolated from persons suffering from symptoms compatible with AIDS. Subtype G was isolated from an asymptomatic blood donor in Cote d'Ivoire. This suggests that most of the HIV-2 groups are pathogenic. It is not known why only groups A and B have successfully established epidemics.

Transmission

HIV-1 and HIV-2 share the same routes of transmission: sexual, mother to child, and via blood or

blood products. The rate of transmission is much lower for HIV-2. In HIV-2 infection, the concentration of virus in the blood (viremia) is generally several logs lower than in HIV-1 infection. A high proportion of people infected with HIV-2 – estimates vary between 30% and 60% – have very low levels of viremia (<100 copies/ml). When viremia is low, the concentration of virus in semen and cervical secretions is also low; therefore, a low viremia indicates a low transmission risk (Gottlieb et al. 2006). It has been estimated that the heterosexual transmission risk is one fifth of that of HIV-1 and that the risk of vertical transmission is one sixth of that of HIV-1 (4% vs. 25%).

Risk Factors

Two important considerations have to be taken into account when assessing the risk factors or associations with HIV-2. First, the risk factors are likely to have changed over time. Iatrogenic spread and blood transfusions may have played an important role during the initial spread, but probably did not contribute significantly to transmission after 1980. Second, due to its low incidence, few studies have been able to prospectively study risk factors, i.e., characteristics or behavior of people preceding HIV-2 acquisition.

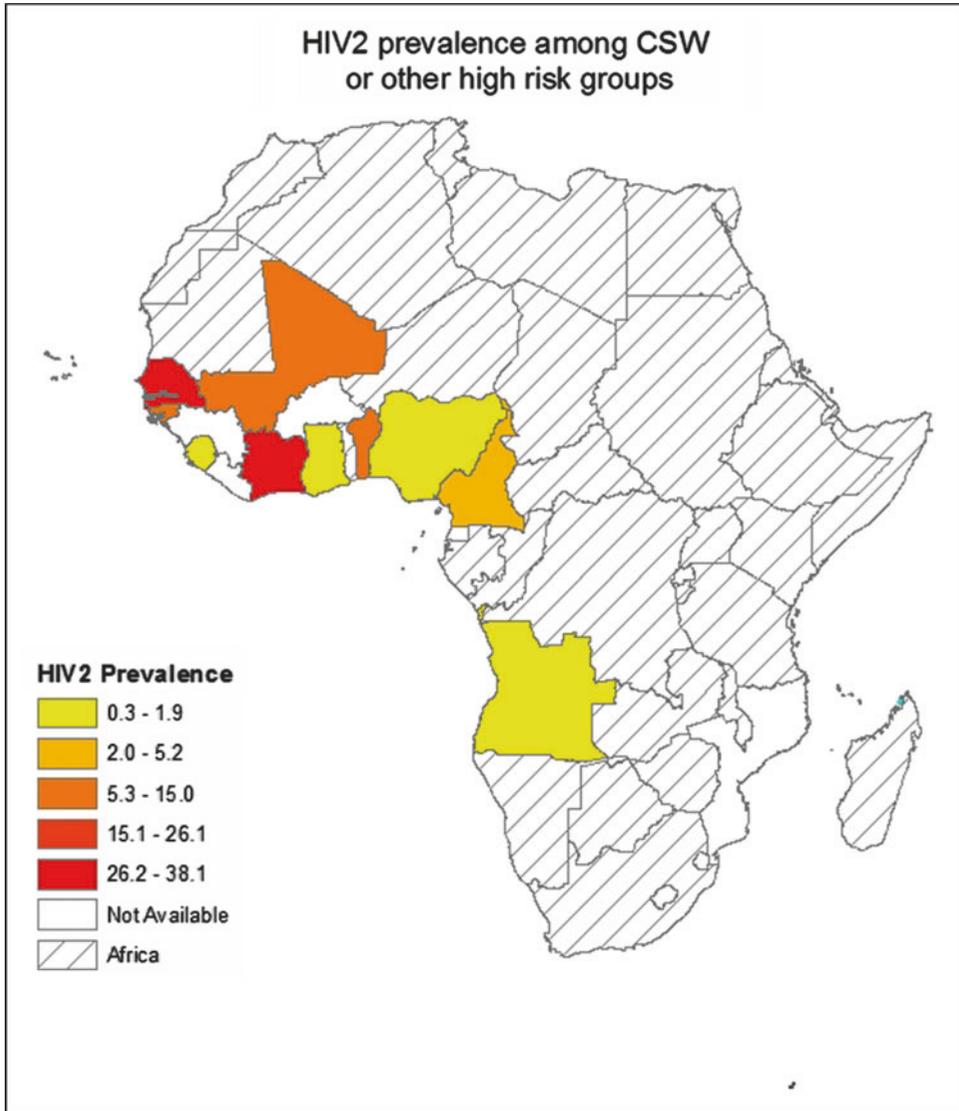

Cross-sectional studies found that HIV-2 infection was associated with having received multiple injections, having been hospitalized, and having undergone ritual excision (in women), suggesting iatrogenic spread. Also, having had sex with a white man, having had extramarital sex, or having worked as a female sex worker (FSW) were associated with HIV-2 in women, which is in line with heterosexual transmission (Poulsen et al. 2000). In studies among younger persons, and thus including more recent HIV-2 infections, a history of travelling and having had genital ulcers, vaginal discharge, or serological evidence of syphilis were associated with HIV-2 infection. These risk factors are also seen in HIV-1 infection and indicate sexual transmission.

Geographical Distribution of HIV-2

The first cases of HIV-2 infection were described in persons from West Africa. Large studies conducted in the late 1980s and the early 1990s confirmed that West Africa, and specifically Guinea-Bissau, was the center of the HIV-2 epidemic. Testing of archived blood samples collected in 1980 in Guinea-Bissau showed antibodies against HIV-2, indicating that the virus must have circulated in the population at that time. A few case reports suggest that some persons were already HIV-2 infected as early as the 1960s in Guinea-Bissau (Pepin 2011). Based on sequence data of the HIV-2 genome (notably of the *env*, *pol*, and *gag* genes), molecular clock analyses have estimated that the introduction of HIV-2 into the human population in West Africa occurred approximately between 1932 and 1962. HIV-1 (subtype CRF02_AG) was introduced later into West Africa, estimated between 1957 and 1986 (de Silva et al. 2012; Lemey et al. 2003).

After the discovery of HIV-2, several countries reported cases of HIV-2 infection and surveys among high-risk populations, pregnant women, and the general population were conducted (Figs. 1, 2, and 3, based on information from a review by de Silva et al. (2010) and updated with more recent data). Guinea-Bissau reported the highest prevalence of HIV-2, 8% in the adult population. The prevalence reached almost 20% in persons older than 45 years old. HIV-2 prevalence is higher in high-risk groups such as female sex workers, tuberculosis patients, or patients attending sexually transmitted diseases (STD) clinics (Fig. 1). For example, in the Gambia in 1993–1995, 22% of female sex workers were HIV-2 infected, while the prevalence among pregnant women was only 1%.

Guinea-Bissau was a colony of Portugal between the early sixteenth century and 1975. HIV-2 has been mostly reported from West Africa, but also in countries outside West Africa which have historical links to Portugal, i.e., Mozambique, Angola, Brazil, and India. The highest prevalence of HIV-2 in Europe has been found in Portugal, with approximately 2,000 cases

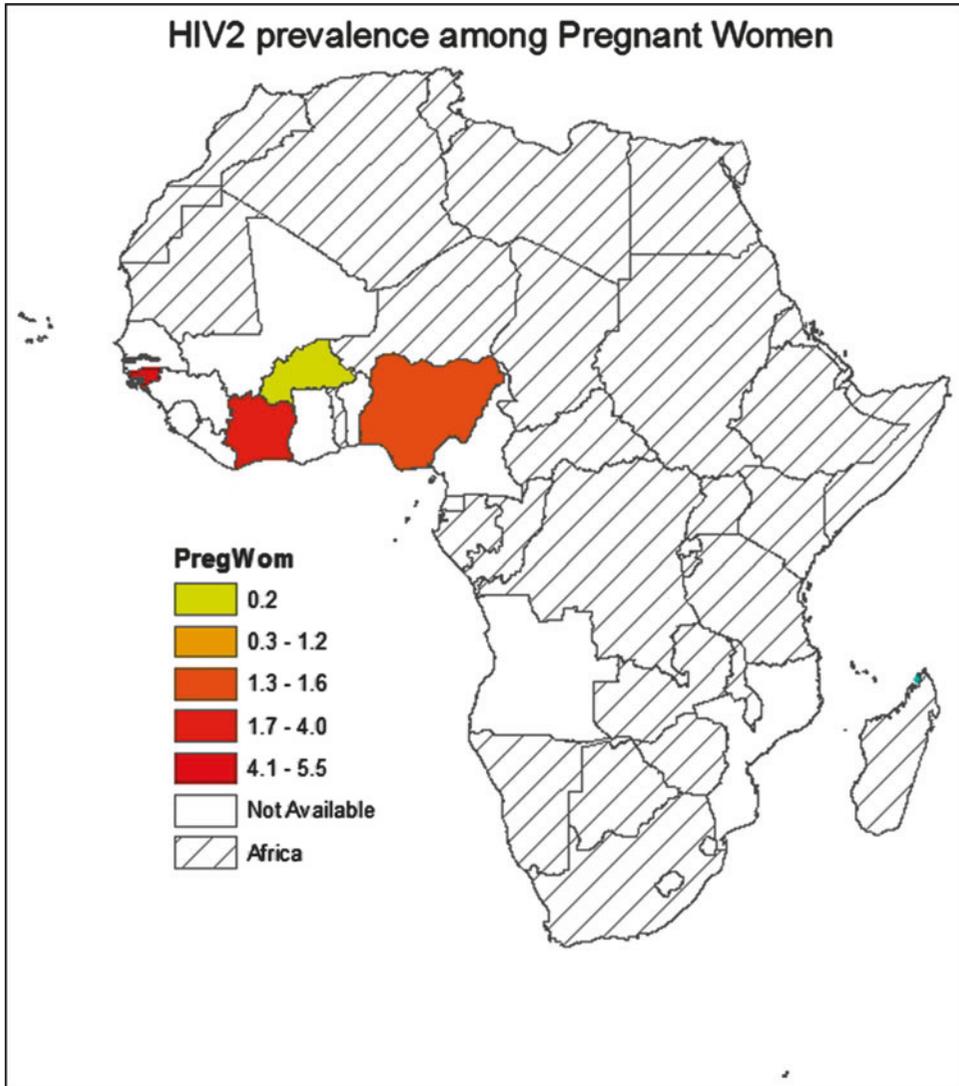

Epidemiology of HIV-2 Infection in West Africa, Fig. 1 Seroprevalence of HIV-2 among female sex workers or other high-risk groups in Africa, by country. Prevalences shown in this figure are the highest prevalences that have been reported for each country. HIV-1/HIV-2 dual infections are included in the HIV-2

prevalence. *White areas* (without stripes) indicate countries where HIV-2 infections have been reported, but no prevalence data are available (Thanks to Dr Mirjam Bakker (Royal Tropical Institute, Amsterdam, the Netherlands) for making Figs. 1, 2 and 3)

reported so far. HIV-2 was mainly found in repatriates and soldiers from the colonial wars in Guinea-Bissau, Angola, and Mozambique, in persons originating from West Africa, or in persons who had sexual partners from West Africa. Genetic studies of HIV-2 corroborate historical

links and epidemiological observations between countries: there is phylogenetic evidence for transmission of HIV-2 between persons from Senegal and Cote d'Ivoire and France and between persons from Guinea-Bissau and Cape Verde and Portugal.

Epidemiology of HIV-2 Infection in West Africa, Fig. 2 Seroprevalence of HIV-2 among pregnant women in Africa, by country. Prevalences shown in this figure are the highest prevalences that have been reported

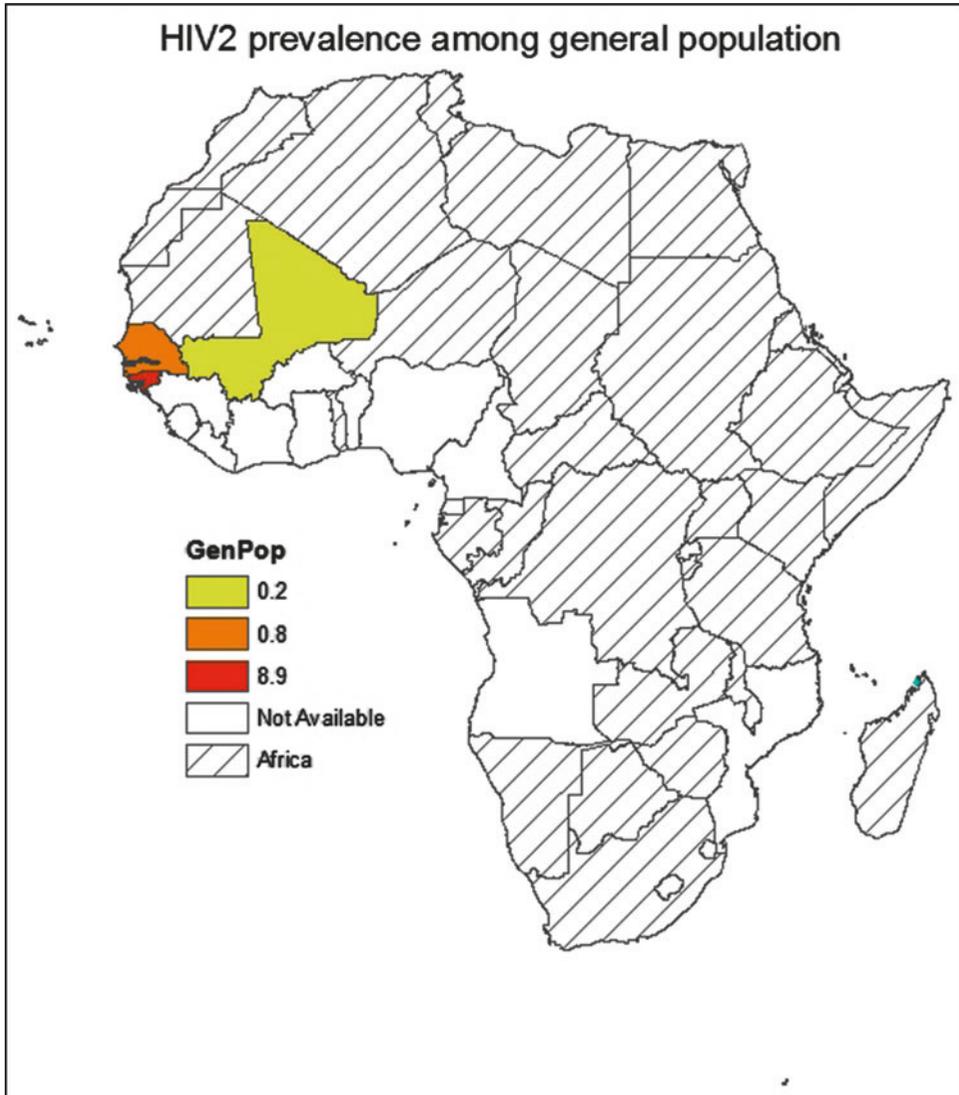

for each country. HIV-1/HIV-2 dual infections are included in the HIV-2 prevalence. *White areas* (without stripes) indicate countries where HIV-2 infections have been reported, but no prevalence data are available

The Spread of HIV-2 in Guinea-Bissau

Guinea-Bissau merits special attention as this country is thought to be the nucleus of the epidemic. Before the first cases of HIV-1 were detected in this country, HIV-2 was widespread. Why did a virus that is much less virulent and less transmissible than its cousin HIV-1 reach a prevalence of 8% in the late 1980s? Both in the capital, Bissau, and in a rural area, Caió, prevalence in the

general population was high (Fig. 3). Three main hypotheses have been postulated and investigated to explain this observation.

First, iatrogenic spread through large vaccination and treatment campaigns may have caused the spread of HIV-2. In the 1950s and 1960s, the Portuguese conducted large treatment campaigns for endemic diseases such as yaws, leprosy, and tuberculosis. In a survey among elderly persons in Bissau, conducted in 2005, having received

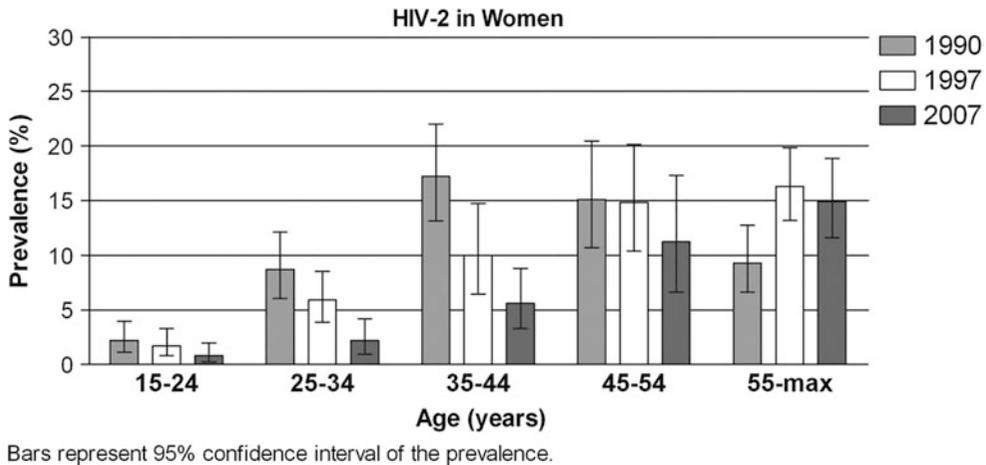

Epidemiology of HIV-2 Infection in West Africa, Fig. 3 Seroprevalence of HIV-2 among general adult population in Africa, by country. Prevalences shown in this figure are the highest prevalences that have been

reported for each country. HIV-1/HIV-2 dual infections are included in the HIV-2 prevalence. *White areas* (without stripes) indicate countries where HIV-2 infections have been reported, but no prevalence data are available

intramuscular treatment for tuberculosis and sleeping sickness were factors associated with HIV-2 infection (Pepin et al. 2006). Vaccinia (smallpox) scars were also associated with HIV-2 infection among persons in both urban and rural Guinea-Bissau (Aaby et al. 2006). Large vaccination campaigns with presumably insufficiently sterilized equipment (e.g., injection needles were used multiple times) are known to

have taken place in Guinea-Bissau before the country reached independence. Phylogenetic analyses of HIV-2 support increased transmission of HIV-2 in 1955–1970 (Lemey et al. 2003).

Second, the protracted War of Independence fought against Portugal between 1963 and 1974 is thought to have facilitated the spread of the virus due to increased sexual risk behavior, unscreened blood transfusions, and possibly

Epidemiology of HIV-2 Infection in West Africa, Fig. 4 HIV-2 prevalence among women by age in three serosurveys in Caio, Guinea-Bissau (van Tienen et al. 2010) (Reproduced with the permission of JAIDS)

increased use of unsterile needles in healthcare facilities.

A third hypothesis that has been proposed for the high initial prevalence of HIV-2 is that the virus may have been more virulent at the start of the epidemic than it currently is. According to this theory, the virus, or certain strains of the virus, became less virulent by adapting to the host. Similar suggestions have been made regarding HIV-1. However, the epidemic may not have been around for long enough to have had such an impact on HIV-2: many of the people who got infected at the time of its presumed higher virulence (the 1960s) were still alive and harboring the virus in the 1980s and 1990s. Also, phylogenetic studies indicate that genetically very similar viruses lead to very different disease courses in infected persons. This suggests that the most important determinant of the outcome of the infection is variation in the host response and not variation of viral strains.

Age and Sex Distribution

The age and sex distributions of people with HIV-2 infection are different from those of people with HIV-1 infection. In HIV-2, prevalence and incidence peak at older adult ages, whereas the peak incidence and prevalence of HIV-1 usually are observed in young adults (HIV-1 prevalence

peaks are now shifting towards older age due to the recent increasing coverage of ART). Figure 4 is an example of the HIV-2 prevalence by age group among women from a general population in Guinea-Bissau, by study year (van Tienen et al. 2010).

The age group with the highest prevalence is older for HIV-2 than for HIV-1 (e.g., for women in 2007 in Guinea-Bissau 45–54 years vs. 20–24 years). This is due to three phenomena: the HIV-2 epidemic is older, survival with HIV-2 is longer, and the transmission rate of HIV-2 is lower, all compared to HIV-1. A clear cohort effect can be seen in Fig. 4: the prevalence increases with age, and within each age group (except ≥ 55 years), the prevalence declines over time. This is compatible with a period of increased transmission in the past. In the case of Guinea-Bissau, this might be linked to the War of Independence. Because older women are more often infected with HIV-2 (a higher prevalence but also a higher incidence) and also more often coinfecting with HIV-1 or human T-cell lymphotropic virus type 1 (HTLV-1), another retrovirus, it has been suggested that older women may be more susceptible to retroviral infections. A better survival of HIV-2-infected women compared to men could also explain the higher prevalence in women. However, studies of mortality of HIV-2-infected people have not been able to confirm this.

Prevalence and Incidence: Rise and Decline

As mentioned previously, HIV-2 was circulating in West Africa before HIV-1 was introduced to this part of Africa. Antibodies against HIV-2 were found in archived blood samples from as early as 1980. Since the 1990s, decreases in prevalence of HIV-2 have been observed in countries where repeated surveys were done, while HIV-1 has risen. The more recent surveys show that HIV-1 is surpassing HIV-2 and is becoming the dominant virus in West Africa. Relatively few studies have reported HIV-2 incidence rates, and in the 1990s, it varied between 0.2 and 1.6 new infections per 100 pyo in Senegal and Guinea-Bissau in general adult populations and FSWs (van der Loeff and Aaby 1999). Both the prevalence and the incidence rate decreased significantly in the 2000s in Guinea-Bissau. It should be noted that these trends represent the natural course of the epidemic; antiretroviral treatment became available in Guinea-Bissau only after 2006, and rollout was slow.

The natural decline of the HIV-2 epidemic might help us understand how the HIV-1 epidemic could be halted as well. Successful antiretroviral treatment (ART) leads to undetectable viral loads and reduces the rate of transmission to almost nil. Thus, antiretroviral treatment programs are expected to lead to “treatment as prevention.” Although this is very promising, more actual studies and more modeling are necessary to estimate what is needed to reduce the reproductive number R_0 (the number of secondary cases in a susceptible population that arise from one infected person) of HIV-1 below 1. When the R_0 of HIV-1 is below 1, transmission would be too rare to sustain the epidemic and HIV-1 would slowly disappear. The declining HIV-2 epidemic could be used as a natural model in which people with undetectable viral load could be compared to people with HIV-1 on successful ART. Studying HIV-2 in detail could thus be used to explore the causes of the decline and so inform “treatment as prevention” programs for HIV-1.

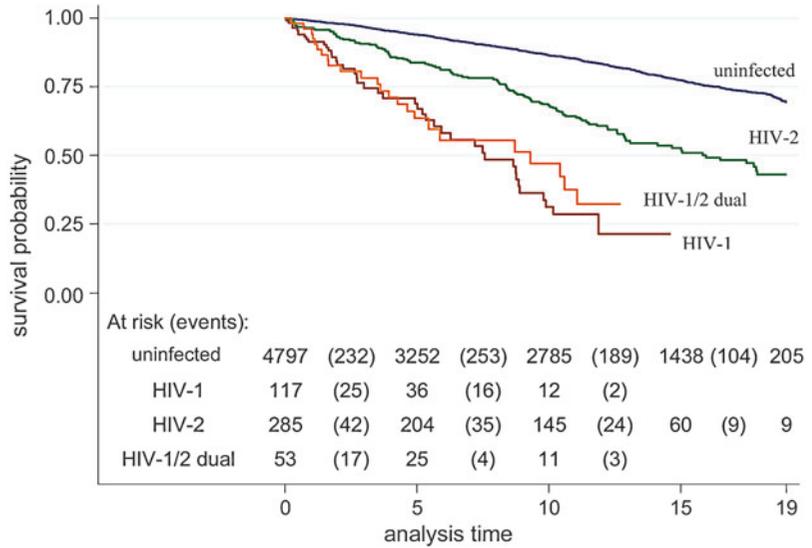

HIV-1 and the Decline of HIV-2

The decline in prevalence in West Africa and elsewhere is consistent with the generally lower viral load and therefore lower transmissibility of HIV-2. In addition, HIV-1 may have a role in the decline of HIV-2 as well. Two different mathematical models explored the contribution of the increase in HIV-1 to the decrease in HIV-2 prevalence. Both suggest that HIV-1 may hasten the decline in HIV-2 by removing susceptible hosts from the population, i.e., individuals at high risk of STDs who drive the spread of HIV-2, contract HIV-1, and die, so they cannot transmit HIV-2 anymore (Anderson and May 1996; Schmidt et al. 2008). Despite the decreased prevalence and incidence, new cases of HIV-2 still occur. This is mainly in older women and in married couples.

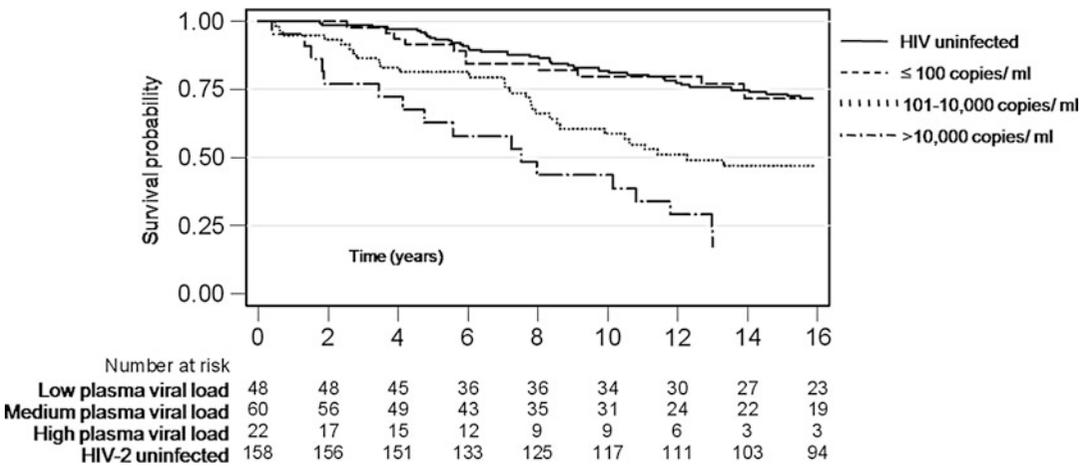

HIV-2 Mortality

The mortality rate of HIV-2-infected people is lower than that of HIV-1-infected people. The median survival after infection (if untreated) is about 11 years for HIV-1; for HIV-2 the median survival time has never been estimated as no seroincident cohort was large enough and followed long enough to establish this. However, based on modeling of CD4 counts and mortality data from a clinical cohort in the Gambia, it was found that half of the HIV-2 infected do not display any disease progression; for the other half, the median time to death was estimated to be 2.7 years longer than that for HIV-1 (Geskus et al. 2009). The mortality rate for HIV-2 infection has been estimated to be twice as high as that of uninfected persons (compared to a 10-fold increased risk of death for HIV-1 infection). In a large community study from Guinea-Bissau, the mortality hazard ratio varied from 1.2 among persons above 60 years of age to 9.1 among the people age between 15 and 29 years. An unadjusted Kaplan-Meier curve illustrates the difference in survival in a cohort study from Guinea-Bissau (Fig. 5) (van Tienen et al. 2011).

Epidemiology of HIV-2 Infection in West Africa, Fig. 5 Kaplan-Meier graph of survival probability by HIV-status, Guinea-Bissau, 1989–2009 (HTLV-1-infected subjects excluded) (van Tienen et al. 2011) (Reprinted in accordance with the Creative Commons Attribution License)

E

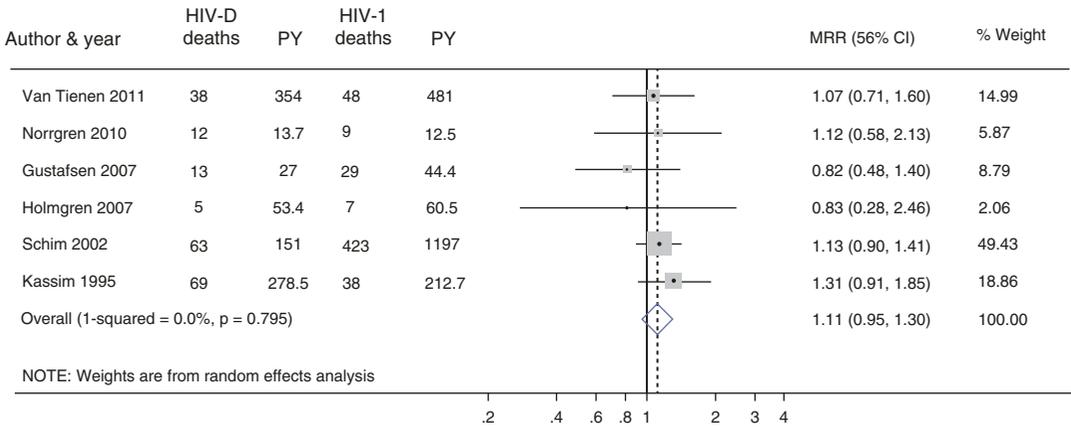

Epidemiology of HIV-2 Infection in West Africa, Fig. 6 Survival probability by viral load of HIV-2-infected and HIV-2-uninfected individuals in Caio,

Guinea-Bissau (Schim van der Loeff et al. 2010) (Reprinted in accordance with the Creative Commons Attribution License)

Thus, in elderly persons, mortality is hardly increased compared to the uninfected population. This is probably due to two factors: first, the background mortality among older individuals is higher than among younger persons and second, there is a survival bias of a group of older individuals who are nonprogressors, leading to a low mortality rate ratio.

The difference in mortality for both viruses is caused by the difference in viral loads. In general, the HIV-2 viral loads are lower than HIV-1 viral

loads. Strikingly, persons with undetectable (<100 viral copies/ml) viral loads (an estimated 30–50% of all HIV-2-infected individuals) have no significantly increased mortality compared to uninfected persons (Schim van der Loeff et al. 2010). In persons with high viral loads, the mortality is similar to that of persons infected with HIV-1 (Fig. 6). Several persons known to be infected with HIV-2 before 1990 were still alive more than 20 years later, but had no HIV-related symptoms.

Epidemiology of HIV-2 Infection in West Africa, Fig. 7 Forest plots showing the individual and combined mortality rate ratios (MRRs) of HIV-D versus HIV-1. (Matser et al. *AIDS* 2014) (Reprinted with permission from AIDS)

Immunological and virological studies have suggested that HIV-2 infection may inhibit the progression of HIV-1 in individuals dually infected by HIV-1 and HIV-2. A recent meta-analysis of studies comparing the mortality rates in HIV-2 and HIV-1 and HIV-2 dually infected individuals found no difference in mortality (Fig. 7) (Prince et al. 2013). Hence, based on epidemiological studies, it seems unlikely that HIV-2 has a mitigating effect on HIV-1 disease progression in dually infected people.

Conclusion

The HIV-2 epidemic has spread mainly in West Africa, and after a high prevalence in the 1980s, it is now an epidemic in decline. The declining epidemic could be used as a natural model to study the most important factors for halting the HIV-1 epidemic by early treatment (“treatment as prevention”). The epicenter of the epidemic is thought to be in Guinea-Bissau, where the highest prevalence has been reported. It is likely that through iatrogenic spread (mass vaccination and treatment campaigns) and a period of increased sexual risk behavior during the War of Independence, HIV-2 has been able to spread widely in Guinea-Bissau. Although the awareness of iatrogenic spread of infections has

increased, lessons can be learned from HIV-2, as it may serve as a model for HIV-1 “treatment as prevention.” Although most countries with reported cases have observed a decline in prevalence, HIV-2 remains a public health problem in West Africa with important excess mortality, and the infection poses diagnostic and therapeutic challenges for physicians, nurses, and healthcare systems.

Epidemiology of Non-AIDS-Defining Malignancies

Andrew E. Grulich

HIV Epidemiology and Prevention Program,
The Kirby Institute, University of New South
Wales, Sydney, NSW, Australia

Definition

AIDS-defining malignancies are those which are included in the case definition of AIDS, namely, Kaposi sarcoma, non-Hodgkin lymphoma, and cervical cancer. *Non-AIDS-defining malignancies* are those other malignancies whose incidence is increased in individuals with HIV infection. In some instances, the term can also refer to any malignancy occurring in an individual with HIV infection. More recently, as the incidence of AIDS has declined in people with access to antiretroviral therapy, the term “HIV-associated malignancy” has become more widely used to describe the same group of malignancies.

Introduction

In the early 1980s, a rare form of skin cancer, Kaposi sarcoma (KS), occurring at greatly increased rates among homosexual men, was a harbinger of the AIDS epidemic. Over the subsequent decade, when it became apparent that non-Hodgkin lymphoma (NHL) and cervical cancer occurred at increased rates in people with HIV, these two cancers were added to the case definition of AIDS when they occurred in an HIV-infected person. Collectively, KS, NHL, and cervical cancer are called AIDS-defining cancers and are separately considered in the entry “► [Epidemiology of AIDS-Defining Malignancies](#).”

Even early in the AIDS epidemic, it was recognized that other cancers also occurred with increased rates. In the mid-1990s, the introduction of highly active antiretroviral therapy (HAART)

changed the clinical face of HIV disease. In particular, it led to immune recovery and the much longer survival of people with HIV. In general, immune recovery was only partial, and subtle effects of long-term mild immune deficiency, including the occurrence of certain cancers, began to emerge.

In this entry, the spectrum of non-AIDS malignancies is defined, and then individual cancer types are examined in detail. These cancers are grouped as (1) cancers with a known infectious cause that occur at increased incidence in people with HIV, (2) other cancers occurring at increased incidence in people with HIV, and (3) cancer types that do not occur at increased incidence in people with HIV.

The Spectrum of Non-AIDS-Defining Malignancies

In the late 1990s, as the survival of people with HIV began to increase, it became more apparent that people with HIV were experiencing higher rates of a number of types of cancer than in the general population. This was identified within large-scale studies which linked population-based AIDS and/or HIV registers with cancer registries in several countries including the United States, Italy, and Australia. Increased rates of a wide range of cancers were identified. Initially, there was considerable debate about whether these cancers occurred at increased rates because of HIV-associated immune deficiency. The alternate explanation was confounding, because people with HIV also experience increased exposure to a number of other common carcinogens including tobacco smoke and sexually transmitted and blood-borne oncogenic viral infections. The answer to whether cancer was truly caused by HIV came in part from studying cancer patterns in solid organ transplant recipients. Solid organ transplant recipients are required to take lifelong immunosuppressive medications and so share long-term immune deficiency with people with HIV. In other respects, they do not share similar carcinogenic exposures. A study published in 2007 conclusively demonstrated that these two

populations have a broadly similar pattern of cancer occurrence, with increased rates of about 20, mostly infection-related cancer types (Grulich et al. 2007). The pattern of increased risk of cancer types is summarized in Fig. 1. More recently, cohort studies of people with HIV, which have included data on CD4-positive lymphocyte count and HIV viral load, have demonstrated that many of these cancers are associated with impaired immune function.

In the remainder of this entry, I will review data on the epidemiology of specific cancer types in people with HIV and their association with the level of immune function.

Infection-Related Cancers

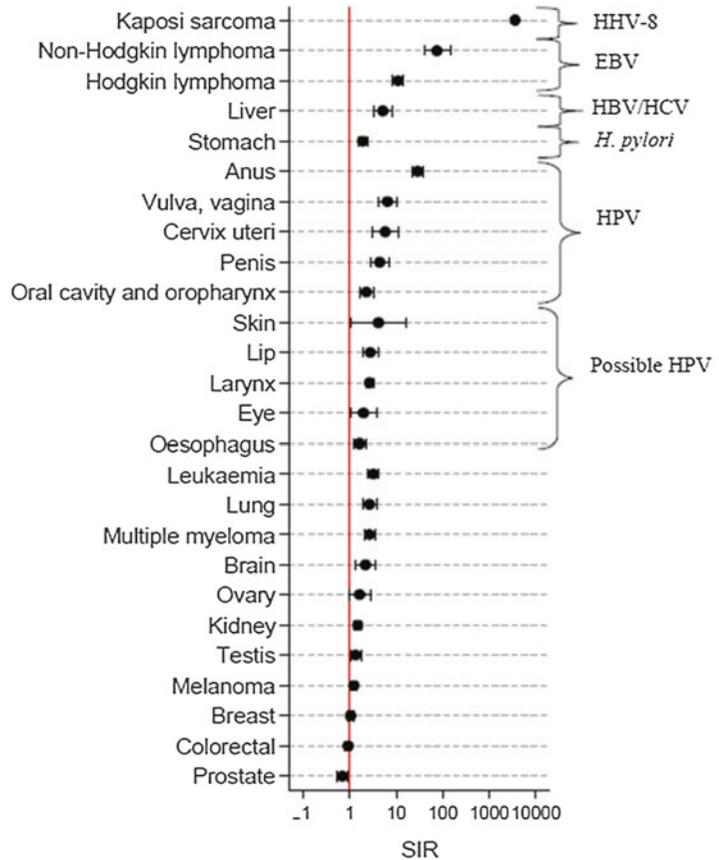

Cancers Related to Epstein-Barr Virus

The World Health Organization's International Agency for Research on Cancer (IARC) classifies Epstein-Barr virus (EBV) as carcinogenic in humans with respect to certain types of non-Hodgkin lymphoma (NHL, including Burkitt lymphoma, immunosuppression-related NHL, extranodal NK/T cell lymphoma of nasal type), Hodgkin lymphoma, and cancer of the nasopharynx (IARC 2009). Data on NHL are summarized in the entry "[► Epidemiology of AIDS-Defining Malignancies](#)" and are not further considered here.

EBV can be detected in 40–50% of cases of Hodgkin lymphoma in developed countries and is even more commonly detected in people with HIV (IARC 2009). Hodgkin lymphoma occurs about 11-fold more commonly in people with HIV than in the general population and is raised about fourfold in organ transplant recipients (Grulich et al. 2007). The increase in risk in people with HIV is not consistent across Hodgkin lymphoma subtypes and is confined to the mixed cellularity and lymphocyte-depleted subtypes. In recent years, rates of Hodgkin lymphoma in people with HIV have been relatively constant, and despite improvements in antiretroviral therapy and immune function, they have not declined. Three cohort studies with longitudinal measurements of CD4 lymphocyte count have described

Epidemiology of Non-AIDS-Defining Malignancies,

Fig. 1 Standardized incidence ratios of cancer types in people with HIV, grouped by infectious cause (Figure based on data presented in Grulich et al. 2007)

E

an association between increasing rates of Hodgkin lymphoma and declining CD4 count (Guiguet et al. 2009; Reekie et al. 2010; Silverberg et al. 2011). At least part of the reason why rates of Hodgkin lymphoma have not declined in people with HIV in recent years is that the association with immune deficiency is much weaker than with NHL and Kaposi sarcoma.

Prospective studies have identified a strong relationship between serological markers of EBV infection and future risk of nasopharyngeal carcinoma (IARC 2009). As nasopharyngeal carcinoma is a rare cancer except in people originating from certain areas of Southeast Asia, there are relatively few data on the association with HIV infection. A US-based linkage study of AIDS and cancer registers described a twofold increase in risk, based on only 39 cases, and a sixfold increase in risk was reported in a Chinese cohort of people with HIV.

Cancers Related to Human Papillomavirus

The IARC classifies certain types of human papillomavirus (HPV) infection as carcinogenic in humans with respect to cancers of the cervix, vulva, vagina, penis, anus, oral cavity, oropharynx, and tonsils (IARC 2009). There is weaker evidence that HPV may be associated with cancer at some other sites, including cancer of the larynx (IARC 2009).

Globally, the most common HPV-associated tumor is cervical cancer. Cervical cancer is an AIDS-defining cancer and is reviewed in the entry “► [Epidemiology of AIDS-Defining Malignancies.](#)”

HPV can be detected in over 80% of cases of anal cancer (IARC 2009). Anal cancer occurs at approximately 30-fold increased rates in people with HIV and is also raised about fivefold in organ transplant recipients (Grulich et al. 2007). Risk is greatest in homosexual men with HIV, but

substantial elevations in risk (greater than tenfold) are also seen in men with other risk factors for HIV and in women with HIV (Chaturvedi et al. 2009). Some cohort studies have described an increase in anal cancer incidence in the HAART era, although a plateau in rates appears to have emerged in recent years. In some settings where homosexual men comprise a majority of people with HIV, anal cancer has become the most commonly occurring non-AIDS-defining malignancy (van Leeuwen et al. 2009). Anal cancer is not strongly related to current immune function, although a more moderate association with declining CD4 count has been described in two recent cohort studies (Reekie et al. 2010; Silverberg et al. 2012). Associations with prolonged duration below a CD4 cell count of 200 cells per microliter (Guiguet et al. 2009) and lower CD4 cell count nadir have also been described. The high incidence of this cancer in people with HIV and the lack of a decline in incidence in recent years have led to anal cancer becoming a substantial health issue in people with HIV. Preventive interventions, including the possibility of a screening test for early detection of anal cancer and its precursors, have received considerable research attention in recent years. However, the introduction of screening at a population level has been impeded by the lack of evidence of the efficacy of treatment of the preinvasive lesion and concerns about the accuracy and the complexity of the screening test.

Fewer data have been published on other HPV-related cancers, and only small numbers have been described in cohort studies of people with HIV (IARC 2009), making a description of the relationship with immune function impossible. For cancer of the vulva and vagina, HPV can be detected in about 40% and 70% of cases, respectively (IARC 2009). The cancers are increased about 6- and 23-fold in people with HIV and in organ transplant recipients, respectively (Grulich et al. 2007). HPV can be detected in about 50% of cases of penile cancer (IARC 2009), and incidence rates are increased 4- and 16-fold in people with HIV and in organ transplant recipients respectively (Grulich et al. 2007). Within the oral cavity, there is substantial

variation in the association of cancer types with HPV. The strongest association is with cancer of the oropharynx and tonsils. In recent series, 60% or more of cases have detectable HPV (IARC 2009). For oral cavity cancer overall, incidence rates are increased two and threefold in people with HIV and in organ transplant recipients respectively (Grulich et al. 2007). A US-based AIDS-cancer linkage study reported a modest 1.6-fold increase in oropharyngeal cancer in people with AIDS (Chaturvedi et al. 2009).

Cancers Related to Hepatitis B Virus and Hepatitis C Virus

The IARC classifies hepatitis B virus (HBV) and hepatitis C virus (HCV) as carcinogenic in humans with respect to hepatocellular carcinoma (liver cancer) and, for HCV only, for certain subtypes of NHL. There is weaker evidence that HBV may be related to NHL and that both viruses may be related to cholangiocarcinoma (IARC 2009).

Liver cancer is increased about five and twofold in people with HIV and organ transplant recipients respectively (Grulich et al. 2007). The risk of liver cancer is greatly increased in people with HIV who are coinfecting with HBV and/or HCV (Guiguet et al. 2009), and thus incidence is particularly high in injection drug users and hemophiliacs with HIV. Two cohort studies have reported a moderate association of increased liver cancer risk with impaired immune function (Clifford et al. 2008; Guiguet et al. 2009).

A US-based AIDS-cancer linkage study has recently reported that risk of cholangiocarcinoma was increased by about 40% in people with AIDS, but this did not reach statistical significance (Sahasrabudde et al. 2012).

Cancers Related to *Helicobacter pylori*

The IARC classifies *Helicobacter pylori* (*H. pylori*) as carcinogenic in humans with respect to gastric carcinoma and low-grade B cell mucosa-associated lymphoid tissue (MALT) gastric lymphoma (IARC 2009).

The incidence of stomach cancer is increased about twofold in people with HIV and in organ transplant recipients (Grulich et al. 2007). When examined by subsite within the stomach,

increased risk does occur at non-cardia sites, where *H. pylori* has been casually associated with cancer (Persson et al. 2012). There is some evidence that EBV may cause a proportion of cases of gastric cancer (IARC 2009), and this is another potential reason why the incidence of gastric cancer is increased in people with HIV.

In the US AIDS-cancer match, gastric MALT lymphoma occurred about sixfold more commonly in people with AIDS than in the general population (Persson et al. 2012). *H. pylori* eradication is frequently associated with complete remission of the MALT lymphoma (IARC 2009).

Merkel Cell Carcinoma

Merkel cell carcinoma is a rare but very aggressive skin cancer. In people with HIV, MCC occurs about 13-fold more commonly than in the general population, and it also occurs at greatly increased rates in organ transplant recipients and other immunosuppressed states including chronic lymphocytic leukemia. In 2008, it was discovered that a polyomavirus, now termed Merkel cell polyomavirus, is clonally integrated in Merkel cell carcinoma tissue (Feng et al. 2008). It is now recognized that Merkel cell polyomavirus is the cause of about 80% of cases of Merkel cell carcinoma.

Cancers Occurring at Increased Rates in People with HIV with No Accepted Infectious Cause

In this section, cancers that have been documented to occur at increased rates in people with HIV, but do not have a well-accepted infectious cause, are discussed.

Lung Cancer

The incidence of lung cancer is increased about 2.7-fold and 2.2-fold in people with HIV and in transplant recipients respectively (Grulich et al. 2007). Lung cancer is a common cancer in the general population of developed countries, and in many developed countries, lung cancer is the most common non-AIDS-defining carcinoma as assessed by the number of cases per year. It is

thus a very important cause of morbidity. Assessing the cause of this excess risk is made complex by the fact that people with HIV have a substantially raised prevalence of tobacco smoking. While tobacco smoking has been controlled for using multivariate techniques in several studies, it is difficult to confidently exclude the possibility of residual confounding by dose or timing of tobacco exposure (IARC 2009).

Another possible cause of the increased lung cancer incidence in people with HIV is an unknown pulmonary infection. In favor of this hypothesis is the fact that several cohort studies have found an association between lower CD4 count and increased lung cancer risk (Guiguet et al. 2009; Reekie et al. 2010; Silverberg et al. 2011), although one well-conducted cohort reported no association with immune function (Clifford et al. 2012). One study reported an association of lung cancer risk in people with HIV with recurrent pneumonia (Shebl et al. 2010), but another found no association of lung cancer with AIDS-related pulmonary disease. Irrespective of the cause, lung cancer is a major public health issue in people with HIV.

Conjunctival Cancer

Squamous cell cancer of the conjunctiva is a rare cancer that has been described as occurring at approximately 12-fold increase in people with AIDS in the United States and also occurs at increased risk in kidney transplant recipients. A marked increase in risk of this cancer has been described in African settings (IARC 2009). Both solar ultraviolet radiation and HPV have been hypothesized to contribute to the etiology of this cancer (Chaturvedi et al. 2009).

Nonmelanoma Skin Cancer

In most parts of the world, data on basal cell carcinoma (BCC) and squamous cell carcinoma (SCC) of the skin are not recorded by cancer registries, and hence there are relatively few data on their occurrence in people with HIV. In solid organ transplant recipients, SCCs occur about 50 times more commonly than in the general population. In that population, SCC also behaves much more aggressively than in the general

population and is a substantial clinical management issue. It is clear that people with HIV are less predisposed toward SCC than are solid organ transplant recipients. Nevertheless, a recent cohort study in California reported that rates of SCC were increased about twofold, which was a similar increase to the incidence of BCC (Silverberg et al. 2013). In that study, SCC but not BCC was related to lower recent CD4 count. The association with immune deficiency is suggestive evidence that an infective agent may be related to SCC. There is suggestive but not definitive evidence that HPV may play a role.

Melanoma

The incidence of melanoma is increased marginally, by about 24%, in people with HIV, and by 2.3-fold in organ transplant recipients (Grulich et al. 2007). In kidney transplant recipients, the current receipt and intensity of immune suppression increase melanoma risk, suggesting that impaired immunity is related to melanoma risk. The absence of a substantially increased risk in people with HIV suggests that HIV-induced immune deficiency may be less closely linked to melanoma risk than the pharmacological immune suppression in transplant recipients.

Lip Cancer

The incidence of lip cancer is increased by 2.8-fold in people with HIV and is increased very markedly, by about 30-fold, in organ transplant recipients (Grulich et al. 2007). In organ transplant recipients, the increase in lip cancer probably reflects the very large increase in risk of SCC of the skin. In this population, increased risk is associated with current immune suppression, and risk rapidly returns to normal in kidney transplant recipients who stop receiving immune suppression because of kidney graft failure.

Esophageal Cancer

The incidence of esophageal cancer is increased by 1.6-fold in people with HIV and is increased about threefold in organ transplant recipients (Grulich et al. 2007). The increase in incidence in people with HIV appears to be similar for adenocarcinoma and SCC of the esophagus (Persson

et al. 2012). The increased alcohol and tobacco exposure of people with HIV is a potential explanation for these increased rates.

Laryngeal Cancer

The incidence of esophageal cancer is increased by 2.7-fold in people with HIV and is increased about twofold in organ transplant recipients (Grulich et al. 2007). Based on a small case series, HPV does not appear to be associated with this cancer in people with HIV. Increased tobacco is a likely cause of the increased occurrence in HIV disease.

Cancers that Do Not Occur at Increased Rates in People with HIV Infection

Given the large range of cancer types that occur at increased rates in people with HIV, it is notable that for several of the cancer types that occur commonly in the general population, incidence is not increased. These cancers include breast cancer, prostate cancer, and colorectal carcinoma.

Breast Cancer

In a meta-analysis of prospective research, breast cancer incidence was neither increased in people with HIV (meta-analysis SIR 1.03, 95% CI 0.89–1.20) nor in transplant recipients (meta-analysis SIR 1.15, 95% CI 0.98–1.36) (Grulich et al. 2007). Studies from earlier in the HIV epidemic described a decreased incidence of breast cancer compared to the general population. Incidence increased toward that of the general population in more recent years. A potential explanation for that pattern is that prior to effective antiretroviral therapy, women with AIDS received less breast cancer screening, and that with prolonged survival, screening rates are likely to have increased.

Prostate Cancer

In the meta-analysis described above, prostate cancer incidence was decreased about 30% in men with HIV. In transplant recipients, incidence was not significantly different to 1 (meta-analysis SIR 0.97, 95% CI 0.78–1.19) (Grulich

et al. 2007). In the United States, the decreased incidence of prostate cancer in people with AIDS was confined to the era when prostate-specific antigen was being used as a screening test. The deficit in incidence was confined to early-stage cancers and not present for advanced cancer. These findings suggest that decreased prostate cancer incidence is related to decreased cancer screening in men with AIDS.

Colorectal Cancer

In the meta-analysis described above, colorectal cancer incidence was not increased in people with HIV (meta-analysis SIR 0.92, 95% CI 0.78–1.08). In transplant recipients, incidence was increased by about 70% (Grulich et al. 2007). The reason for the increased incidence in organ transplant recipients is unclear.

Conclusion

As the HIV epidemic unfolds, the pattern of cancer occurrence in people with HIV has continued to change. A constant theme has been that people with HIV experience increased oncogenic exposure compared to the general population, and this has led to patterns of cancer that are often very distinct. Over the years, these increased exposures have changed but in most populations have included immune deficiency, tobacco and alcohol, and oncogenic blood-borne and sexually transmitted infectious agents. The occurrence of immune deficiency in millions of people has given us a unique opportunity to examine the role of infection in carcinogenesis. For many types of cancer, this has helped us delineate the role of infection in causing cancer. For a few others, most particularly for prostate and breast cancer, the absence of any increased risk in either people with HIV or organ transplant recipients has provided strong evidence that infection appears not to be an important cause.

The HIV epidemic is over 30 years old, and most people with HIV have acquired infection in early adulthood. With effective antiretroviral therapy, these individuals are living substantially longer, and a substantial aging of the HIV-infected

population is occurring. As a result, the large-scale interaction of the carcinogenic effects of mild immune deficiency with the much higher cancer incidence that is experienced in old age will occur. If people with HIV carry the relative risks of HIV-related cancer into older age, that will lead to a very large increase in the burden of HIV-related cancer. Such increases are already beginning to happen. However, to the extent that effective antiretroviral therapies can completely or nearly completely remove the oncogenic effect of immune deficiency, then such increases may be lessened. Further follow-up of large cohorts of people with treated HIV is required to clarify these issues.

Epstein-Barr Virus (EBV)

Lindsey Hutt-Fletcher

Department of Microbiology and Immunology, Center for Molecular and Tumor Virology and Feist-Weiller Cancer Center, Louisiana State University Health Sciences Center, Shreveport, LA, USA

Definition

There are more than 100 viruses in the herpesvirus family, which is divided into three subfamilies, alpha, beta, and gamma, based on the genome structure and biological behavior of the viruses. Epstein-Barr virus (EBV) is one of the eight herpesviruses currently known to infect humans and is a member of the gammaherpesvirus subfamily, genus *Lymphocryptovirus*. Like all herpesviruses it can establish latent infections and persist for the lifetime of the host. In some individuals it behaves more as a commensal than a pathogen, while in

others it can cause significant and even life-threatening disease.

Introduction

All viruses are problematic for those who are infected with the human immunodeficiency virus (HIV), but the herpesviruses, which are often carried by the vast majority of individuals worldwide and are typically fairly well controlled by a functioning immune system, pose a particular concern. EBV, like its fellow oncogenic gammaherpesvirus, ► [Kaposi's sarcoma-associated herpesvirus](#), can contribute significantly to the morbidity and mortality of HIV. In the developing world primary infection with EBV, which is orally transmitted in saliva, usually occurs in the first few years of life. In the developed world infection generally occurs somewhat later in the second decade or beyond. Few individuals anywhere, however, escape infection by midlife and in none has elimination of the virus been documented.

Biology of the Virus and Colonization of the Host

EBV shares the structural characteristics of all herpesviruses. It has a relatively large linear double-stranded DNA genome of approximately 175 kb, which encodes more than 80 genes. The genome is tightly housed in a proteinaceous icosahedral capsid and is wrapped in a lipid envelope carrying multiple copies of eleven different membrane glycoproteins. An additional space between the envelope and the capsid includes proteins and RNAs capable of modifying virus and host cell function. These are collectively known as the tegument (Kieff and Rickinson 2007).

EBV has two major target cells, B lymphocytes and epithelial cells, and it appears to behave very differently in each. The prevailing dogma in the field is that, in vivo, virus primarily establishes long-term latency in B cells and primarily replicates in epithelial cells.

In an uncomplicated, asymptomatic, primary infection, incoming virus, either cell-free or

associated with lymphocytes found in saliva, accesses B cells in the lymphoid tissue of Waldeyer's ring, the tonsils, and adenoids that surround the pharynx (Thorley-Lawson and Gross 2004; Hislop et al. 2007). This occurs perhaps directly or perhaps subsequent to an initial round of replication in a mucosal epithelial cell. B cell infection does not immediately lead to productive replication, but instead the virus genome circularizes and remains extrachromosomal and all initial transcripts are devoted to maintaining the episome and changing the behavior of the cell.

This type of latent infection is easily modeled *in vitro* by infection of peripheral B cells and their immortalization into the lymphoblastoid cell lines that are so frequently used for study of human tissue. It involves expression of a full panoply of latency proteins, the latency III phenotype or growth program, including six EB nuclear antigens or EBNA, EBNA 1, EBNA2, EBNA3A, EBNA3B, EBNA3C, and EBNA-LP; the latent membrane proteins, latent membrane protein 1 (LMP1) and latent membrane protein 2 (LMP2); two sets of small, abundant untranslated RNAs, EBER1 and EBER2; and some miRNAs. These collectively drive the cell to become a proliferating blast cell in which the latent virus episome is replicated by host polymerases (Kieff and Rickinson 2007). In one prevalent model of colonization of the host (Thorley-Lawson and Gross 2004), they are considered responsible for initiating the passage of the infected cell down a pathway that parallels that of an antigen-stimulated B cell during a normal immune response. Unlike in the lymphoblastoid cell line *in vitro*, where continued expression of the latency III phenotype maintains the cell in a proliferative state, a switch in promoter usage is then thought to limit expression to the latency II phenotype in which a subset of latency proteins including EBNA1, LMP1, and LPM2 are expressed. This mimics positive selection by antigen stimulation, rescues the cell from the default of apoptosis, and enables it to emerge as a long-lived virus-carrying memory B cell. Memory B cells can circulate in the periphery and seed distant sites. Protein expression in the memory B cells can then be further limited to the

latency I phenotype, in which only EBNA1 and some miRNA are expressed. EBNA1 tethers the genome to the chromosome, which is required for its maintenance in dividing cells (Frappier 2012). In addition to these phenotypes, a resting cell may express no virus proteins at all. This means that while an emerging immune response, primarily a CD8⁺ T cell response (Long et al. 2011), can control cells that express EBV-encoded proteins, resting memory cells remain invisible to the immune system and persist as the long-term reservoir of virus in the infected host. Sporadic terminal differentiation into plasmablasts in Waldeyer's ring triggers reactivation of virus into the lytic cycle, leading to the ultimate death of the cell and production of virus. At this point virus can reenter an epithelial cell and undergo amplification for transmission in saliva to a new host or for reinfection of a B cell and replenishment of the latent reservoir, completing the ongoing cycle of persistence; infectious virus is thus continually found in saliva in healthy carriers (Jiang et al. 2006). In individuals treated over very long periods with valacyclovir, which inhibits lytic virus DNA replication mediated by the viral DNA polymerase but does not affect the latent episome, the frequency of latently infected memory cells is reduced. It has, however, been estimated that it would take at least 11 years of daily therapy to eliminate the latent reservoir entirely (Hoshino et al. 2009).

Despite its assumed occurrence *in vivo*, full lytic replication resulting in production of new virions has not yet been achieved *in vitro* in epithelial cells. In these cells, if EBV persists at all, which it frequently does not, the virus becomes latent. Because of this experimental limitation, lytic replication of EBV has primarily been studied by reactivating virus in latently infected B cell lines. A variety of stimuli including cross-linking of surface immunoglobulin, which may mimic events leading to terminal differentiation triggered by antigen cross-linking or addition of transforming growth factor beta 1, phorbol esters, or histone deacetylase inhibitors, can be used to induce virus reactivation in a variable proportion of cells. Thus a picture of the entire life cycle of the virus at the cellular level comes not from a

continuum but from piecing together early events involving virus entry, which can be studied in both cell types and reactivation from latency.

Infection of a B cell is initiated by attachment of the virus through the binding of one of the envelope glycoproteins, gp350, to the cellular complement receptor type 2, CR2/CD21 (Hutt-Fletcher 2007). The virus is then endocytosed into what becomes a thin-walled vesicle or endosome, and its envelope fuses with the endosomal membrane to deliver tegument and capsid into the cytosol. Fusion of virus and cell is triggered by an interaction between envelope glycoprotein gp42 and cellular human leukocyte antigen (HLA) class II. Glycoprotein gp42 exists as part of a trimeric complex with glycoproteins gH and gL (gHgL) to which it is thought to transmit the activating trigger. Current models (Connolly et al. 2011) propose that the activation of gHgL via gp42 in turn activates the core virus fusion machinery comprised of gHgL and glycoprotein gB. Glycoprotein gB is thought to be the ultimate fusogen, but it requires gHgL for function.

As on a B cell, epithelial cell infection may be initiated by binding of glycoprotein gp350 to CR2, which is expressed on some, though not all, epithelial cells. Infection of a CR2-negative epithelial cell *in vitro* can be more efficient if cells are overlaid with virus-producing B cells (Imai et al. 1998) than if cell-free virus is used, but the major players in attachment and fusion are probably the same. In addition to gp350 binding, attachment can also occur as result of binding of the dimeric complex of gHgL to one of three integrins, $\alpha v\beta 5$, $\alpha v\beta 6$, or $\alpha v\beta 8$. These same integrins then directly trigger the core machinery of gHgL and gB to mediate fusion with epithelial cells, which lack constitutive HLA class II expression (Chesnokova et al. 2009). The use of two different triggers of fusion has allowed the virus to evolve an ingenious strategy for trafficking alternately between B cells and epithelial cells during the cycle of persistence. The virion contains both dimeric gHgL complexes and trimeric gHgLgp42 complexes. Only the trimeric complexes can support fusion with B cells because of the required interaction between gp42 and HLA class II. Only dimeric complexes can support fusion with an

epithelial cell because of the required interaction between gHgL and an integrin, which is blocked by the presence of gp42. In a B cell with replicating EBV, some trimeric complexes interact with HLA class II in the endoplasmic reticulum and are lost to the HLA class II trafficking pathway. Virus emerges rich in dimeric complexes and is about fivefold more infectious for an epithelial cell than a B cell. Conversely, virus emerges from an HLA class II-negative epithelial cell with more trimeric complexes and can be as much as one hundredfold more infectious for a B cell than an epithelial cell (Borza and Hutt-Fletcher 2002).

Once in the cytoplasm of the cell, the virus ultimately travels to the nucleus where the genome and some virus proteins enter through the nucleopore and the episome is established. The events that follow initiation of lytic reactivation then follow a pattern similar to those of other herpesviruses that enter a productive lytic cycle directly. Gene expression is divisible into three general classes, immediate early, early, and late. The immediate early proteins Zta and Rta, encoded by the BZLF1 and BRLF1 genes, are transactivators. Expression of these immediate early proteins is followed by the activation of expression of early proteins, which include enzymes required for DNA synthesis, and finally late proteins, which are principally the structural components of the new virion (Kieff and Rickinson 2007). Assembly of the DNA-containing capsid occurs in the nucleus, and it is assumed, primarily by analogy with work done with other herpesviruses, to follow an envelopment-deenvelopment pathway of egress (Mettenleiter 2002). It is believed that the capsid first acquires a primary envelope as it buds through the inner nuclear membrane; loses it as it fuses with the outer nuclear membrane; acquires tegument proteins and a secondary envelope as it buds into a compartment of the secretory pathway, possibly the trans-Golgi; and is released from the cell by exocytosis.

The latently infected resting memory B cell can evade immune recognition by virtue of expressing few or no EBV proteins. The virus has also, however, evolved a series of approaches to blunting both innate and adaptive immune responses to

lytic cycle proteins. Three early proteins, pBNLF2A, pBILF1, and pBGLF5, have been identified as variously binding to the TAP transporter and interfering with peptide delivery to HLA class I, binding to HLA class I itself and blocking its export, and effecting a general shutoff of host protein synthesis, which limits the expression of new HLA proteins. Perhaps to compensate for the loss of HLA protein, which could activate natural killer (NK) cell recognition, one of the EBV miRNAs can in turn reduce expression of the NK activating ligand MicB. The immediate early protein, Zta, downregulates HLA class II by targeting inhibiting transcription of the class II transactivating protein, and the glycoprotein gp42 can interfere with HLA class II recognition by CD4+ T cells (Long et al. 2011).

Disease Associated with Primary Infection

Primary infections with EBV, particularly those occurring before adolescence, are almost always asymptomatic or at least unrecognized. However, as many as 70% of those in whom infection first occurs during adolescence or later in life develop infectious mononucleosis (Odumade et al. 2011). This syndrome is generally thought to be an immunopathology and to reflect a more intense version of what occurs during an asymptomatic infection, though why it occurs more frequently in adolescence than in infancy remains unclear. The incubation period is estimated at about 6 weeks, which, together with the fact that mononucleosis does not occur epidemically, has made the early events difficult to document. Once the classic symptoms of fever, sore throat, fatigue, and cervical lymphadenopathy appear, sometimes accompanied by eyelid edema, splenomegaly, and liver abnormalities, one of the pathognomonic features is a lymphocytosis including large atypical lymphocytes. These atypical cells are activated CD8+ T cells, and in mononucleosis caused by EBV, they are directed at controlling latent and lytically infected cells. Responses to epitopes derived from lytic cycle proteins dominate. The onset of symptoms coincides with the

activation and proliferation of the CD8+ T cells, and they, with attendant cytokines and perhaps an increase in the number of NK cells in the periphery, are thought to be primarily responsible for the clinical symptoms (Hislop et al. 2007; Odumade et al. 2011). Diagnosis is then typically based on these clinical symptoms, on the presence of a lymphocytosis and also on the production of heterophile antibodies, which appear transiently during the acute phase. These antibodies are measured by the monospot test in which agglutination of the red blood cells of sheep or other species is assessed. Heterophile-negative infectious mononucleosis does, however, occur, and diagnosis may need to be further refined by examining specific antibody responses. Acute infection is typically associated with high levels of antibodies to early lytic (EA) and late lytic antigens (VCA), in particular immunoglobulin M (IgM) antibodies, and absence of antibodies to EBNA1, which become more readily detectable in months following acute disease (Odumade et al. 2011).

Uncomplicated infectious mononucleosis resolves as cells expressing EBV antigens decline in number, with an accompanying decrease in the number of reactive activated CD8+ T cells. There are, however, two extremely rare disorders that can follow primary infection (Hislop et al. 2007). One occurs in patients with a genetic disorder, X-linked lymphoproliferative disease (XLP), in which there is a mutation in the SH2D1A gene encoding SLAM-associated protein (SAP). SAP deficiency produces multiple immunologic abnormalities including defects in NK and T cell effector functions. Following EBV infection there is an exaggerated NK and CD8+ T cell response, but one which fails to control infected cells. High levels of cytokines are produced, macrophages become activated, and a hemophagocytic syndrome can develop and prove fatal. The second disorder is not familial but occurs more commonly in children in Southeast Asia than elsewhere. It appears to result from an unusual entry of EBV into T cells and NK cells. High levels of cytokines are again produced, and virus loads remain very high in peripheral blood. A potentially fatal viral-associated hemophagocytic syndrome may develop, or the disease may rather present with

chronic or recurrent mononucleosis symptoms accompanied by large expansions of EBV-positive NK and T cell clones. In vitro studies of infected T cell lines have demonstrated the down-regulation of SAP by LMP1, suggesting that the underlying pathogenesis of the disorder may resemble that of XLP.

Diseases Associated with Long-Term Carriage of Virus

For the vast majority of infected individuals, long-term carriage of EBV has little apparent consequence. EBV-induced infectious mononucleosis does not recur, and although virus shedding continues indefinitely, it is controlled and has no deleterious effects. The virus is, however, potentially oncogenic. It has after all evolved, to profoundly change the behavior of latently infected cells, and has been implicated in the development of long list of cancers (Rickinson and Kieff 2007). Some of these, including ► [plasmablastic lymphoma and leiomyosarcoma](#), which are almost exclusively seen in HIV-infected individuals, ► [aids-associated Burkitt's lymphoma](#), ► [AIDS-associated Hodgkin's lymphoma](#), and ► [immunoblastic lymphoma](#), are linked in some way to immune suppression. Others such as endemic and sporadic Burkitt's lymphoma, Hodgkin's lymphoma, NK/T cell lymphoma, undifferentiated nasopharyngeal carcinoma, and gastric carcinoma are not. Some are always EBV associated; some have only a partial association.

The role that the virus plays in immunoblastic lymphomas in the context of iatrogenic immunosuppression is possibly the most straightforwardly etiologic. Posttransplant lymphoproliferative disorders occurring early after transplant-related immunosuppression, most of which are immunoblastic lymphomas, can begin as polyclonal expansions of EBV-infected B cells in uncontrolled latency III and may respond to reduction in immunosuppression, suggesting that they are driven by EBV gene expression (Cohen 2005). They are most common in EBV-seronegative recipients, consistent with the assumption that it is failure to control initial

infection of a B- and a failure of the infected cell to transition into the resting memory B cell compartment cell (Thorley-Lawson and Gross 2004). Many such tumors, however, particularly those that arise several years after transplantation, are monoclonal and may carry mutations and chromosomal abnormalities. The vast majority are still EBV positive, but the role of the virus is less certain. This is also the case for the systemic EBV-associated AIDS-associated lymphomas, which, although they are associated with immune deregulation, can arise in patients with relatively high CD4 counts. In general, their incidence has not dropped as profoundly as certain other tumors, such as Kaposi sarcoma, with the advent of highly active antiretroviral therapy (HAART) (Appley et al. 2000). However, some EBV-associated lymphomas, such as primary central nervous system lymphoma, are generally associated with profound immunosuppression and are rarely seen in HIV patients receiving HAART.

Endemic Burkitt's lymphoma is the tumor in which EBV was originally identified. It is a tumor typically seen in children in East Africa in areas of holoendemic malaria, essentially always carries latent virus, and generally expresses a latency I phenotype. Sporadic and AIDS-associated Burkitt's lymphomas, found elsewhere, are less consistently associated with EBV. The principal underlying cause of all Burkitt's tumors is believed to be the c-myc translocation that they all carry. They are typically B cells that have undergone somatic hypermutation, a process during which any B cell is more vulnerable to the occurrence of inappropriate translocations. EBV upregulates the activation-induced deaminase required for hypermutation and translocation and can counterbalance the apoptotic effects of c-myc overexpression (Gromminger et al. 2012). EBV, HIV, and malaria are also all potent B cell drivers, and this is one possible contribution that each may make to the development of the tumor (Magrath 2012).

About 50% of non-AIDS-associated Hodgkin's lymphomas are EBV positive, and the risk for the development of Hodgkin's lymphoma is increased about fourfold following infectious mononucleosis. Many Hodgkin's lymphomas

and most EBV-positive lymphomas, which typically expressed the latency II phenotype, have nonproductively rearranged immunoglobulin genes, and it has been suggested that the role of EBV may be to rescue such a cell, which otherwise would be lost to apoptosis because of the absence of antigen stimulation (Thorley-Lawson and Gross 2004).

Extranodal nasal NK/T cell lymphomas and undifferentiated lymphoma are relatively rare tumors, most common in East Asia, and are typically also associated with EBV (Nava and Jaffe 2005). As noted above infection of NK and T cells is not typically seen in uncomplicated infection with EBV, and these cells are not known to harbor virus in generally healthy individuals. However, just as infection of NK and T cells in the context of viral-associated hemophagocytic syndrome has potentially life-threatening outcomes, the EBV-positive NK/T cell lymphomas are particularly aggressive. It is perhaps of interest that both are most common in the same part of the world.

Essentially all undifferentiated nasopharyngeal carcinomas (NPC) carry latent EBV, often with a latency II phenotype. It is generally agreed that EBV is an essential risk factor for the disease, but the view that is developing is that it may play the role of a tumor promoter rather than a tumor initiator (Lo et al. 2012). Although the cancer occurs worldwide, it is most common in ethnic Southern Chinese, in Eskimos of Alaska and Greenland, and in some populations in North Africa. In Southern China, the annual incidence rate in men, in whom the disease is more prevalent, is more than 20 per 100,000. NPC also shows a familial distribution which has facilitated studies of its etiology. The current model of tumor development is that genetic abnormalities, perhaps exacerbated by exposure to carcinogens, facilitate infection and latency of EBV. EBV then contributes further to disease as a result of expression of RNAs and proteins that influence the cell environment, perhaps effect epigenetic changes, and lead to outgrowth of a faster growing clone (Lo et al. 2012). High titers of antibodies to lytic cycle proteins presumably reflective of a burst of lytic replication precede development of disease by several years and are prognostic (Zeng

et al. 1985). The association of EBV with gastric cancer is less strong with only about 10% of cases being positive, but on a global scale this amounts to possibly the largest tumor burden associated with the virus. Again, it is generally believed that EBV is playing some role in the development of the cancer and emphasis has been put on the epigenetic changes that it can induce, particularly, CpG island methylation.

Finally, it should be noted that there is one, and currently only one, disease associated with lytic replication of EBV, namely, oral hairy leukoplakia (OHL). OHL was first recognized at the beginning of the AIDS epidemic. It is a feature of substantial immunosuppression and is infrequently seen outside the context of full-blown AIDS. It is an epithelial lesion, resembling thrush in appearance and is typically seen on the lateral borders of the tongue. In patients receiving HAART, it is rarely seen (Nokta 2008).

Vaccines and Therapeutics

To date there is no licensed vaccine for EBV, although there is a general consensus that there is a need for both a preventive and a therapeutic vaccine. One phase 2 trial of a soluble form of the glycoprotein gp350 has been performed (Sokal et al. 2007). It failed to prevent infection but did significantly reduce the incidence of infectious mononucleosis in those who were infected. It has been suggested that T cell epitopes should be included in any improved vaccine to eliminate B cell infections (Long et al. 2011), although a recent study of the efficacy of a combination of gp350 and EBNA3 proteins from the very closely related lymphocryptovirus in rhesus monkeys did not support this (Sashihara et al. 2011). Use of gp350 alone was the most effective approach in this model, and it significantly reduced virus load. Clearly more work is needed to explore additional candidate proteins.

EBV replication is sensitive to valacyclovir and related drugs, but no EBV-associated disease, beyond OHL has been shown to be amenable to treatment with them. Considerable progress, however, has been made toward generating

EBV-specific T cells for therapy of posttransplant lymphoproliferative disease, and efforts are ongoing to extend the approach to treatment of other tumors expressing EBV antigens. The main challenge has been to overcome the potentially immunosuppressive environment of the tumor and the fact that there are fewer CD8⁺ epitopes in those tumors that express the latency II phenotype (Long et al. 2011).

Conclusion

Like many of its herpesvirus brethren, EBV is a very successful virus that has evolved primarily for peaceful coexistence with its host. Even the best of relationships can go wrong, however, and, given the vast numbers of people who carry EBV, even relatively rare outcomes can have significant consequence. The ever-growing list of diseases associated with long-term carriage gives pause for concern. Several of the tumors arising in individuals at known risk, transplant recipients or populations at risk for NPC, are potentially amenable to early diagnosis by monitoring for increased DNA loads in blood or, in the case of NPC, altered antibody profiles, and these kinds of preemptive measures are ongoing. There has been no big effort to this point to interfere with infection *ab initio*, but this may be changing. Prevention of infection with any virus capable of establishing latency is extremely challenging, as experience with HIV vaccines has shown us. Unlike HIV, EBV is, however, antigenically very stable, so the prospects for success are brighter.

Definition

Religion and spirituality have social, cultural, and historical importance in most societies. Indeed, some argue that religion and spirituality are at the heart of being human and are an important aspect of socialization. Nevertheless, until recently, religion and spirituality were at best ignored and at worst denigrated by social scientists and health professionals (Koenig et al. 2001). Acceptance of religion- and spirituality-related research has been fueled by empirical evidence supporting the efficacy of faith-based health promotion interventions and the relationship between dimensions of religion and numerous mental and physical health outcomes (Koenig et al. 2001; DeHaven et al. 2004; Campbell et al. 2007; Yeary et al. 2012). In the area of sexual health, dimensions of religion and spirituality have been associated with several HIV risk behaviors

(Koenig et al. 2001). However, most HIV-related religion-health research is cross-sectional, and the faith-based HIV risk-related interventions that have been conducted are primarily among Protestant Christian study populations in the United States. As a result, the specific ways that positive (e.g., religious support and religious coping) and negative (e.g., stigma and social isolation) dimensions of religion and spirituality affect HIV risk behaviors are poorly understood.

Advantages of Faith-Based HIV-Related Interventions

The Centers for Disease Control and Prevention and the 2010 National AIDS Strategy for the United States have both called for greater involvement of faith communities in addressing HIV in the United States (Sutton and Parks 2013). Likewise, international organizations such as the Joint United Nations Program on HIV/AIDS, the United Nations Children's Fund, the World Health Organization, and the United States Agency for International Development have also appealed to faith-based organizations to help address HIV (Woldehanna et al. 2005). There are multiple reasons for requesting greater involvement from faith-based organizations. Partnering with religious organizations often adds credibility to community-based health research (Campbell et al. 2007). Faith-based organizations can provide a unique and opportune venue to recruit

participants and carry out community-based health promotion research because of their stable memberships, regularly held meetings, and available resources (Campbell et al. 2007). Furthermore, studying the role of religion and spirituality in health promotion may be particularly important for research efforts targeting health disparities in minority and underserved populations (Campbell et al. 2007) since many faith-based interventions in these communities frequently enjoy enhanced cultural relevance (DeHaven et al. 2004). These benefits are believed to be due to the community's extant view of local faith-based organizations as sources of spiritual support and social outreach and religion's role as a source of personal strength and cultural cohesion (Levin et al. 2005).

Core Elements of Faith-Based Interventions

Most faith-based HIV interventions share common fundamental elements. A critical element of several faith-based interventions is the use of a community-based participatory research (CBPR) approach to support collaborative partnerships between the faith community and the researchers (Francis and Liverpool 2009; Williams et al. 2011). The involvement of members of the faith-based organization in intervention development, implementation, evaluation, and even dissemination can be advantageous to all parties. Collaboration can help to establish trust, build effective and equitable partnerships, create open and honest dialogues, and allow researchers to gain a better understanding of the attitudes and norms of the faith community, while members of the faith community gain a better understanding of research methodology and a sense of ownership in the intervention and its outcomes (Francis and Liverpool 2009; Williams et al. 2011). Following CBPR principles may also result in a more effective and sustainable faith-based intervention, greater participation by the faith-based organization, and greater cultural understanding and sensitivity among the researchers (Francis and Liverpool 2009; Williams et al. 2011).

Another core element of faith-based HIV-related interventions is the use of cultural targeting, defined as "the use of a single intervention approach for a defined population subgroup that takes into account characteristics shared by the subgroup's members (p. 136)" (Kreuter et al. 2003). Thus, culturally targeted faith-based HIV prevention, testing, and support messages should be adapted to be applicable to the beliefs and values of the faith community. Incorporating content that is culturally, socially, and historically relevant to the characteristics and religious beliefs of the community will enhance the intervention's relevance and comprehension among participants (Campbell et al. 2007; Williams et al. 2011). Cultural targeting of the intervention design, materials, and content naturally flows from the use of a collaborative and equitable approach to research. Lastly, the use of nonjudgmental and non-stigmatizing language and content is essential to any HIV-related intervention. Compassion and support are often the hallmarks of faith-based interventions because compassion and support for the sick and vulnerable are central tenets of most religions and faith-based organizations. However, early in the collaboration, partnering researchers may need to help faith leaders address lingering stigma surrounding HIV within their communities of faith (Francis and Liverpool 2009).

Definitions of Faith-Based Interventions

According to DeHaven et al. (2004), an intervention is faith-based only if it arises from a church's health ministry or a special interest group (DeHaven et al. 2004). In contrast to this strict criterion, Lasater et al. (1997) describe four levels of faith-based interventions. The first level requires the church to be used as the recruitment site for the intervention; the second level requires that the intervention be delivered at a church; the third level includes members of local churches in intervention delivery; the fourth level includes spiritual elements in the health message of the program (Lasater et al. 1997). Most published faith-based HIV-related interventions fulfill the requirements of being faith-based according to

these definitions (Williams et al. 2011). Faith-based interventions may also vary by the extent to which they incorporate religious or spiritual elements into their intervention content (e.g., interventions being faith-based versus church-placed), which can range from matching observable characteristics on printed materials to adapting intervention content to comply with core cultural values and sociohistorical factors (Resnicow et al. 1999).

Barriers and Challenges to Faith-Based Interventions

The primary challenge to implementing faith-based HIV interventions is reconciling religious doctrines with HIV risk behaviors, including illegal drug use and unprotected sex outside of a monogamous relationship or marriage. Many religious traditions emphasize abstinence until marriage and consequently may be resistant to endorsing sexual education programs that include other risk reduction strategies. However, empirical findings support the use of comprehensive sexual education curricula as a more effective method of reducing HIV risk (Underhill et al. 2007). Researchers must appreciate the difficult position of faith leaders who seek to host interventions in their places of worship; researchers may need to be willing to compromise and revise intervention content and project goals accordingly. Other strategies that may help navigate this sensitive negotiation process include providing faith leaders with knowledge about the HIV epidemic in their community and similar communities and actively collaborating with faith leaders throughout the intervention so they feel a sense of ownership in the intervention and its outcomes. Researchers can also address this challenge by developing faith-based interventions that allow participants to use a personal construction of spirituality and faith rather than utilizing formal religious tenets. An example of a faith-based intervention that does this is discussed below (Margolin et al. 2006).

Stigma and homophobia are also barriers to effective faith-based interventions. Gay, lesbian,

bisexual, and transgender individuals have reported experiencing stigma and homophobia at places of worship, which may limit their access to the support and prevention efforts offered by religious communities and may inadvertently increase vulnerability to HIV (Sutton and Parks 2013). Additionally, stigma surrounding relationship types and dynamics that are unfamiliar and/or unapproved by the faith community continue to be barriers to HIV interventions in faith-based settings. For example, religious communities may face uncertainty in handling sexual relationships outside of traditional marriage, sexual relationships with more than one partner, same-sex relationships, and relationships that do not conform to typical gender roles. When working with faith communities, stigma and homophobia must be addressed in the formative phases of intervention development. Innovative solutions can be devised when researchers and faith leaders have open and honest dialogues about these difficult topics and work to reach compromises that promote the sexual health of the population of interest. Furthermore, extending these conversations to all religious leadership and congregants will help reduce stigma and normalize discussions of HIV in their community (Nunn et al. 2012). Another strategy is to collaborate with local public health agencies to provide faith-based intervention participants with evidence-based materials about HIV risk reduction. This will allow faith leaders to frame intervention content in a manner that is congruent to their religious values while allowing participants to receive a comprehensive sexual health message (Francis and Liverpool 2009). Framing HIV risk reduction in a culturally appropriate manner may help to reduce stigma. For instance, conceiving of HIV risk reduction in terms of social justice or public health rather than sexuality, or framing support for people living with HIV or at risk for HIV in religious values of compassion and caring for the sick, may make the message more acceptable to the faith community (Francis and Liverpool 2009; Nunn et al. 2012).

Another barrier to effective faith-based interventions is that religious communities may not believe that their members are at risk for

HIV. Many faith communities remain silent about the presence of extramarital relationships, concurrent partnerships, same-sex relationships, drug and alcohol use, and risk of sexually transmitted infections in their community. Such silence is a long-standing tradition in some communities that deem such behavior as sinful, and social norms opposed to discussing such topics in a place of worship further support this silence. Without innovative strategies to overcome this challenge, researchers may have a particularly difficult time partnering with these faith communities. However, researchers can encourage such faith communities to begin to talk about these difficult topics by providing information about HIV risk in their community, culturally tailoring HIV-related messages and programs in a manner that is appropriate for the faith community, and presenting the leadership of the faith-based organization with diverse options about how they can address HIV in their community (i.e., HIV prevention, HIV testing, and/or supporting people living with HIV) (Nunn et al. 2012). In addition to the challenges listed above, mistrust between churches and researchers, reciprocal misunderstanding of values and norms (e.g., appropriate language and content for a faith-based setting versus the need for a control condition), competing agendas and priorities (e.g., evangelism versus evaluation), the difficulty of integrating the complex topic of religion and spirituality into any health promotion intervention, and the perpetual lack of resources act to heighten the barriers that limit the development and dissemination of faith-based interventions that address HIV (Margolin et al. 2006; Williams et al. 2011).

Special Ethical Considerations of Faith-Based Interventions

Plante (2007) recommends four ethical concerns that should be addressed when integrating faith into health promotion: respect, responsibility, integrity, and competence (Plante 2007). *Respect* for religious beliefs and values is critical in every HIV-related intervention. However, while conducting faith-based interventions, researchers

and faith leaders alike must examine their own religious and spiritual beliefs and ensure that they do not impose their beliefs onto intervention participants. Although researchers are not required to agree with the faith traditions of the study population, it is critical that they be respectful of the faith traditions of the study population. This is a particularly delicate matter when dealing with behaviors and populations that are frequently not accepted by the faith community. Collaboration with members of the faith community and local faith leaders and extensive formative research will help ensure that intervention participants are being respected and that the intervention is appropriate for the population of interest. Additionally, the use of CBPR approaches will help assure that disputes between faith community beliefs and researcher recommendations are appropriately vetted by all stakeholders involved in the intervention. Researchers considering conducting faith-based HIV-related research can also engage in thorough reflective analysis of personal religious beliefs prior to conducting such research. Reflection should be aimed at addressing judgmental attitudes toward differing faith beliefs and establishing an open dialogue about ways to understand and respect the faith beliefs of others.

The use of faith to culturally adapt health promotion interventions demonstrates *responsibility* to the religious beliefs of the study population. Conversely, ignoring the faith of individuals at risk for and living with HIV has the potential to be ethically irresponsible, especially if the incorporation of faith-based elements will enhance the relevance, effectiveness, and sustainability of the intervention. Researchers are responsible for acknowledging the importance of faith beliefs and should use faith as an innovative tool for culturally adapting HIV-related interventions. Similar to strategies to ensure respect, responsibility to the study population is enhanced through formative research with members of the faith community and potential participants. Likewise, beliefs that increase HIV risk behaviors should be acknowledged and addressed in a sensitive manner.

Integrity demands that researchers conducting research in communities of faith must not try to

usurp the role of faith leaders in that community. The role of the researcher is to collaborate with faith leaders and congregants to create HIV interventions that are appropriate for that community. Most HIV researchers are not trained in theology, philosophy, or religion and therefore should not overstep their contribution to the faith-based adaptation of the HIV intervention. This is particularly important for researchers that are members of the same or similar religious group as the community they are working with. Researchers must be honest regarding their limitations. Similarly, faith leaders must not force their religious beliefs on intervention participants.

Lastly, *competence* on how to appropriately address HIV-related topics in a faith-based setting cannot be assumed. Researchers desiring to create faith-based interventions should take advantage of the growing literature on the topic, attend conferences and workshops on the topic, and most importantly seek out partnerships with faith leaders that are willing to collaborate on these topics. Furthermore, researchers should carefully examine themselves for potential biases against certain religious beliefs.

Examples of Faith-Based HIV Interventions

Three published faith-based interventions can provide examples of the diversity of faith-based interventions and ways that faith elements can be incorporated into HIV-related interventions. These interventions were selected because they were current, provided outcome data, and were descriptive in their use of faith-based elements. While the three major topics that faith-based interventions typically address are HIV prevention, HIV testing, and supporting people living with HIV, the interventions described below address only HIV prevention and HIV testing. Although there were several reports on the work of faith-based organizations, particularly the Catholic Church, to provide financial, spiritual, emotional, and physical support to people living with HIV, few provided outcome data and therefore were not included in this discussion.

Spiritual Self-Schema (3-S) Therapy was a spirituality-focused clinic-based randomized-control psychotherapy intervention designed to promote drug abstinence and HIV prevention behavior among methadone-maintained individuals with negative or unknown HIV serostatus (Margolin et al. 2006). Therapists used a framework based on the Buddhist Noble Eightfold Path and promoted mindfulness exercises and meditation to support participants' weakening of their addict self-schema and development of their spiritual self-schema. Unlike the addict self-schema, the new spiritual self-schema would be motivated to abstain from drugs and reduce risk of HIV transmission. A Buddhist framework was chosen because it was compatible with cognitive behavioral therapy and multiple belief systems and allowed participants to personally define their own spiritual beliefs. Seventy-two participants received either standard care or 3-S therapy. Compared to the standard of care participants at post-treatment, controlling for demographic variables and pretreatment risk behavior, participants who received 3-S therapy reported greater motivation for HIV prevention and were eight times less likely to report HIV risk behavior during the prior month (Margolin et al. 2006).

YOUR Blessed Health (YBH) was a community-initiated multi-level intervention that aimed to improve HIV risk reduction skills and behaviors and increase HIV awareness and knowledge among African American youth ages 11 to 25 years old by improving the capacity of religious leadership to address HIV/AIDS and sexual risk behavior (Griffith et al. 2010a, b). Several activities were used to accomplish this goal, including HIV awareness group sessions for youth, group sessions for adults, extensive training for religious leadership, church-wide HIV awareness and stigma reduction activities during weekly services, and community-wide HIV awareness activities. A community-owned and community-managed approach to CBPR was used to design, implement, and evaluate the intervention. In keeping with CBPR and ethical principles described above, each of the 42 faith-based and community-based participating organizations was allowed to tailor the YBH intervention as they

saw fit. Typically, adaptation was focused around the structure, frequency, and timing of the sessions. Although qualitative findings were promising, there were no significant differences in HIV-related outcomes among intervention participants. However, researchers and community partners count the real success of the project as their ability to build capacity within their faith community and to initiate changes in community norms.

Taking It to the PEWS (TIPS) is another example of a CBPR intervention (Berkley-Patton et al. 2010). Rooted in the Black Church Week of Prayer for the Healing of AIDS in Kansas City, the TIPS program was a community-initiated and collaboratively developed intervention to increase HIV awareness and testing and reduce HIV-related stigma within African American communities and churches. Church partners selected these topics as the focus of the TIPS program because they were considered less controversial and potentially less divisive than sexual risk reduction (i.e., condom use). A detailed needs assessment and an equitable and collaborative partnership with faith leaders were integral to the intervention. Intervention materials and activities were religiously tailored, church leadership served as interventionists, and the program was designed to fit in with already-ongoing church activities. Twelve Kansas City churches participated in the TIPS program, reaching approximately 3,400 church and community members. Process evaluation findings using focus group and implementation data were promising. Church members that reported high TIPS exposure had significantly lower HIV stigma, greater positive feelings about church involvement in HIV, and greater readiness to be tested for HIV.

Conclusion

Despite barriers and challenges, faith communities and researchers have readily collaborated in the development and implementation of several interventions that relate to HIV prevention including sexual risk reduction, substance abuse treatment, injection drug use risk reduction, HIV

testing, and support for people living with HIV/AIDS. There is a need for more faith-based HIV prevention research and outcome-focused religion-HIV risk-related research. Although relatively few in number, faith-based interventions offer an innovative approach to addressing HIV that has the potential to enhance the effectiveness of community-based research efforts.

²Duke Global Health Institute, Duke University, Durham, NC, USA

Definition

This chapter describes family-based HIV prevention interventions and research on their efficacy. Both domestic and international interventions are discussed.

Risky sexual behaviors that can lead to HIV infection are influenced both by the characteristics

of an individual and the characteristics of their interpersonal, social, and cultural environment. The recognition of these layers of influence has prompted the development of ► **multilevel and structural approaches to HIV prevention** that go beyond targeting only the individual. For adolescents, the family can be a particularly significant external system of influence, characterized primarily by parent-adolescent relationships and interactions (Bastien et al. 2011; DeVore and Ginsburg 2005). Research has shown consistent links between parenting behaviors and characteristics and adolescents' sexual risk taking (DeVore and Ginsburg 2005; Kincaid et al. 2012).

The definitions of “families” and “parents” are quite broad and flexible in the HIV prevention literature; generally these terms identify the primary caregiver(s) for an adolescent regardless of biological relationship, with emphasis on the role and relationship to the adolescent. Caregivers can be biological parents, grandparents, adoptive parents, guardians, other extended family members, or even an older sibling and are referred to as “parents” in this chapter. Likewise, a “family” may be a parent-adolescent dyad or a large household whose members share responsibility for an adolescent's well-being. Regardless of family structure, the central goal of family interventions is to build and support family systems that can protect adolescents from contracting HIV.

The family provides a unique and promising point of intervention, as parents are in a position to serve as teachers, role models, sources of support, and monitors of their adolescent's behavior (Pequegnat and Bell 2012). Working at the family level can therefore generate change across these multiple roles. Further, the family unit is generally a constant structure in adolescents' lives and can wield ongoing influence long after an intervention ends. The consistent presence of the family may protect against the common problem of waning intervention effects over time, a major concern in the field of HIV prevention. Family-based interventions are particularly advantageous because they provide information and skills to multiple people who are connected with one another, rather than relying only on an individual's ongoing self-motivation to maintain behavior change.

Parenting and Sexual Risk Behaviors

Specific parenting practices have been shown to prevent or reduce adolescent sexual risk behaviors, a key component of HIV prevention. Parents' monitoring of their adolescent's activities, whereabouts, and relationships has emerged as one important protective factor against risk sexual behavior; adolescents who are monitored closely are less likely to engage in risky sexual behaviors, including unprotected sex and early sexual debut. Most studies of parent-adolescent communication have also reported that higher-quality communication between adolescents and their parents is protective against risky sexual behaviors, particularly when the communication includes frequent, informed, and comfortable discussions about sex. In addition, parents' warmth and involvement in their adolescent's activities have been identified as positive parenting practices that reduce high-risk sexual behavior. For adolescents with specific risk factors for HIV infection, such as living in poverty, being part of a marginalized group, or having a psychiatric illness, the family unit is an especially promising source of protection, as broader community support systems can be less accessible and may provide fewer resources to these subpopulations.

Aims of Family-Based Interventions

As parents have the potential to directly impact adolescent risk behavior, family-based interventions to prevent HIV offer promise to reduce HIV incidence. Multiple family-based prevention interventions have been developed, most within the past 15 years, often with the objective to ► [Delayed Sexual Debut](#) among younger adolescents and to decrease risk behavior of sexually active teens (Downing et al. 2011; Pequegnat and Bell 2012).

The mechanisms of HIV prevention vary across interventions. Some family-based interventions focus primarily on improving knowledge and attitudes about HIV within the family, while others include more active behavioral components to build parenting skills that are associated

with reductions in sexual risk behavior. Most often, family-based interventions aim to improve parent-adolescent communication by expanding the content and increasing the frequency of conversations parents have with their adolescent about sexual risk and HIV (Bastien et al. 2011). Effective communication maximizes the synergistic impact of knowledge and parenting techniques, as transferring information and values to adolescents is likely to be more successful if parents are able to provide support, warmth, involvement, and effective monitoring as well.

Structure and Strategies of Family-Based Interventions

The first step in most family programs is often to give parents accurate and appropriate information pertaining to HIV prevention and sexual risk behaviors. The interventions then seek to build parents' comfort with the material and confidence to initiate conversations with their adolescents. Some interventions have relied on multimedia formats, such as audio CDs or videotapes, to deliver information to parents in the home setting. These multimedia strategies serve to allow parents to complete much of the intervention privately and at their convenience. However, most family-based interventions bring together multiple families in group sessions to deliver didactic information.

The length of family-based interventions varies greatly, and there is little consensus about optimum intervention exposure. Most interventions are delivered in multiple sessions, ranging from three to more than a dozen, often occurring once per week. Some programs target only the parents, while some include the adolescents as well. In interventions that involve both, parents and adolescents are often initially separated to deliver more targeted education on topics such as effective disciplining practices for parents or peer pressure for adolescents. Parents and adolescents are then brought together for discussion and/or skills practice. The separate groups can allow for more candid discussions about sex and HIV by confirming basic knowledge, answering

initial questions, and reducing discomfort – before adolescents and parents are asked to discuss these topics as a large group.

Successful family interventions are characterized by their participatory nature, engaging participants in interactive activities beyond the presentation of didactic material and discussion. Participatory activities for adolescents may include practicing condom use skills or engaging in role-play to refuse unwanted sex; parents may role-play to practice conversations with adolescents, particularly in interventions that aim to improve parent-adolescent communication and relationships. Participatory family interventions often have the most integrated designs, equally emphasizing both education and practice.

Some interventions have targeted either mothers or fathers specifically, as well as either daughters or sons. The gender of the parent and adolescent is not necessarily matched; for example, an intervention may aim to help mothers reduce risk behaviors of their sons through understanding their developmental challenges (Jemmott et al. 2000). In general, gender-specific interventions have been developed primarily for mothers, or female caregivers, because male caregivers have been more difficult to engage. Efforts to involve fathers are growing, however, by developing specific interventions for fathers and engaging them in family interventions more generally.

Interventions Tailored for Specific Populations

Perhaps even more than other types of interventions, family-based interventions must be tailored, as family structures and interaction styles can vary significantly across contexts, cultures, and populations (e.g., substance users). Further, sexual behaviors are often tied closely to value systems, religious beliefs, and cultural and social norms. The settings in which interventions are delivered should be selected appropriately for the intended recipients. In response to varied needs across subgroups, tailored interventions have been developed for specific populations both in the United States and internationally.

Ethnic Minorities. In the United States, tailored family-based interventions have been developed for several specific populations, with the largest number for African American and Latino families. Tailoring interventions for different ethnic groups allows the intervention content to go beyond the basic HIV prevention messages and skills to address some of the contextual challenges faced by specific populations. For example, an intervention for African American families in the rural south may integrate a focus on racial socialization (Murry et al. 2011). *Familia Adelante*, an intervention for Mexican-American families developed in 1993 and most recently implemented in 2003 among urban families in California, concentrated specifically on acculturative stress with the aim of reducing overall family stress and thus improving adolescent substance use behavior, attitudes toward HIV risk behavior, and psychosocial coping (Cervantes et al. 2011). Targeted interventions can also include discussion of HIV rates, norms for sexual behavior, and most common modes of transmission in that specific population.

Adolescents with Specific Risk Factors. Interventions have been developed for populations of adolescents who have specific risk factors that can increase their chances of contracting HIV, particularly substance use and mental health problems. One rationale for these types of programs is that similar family-level characteristics may underlie various adolescent risk behaviors and contribute to psychological distress. Thus, rather than focusing only on the adolescent's specific risk behavior or mental health symptoms, these interventions target family-level characteristics. For instance, a community-based study in low-income areas of Baltimore, MD, found that emphasizing parental monitoring – which is shown to be protective against HIV risk behavior – provided protection against adolescent substance use in both the short and long term (Wu et al. 2003). *Project STYLE* is an intervention for adolescents in treatment for mental health problems. The school-based intervention aims to improve family communication about sex while also addressing the coercive patterns of communication that can often develop in families affected by mental health concerns

(Donenberg et al. 2012). Efforts are also underway to develop interventions specifically for families of gay, lesbian, and bisexual youth.

International Settings. Outside of the United States, most family-based intervention development has been focused in developing countries, particularly in sub-Saharan Africa, where HIV rates are the highest. Family-based interventions have been developed or adapted specifically for these settings, as familial and cultural norms, as well as the factors contributing to HIV risk, vary by setting.

In many parts of sub-Saharan Africa, extended family members are integral to the family system. Being part of these larger family units is often a main source of identity, and family members may share resources freely with one another. In rural areas in particular, members of extended families and multiple generations of a family may live together and share material resources and household responsibilities (e.g., care of children and adolescents, farming). These familial norms influence the effective design and implementation of family-based interventions.

Cultural values and religious beliefs are especially important to consider when working in international settings. Examples include norms around gender roles, with males holding decision-making power, or religious beliefs that strongly discourage condom use. Culture and religion are also natural sources of support on which interventions can build if they are recognized as community strengths.

Some US family-based interventions have been effectively adapted for an international setting. The *CHAMP (Collaborative HIV/AIDS Prevention and Adolescent Mental Health Project; Baptiste et al. 2006)* intervention, originally implemented in Chicago, was adapted for South Africa. CHAMP is a family-based program that targets improved parenting skills and youth social problem-solving, among other aspects of family well-being. To tailor CHAMP, developers conducted ethnographic research in KwaZulu-Natal, South Africa, and identified changes needed in the adapted program (e.g., addition of a session on bereavement; changing the structure to a cartoon-based format rather than written).

Families Matter! is an intervention for 9- to 12-year-olds and their caregivers first adapted for Kenya from a US-based program (*Parents Matter!*). Adaptation was guided by a needs assessment involving focus groups with community members and consultation with local experts in HIV prevention (Poulsen et al. 2010). In this case, formative research found the original content to be largely relevant but changed the format of some of the materials and changed the name to include “families” to be more inclusive of all types of caregivers. *Families Matter!* is now being adapted for other countries as well.

Children and adolescents orphaned by HIV/AIDS in sub-Saharan Africa require specific consideration in developing family-based interventions. Orphans are a particularly vulnerable group, with some studies finding that they exhibit higher levels of risk behavior and/or mental health problems that can increase HIV risk during adolescence or in the future (Operario et al. 2011; Thurman et al. 2006), as well as mental health problems that can increase HIV risk behavior (Cluver and Gardner 2007; Puffer et al. 2012). Extended family members often assume responsibility for a child or adolescent after the death of their parents, though families living in low-resource communities often do not have or allocate the resources to accommodate these children’s needs. HIV prevention interventions for orphans have often focused on increasing the financial and material resources allocated to orphaned children and adolescents, such as providing their new caregivers with grants to reduce the extra financial burden, providing cash transfers, or setting up savings accounts for orphans themselves (Cluver et al. 2013; Han et al. 2013). Economic interventions can help close the resource gap and thus decrease orphans’ vulnerability to HIV.

Evaluating the Effects of Family-Based Interventions

The effects of family-based interventions are typically measured by (a) reduction of sexual risk

behaviors, (b) improved knowledge or attitudes about sexual risk behavior and HIV, and (c) improved family interactions and characteristics that have been linked to safer behaviors.

Within behavioral outcomes, some family-based interventions report increased condom use, often measured by whether or not the adolescent used a condom the most recent time they had sex. Intervention studies have also documented reduced frequency of adolescents engaging in a variety of sexual behaviors (from kissing to intercourse). For adolescents who are not yet sexually active, some interventions reported delayed sexual initiation beyond the expected age-given norms for their context.

Interventions have also achieved improved knowledge about HIV among adolescents and parents and increased confidence to use risk reduction skills among adolescents. Adolescents report feeling more able to refuse unwanted sex and more confident that they can use condoms, both in terms of understanding how to use them and how to initiate conversations about condom use with partners. Adolescents in some interventions also report increased intentions to engage in less risky behavior in the future.

Parents in family-based interventions have exhibited significant improvement in use of positive parenting behaviors, including improved monitoring of adolescent behavior and increased warmth and support in their interactions with their adolescent. Perhaps the most common parenting outcome is improved parent-adolescent communication about topics related to sexual behavior and HIV. Parents and adolescents report more frequent discussions on these topics, and parents report higher self-efficacy to provide accurate information about HIV to their adolescent and to initiate these discussions.

The ultimate behavioral impacts of these improved parenting skills are unclear. For instance, while some research documents clear links between communication and adolescent sexual behavior (Bastien et al. 2011), other research shows no direct connection between the two (Downing et al. 2011). The effects of improved parenting also may differ by gender and other

characteristics. For example, some evidence suggests that while certain aspects of parenting, including monitoring, warmth, and emotional connection, are protective overall, improved monitoring is more effective for boys while the latter two qualities are more beneficial for girls (Kincaid et al. 2012). Thus, the impacts of changing parenting strategies and family interactions are complex, and more research is needed to determine which family characteristics are most important to target and for whom.

Limitations and Future Directions

Perhaps the most difficult aspect of studying the effects of family-based interventions is measurement. Accurately measuring whether a behavior has successfully been prevented or changed requires long-term follow-up, which is often not possible or feasible. The alternative is to measure behaviors that are associated with and/or thought to precede sex, such as kissing or spending time alone with the opposite sex. However, it is unclear whether these behaviors are truly indicators of future sexual *risk* behaviors.

Measuring behavior, both of the adolescent and parents, is difficult given reliance on self-report measures. Participants often understand how parents or adolescents “should” behave, which can lead to over-reporting of positive parenting strategies among parents and safer sex behaviors among adolescents. Measuring biological outcomes is an alternative strategy that would significantly improve confidence in intervention outcomes in terms of actual changes in sexual behavior. Biological indicators, such as rates of sexually transmitted infections or pregnancy, are very seldom used, though this is a clear future direction for the field. Finally, family relationships and interactions are complex, and current measures do not adequately capture the family dynamics that surely play a large role in the behavioral changes that are observed in intervention trials. Understanding these more complex interactions would be invaluable to improving future intervention development.

Conclusions

The evidence base for family-level interventions for HIV prevention is growing, and interventions are showing promising outcomes, particularly in increasing condom use and self-efficacy to engage in safer sexual behavior among adolescents. Family-based interventions also have been shown to improve parenting practices, including monitoring and warmth, as well as parent-adolescent communication. Multiple interventions have been developed and tailored for specific at-risk populations, including adolescents living in developing countries where HIV prevalence is high and adolescents with risk factors such as substance use and mental health problems. Research to evaluate the effectiveness of family-based interventions would be strengthened by the development and validation of measures to more accurately assess adolescent and parent behaviors, as well as the longer-term effects of interventions to prevent future risk behavior and HIV infection.

Female Condoms

Susan Tross and Theresa Exner
HIV Center for Clinical and Behavioral Studies,
New York State Psychiatric Institute, Columbia
University Medical Center, New York, NY, USA

Definition

This chapter will introduce the female condom, review its basic properties, present progress in, and barriers to, its public health promotion, and identify priorities for future promotion. It will present the history, efficacy, and acceptability of the female condom; implementation and evaluation of female condom promotion programs; and implications for future action. The reader is also referred to the comprehensive overview of the female condom by Gallo et al. (2012).

Urgent Need for Female Condom Promotion

Worldwide, one-half of people living with HIV are women (UNAIDS 2010). In the countries of sub-Saharan Africa, infection is more likely among women than men. For every ten men infected, 13 women are infected (UNAIDS 2010).

Among women, heterosexual intercourse is the primary route of HIV, as well as sexually transmitted infection (STI) transmission (UNAIDS 2010). At the same time, pregnancy is also a salient goal and, under some circumstances, concern of women. However, the passive nature of the female gender role in heterosexual relationships, in many countries, can make women's initiation of safer sex practices problematic. In male-dominated relationships, women's discussion of safer sex can elicit hostility and, even, rejection or abuse, from the male partner (Wingood and DiClemente 2000; Gender role 00062). Taken together, these factors make the promotion of female-controlled methods for dual protection – with respect to HIV and STI transmission as well as contraception – an urgent priority.

Currently, breakthroughs in antiretroviral treatment (ART), treatment as prevention (Cohen et al. 2011), vaginal microbicides (Abdol Karim et al. 2010; Pre-exposure Prophylaxis (PrEP): oral and topical (microbicides), Prevention of HIV 00378), and pre-exposure prophylaxis (PrEP) (Grant et al. 2010; Post-exposure Prophylaxis 00329), have led the global public health community to embrace the goal of an AIDS-free generation. This is extremely heartening. However, until economic, political, and health care infrastructure conditions can support universal scale-up, it is imperative to maximize the reach of currently feasible, accessible, and effective HIV prevention methods. Until PrEP becomes an established, safe, available, and affordable prevention option, the male condom is the only widely accessible means of HIV/STI prevention. Yet, it is limited by being a male-controlled method – within an epidemic that, globally, affects men and women nearly equally (UNAIDS 2010). The female condom is the only female-controlled method that has both contraceptive efficacy and high likelihood of STI prevention efficacy (e.g., Lytle et al. 1997).

Description of the Female Condom

The first female condom (FC1) was a flexible polyurethane cylinder, which covers the vaginal canal – between its inner ring, fitting the cervix, and its outer ring, fitting the opening of the vagina. FC1 was developed and manufactured by the Female Health Company, in Chicago, and approved, by the United States Food and Drug Administration (USFDA), for contraception and HIV/STI protection, in the event that a male latex condom was not accessible, in 1993. The second female condom (FC2), also from the Female Health Company, superseded the FC1, in 2005 – improved by its synthetic latex composition, lower cost, and quieter use. It carries the approval of the USFDA (as of 2009); CE Mark, endorsing for use in the European Union; approval by the World Health Organization Female Condom Technical Review committee; and recommendation for use by United Nations agencies. Currently, it is available, in over

100 countries, through public health initiatives, and in 20 middle and high-income countries, for purchase (Gallo et al. 2012). Three other female condoms are in different stages of development or marketing and distribution. The Reddy Condom (Medtech Products, Chennai, India) and the Cupid Female Condom (Cupid Ltd., Mumbai, India) are both latex condoms that contain inner sponges to better secure insertion; both have CE Mark, but not WHO Female Condom Technical Review approval. The Woman's Condom is a product of the Program For Appropriate Technology in Health (PATH) (Seattle, USA), an international, nonprofit, nongovernmental organization (NGO), which has been at the forefront of advancing new health technology and systems, including the female condom. The Women's Condom is a thin polyurethane film pouch, inserted within a capsule, and then released when the capsule dissolves; foam helps steady the condom, along the vagina. The Women's Condom was licensed to Dahua Medical Apparatus Corporation (Shanghai, China) in 2008; it obtained its CE Mark in 2010 and its Shanghai Federal Drug Administration (FDA) approval in 2011. Work is in progress to seek USDFA approval.

The female condom offers several important benefits for women, over the male condom (HIV Prevention and Women 00311). Most importantly, it is female-controlled. In addition, it has the following advantages: it can be inserted and worn 24 h prior to sexual encounter – allowing for greater spontaneity during sex. It covers more area of the female genitalia – and, thus, better protection from infections transmitted via skin or mucosal membranes (Gallo et al. 2012). It can produce greater sensation for both the woman and her male partner. As non-latex, it can be used with oil-based lubricants.

Use of the Female Condom

Like the male condom, correct female condom use requires a series of steps; without which efficacy can be compromised. These include checking expiration date; checking for condom damage; placing inner ring against cervix, to insert; twist

the outer end of the condom, before pulling the condom out, to remove, etc.). In fact, across studies, rates of female condom “failures,” consisting of lapses or errors in such steps, have been estimated to occur during 2.5–25% of uses (Gallo et al. 2012). It should be noted that male condom use is also susceptible to these lapses as well. It should also be noted that WHO has developed standards for reuse of female condoms (i.e., including disinfecting, washing, and drying) – up to five uses – to address this practice, especially in resource-poor environments (WHO 2002). However, in the absence of supporting evidence of efficacy, this is not recommended.

Efficacy of the Female Condom

Contraceptive Efficacy

There is converging evidence from prospective observational studies of the substantial contraceptive efficacy of the FC1 female condom. Studies may distinguish pregnancy rates for two patterns of use, over a 6-month or 1-year periods: “perfect” and “typical.” A pioneering study (Bounds 1992) obtained a 15% pregnancy rate, for typical use, over a 1-year period, in the UK. Farr et al. (1994) obtained (6-month) pregnancy rates of 22.2% (typical use) and 9.5% (perfect use) for women in Latin America and of 12.4% (typical use) and 2.6% (perfect use) for US women. Trussell (1998) obtained (6-month) pregnancy rates of 3.2% (typical use) and 0.5% (perfect use) for women in Japan. Both the FC1 and FC2 product descriptions cite pregnancy rates of 21% (typical use) and 5% (perfect use) for the female condom, and of 18% (typical use) and 2% (perfect use) for the male condom. There are no randomized clinical trials from which to obtain direct, contemporaneous comparative data.

STI/HIV Prevention Efficacy

There is converging, though not uniform, evidence from laboratory, observational, and intervention research of the efficacy of the FC1 female condom for STI prevention.

Several studies have examined the efficacy of FC1 for STI prevention. It should be noted that,

while highly promising, these sometimes used crossover, sometimes prospective comparison, and, only sometimes, randomized control designs.

Crossover Designs Galvao et al. (2005) used a crossover design – to randomize Brazilian women in a family planning clinic to two conditions (i.e., instruction to use two female condoms followed by the use of two male condoms and instruction to use two male condoms followed by the use of two female condoms). Analysis used the presence of prostate-specific antigen (PSA) in post-intercourse vaginal specimens as the primary outcome, as a biomarker for semen contact. The rate of PSA detection was greater in the female condom than in the male condom specimens. Another crossover study (Valappil et al. (2005) used similar crossover conditions with ten female and male condoms. The rate of PSA detection was comparable in both female condom and male condom specimens. It should be noted that, in crossover studies, self-reports of use problems (e.g., slippage) were greater for female condoms than for male condoms. However, as Gallo et al. (2012), as well as others, observe, self-reported problems decline as experience increases. Two, or even ten, condom uses may provide too brief exposure to gain proficiency and comfort with the female condom.

Prospective (Nonrandomized) Comparison Designs Soper et al. (1993) compared two groups of women with trichomoniasis in public clinics in four US cities – who either agreed to use the female condom or received treatment as usual. At 45-day follow-up, reinfection rates were equivalent in the two groups. Macaluso et al. (1999) also compared two groups of women in US public clinics – who either agreed to use female condoms (i.e., as alternatives when male condoms are not accessible) or received male condoms. Among consistent condom users, the rate of gonorrhea and chlamydia were comparable in both conditions. In a quasi-experimental design, French et al. (2003) provided counseling and either female condoms or male condoms to women, respectively, presenting on alternate weeks, to a Philadelphia STI clinic. At 6–12-month follow-up,

women in the female condom condition had a lower rate of positivity on a composite measure of infection with at least one of the following STIs: chlamydia, gonorrhea, syphilis, or trichomoniasis. However, the rate did not significantly differ with that of the male condom condition.

Randomized Trials In a randomized design using brothel as the unit of randomization, Fontanet et al. (1998) compared female sex workers in Thailand in two conditions – who either received counseling around male condoms or around a hierarchical message (i.e., combining male condoms and female condoms, as an alternative when male condoms are not accessible). At 24-week follow-up, women in the hierarchical message condition showed a decrement in the rate of positivity on a composite measure of infection (i.e., including gonorrhea, chlamydia, trichomoniasis, or genital ulcer disease), in comparison to those in the male condom condition. However, this did not reflect a statistically significant difference. In a randomized design of a structural intervention, using plantation as the unit of randomization, Feldblum et al. (2001) compared women in Kenya in two conditions – community-level campaign, counseling, and provision of male or female condoms versus campaign, counseling, and provision of male condoms only. At 6-month and 12-month follow-ups, the two conditions were comparable in rates of positivity on a composite measure (i.e., including gonorrhea, chlamydia, or trichomoniasis). It should be noted that secondary analysis highlighted provider reluctance about the female condom as an important obstacle to efficacy in the combined condom condition (Welsh et al. 2001).

While the above discussion has focused on the efficacy of female condom interventions on biological STI markers, their impact on condom use uptake is a crucial part of this efficacy. In addition to female condom provision, these interventions are based on cardinal behavioral science principles – that efficacious HIV safer sex interventions for women must include (cognitive, behavioral, and interpersonal) skills building for correct condom use, decision-making, and negotiation with male partners. It should be noted that

increments in protected intercourse occasions are an underlying finding of the above interventions (Fontanet et al. 1998; French et al. 2003; Artz et al. 2000).

It can be concluded that, thus far, research has provided support for the equivalent efficacy of female and male condoms to confer STI protection. However, this research points to a few possibly crucial gaps in the work to date. First, the research suggests that interventions might be more efficacious – if they afforded more experience with the female condom, perhaps over a longer period, and perhaps with more ongoing troubleshooting and problem-solving with providers, as consumers gain real experience. Second, the research also points to a critical, unresolved problem in female condom promotion: substantial, although variable, acceptability among consumers, both female and male, but low uptake. Third, the research highlights low acceptability among clinic providers, who are a potential primary link to female condom use in consumers and who would be important targets for female condom promotion programs.

Acceptability and Uptake of the Female Condom

Acceptability is an essential component in making the link between the existence of a robust, accessible, and affordable female condom and its uptake. The female condom acceptability and uptake research makes some important distinctions. First: among consumers of various types of related clinic services (e.g., STI clinic, family planning clinic, HIV clinic, and others), a preponderance of studies show that short-term acceptability of the female condom is high (UNDP/UNFPA/WHO/World Bank Special Programme of Research, Development and Research Training In Human Reproduction 1997). Second: however, acceptability in the general population is far lower. For example, in the 2002 US National Survey of Family Growth (Mosher et al. 2004), 1.9% of childbearing aged women reported ever using the female condom. Third: acceptability and uptake in high HIV seroprevalence, developing

countries (e.g., Brazil, South Africa, and others) exceed that in developed countries (e.g., the USA, the UK) (Warren and Philpott 2003). It has been reasoned that, in the former, the immediately palpable toll of HIV is a potent driver of this.

Acceptability is a multilevel phenomenon – which is operative at the consumer, provider, systems, and policy levels. Below existing knowledge of factors (i.e., barriers and promoters) underlying attitudes toward female condoms, at the consumer and provider levels, are summarized:

Consumers Short-term acceptability studies conducted in a wide range of settings (UNDP/UNFPA/WHO/World Bank Special Programme of Research, Development and Research Training In Human Reproduction 1997) demonstrate that the female condom is acceptable to diverse populations of both women and men, with the proportion trying the method ranging from 37% to 96%. A consistent finding is that women report that the female condom enhances their safer sex bargaining power within their sexual relationships (e.g., Gollub 2000). However, when the gendered power inequity in a relationship is too daunting, this is a powerful barrier to female condom use. In addition, physical aspects of the female condom (e.g., length, difficulty manipulating it to insert or remove, discomfort, and others) that – at least initially – can be awkward or challenging, can – before sufficient familiarity – be deterrent to use (Hirky et al. 2003). Cost and limited accessibility can be another barrier to use.

Providers Provider attitude toward female condoms is a pivotal variable in consumer uptake of female condoms. Studies of female condom acceptability among providers demonstrate rates that markedly lag behind those of consumers. In a study of 27 ART programs in Africa, Asia, and South America, only 32% reported providing female condoms, while 96% provided male condoms (Spaar et al. 2010). In a study of providers in four types of clinics in New York State, while the majority acknowledged the equal efficacy of the female and male condoms for pregnancy and disease protection, they also expressed reluctance to recommend the female condom to their clients.

They attributed this to the lack of familiarity and inexperience with it, as well as the lack of access. They also expressed some of the same concern with its physical aspects, as did consumers (Mantell et al. 2003).

Structural Barriers to Female Condom Promotion

Widespread promotion of the female condom has faced numerous barriers in the political and social environment. In 2008, female condoms accounted for only 0.8% of condoms distributed in sponsored programs (UNFPA 2008). In the USA, these barriers have included negative press, limited advertising and marketing, higher cost relative to the male condom, limited distribution in the public health system, and inadequate training of providers.

Implementation and Evaluation of Female Condom Promotion Programs

In order to bridge the divide between acceptability and uptake, the complex interplay of consumer, provider, health service delivery system, and policy factors must be incorporated into intervention (Social Contextual Factors in HIV Prevention 00295). HIV prevention science has evolved to address broader contextual factors that affect sexual risk behavior (Blankenship et al. 2000). Internationally, a variety of structural interventions have been mounted to promote female condoms, including mass media campaigns, free distribution programs in the public sector, and training of health care providers. In Washington DC, a citywide female condom distribution campaign was determined to be cost-effective – in deterring 23 infections – after the distribution of its first 200,000 condoms (McNeil 2012).

However, comprehensive multilevel structural interventions – that integrate consumer, provider, and systems approaches – have the maximum potential to advance female condom uptake. Four examples of system-wide interventions provide evidence of this potential. In South

Africa, a national female condom introduction program implemented free condom distribution in multiple venues (e.g., public sector clinics, community-based organizations, social marketing outlets, commercial pharmacies, etc.) and provider training in female condom counseling in eight (of nine) provinces (Mqhayi et al. 2003). In Brazil, a comprehensive initiative, including community advocacy, provider training in female condom use counseling, integration of female condoms into existing public sector programs, and consistent access to female condoms. In Nigeria, a combined free condom distribution and provider counseling program in six family planning clinics, increased purchase of condoms and other barrier methods (i.e., from purchases at 2% of visits, at outset, to 9% of visits, 18 months later), primarily accounted for by purchase of female condoms (Adeokun et al. 2002). In New York State, Exner et al. (2012) conducted a randomized clinical trial of a system-level intervention to promote female condom-positive organizational policy, counseling, and client use – in 44 agencies receiving funds from the NYS AIDS Institute. The intervention consisted of (1) Agency level: female condom, provision, female condom program and policy toolkit, and 12 months of (telephone) technical support, and (2) Counselor level: 1-day female condom training workshop and 12 months of (telephone) technical support. At the counselor level, several significant effects were obtained: increase in proportion of heterosexual women and men counseled on the female condom, increase in female condom knowledge, and increase in self-efficacy to conduct female condom counseling and in positive attitude toward the female condom. At the client level, a few significant effects were obtained: increase in client intention to use female condoms and increase in female condom knowledge.

Conclusion

Gender inequities in power, along with restrictive and polarized gender roles, make it difficult for many women to negotiate safer sexual relations. In developing countries, and in some areas of

developed countries, women's economic and social dependence on men may further limit women's relationship power. Gendered power also creates the potential for sexual coercion and other forms of intimate partner violence against women. For women in primary relationships, negotiating condom use may be even more difficult than in casual partnerships. These factors highlight the urgency of promoting the female condom – as a female-controlled method of protection against HIV and STIs – while also affording women another contraceptive option.

Findings from several effectiveness studies have indicated that the female condom is at least as effective as the male condom in preventing STIs. Converging studies show that short-term acceptability of the female condom is high among diverse groups of women and men in many settings. Yet, even with indications of high efficacy, effectiveness and acceptability, the female condom has not been as widely used as expected. As noted in the WHO's discussion of introducing new contraceptive technology, acceptability and uptake are driven by complex interactions among individual, partner, provider, and health system factors. Multilevel, multi-component, structural interventions that also target broader social and environmental factors are needed to have maximal impact on female condom access, acceptability, and uptake.

Definition

Sex work is a nonjudgmental term that connotes the sale or exchange of consensual sexual services between adults. As it is work, sex work should be considered through a labor rights framework. Specific labor rights language is outlined in the “International Labour Organization (ILO) Recommendation concerning HIV and AIDS and the World of Work” (No. 200). The Recommendation promotes fair and safe working conditions for all workers, including sex workers, working under all forms or arrangements at all workplace types in

both the formal and informal sectors (International Labour Office 2010). It also seeks to ensure universal access to stigma-free HIV prevention, treatment and care services among all workers, and the full protection of the human and labor rights of all people living with HIV in the workplace.

Background

Within the understanding of sex work as work, it is important to recognize the diversity of types of workers, work settings, and exchange dynamics that exist. Sex workers may be female, male, or transgender persons, and they may receive money or goods in exchange for sexual services on a regular basis or occasionally (UNAIDS Guidance Note on HIV and Sex Work, UNAIDS 2009, Updated 2012). Sex workers and their clients also come from diverse socioeconomic, cultural, and religious backgrounds, as well as sexual orientations. Sex work may take place in a formal sex work venue such as a brothel, informally in bars or other entertainment establishments, or the street, or in the context of other public or open spaces. Sex workers and their clients increasingly communicate via the Internet and mobile phones. Additionally, sex work may or may not involve a third party who facilitates the negotiation of sexual services and profits from them, beyond the sex worker and their client.

There are limited data on the numbers of persons engaged in sex work across settings. However, one secondary analysis calculated the proportion of adult women engaged in sex work across different geographic regions. In sub-Saharan Africa, this proportion ranged from 0.4% to 4.3%. In Asia, the proportion of adult females engaged in sex work ranged from 0.2% to 2.6%. In Eastern Europe, it was from 0.4% to 1.4%, and in Western Europe it was from 0.1% to 1.4%. In Latin America and the Caribbean, the proportion of women involved in sex work was 0.2–7.4% (Vandepitte et al. 2006). Few data are available regarding how many men and transgender people are engaged in sex work.

Epidemiology of HIV Among Sex Workers

Globally, female, male, and transgender sex workers all bear a disproportionately high burden of HIV across geographic settings and epidemic settings (Beyrer et al. 2015).

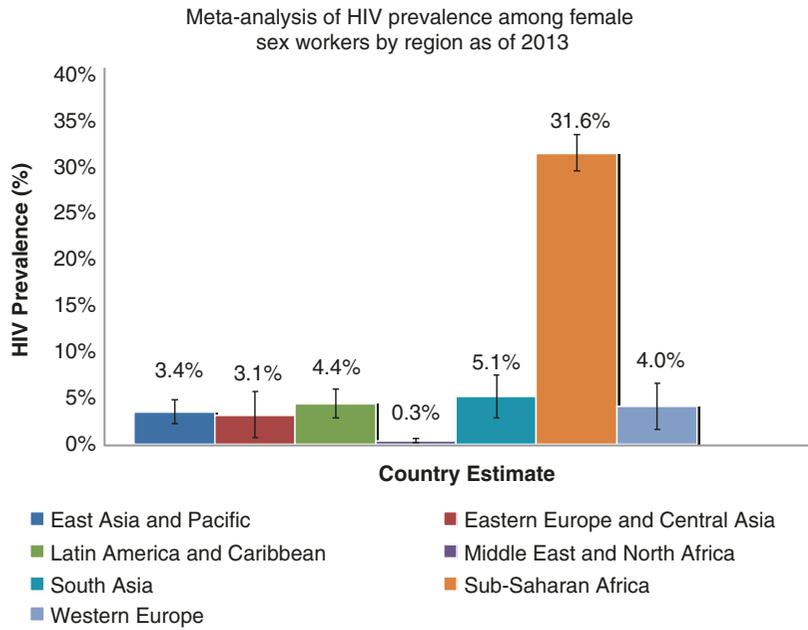

Female Sex Workers

A systematic review was conducted on the epidemiology of HIV among female sex workers in low- and middle-income countries using data from 2007 to 2011 from over 50 countries and representing about 100,000 female sex workers. This review documented a pooled global HIV prevalence of 11.8%. The authors also found that female sex workers have 13.5 times greater odds of being infected with HIV than adult women in the overall population (Baral et al. 2012; Kerrigan et al. 2013).

This review was updated in 2013 and expanded to include higher income countries (Beyrer et al. 2015). A total of 79 countries and over 437,000 female sex workers were included. As seen in Fig. 1, findings from that analysis show that the sub-Saharan African region continues to have the highest pooled HIV prevalence among female sex workers at 31.6%. Additionally, all countries where female sex workers had an HIV prevalence of 50% or greater were located in Southern Africa. The regional HIV prevalence among female sex workers in South Asia was 5.1%, followed by 4.4% in Latin America and the Caribbean, 4.0% in Western Europe, 3.4% in East Asia and the Pacific, 3.1% in Eastern Europe and Central Asia, and 0.3% in the Middle East and Northern Africa (Beyrer et al. 2015).

Despite sex workers' increased risk for HIV across geographic and epidemic settings, there has been little research conducted on the experiences and needs of sex workers living with HIV. A recent global review of HIV treatment outcomes among female sex workers found that current antiretroviral therapy (ART) use among HIV-infected female sex workers was only 38%. Ever use of ART among HIV-infected female sex workers in high-income countries was 80% versus 36% in low- and middle-income countries. Based

Female, Male and Transgender Sex Workers, Epidemiology of HIV/AIDS, Fig. 1 Meta-analysis of HIV prevalence among female sex workers by region as of 2013 (Beyrer et al. 2015)

F

on available data, the review found that 57% of female sex workers on ART were virally suppressed (Mountain et al. 2014).

An analysis of population attributable fractions of HIV estimated that 15% of HIV in the female adult population in 2011 was attributable to occupational exposure during sex work. This same analysis estimated that approximately 106,000 HIV-related deaths occurred among female sex workers globally, with the vast majority of those deaths (98,000) occurring among sex workers in sub-Saharan Africa (Pruss-Ustun et al. 2013).

Male Sex Workers

In 2013, 27 of 192 countries reported data to the United Nations General Assembly (UNGASS) on HIV prevalence among male sex workers. Seven countries reported an HIV prevalence of greater than 20%, ten between 10–20%, and ten less than 10%. Data available from five African countries showed a median HIV prevalence of 12.5% among male sex workers. In ten European countries, the median HIV prevalence among male sex workers was 8.9%, as reported between 2007 and 2013. Additionally, a heavy burden of HIV among male sex workers in North America has also been

documented through various studies, with prevalence ranging between 5% and 31% (Baral et al. 2015).

Transgender Sex Workers

Data on transgender sex workers are even more limited. A meta-analysis of 25 studies from 14 countries (*n* = 6405) found an overall crude HIV prevalence among transgender sex workers of 27.3%. This was significantly higher than other transgender women (15%) in the review (Operario et al. 2008).

Structural Risk of HIV Among Sex Workers

Sex workers may experience heightened risk for HIV infection due to biomedical, behavioral, and structural factors. For example, they may experience HIV risk due to behavioral factors such as multiple and concurrent sexual partners, lack of ability to negotiate consistent condom use, and untreated sexually transmitted infections. However, structural factors are increasingly understood as the most significant factors driving sex

workers' increased risk for HIV (Shannon et al. 2015). For example, sex work is criminalized in some form in 116 countries (Global Commission on HIV and the Law 2012). Even in settings where sex work is not explicitly illegal, laws and policies are often indirectly used to negatively impact sex workers. Laws and policies prohibiting carrying condoms, public loitering, or "indecent" behavior laws are frequently used to harass and arbitrarily arrest sex workers and/or extort bribes from them (Open Society Foundations 2012). Criminalization and punitive policies related to sex work have been found to be associated with inconsistent condom use and increased HIV risk. Laws and policies that penalize and marginalize sex workers may also exclude them from participating in the formation and implementation of national HIV responses (Decker et al. 2015).

In addition to legal and policy issues, sex work is often highly socially stigmatized, and many sex workers face various forms of stigma and discrimination from community members, family and friends, government agencies, and healthcare facilities. Sex workers may also experience stigma and discrimination related to their gender, sexual orientation, HIV status, socioeconomic position, race/ethnicity, and/or substance use behaviors. Linked to these multiple forms of stigma, widespread human rights abuses, including high levels of physical and sexual violence, have been documented among sex workers in numerous settings including at the hands of state (e.g., police) and non-state actors (e.g., sexual partners, community members). These socio-structural factors interact to create significant barriers to the health and human rights of sex workers, including obstacles to HIV prevention, treatment, and care (Decker et al. 2015).

Modeling conducted for diverse settings such as Canada, India, and Kenya has also estimated that addressing specific key structural factors such as violence, police harassment, safer work environments, and decriminalization could avert 33–46% of incident HIV infections among female sex workers over the next decade. These analyses found that the single most important intervention that could impact HIV among sex workers would

be the decriminalization of sex work, which would have a substantial effect across both generalized and concentrated HIV epidemics (Shannon et al. 2015).

Community-Led Responses to HIV Among Sex Workers

Research findings point to a number of promising interventions to address the burden of HIV among sex workers across epidemic settings. In particular, approaches that address the structural context of sex workers' risk for HIV infection, as described above, have shown particular promise. For example, community empowerment-based responses have been shown to be effective in reducing sex workers' risk for HIV and sexually transmitted infections (STIs). A recent systematic review and meta-analysis examined the effectiveness of community empowerment-based approaches to preventing HIV among female sex workers in low-income and middle-income countries. Meta-analysis results revealed that community empowerment approaches among sex workers were associated with a 32% reduction in HIV prevalence as well as significantly decreased odds of gonorrhea, chlamydia, and high-titer syphilis. The odds of syphilis were reduced by almost half with a community empowerment approach. Additionally, this approach was associated with an approximately threefold increase in the odds of consistent condom use between sex workers and their clients across geographic settings (Kerrigan et al. 2015).

Community-led approaches involve a process by which sex workers themselves take collective ownership of programmatic initiatives to achieve the most effective HIV outcomes and to address social and structural barriers to their health and human rights. Such approaches often start by promoting cohesion within the sex worker community through peer-led activities, then mobilizing the collective power of sex workers to improve access to social and material resources including HIV services. Community empowerment approaches among sex workers have been recognized as a UNAIDS Best Practice for more than a

Female, Male and Transgender Sex Workers, Epidemiology of HIV/AIDS,

Fig. 2 Essential elements of comprehensive, community-led responses to HIV among sex workers (WHO et al. 2013)

F

decade and now underpin multiple UN policy documents regarding the HIV response among sex workers including normative guidelines (WHO et al. 2012) and a comprehensive program implementation tool for female, male, and transgender sex workers (WHO et al. 2013).

The “Implementing Comprehensive HIV/STI Programs with Sex Workers” tool starts with the recognition of community empowerment as the central component of a comprehensive programmatic approach to HIV among sex workers integrating biomedical, behavioral, and structural interventions as seen in Fig. 2. The tool then outlines five other essential programmatic elements including: addressing violence against sex workers; community-led services such as peer education and drop-in centers where sex workers can come together and organize; condom and lubricant programming; clinical and support services for fundamental prevention, treatment, and care; and program management and organizational capacity building (WHO, UNFPA,

UNAIDS, NSWP, The World Bank, UNDP 2013).

While the tool provides concrete recommendations and examples from successful programs, its use and components must be tailored to the diverse needs of female, male, and transgender sex workers across diverse sociocultural settings. For example, in geographic settings where sex work and injection drug use may intersect to create higher risk, such as the epidemics of Eastern Europe and Central Asia, ensuring that sex workers have access to tailored harm reduction services is critical to preventing HIV transmission.

Biomedical HIV Prevention Interventions Among Sex Workers

Mathematical modeling has shown that biomedical interventions such as pre-exposure prophylaxis (PrEP) and treatment as prevention could

significantly reduce HIV incidence among sex workers in South Africa, where HIV among sex workers remains quite high, demonstrating reductions of 40% over a 10-year period (Bekker et al. 2015). Additionally, improving coverage rates and virologic suppression through ART scale-up efforts among female sex workers in Kenya has also been shown through modeling to have a substantial effect, averting up to 34% of HIV infections over the next decade (Shannon et al. 2015). While biomedical interventions hold significant promise to address the HIV heightened risk of sex workers, it is critical that these services be part of a holistic package of services based on the stated needs of the sex worker community.

Related to this point, in other modeling analyses researchers demonstrated the potential impact of integrating universal access to HIV treatment within a community empowerment approach among female sex workers in Kenya, Thailand, Brazil, and Ukraine. When equitable access to HIV treatment for sex workers was paired with the expansion of a comprehensive community empowerment approach, modeling demonstrated that up to 31,200 new infections among female sex workers could be averted. These analyses also showed that by taking comprehensive (combining biomedical, behavioral, and structural elements), community empowerment-based approaches to HIV among female sex workers to scale, these countries can significantly reduce HIV incidence among sex workers and the overall adult population (Wirtz et al. 2014).

Achievements and Gaps in Implementation

Sex worker programs have had significant successes promoting the consistent use of condoms, perhaps more than those for any other affected population (Bekker et al. 2015). The number of countries reporting condom use at last commercial sex has risen steadily over the years as a result in part of the expansion of community-led peer education and condom distribution. Based on available UNGASS data, 44 countries reported higher

condom use at last sex between female sex workers and their clients in 2012 as compared to 2009: 85% versus 78% (UNAIDS 2013). Modeling of data from South Africa suggests that condom promotion activities may have already reduced HIV incidence in South African sex workers and their clients by up to 70% (Bekker et al. 2015). While these are positive trends, there are still significant ongoing gaps in addressing the risk for HIV among sex workers. To date the percent of global donor funding allocated to HIV services for sex workers has often been just a few percentage points of the total allocations made (UNAIDS 2013). This level of investment does not match the scope of sex work or the burden of disease faced by sex workers.

There are also important coverage gaps. A global review of HIV among sex workers found that across eight focal case study countries less than 50% of sex workers in those settings had access to basic prevention services (Kerrigan et al. 2013). While UNGASS indicators may show relatively high levels of having “received a condom” in the last year or “know where to test for HIV,” such program indicators do not adequately capture the broader health and human rights challenges faced by sex workers.

As community-led approaches to the HIV response among sex workers take root and are expanded, indicators of progress also need to expand to include measurement of structural intervention components as well as the processes and outcomes of community empowerment over time (WHO et al. 2013). These indicators may include measures of sex worker leadership, organizations, governance, decision-making, resource mobilization, control over funds, and engagement with the wider society to reduce sex work-related stigma at the community level, as well as potential shifts in laws and policies that disempower sex workers and create barriers to their health and well-being (Narayanan et al. 2012).

Additionally, barriers to scale-up and implementation of evidence-based, community-driven responses to HIV among sex workers have been shown to exist at various levels, including global discourse and donor investment priorities, national laws and policies criminalizing sex

work, and intersecting forms of social exclusion including sex work-related stigma, discrimination, and violence at the local level (Kerrigan et al. 2015).

Knowledge Gaps and Implementation Science

Moving forward in the response to the HIV epidemic among sex workers, we must continue to implement, expand, and evaluate the effectiveness of comprehensive, rights-based policies and programs in varied settings and among all types of sex workers including female, male, and transgender. Critical implementation science questions must also be addressed regarding the process and impact of community-led initiatives as they incorporate novel biomedical approaches, including ART-based prevention strategies.

Examples of important topics and operations research questions may include how to better integrate HIV and other health (reproductive health, substance use, etc.) and social services to serve sex workers' needs and improve HIV outcomes, how to reduce societal stigma regarding sex work at the community level, how to ensure that sex workers are appropriately screened and referred to tailored violence prevention and care services, and how to best promote the financial security and economic empowerment of sex workers.

In these efforts, sex worker organizations seek to lead intervention implementation as well as play a central role in the science of implementation by documenting their own experiences and efforts to respond to HIV while promoting and protecting their human rights. Several ongoing South-to-South initiatives have evolved in this regard working to document and then transfer community-led, programmatic lessons learned from one lower- or middle-income context to another. This has included distilling and sharing lessons on community mobilization from the internationally recognized sex worker-led responses to HIV in India to the generalized epidemics in sub-Saharan Africa where HIV prevalence among sex workers continues to be unacceptably high (Kerrigan et al. 2015).

Conclusions

Available evidence indicates that the greatest impact on the HIV risk of sex workers will be achieved through decriminalization of sex work and the implementation and scale-up of a comprehensive, community-led response to HIV. This response will include strategic combinations of biomedical, behavioral, and structural interventions that are context specific. Significant resources and advocacy are needed to shift the field toward a rights-based approach that responds to the multifaceted needs and realities of sex workers.

Fusion

Lu Lu and Shibo Jiang

Key Laboratory of Medical Molecular Virology of Ministries of Education and Health, Shanghai Medical College and Institute of Medical Microbiology, Fudan University, Shanghai, China

Definition

- Virus-cell fusion and cell-cell fusion are the primary means by which the human immunodeficiency virus (HIV) enters and replicates in human target cells. The glycoproteins gp120 and gp41 make up the outer coat (envelope) of HIV. Typically, an HIV virus particle, or virion, infects its host target cell by binding its envelope glycoprotein to a cellular receptor and ► **CXCR4, Co-receptors**, i.e., molecules that are present on the cell surface for ligand binding. Thus, HIV enters the host cell by fusion between viral and cytoplasmic membranes (direct membrane fusion) or between viral and endosomal membrane (endocytosis). The cytoplasm consists of the whole cellular contents, excluding the nucleus, whereas the endosome is a membrane-enclosed compartment of the endocytic pathway. The functions of endosomes include:
 - The transport of molecules internalized from the plasma membrane to the lysosome (a cell organelle containing digestive enzymes capable of degrading the constituents of living matter)
 - The transportation of microbes into the cytoplasm for infection

For an HIV virion in an infected cell to infect another target cell, two modes of fusion are observed: cell-cell fusion, where fusion occurs between membranes of the HIV-infected cell and target cell, and cell adhesion where binding between an HIV-infected cell and an uninfected target cell occurs with the assistance of cell adhesion molecules. Therefore, membrane fusion is a key step for HIV entry into the host cell to enable the delivery of its genetic material.

Virus-Cell Fusion

Virus-cell fusion is the primary means by which HIV delivers its genetic material into the human host cell, e.g., CD4⁺ T cells. As noted above, the outer coat of the HIV virus consists of two prominent envelope glycoproteins, a surface subunit gp120 and a transmembrane subunit gp41, and both envelope glycoproteins are utilized by HIV to fuse its membrane with that of the target cell.

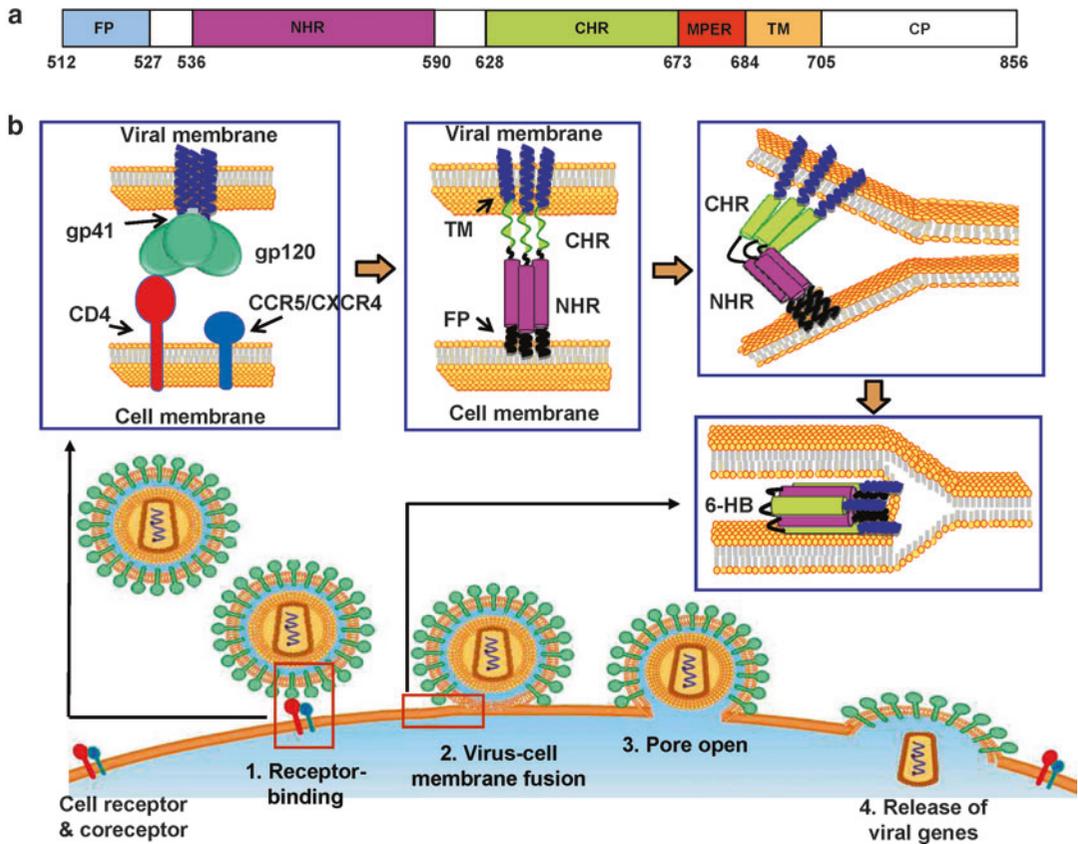

The gp120 subunit is responsible for virus binding and host tropism, i.e., the way in which different viruses preferentially attack specific host species or specific cell types in their hosts. The gp41 subunit mediates the actual viral fusion process. The gp41 molecule consists of an extracellular domain (ectodomain), a transmembrane domain (TM), and a cytoplasmic domain (CP). The ectodomain is composed of several functional regions, including a fusion peptide (FP), a N-terminal heptad repeat (NHR), a C-terminal heptad repeat (CHR), and a membrane-proximal external region (MPER) (Fig. 1a). A heptad repeat is a structural motif consisting of a repeating pattern of seven amino acids, which forms the basis for coiled-coil helix bundle. It is the HIV-1 gp41 subunit protein that plays a key role in mediating the fusion between the viral envelope and the target cell membrane by either direct membrane fusion or endocytosis, as described below.

Fusion Between Viral Envelope and Cytoplasmic Membrane (Direct Membrane Fusion)

The simplest and most common way for HIV and many other enveloped viruses to enter target cells is

through direct membrane fusion. In this scenario, the viral envelope membrane fuses with the target cell membrane, and the viral capsid, which contains the genetic material of the virus, is then delivered into the target cell (Hernandez et al. 1996).

More specifically, before the start of membrane fusion, gp41, which is sheltered by gp120, maintains its native, metastable conformation with its FP buried inwards. Next, the viral gp120 binds to the CD4 molecule, which is the primary receptor for HIV-1, on the target cell. This causes a structural change of gp120, allowing it to bind with a specific chemokine (small proteins secreted by cells) receptor on the cell surface, either CCR5 or ► [CXCR4, Co-receptors](#). CCR5 serves as the coreceptor for the macrophage-tropic or CCR5-using (R5) viruses, while ► [CXCR4, Co-receptors](#) is the coreceptor for T cell line-tropic or CXCR4-using (X4) viruses (Berger et al. 1999). After binding takes place, the viral transmembrane subunit gp41 is released from its metastable state and changes its conformation. The previously buried FP at the N-terminus of gp41 springs out toward the target cell membrane and inserts itself into the cytoplasmic membrane in either oblique or lateral direction. At this time, the N-terminal and C-terminal regions of the gp41 ectodomain (NHR and CHR, respectively) come into play, and the viral membrane is forced into proximity with the cell membrane. To accomplish this, interaction between the aforementioned NHR and CHR helices forms a thermodynamically stable six-helix bundle, which consists of three NHR helices that form a trimeric coiled coil with the exposed hydrophobic grooves and three CHR helices that bind to hydrophobic grooves in an antiparallel orientation. This event leads to the release of energy that, in fact, brings the viral and target cell membranes into close proximity for hemifusion of the two proximal layers of membranes (Chan et al. 1997; Weissenhorn et al. 1997). Finally, the two most distant layers of the membranes fuse together, driving the formation of the fusion pore, through which the viral capsid is released into the cytosol (the fluid component of the cytoplasm) of the target cell, which starts a new replication cycle of the virus (Fig. 1).

Fusion, Fig. 1 Schematic representation of the HIV-1 gp41 and the model of fusion between HIV-1 envelope and cytoplasm membrane of the target cell. (a) Schematic view of the HIV-1 gp41 molecule. *FP* fusion peptide, *NHR* N-terminal heptad repeat, *CHR* C-terminal heptad repeat,

Fusion Between Viral Envelope and Endosomal Membrane (Endocytosis)

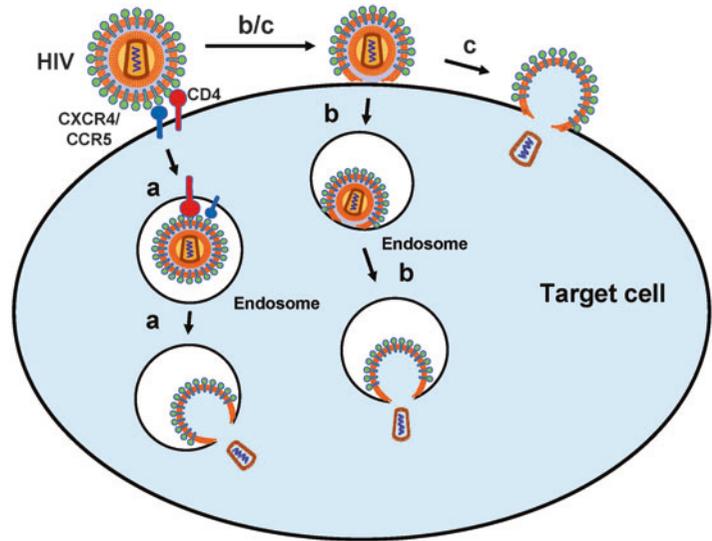

Endocytosis is the process by which a cell absorbs molecules (e.g., proteins) or particles (e.g., virions) from outside the cell by engulfing the molecules or particles with its cell membrane. Endocytosis is also an important pathway for some enveloped viruses (influenza), to enter target cells in a pH-dependent manner.

HIV can enter host cells through direct membrane fusion, as described above, while it has been shown that HIV entry cannot be inhibited by lysosomotropic reagents that completely block the entry of pH-dependent viruses. Therefore, it has been widely accepted that viral entry does not involve endocytosis. However, recent studies

have shown that endocytosis is indeed an alternative pathway for HIV to enter the target cell (Mercer et al. 2010).

After the HIV virion attaches to the CD4+ target cell via the interaction between gp120 and the CD4 receptor, gp120 may or may not bind with the coreceptor, CCR5 or \blacktriangleright CXCR4, Co-receptors, before endocytic uptake of virus particles. While some viral particles may have been destroyed in the matured endosome, others may be able to fuse their envelope membranes with endosomal membranes, resulting in the release of the viral capsids from the endosome into the cytosol (Miyachi et al. 2009) (Fig. 2a). After the virion binds to CD4 and a coreceptor, still another model indicates that its gp41 succeeds in forming

Fusion, Fig. 2 Multiple models of HIV-cell fusion. (a) Endocytosis after virus-cell binding. (b) Endocytosis after virus-cell fusion. (c) Direct membrane fusion and pore formation

F

a coiled-coil six-helix bundle, pulling the viral and target cell membranes together for fusion. In this model, the virion enters the endosome and releases its genetic material through the fusion pore in the endosomal membrane (Miyachi et al. 2009) (Fig. 2b). However, the molecular mechanisms controlling the endocytosis of HIV have not been clearly determined, and the viral and cellular cofactors that are involved in the endocytotic process are not fully understood.

Cell-Cell Fusion (Syncytium Formation)

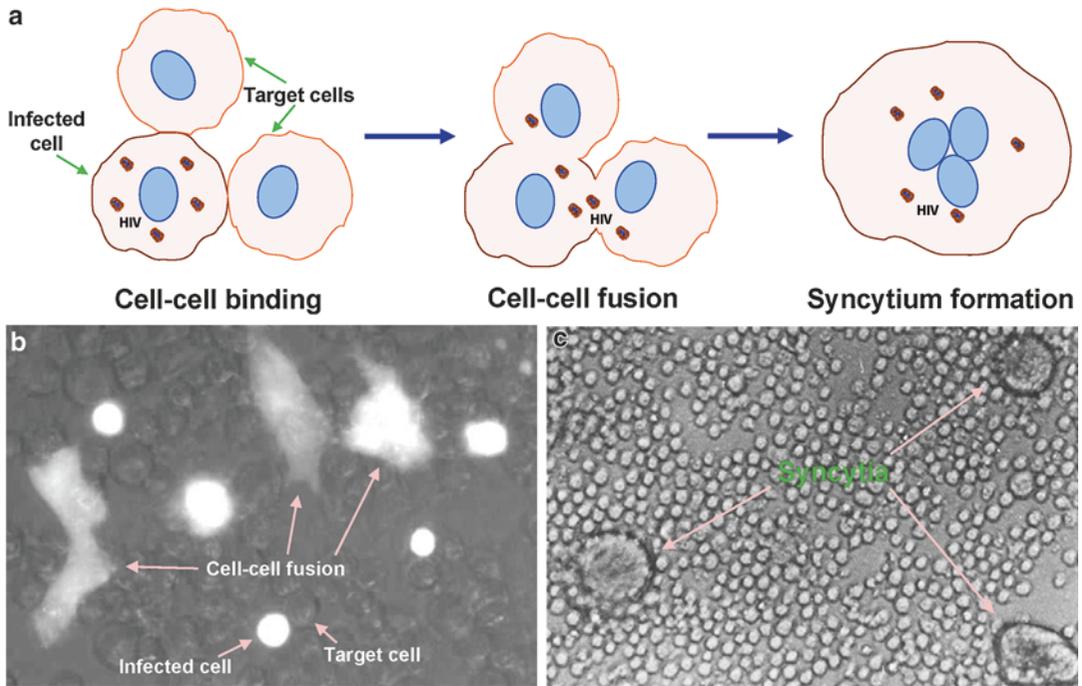

Cell-cell fusion is a natural process that occurs in physiological conditions, such as embryogenesis and morphogenesis, and the differentiation of muscle, bone, and trophoblast cells, as well as pathological conditions, e.g., cancer metastasis. Cell-cell fusion is also an effective way for cell-to-cell spread of many enveloped viruses, such as herpes simplex virus (HSV), respiratory syncytial virus (RSV), and HIV (Hernandez et al. 1996).

The syncytium is a giant cell with multinuclei resulting from multiple cell fusions of cells with a single nucleus. It can form under physiological conditions, e.g., the formation of skeletal muscle, or under pathological conditions, such as generation of binucleated and metastasizing tumor cells. Syncytia can also form when the host cells are

infected with some of the enveloped viruses, such as RSV and HIV. At the late stage of HIV-induced cell-cell fusion, syncytia appear when one or two HIV-infected cells fuse with several uninfected target cells.

In this case, after HIV replication, the cellular-produced HIV envelope glycoproteins gp120 and gp41 are transported to the cell surface. These HIV-infected cells can then bind to uninfected CD4⁺ T cells through the interaction between the viral envelope glycoproteins on the surface of the infected cells and the CD4 receptor and coreceptor (e.g., ► **CXCR4, Co-receptors**) on the surface of the uninfected cells (Dimitrov 1997). Similar to virus-cell fusion, the gp41 molecule on the cell surface changes conformation by inserting its FP into the uninfected cell membrane and forming a six-helix bundle, resulting in the fusion of the infected and uninfected cells. With the opening and expansion of the fusion pore in the cell-contact zone, the viral genetic material is easily transported into the uninfected cell. If one HIV-infected cell fuses with several uninfected cells, a syncytium forms at the late stage of cell-cell fusion (Fig. 3a).

HIV-induced cell-cell fusion and syncytium formation can be observed under a microscope. HIV-infected cells are labeled with a fluorescent dye and mixed with the uninfected CD4⁺ target cells. If a fluorescence-labeled HIV-infected cell

Fusion, Fig. 3 HIV transmission via cell-cell fusion. (a) Schematic representation of HIV-mediated cell-cell fusion and syncytium formation. (b) Microscopic view of an

HIV-infected cell fusing with a target cell. (c) Microscopic view of HIV-mediated syncytium formation

fuses with one or more uninfected cells, the fluorescent dye in the labeled HIV-infected cell diffuses into the uninfected target cells, resulting in decreased fluorescence intensity and increased size of the fluorescence-positive cell (Fig. 3b). Therefore, the fluorescence-labeled HIV-infected cells, both fused and unfused with uninfected cells, can be easily distinguished and counted under a fluorescent microscope (Lu et al. 2003). About 2–3 days after coculture of HIV-infected cells and uninfected cells, significant formation of syncytia containing multinuclei resulting from the fusion of multiple cells can be observed and quantified under an inverted microscope (Fig. 3c).

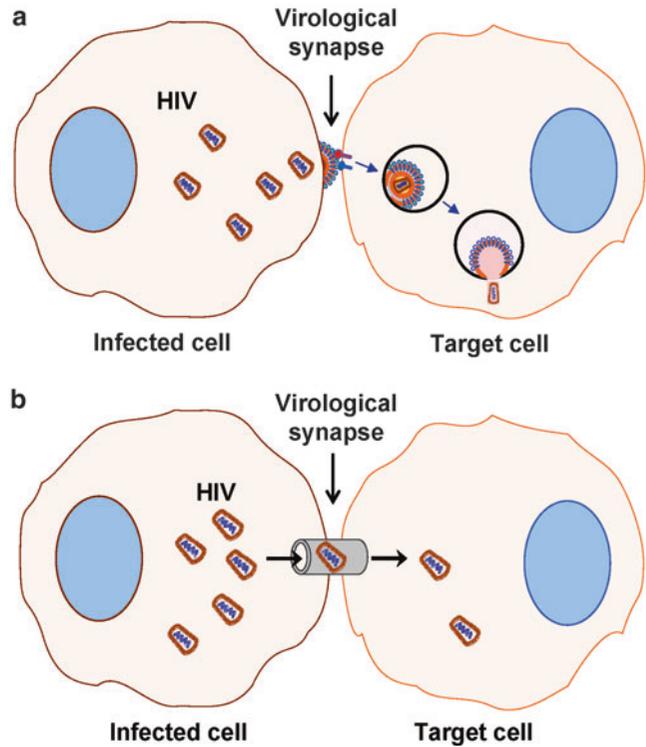

HIV Cell-to-Cell Transmission via Virological Synapse

A synapse is generally defined as a junction structure between neurons that permits a neuron to pass chemical or electrical signals to another neural cell, designating “chemical synapse” or “electrical

synapse,” respectively. Later, an “immunological synapse,” which is the interface between an antigen-presenting cell, a type of immune cell (such as dendritic cell) that can display an antigen to other immune cells (e.g., T cells) to boost immune response, and lymphocytes, a type of white blood cell involved in the immune response, was discovered as a molecular machine controlling T cell activation (Grakoui et al. 1999). Subsequently, an intercellular adhesive structure that formed between infected and uninfected CD4⁺ T cells, called a “virological synapse,” was identified (Jolly et al. 2004). In the virological synapse, the viral envelope glycoproteins, gp120/gp41, and the cellular receptors, CD4/▶ CXCR4, Co-receptors, were found to colocalize at the site of cell-cell contact, suggesting that the virological synapse may be involved in virus assembly or transmission.

Using a quantitative 3D video microscopy and fluorescent clones of HIV to visualize cell-to-cell transfer of HIV, researchers observed that an infected CD4⁺ T cell came into contact with an

Fusion, Fig. 4 Cell-to-cell transmission of HIV via virological synapses. (a) HIV spreads across a virological synapse between an HIV-infected cell and an uninfected CD4⁺ cell via endocytosis. (b) HIV travels along a “membrane nanotube” to enter the target cell

F

uninfected CD4⁺ T cell to create a virological synapse at their junction. The fluorescent viral particles in the infected T cell then moved toward the synapse and entered into the uninfected cell within a few minutes (Hubner et al. 2009). Mature HIV virions have been observed to be transmitted across the virological synapse through direct membrane fusion, whereas immature virions may be taken up into the target cell by endocytosis and then fuse from within the endosomal compartment when maturation is complete (Fig. 4a). Besides assembling a single large-scale virological synapse containing pairs of conjugated cells, HIV can mediate the formation of “polysynapses” targeting multiple cells for more effective cell-to-cell transmission of HIV. In rare circumstances, HIV can also travel along an intercellular tubular structure termed “membrane nanotube” that joins the infected and uninfected T cells through a “micro-synapse” to enter into the target cell (Fig. 4b).

The virological synapse plays a key role in the presence of an adhesive junction between infected and uninfected cells, which is sufficiently stable to allow the transfer of virus to the target cell. The

high affinity binding of gp120 to the CD4 receptor molecule may be the initial force to hold the interacting T cells together, while the subsequent stable adhesive junctions may be maintained by integrin-ICAM interactions. Integrin is an adhesive protein that promotes interactions between a cell and its environment, while ICAM is a glycoprotein on the cell surface that mediates adhesive interaction important for the immune response. It is believed that cell-bound HIV transmission through a virological synapse is more than a 1,000-fold more effective than transfer of cell-free virus (Hubner et al. 2009). Therefore, direct cell-to-cell transfer through a virological synapse may be more efficient than that accomplished via cell-cell fusion, as illustrated above.

HIV Fusion as a Drug Target: HIV Fusion Inhibitors

Both virus-cell fusion and cell-cell fusion can serve as targets for the development of anti-HIV drugs. In the early 1990s, two groups discovered

that the synthetic peptides derived from the sequence of the HIV-1 gp41 CHR region could potentially inhibit HIV-induced cell-cell fusion and HIV-cell fusion (Jiang et al. 1993; Wild et al. 1994). One of the peptides, T20, was approved by the Food and Drug Administration (FDA) of the United States as the first HIV fusion inhibitor (brand name, Fuzeon; generic name, enfuvirtide) for treatment of HIV-infected patients who fail to respond to the current anti-HIV drugs.

CHR peptide blocks the six-helix bundle formation between the NHR and CHR regions of the viral gp41, a critical step in HIV-cell and cell-cell fusion events (Liu et al. 2007). Structurally, the synthetic peptide with the CHR sequence can compete with the viral gp41 CHR region to bind with the viral gp41 NHR region. Thus, the viral gp41 CHR is unable to form a six-helix bundle with the viral gp41 NHR, and viral fusion with the target cell is effectively blocked. Similarly, HIV-infected cells cannot fuse with uninfected target cells in the presence of the CHR peptide because this peptide blocks the six-bundle formation between the NHR and CHR regions of gp41 on the surface of the HIV-infected cells.

Compared to other anti-HIV drugs that target the HIV replication steps inside the host cell, enfuvirtide has more advantages because it targets the HIV fusion step and inhibits HIV infection before the virus can enter the host cell. This “keep the enemy outside the gates” strategy minimizes the harm of the virus to the body. Otherwise, once the virus enters the host cell, it inserts its genetic material into the human genome to establish a latent reservoir and produces viral proteins that affect the functions of the infected immune cell.

Because of the different mechanism of action, enfuvirtide can be used in combination with other anti-HIV drugs in highly active antiretroviral therapy (HAART) for treatment of HIV patients with multidrug resistance. However, the clinical application of enfuvirtide is limited because of its weaknesses: (i) lack of high potency, requiring it to be used at a dosage of 180 mg per day, resulting in high cost; (ii) short half-life, necessitating injection twice a day; (iii) tendency to quickly induce

drug-resistant HIV-1 strains (Cai and Jiang 2010). These problems have promoted the development of next-generation HIV fusion inhibitors. Currently, several peptides with improved efficacy, half-lives, and resistance profiles are under clinical development. Since enfuvirtide cannot be taken orally, several groups have been developing small-molecule HIV fusion inhibitors that also target the HIV-1 gp41 (Jiang et al. 2011). The advantages of the small-molecule compound-based HIV fusion inhibitors include their oral availability and relatively low cost of production.

Besides the pathways of HIV-cell fusion and HIV-induced cell-cell fusion, HIV can also be transmitted through endocytosis and virological synapses, as described above. However, it is questionable whether enfuvirtide can effectively block the transmission of HIV via endocytosis or virological synapse. Since this peptide drug cannot enter cells, it cannot block intracellular viral fusion. This calls for more extensive research on these alternative pathways of HIV fusion.

Conclusion

To infect a host cell, HIV must enter the target cell through virus-cell fusion, cell-cell fusion, or an alternative pathway. A cell-free virion first attaches to the target cell via the interaction of its envelope glycoprotein gp120 with its primary receptor (CD4) and Co-receptors (CCR5 or ► [CXCR4, Co-receptors](#)) on the surface of the target cell. Virus-cell fusion is subsequently initiated through direct membrane fusion or endocytosis. A virion in an infected cell can also enter the target cell through cell-cell fusion. The HIV-infected cell first attaches to the target cell via the interaction between the viral envelope glycoprotein gp120 on the surface of the HIV-infected cell and the receptor/Co-receptors on the surface of the target cell. Cell-cell fusion is then completed, resulting in syncytium formation. A virion in an infected cell can also enter the target cell through a virological synapse formed at the junction between HIV-infected and uninfected cells. The viral genetic material is then released to the target cell to initiate a new replication cycle.

Fusion between viral and target cell membranes (direct membrane fusion) has long been recognized as the primary means of HIV entry into the target cell. However, recent studies have challenged this hypothesis, suggesting that endocytosis may be the predominant pathway of HIV entry. However, more investigation is needed to gain better insight into the fusogenic mechanisms of HIV entry by endocytosis.

In contrast to cell-free HIV transmission via virus-cell fusion, it is widely agreed that cell-associated HIV transmission is much more effective via cell-cell fusion. On the other hand, recent studies indicate that spread of cell-associated HIV through the virological synapse is even more efficient than transmission via cell-cell fusion. Currently, most researchers believe that both pathways are important for HIV cell-to-cell transmission.

The discovery of CHR peptides as HIV fusion inhibitors, such as enfuvirtide, has opened a new avenue for developing anti-HIV drugs. However, the peptide drug is too expensive for production and lacks oral availability. Therefore, the development of small-molecule HIV fusion inhibitors with oral availability and low production cost is urgently needed. Research and development of new drugs targeting the alternative pathways of HIV fusion (e.g., endocytosis) are also needed.

Gamma Delta T Cells

C. David Pauza¹ and Zheng W. Chen²

¹Department of Medicine, Institute of Human Virology, University of Maryland School of Medicine, Baltimore, MD, USA

²Department of Microbiology and Immunology, Center for Primate Biomedical Research, University of Illinois College of Medicine Chicago, Chicago, IL, USA

Definition

Human T cells recognize infectious agents or cancer through two main types of cell surface antigen receptors. CD4+ or CD8+ cells express alpha and beta chains to form the $\alpha\beta$ T cell receptor (TCR). An alternate T cell receptor is made from gamma and delta chains ($\gamma\delta$ TCR). The $\alpha\beta$ TCR recognizes peptides presented by major histocompatibility complex (MHC) molecules. Molecular targets for $\gamma\delta$ TCR include non-peptidic antigens that are recognized without MHC presentation. During early phases of HIV disease, the major subset of $\gamma\delta$ T cells in blood is extensively depleted or inactivated. Consequently, HIV patients have profound $\gamma\delta$ T cell deficiencies and fail to generate normal $\gamma\delta$ T cell responses to phosphoantigens (five-carbon pyrophosphates made by the host or selected microbes). The phosphoantigen response is important for natural tumor immunity, for tuberculosis resistance, for

immune regulation and probably for HIV control. Thus, $\gamma\delta$ T cell depletion occurring in every infected patient is an important part of HIV-associated disease. After prolonged treatment, HIV patients begin to reconstitute the $\gamma\delta$ T cell subset but immunotherapy will be needed to reconstitute normal levels of cell function. The goals for HIV-related $\gamma\delta$ T cell studies are to define the impact of depletion on disease, including HIV-associated cancer or opportunistic infections, and test therapeutic interventions capable of activating critical effector functions in $\gamma\delta$ T cells once they have been reconstituted during prolonged antiretroviral therapy.

$\gamma\delta$ T Cell Functions in the Healthy Immune System

$\gamma\delta$ T cells make up 3–10% of T cells in circulation. They are distinguished from conventional CD4+ or CD8+ T cells because they express a unique T cell receptor (TCR) and recognize molecular targets other than processed peptides. $\gamma\delta$ T cells are present in mammals but their composition and functions in primates and human beings are distinct from all other species (Kalyan and Kabelitz 2013). The uniqueness of primates and man is due to a special γ -chain gene designated V γ 2 (V γ 9 in an alternate nomenclature). The V γ 2 chain is usually combined with V δ 2 chain to form the V γ 2V δ 2 T cell receptor. The unique V γ 2 T cell receptor γ -chain gene endows cells with

a capacity to recognize and proliferate in response to stimulation by five-carbon pyrophosphate molecules collectively termed phosphoantigens (PAg). The most common PAg are isopentenyl pyrophosphate (IPP), an intermediate of isoprenoid biosynthesis in man, and hydroxymethyl-but-2-enyl pyrophosphate (HMBPP) produced by bacteria, protists, fungi, and plants (Riganti et al. 2012). IPP concentrations increase to stimulatory levels when cells are stressed by infection or undergo transformation to malignant states. Drugs used commonly for treating bone disorders (bisphosphonates) block the conversion of IPP, and it then accumulates to levels sufficient for activating V γ 2 cells. Bisphosphonates also cause activation and proliferation of $\gamma\delta$ T cells in patients, but require simultaneous administration of interleukin-2 (IL-2). Animal studies and limited human clinical trials confirmed the ability of HMBPP to activate and expand V γ 2V δ 2 T cell populations in vivo. On a molar basis, HMBPP is much more potent than the mammalian analog IPP. Cells capable of responding to PAg or aminobisphosphonate stimulation represent approximately 4% of total lymphocytes among HIV-negative healthy adults. $\gamma\delta$ T cell subsets are usually named for the γ -chain and PAg-responsive cells are known as the V δ 2 T cell population.

In addition to the major V δ 2 T cell population in blood, a minor group of $\gamma\delta$ T cells expresses the V δ 1 TCR chain (along with any of several V γ chains) and comprises around 30% of $\gamma\delta$ T cells in blood. The V δ 1 cells are more common among intraepithelial lymphocytes in mucosal epithelial tissues than in blood. The roles for tissue-resident V δ 1 cells are not completely understood but they seem to regulate stress responses, cytokine expression, and recruitment of leukocytes or inflammatory cells to sites of damage and infection. The V δ 1 T cells respond to bacterial lipids or related molecules and participate in the complex regulation of mucosal immunity. These two subpopulations V δ 2 and V δ 1 T cells are more numerous than all others. Less is known about the functions of minor $\gamma\delta$ T cell subsets in man.

While V δ 2 cells and their responses to PAg are nearly ubiquitous among HIV-negative individuals,

their circulating levels are affected by age, gender, and race. V δ 2 cell levels peak at around 20 years of age and then decline steadily throughout life. During the decline, cell levels in men and women begin to diverge around the sixth decade, when women can have nearly three times higher levels of circulating V δ 2 T cells (Caccamo et al. 2013). In addition, V δ 2 levels in blood are affected by race with European-origin individuals in North America having up to fourfold higher baseline levels of V δ 2 T cells compared to matched populations of African-origin individuals (Cairo et al. 2010), and Asians being more similar to European-origin donors. However, strong responses to PAg stimulation were seen among all healthy donors and are sufficiently vigorous to assure a high degree of function. These numerical differences are mainly important for natural history studies of HIV disease where loss and reconstitution of V δ 2 T cells are valuable markers for treatment success or failure.

The Impacts of HIV Disease on $\gamma\delta$ T Cells

Our interest in $\gamma\delta$ T cells is driven by a need to explain the causes and consequences of dramatic changes to V δ 2 T cells during HIV infection (Li et al. 2013). The vast majority of V δ 2 cells do not express the CD4 receptor for HIV and are not susceptible to HIV infection either in patients or in the laboratory. Despite this property, V δ 2 T cells are one of the first T cell subsets impacted by HIV, being depleted and made less functional during early stages of disease. The V δ 2 T cell counts continue to decline or remain low as long as there is active viremia. Among advanced HIV patients with <200 CD4 T cells/mm³ of blood, the important PAg-reactive V γ 2V δ 2 T cells are nearly extinguished. Prolonged, successful antiretroviral therapy leads to slow reconstitution of V γ 2V δ 2 T cells in a process that depends on new T cell synthesis, but normal cell counts, robust effector-memory subsets, and strong responses to PAg are not recovered completely even after more than 10 years of treatment-associated virus suppression.

The loss of V δ 2 T cells seems greatest during acute or early stages of HIV disease when viremia

is high before starting antiretroviral therapy. One mechanism for deleting V δ 2 T cells depends on the unusually high levels of chemokine receptor CCR5. The CCR5 is so dense on V δ 2 cells that envelope glycoprotein of HIV (gp120) binds tightly even in the absence of cell surface CD4. The complex of HIV envelope glycoprotein and CCR5 signals cells through p38 MAP kinase and activates caspases that are eventually responsible for the death of V δ 2 cells (Li and Pauza 2011). This mechanism promotes depletion of a CD4-negative CCR5-positive cell without direct infection and likely explains why V δ 2 T cell depletion is greatest during high viremia when viral proteins, including envelope glycoprotein, are at peak levels. Other mechanisms may also promote V δ 2 cell depletion including apoptotic cell death resulting from chronic activation or cytokine exposure during HIV disease.

V γ 2V δ 2 T cells are thought to have direct roles in controlling HIV through cytotoxic destruction of infected cells, producing β chemokines that block HIV entry or promoting Th1 antiviral immunity (Agrati et al. 2011). Losing normal $\gamma\delta$ T cell functions of tumor surveillance, broad pathogen resistance, and immune regulation likely impact the comorbidities of HIV/AIDS. Accordingly, HIV-mediated depletion of V δ 2 T cells is a mechanism for viral immune evasion and an important part of the explanation for chronic/persistent HIV disease. It was often seen that the proportion or absolute count of V δ 1 T cells was increased in blood when V δ 2 T cell levels declined (Wesch et al. 1998). Whether this is a compensatory or homeostatic mechanism is not known. The increase in V δ 1 cells may be related to bacterial translocation with direct activation and proliferation of the responding subset.

Relationships Between Clinical Status of HIV Disease and $\gamma\delta$ T Cells

Relationships between $\gamma\delta$ T cell levels, functional responses to PAg, and disease progression were studied in many clinical settings including former plasma donors from southern China who became infected with HIV due to contaminated blood-

drawing equipment (Li et al. 2013). Because these individuals were infected at roughly the same time and with similar strains of HIV, there was a unique opportunity to understand relationships between HIV progression and $\gamma\delta$ T cells without the complicating factors of multiple virus strains and different routes for virus exposure. In these patients, V δ 2 T cell levels were highly sensitive to viral RNA burden but less affected by changing CD4 T cell count even though cell levels and function were lowest in patients with CD4 counts <200 cells/mm³ of blood. $\gamma\delta$ T cell levels and function were also evaluated in patients who control HIV without antiretroviral therapy (elite controllers), patients where virus replication is suppressed for up to 10 years by effective treatment, and patients who retain CD4 T cells despite chronic low-level viremia in the absence of therapy.

Approximately 1 in 1,000 HIV-infected individuals in the United States have the capacity to suppress virus replication to extremely low levels without the need for antiretroviral therapy. Termed natural virus suppressors or elite controllers, these individuals provide important models for understanding normal host immune mechanisms related to disease resistance. Compared to matched controls where virus was suppressed by antiretroviral therapy, elite patients had V δ 2 T cells equal to or above the levels found in HIV-uninfected controls indicating an association between higher V δ 2 T cell function and favorable clinical status (Pauza et al. 2011). Patients receiving antiretroviral therapy showed slow reconstitution of the V δ 2 T cell population but did not regain normal levels or functional responses after 7–10 years of treatment. V δ 2 T cell levels were lowest in patients with chronic viremia irrespective of CD4 count, reinforcing the relationship between viral RNA burden and V δ 2 T cell depletion.

Overall, quantitative depletion of V δ 2 T cells and reduced PAg responses characterize the normal course of HIV infection and disease. In advanced HIV disease where CD4 T cell counts are below 200 cells/mm³, the PAg-reactive V δ 2 T cell subset was extinguished in nearly all patients. Without these important cells, it is not

surprising that patients experienced increased risk for a variety of opportunistic infections and malignancies – both are conditions that are confronted in healthy individuals by the presence of functional $\gamma\delta$ T cell populations (Li et al. 2013; Chen and Letvin 2003).

$\gamma\delta$ T Cells and Immunity to Pathogens or Cancer

Much of our understanding of immunity is based on defining T cell or antibody responses against specific proteins derived from pathogens or tumor cells. Understanding PAg-reactive $\gamma\delta$ T cells is uniquely challenging because they do not respond to peptide antigens and do not require polymorphic histocompatibility molecules for antigen presentation. Significant efforts are underway to understand how $\gamma\delta$ T cells contribute to the control of pathogens including HIV or cancer. These studies will show whether therapeutic intervention aimed at $\gamma\delta$ T cell recovery is warranted as a treatment for HIV disease. First, we need to understand how $\gamma\delta$ T cells participate in the control of other diseases that are important for HIV+ patients.

A key function of $\gamma\delta$ T cells is the ability to recognize and kill certain types of tumor cells and cancer is emerging as a major cause of death among HIV patients. PAg- or bisphosphonate-stimulated V δ 2 T cells express a variety of cell surface recognition molecules capable of distinguishing tumor cells from normal cells. In vitro, V δ 2 T cells are potent killers of B cell lymphoma but not T cell leukemias (targeted by V δ 1 cells) and have varying capacities to kill cell lines representing many types of solid tumors. This capacity for tumor-specific cell killing gives $\gamma\delta$ T cells an important role in our understanding of natural mechanisms for tumor surveillance and immunity (Fournie et al. 2013). Since the main tumor-killing subset of $\gamma\delta$ T cells (V δ 2) is amplified in healthy individuals due to chronic PAg exposure, they serve as a constant guardian against malignant disease. Further, $\gamma\delta$ T cells have the ability to activate tumor killing by natural killer cells which lack a TCR but are also potent in recognizing and destroying tumor cells. Depleting

$\gamma\delta$ T cells during HIV disease eliminates their direct contribution to tumor immunity and degrades the functional capacity of NK cells. As might be expected, a reduced capacity for tumor surveillance leads to increased risk for many cancer types. The broad impact of HIV disease on cancer, where many types of cancer are at elevated rates among HIV patients, is distinct from other viruses that promote specific cancers such as human papillomavirus that promotes anogenital and oral epithelial cancer. Consequently, the elevated cancer risk in HIV patients is likely related to fundamental defects in tumor immunity including loss of V δ 2 T cells.

The V δ 2 T cells also comprise a natural barrier and important mechanism of resistance against many infectious diseases (Chen and Letvin 2003). The response to infection also shows the need for both PAg and cytokines to activate V δ 2 T cells. In vitro studies showed that IL-2, IL-15, or IL-21 is needed for PAg-mediated proliferation of V γ 2V δ 2 T cells. In vivo studies demonstrated that PAg plus IL-2 co-treatment, but not IL-2 or PAg alone, induced proliferation of V δ 2 T cells. Primary infections in macaques and humans with viruses or pathogens that are incapable of generating PAg failed to induce V δ 2 T cell proliferation despite high levels of cytokines produced during the infection. Mutant strains of *Listeria monocytogenes* that no longer produce the PAg HMBPP failed to elicit V δ 2 T cell proliferation during infection and proved that cytokine alone did not cause V δ 2 T cell proliferation. Other cytokines may also contribute to PAg-stimulated expansion of V δ 2 T cells during microbial infections. Mycobacterial infections of macaques induced major expansion of V δ 2 T cells and coincident expression of variant IL-4 (VIL-4) mRNA encoding a protein with the same N-terminus 97 amino acids found in IL-4, but a unique C-terminus 96 amino acids that included a signaling-related proline-rich motif. The expressed and purified VIL-4 protein acted as new cytokine to expand PAg-stimulated V γ 2V δ 2 T cells and promote heterologous effector cells capable of producing IL-4, IFN- γ , and TNF- α .

Plasmodium falciparum, a cause of malaria, also produces high levels of PAg and affects

V δ 2 T cell levels. First-time exposure to *Plasmodium falciparum* as an adult (traveler's malaria) caused severe, acute-onset disease with sharp depletion of V δ 2 T cells. In endemic malaria where disease is less severe, V δ 2 T cells are not depleted, and indeed, rising V δ 2 cell counts are associated with the convalescent phase of infection.

Strong V δ 2 T cell responses were also seen in nonhuman primates (Ali et al. 2007) infected with *Yersinia pestis* or *Listeria monocytogenes*, as well as in humans infected with pathogens of salmonellosis, brucellosis, legionellosis, tularemia, toxoplasmosis, leishmaniasis, and others. SIVmac- or SHIV-infected macaques were not able to sustain clonal expansion of V δ 2 T cells after infection with *M. bovis* BCG that is normally a strong stimulator of $\gamma\delta$ T cells. When retrovirus infection of macaques was controlled by antiretroviral therapy, V δ 2 T cells regained the response to mycobacterial coinfection. If V δ 2 T cells were activated early after SIV or SHIV infection, animals did not develop tuberculosis-like disease (Shen et al. 2004). The V δ 2 T cells are part of host defense against mycobacteria and loss of V δ 2 T cell function is an important factor in the increased susceptibility to mycobacterial tuberculosis.

V δ 2 T cells appear to be depressed in terms of frequency or effector function, both during chronically active tuberculosis and chronic HIV. The loss of V δ 2 T cell functions could be a cause or consequence of active TB. It is also possible that prolonged exposure of V δ 2 T cells to significant levels of mycobacterial PAg plus cytokines leads to phenotypic and functional changes that depress immune capacity. Studies of V δ 2 T cells in the setting of HIV-1/Mtb coinfection in humans demonstrated that HIV+ patients with active TB showed defects in total or cytokine (interferon- γ , IFN- γ)-producing V δ 2 T cells when compared to healthy individuals. Interestingly, the frequencies of PAg-stimulated IFN γ + V γ 2V δ 2 T cells were significantly higher in latent Mtb coinfection of HIV-1+ persons than in HIV-1+ TB patients or healthy individuals, suggesting a positive role for $\gamma\delta$ T cells in TB control. Potent V δ 2 T cell responses coincided with maintaining Mtb

latency in HIV-1+ persons with CD4+ T cell counts $>200/\text{mm}^3$ of blood (Shao et al. 2008).

These examples, both of pathogen resistance and tumor cell killing, describe a direct role for V δ 2 T cells in reducing the incidence and severity of infectious diseases. In addition, V δ 2 T cells are known to secrete high levels of cytokines capable of promoting viral or bacterial immunity. In HIV disease, loss of V δ 2 T cells reduces the capacity to resist both opportunistic infections and cancer, with the additional consequences of lowering thresholds for immune responses and contributing to the broad immunodeficiency seen in HIV/AIDS.

$\gamma\delta$ T Cells as Targets for Immunotherapy

Key observations that V δ 2 T cell levels and function are highest among elite controller patients and V δ 2 responses are related to Mtb control encourage efforts to develop immunotherapies aimed at increasing the levels and function of V δ 2 T cells in patients with HIV. The goal would be to stimulate and proliferate V δ 2 T cells in patients receiving antiretroviral therapy in order to match the levels of function found in elite HIV controllers or patients who suppress Mtb. In order to approach this goal, it is necessary to understand the unique status of V δ 2 T cells in patients receiving antiretroviral therapy.

Successful antiretroviral therapy achieves at least three outcomes: (1) changes in clinical status including increased lifespan, improved responses to opportunistic infections, decreased requirement for bacterial prophylaxis, and reacquisition of normal responses to conventional vaccines; (2) plasma viral RNA suppressed and maintained at undetectable levels; and (3) reconstituted CD4 T cell counts approaching the normal ranges for healthy adults.

Among treated HIV patients who successfully reconstituted CD4 T cells, neither V δ 2 T cell levels nor functional responses recovered to the same extent. In general, V δ 2 T cells remained below 0.5% of lymphocytes and manifested poor in vitro responses to PAg stimulation. When tested for tumor cell killing, V δ 2 T cells from treated

patients remained ineffective as tumor cell killers. A more detailed analysis of circulating V δ 2 T cells, based on DNA sequencing of individual V γ 2 chains present in blood of treated HIV patients, showed that CD4 reconstitution was accompanied by increased complexity in the V δ 2 T cell population. Unlike HIV-negative controls, these new cells retained a naïve phenotype indicating they had not responded to PAg or converted to memory cells as would be expected for cells from HIV-negative individuals. Without responding to PAg, the cells cannot switch to memory phenotype and do not proliferate or restore normal cell counts. These findings show that new V δ 2 T cells were produced and entered the circulating pool during the years of antiretroviral therapy, but functional responses were not recovered to the same extent.

V δ 2 T cell populations reconstituted during prolonged HIV therapy included V γ 2 gene sequences capable of responding to PAg stimulation, even if the observed response was low (Chaudhry et al. 2013). This is an encouraging sign for the possible development of immunotherapy aimed at activating V δ 2 T cells. Since V δ 2 T cell responses depend less on the genetic background of the host and can be triggered to proliferate and acquire cytotoxic killer cell function simply by adding PAg plus cytokine, one therapeutic approach can be tested in many individuals. Consequently, we now recognize opportunities for clinical trials using bisphosphonates plus IL-2 or PAg plus IL-2, to activate and proliferate V δ 2.

It remains unsolved why newly synthesized V δ 2 T cells appear during prolonged therapeutic suppression of HIV but fail to proliferate back to levels seen for matched, HIV-negative controls. Even though new cells were born into an environment essentially sterile of HIV due to effective treatment, the cells failed to acquire full functionality on par with uninfected individuals. If immunotherapy targeting V δ 2 T cells is to be successful in the future, appropriate stimulation conditions must be developed. Recent studies showed that the bisphosphonate zoledronate (Zometa) plus IL-15 stimulated V δ 2 T cells from treated HIV patients. Treated cells had moderate to strong

proliferation responses during in vitro culture and this approach might be suitable for in vivo therapy. In a pilot study treating HIV patients with zoledronate plus IL-2, there were few adverse events. With this as a starting point and strong arguments supporting the development of immunotherapies targeting V δ 2 T cells, we anticipate progress in this field to help reconstitute immunity in patients treated for HIV (Pauza et al. 2011).

Conclusions

Extensive destruction of V δ 2 T cells with loss of phosphoantigen responses is an important feature of HIV disease. Depletion and inactivation of this T cell subset reduces the capacity for natural tumor immunity and increases susceptibility to opportunistic pathogens including *M. tuberculosis* that can be devastating in HIV patients. V δ 2 T cell levels declined when vRNA was highest and only elite controller patients had normal levels and function of these cells, arguing that V δ 2 T cells are important for controlling viral disease. The V δ 2 subset of $\gamma\delta$ T cells can be stimulated in patients by clinically approved drugs (bisphosphonates or phosphoantigens plus IL-2) that are already showing promise in cancer treatment studies. Among treated HIV patients with prolonged virus suppression and CD4 T cell reconstitution, V δ 2 T cells were replenished, but not back to normal levels. This means that treatments to activate V δ 2 T cells, using potent, exogenous stimulation, are needed to activate their full immune function. Future immunotherapy studies in HIV patients will test the benefits of targeted V δ 2 T cell immunotherapy for reducing cancer risk, combating opportunistic infections including *M. tuberculosis*, and restoring normal immune capacity with the goal of slowing HIV disease.

Definition

Men who have sex with men (MSM) include gay and bisexual men, MSM who do not identify as gay or bisexual despite their behaviors, male sex workers, and transgender men who have sex with men who identify as gay or have sex with other men. The term “MSM” was originally intended to describe same-sex behaviors between men rather than identities, orientations, or cultural categories. It was designed to be less stigmatizing than culturally bound terms such as gay, bisexual, or homosexual and has been useful as an epidemiologic tool to help characterize the HIV pandemic in challenging contexts. However, in the era of HIV, there are growing contingents who now identify as MSM and feel a connection with the MSM community challenging the initial intention

of the term. Separately, the term in 2016 is often used interchangeably with the term gay which can be dehumanizing to those who identify as members of the LGBT Community (Trapence et al. 2012). And given the dynamic nature of people, these definitions may further evolve in the years to come. However, for this paper, we will use the term MSM as a broad epidemiologic characterization in the context of the HIV pandemic.

Introduction

Globally, MSM are among the highest-risk people to acquire and transmit HIV infection (Fig. 1). The reasons for this are multifaceted and may be manifested in diverse ways for different individuals. Traditionally, epidemiologic studies have focused on measuring individual-level risk factors for HIV acquisition such as condom use and number of sexual partnerships. However, there is increasing recognition of the importance of social, network-level, and structural determinants for HIV infection risks among MSM. In addition to individual biological factors (e.g., the increased susceptibility of anal mucosa to HIV infection) or behavioral characteristics (e.g., frequent partner exchange among some MSM), social and sexual networks, community environments, law and policies, and the stage of HIV epidemic in the area in which the individual resides may also play a role in potentiating HIV spread (Baral et al. 2013a; Beyrer et al. 2012a; Sullivan et al. 2012). This chapter will begin with an overview of the drivers of HIV risk and then focus on the epidemic of HIV among MSM in various regions of the world, including concentrated and generalized epidemics in high- and low-income settings.

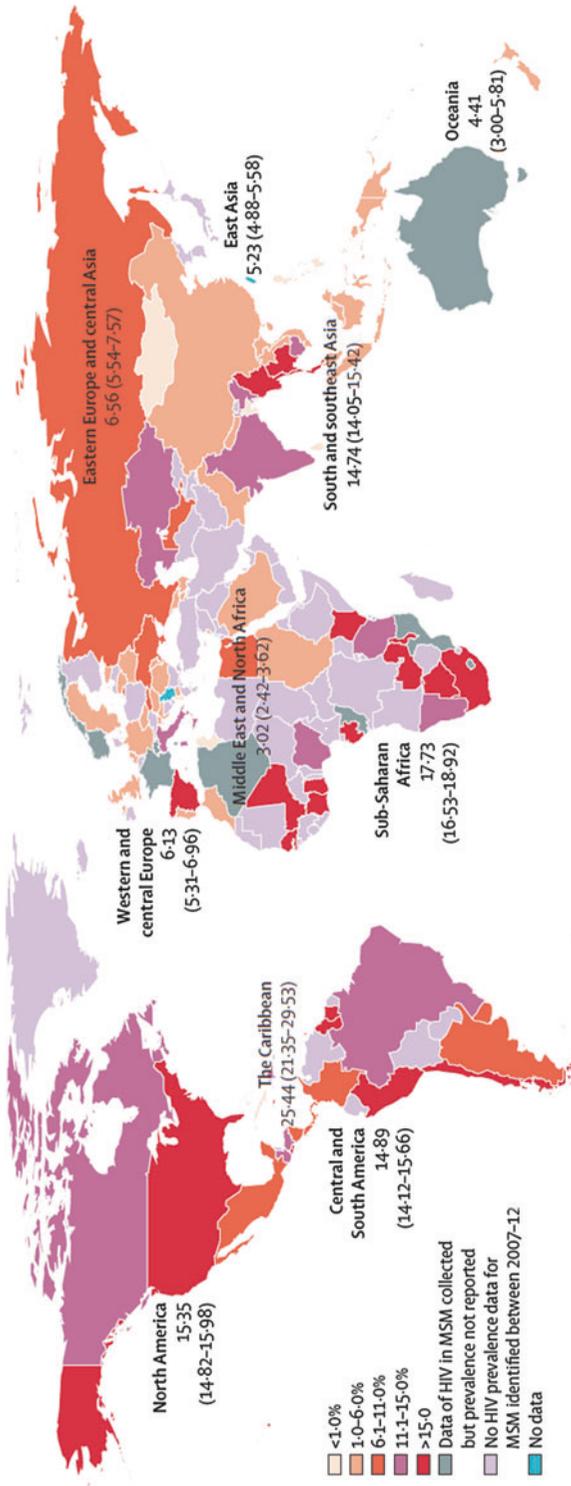

Individual-Level Risks

Individual-level risks for HIV acquisition in MSM have been well documented and include condomless insertive and receptive anal intercourse with serodiscordant and viremic sexual partners, high frequency of casual male partners, high number of lifetime male partners, injecting drug use, high viral burden in the index partner, and non-injection drug use, including use of

amphetamine. In addition, MSM may be at risk for a wide variety of other sexually transmitted infections, which can facilitate HIV transmission and acquisition through genital tract inflammation involving the local recruitment of more HIV target cells, ulcerations, and abrasions (Mayer et al. 2012; Mayer and Venkatesh 2011). Moreover, many of these infections are asymptomatic resulting in limited diagnosis and therapy in the context of syndromic STI surveillance. However, one of the primary driving forces behind the disproportionate HIV disease burden among MSM globally is the high per-act and per-partner transmission probability of HIV transmission from receptive anal sex. Rectal exposure to HIV infection is biologically different from vaginal exposure: the gut has a huge potential transmission space and is an immune organ with high density of HIV target cells and contains a friable and easily disrupted epithelium. These factors result in a high per-act HIV transmission probability during anal sex – more than a log higher than during vaginal sex (1.4% vs. 0.08%) (Baggaley et al. 2010).

Network-Level Risks

Among MSM, sexual-network-level risks can also facilitate HIV spread and key entry points for the delivery of interventions. Although individual-level risks are similar for men and women for receptive anal sex with a serodiscordant and viremic sexual partner, male-male sexual partnerships differ since each partner can engage in either insertive or receptive sexual positioning. This sex role versatility, coupled with the high per-act risk of HIV transmission during rectal exposure, leads to high individual, couple-based, and network-level HIV transmission risks. Social and peer-group norms, availability of condoms in networks, and high HIV/STI prevalence in networks can also affect the spread of HIV. Molecular epidemiologic studies of HIV conducted among MSM demonstrate substantial clustering of HIV infection within MSM networks, a high frequency of multiple transmitted viral variants, and more rapid HIV spread through sexual networks (Beyrer et al. 2012a). In addition, larger sexual networks provide increased

Gay men and other Men who have sex with men (MSM), Epidemiology of HIV/AIDS Introduction, Fig. 1 Global HIV prevalence in MSM, from studies published 2007–2011. Data are prevalence (95% CIs) (Reprinted from The Lancet, volume 380, Beyrer C, Baral SD, van Griensven F, Goodreau SM, Chariyaletsak S, Wirtz AL, and Brookmeyer R. Global epidemiology of HIV infection in men who have sex with men, pp 367–77, Copyright (2012), with permission from Elsevier)

opportunities for exposure to HIV-infected partners and consequently HIV acquisition among MSM. In the era of increasing use of digital spaces to find sexual partners, sexual networks may be increasingly large where people are less likely to know the status of their partner.

However, social network characteristics such as the provision of social support, reinforcement of protective social norms, and social capital, including social cohesion, participation, and inclusion, can help to reduce the spread of HIV. Other social associations with beneficial HIV-related outcomes include having a confidante, believing in collective efficacy, participating in same-sex-oriented public events, being “out” as an MSM (i.e., self-acceptance), and knowing other MSM in one’s city. Social factors can encourage consistent condom use and participation in HIV prevention programs, and they have been associated with decreased HIV infection (Baral et al. 2014a).

Community-Level Risks

Community environments, including network ties, relationships between organizations and groups, and geographical/political regions, can either promote health and well-being or serve as a source of stigma and HIV risk enhancement. Stigma toward MSM in communities can limit the provision and uptake of HIV prevention, treatment, and care services. For example, culturally insensitive health workers may result in MSM avoiding HIV prevention services; or even more problematically, MSM living with HIV may avoid HIV treatment services. Reduced utilization of health and HIV services by MSM, due to enacted or perceived discrimination, may limit knowledge of the risks of unprotected anal intercourse and opportunities for access to prevention services. Stigma and discrimination, such as exposure to homophobic abuse, homophobia, or homonegativity; a lack of social support; shame, blame, and social isolation; and victimization at school or work, have all been associated with negative HIV-related outcomes. These adverse outcomes include reduced rates of HIV testing, increased risk for

HIV infection, lower likelihood of discussing or disclosing HIV/AIDS status with male partners, increased condomless anal sex, and engagement in HIV treatment for those living with HIV. However, MSM community support such as MSM-specific health promotion can have positive impacts such as encouraging condom use through education and sex-positive messaging (Baral et al. 2014a).

Structural-Level Risk

Administrative policies such as the criminalization of same-sex practices in many countries and exclusion of MSM from national surveillance programs have contributed to the limited provision of focused, accessible HIV prevention and treatment strategies for MSM. These punitive policies present significant barriers to HIV prevention and meaningful engagement in treatment. Moreover, they have been associated with higher levels of violence and stigma against MSM, decreased funding for programs for MSM, increased fear of seeking healthcare leading to decreased clinical engagement, and ultimately higher HIV incidence and prevalence. Criminalization promotes multiple forms of stigma as well as structural and cultural violence, which in turn worsen health conditions for MSM and entire communities (Baral et al. 2014a).

Epidemic Stage

The individual-, network-, community-, and law- and policy-level risks discussed previously cannot create HIV infections, and moreover, there is nothing inherently harmful about condomless anal sex. These factors can only increase or decrease the probability of transmission of an infection that is currently prevalent. Consequently, it is the stage of the epidemic within the social and sexual network, community, and country that primarily determines the risk for HIV acquisition in the individual. For example, an individual living in an area of high HIV prevalence will have a greater chance of a shared sexual network with someone who is living with HIV and not virally suppressed than someone living in an area of low prevalence.

MSM in Concentrated Epidemics

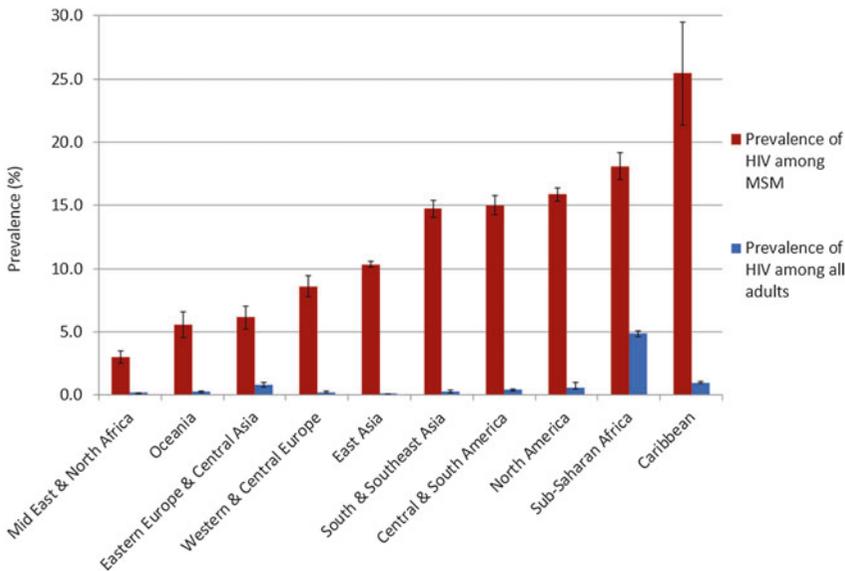

A concentrated epidemic has been traditionally defined as an HIV prevalence of less than 1% among all reproductive-age adults but more than 5% in any key population including MSM in a given country (WHO and UNAIDS 2000). Outside Eastern and Southern Africa, the epidemiology of HIV is primarily represented by concentrated epidemics among key populations including MSM, sex workers, people who inject drugs, and transgender women. In many regions, the HIV prevalence among MSM is over 10%, and the ratio of HIV prevalence in MSM to that of the others in the population is disproportionately high (Beyrer et al. 2013a) (Fig. 2).

High-Income Settings

The burden of HIV among MSM in many high-income settings can be characterized as a predominantly male-concentrated epidemic, with a median male/female case ratio of 2.5:1 and men making up more than 75% of the prevalent HIV

infections (Sullivan et al. 2014). Even as the HIV epidemic among adults is primarily stable or decreasing in most settings, the HIV epidemic among MSM continues to increase in many high-income countries, including the USA (Centers for Disease Control and Prevention 2010). The USA accounts for over 30% of total infections in high-income countries with significant disparities across income levels of MSM (Sullivan et al. 2014), with ethnic and racial minority MSM carrying a disproportionate local HIV burden (Millett et al. 2012).

High-income countries exhibit greater coverage of antiretroviral therapy (ART), larger extent of HIV diagnosis among people living with HIV, and greater access to healthcare services and social structures that facilitate accurate reporting of male-to-male sex risks. However, there have been reemergent epidemics in MSM in many high-income settings where the overall HIV epidemic is otherwise in decline – including Australia, France, the UK, and the USA (Sullivan et al. 2014). The disparities in the burden of HIV

Gay men and other Men who have sex with men (MSM), Epidemiology of HIV/AIDS Introduction, Fig. 2 Pooled HIV prevalence among MSM and among all men of reproductive age, by region, 2012. HIV prevalence among adults (Data from *UNAIDS report on the global AIDS Epidemic: 2012*. Joint United Nations

Programme on HIV/AIDS (UNAIDS). Geneva: 2012. Adapted from The Lancet, volume 380, Beyrer C, Baral SD, van Griensven F, Goodreau SM, Chariyalertsak S, Wirtz AL, and Brookmeyer R. Global epidemiology of HIV infection in men who have sex with men, pp 367–77, Copyright (2012), with permission from Elsevier)

observed within the USA among different populations of MSM suggest that the early initiation of appropriate ART does result in fewer HIV infections and reduced likelihood of HIV transmission. In the USA, HIV infections among MSM overall remained relatively stable between 2002 and 2011 though this average omits the increasing disparities in the burden of HIV observed in the US context among MSM generally attributed to socioeconomic determinants. HIV infections in MSM aged 13–24 years are estimated to be increasing at roughly 10% per year since 2002 (Johnson et al. 2014). Similar trends have been reported among gay and other MSM in the UK, where treatment coverage is higher than in the USA (Yin et al. 2014). Biological, couple, network-level, and community-level influences are likely crucial to understanding why HIV transmission rates remain so high in these populations of MSM. Given the rapid transmission that appears to take place within sexual networks of MSM when someone is acutely HIV infected, the bar for preventing HIV infection within these sexual networks is very high. In addition, breaking chains of HIV transmission necessitates not just coverage of HIV testing but the diagnosis of people during the acute infection stage followed by an effective intervention. Thus, we do not know yet whether universal treatment approaches will work for MSM since so many of these men are diagnosed often too late to prevent HIV transmission events (Sullivan et al. 2014).

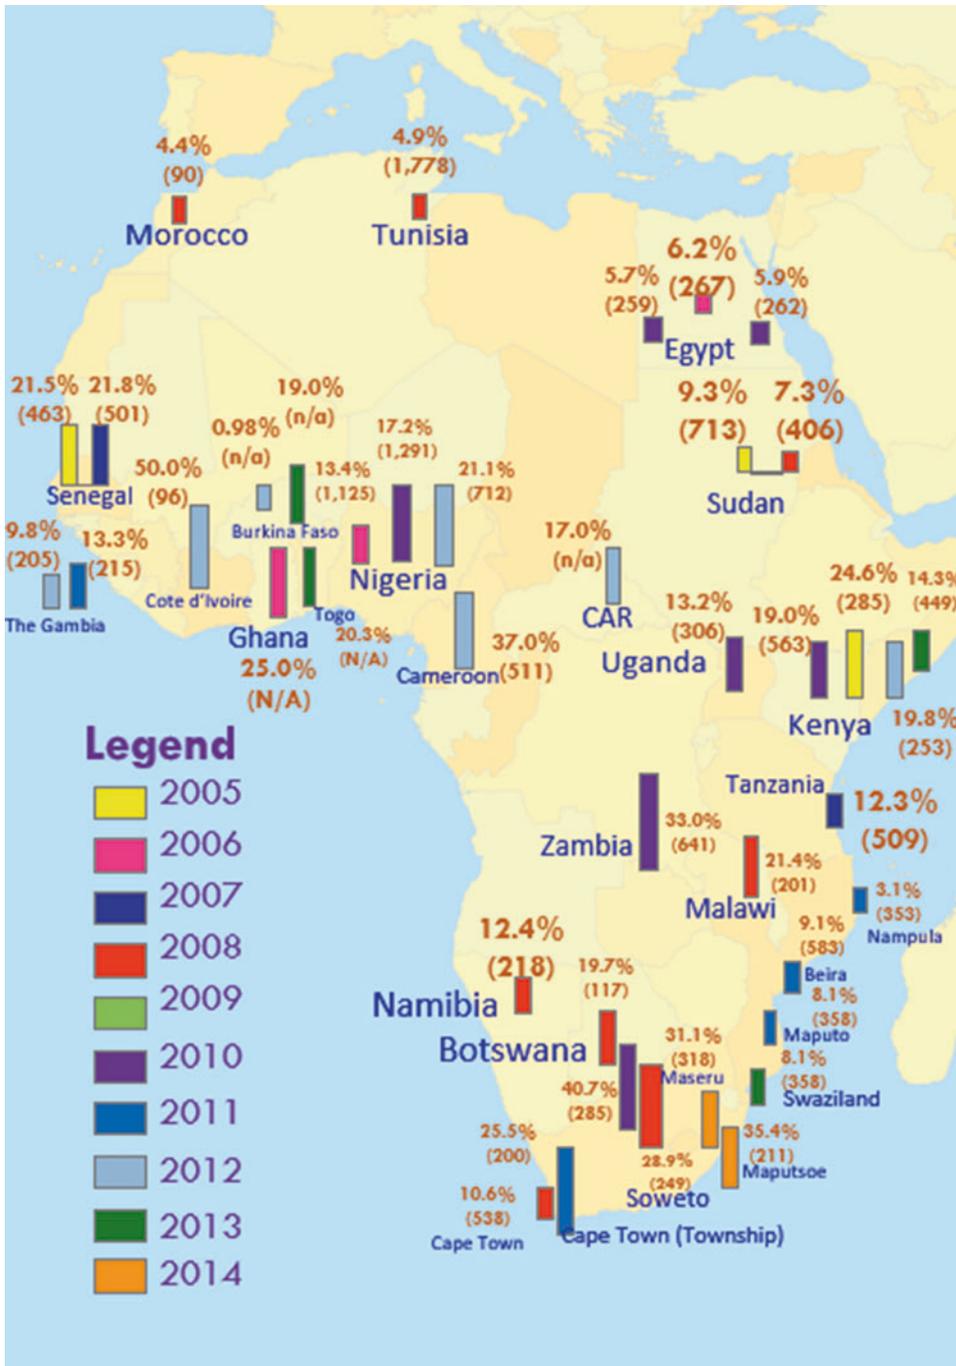

Low- and Middle-Income Settings

The concentrated HIV epidemic among MSM transcends country income level. In low- and middle-income countries, MSM are estimated to have 19 times the odds of living with HIV compared with other people (Baral et al. 2007; the Foundation for AIDS Research and Johns Hopkins Bloomberg School of Public Health 2012). According to a meta-analysis of 15 South American countries, the HIV prevalence among MSM is generally greater than 10%, and the odds of having HIV in MSM is almost 34 times than in the general population (Baral et al. 2007). In the Middle East and North African countries, HIV prevalence among MSM appears to be low, but emerging HIV epidemics have been documented

among MSM in Egypt, Jordan, Lebanon, Oman, and Syria (Mumtaz et al. 2010). In Eastern Europe and Central Asia, HIV incidence is highest among dual risk people who inject drugs (PWID) and are MSM, expanding the established local HIV epidemics driven by PWID combined with limited coverage of effective tools to decrease parenteral transmission of HIV. In South, Southeast, and Northeast Asia, MSM transmission, PWID transmission, and heterosexual transmission all contribute significantly to the HIV epidemic (Beyrer et al. 2010). In sub-Saharan Africa, the prevalence of HIV among MSM is higher than that of age-matched men in all settings (Fig. 3).

For several years the HIV epidemic among MSM in low- and middle-income countries was ignored by many governments, donors, and societies. Although attitudes have steadily shifted to address the needs of MSM, in many parts of the world, a hidden epidemic remains that is exacerbated by stigma, discrimination, and violence. Same-sex sexual practices are punished as crimes in roughly 75 countries, with penalties ranging from fines to imprisonment and in some cases even death. In much of the world, national HIV epidemiological surveys do not assess the impact of HIV on MSM. Unfortunately, this willful ignorance results in a lack of acceptable data regarding HIV risk in MSM, which is then used by governments to justify the limited investment in the HIV prevention and treatment needs of this population (the Foundation for AIDS Research and Johns Hopkins Bloomberg School of Public Health 2012).

To improve low- and middle-income countries' responses to HIV/AIDS, it is essential that services expand to include MSM as a key population in line with the attributable fraction of HIV infections. A more distinctive understanding of the diversity of epidemics among MSM in low- and middle-income countries is needed. Because these men are hidden from the broader community, there is notable underreporting of MSM behavior in population-based surveys, and there has been limited work on the type of surveillance necessary to characterize these men and the epidemics affecting them. Correlates of prevalent HIV infection in low- and middle-income countries include the individual-level HIV risk factors similar to those found in concentrated HIV epidemics, as

Gay men and other Men who have sex with men (MSM), Epidemiology of HIV/AIDS Introduction, Fig. 3 HIV prevalence among MSM in Africa (Modified from van Griensven et al. 2009)

well as community-level structural factors, such as stigma, being blackmailed, and history of homophobic abuse (Baral et al. 2014b). Additional risk factors for HIV in low- and middle-income settings

include social isolation, limited healthcare access, and social stigma that restrict HIV surveillance and the coverage of comprehensive HIV prevention programs.

Overall, the odds of having HIV infection are markedly and consistently higher among MSM in each geographic locale than among the adult populations across Asia, Africa, and the Americas. Indeed, MSM from low- and middle-income countries appear to be understudied and underserved and are in urgent need of prevention and care (Beyrer et al. 2012b). Factors contributing to the lack of sufficient knowledge include limited data regarding adolescent MSM and MSM from specific regions such as North Africa and the Middle East. Prevention strategies that lower biological transmission and acquisition risks, such as early treatment and PrEP, offer promise for controlling the expanding epidemic in MSM in these settings; however, their potential effectiveness may be limited by structural factors that contribute to suboptimal health-seeking behaviors and by the refusal of governments to address regulatory and other structural barriers and make PrEP available. More intensive efforts will be required to reach younger MSM, expand testing and treatment, and implement effective prevention tools such as PrEP in diverse geographic settings. In addition, these efforts will likely have to be coupled with community efforts around safe sex practices and condom use. Ultimately, the challenge will be not just linking people to these programs but will be about securing long-term retention – and this will require significant study leveraging the best implementation research approaches.

MSM in Generalized Epidemics

Generalized HIV epidemics are generally categorized as regions with HIV prevalence rates above 1% in adults or in antenatal clinics. With few exceptions, generalized HIV epidemics are limited to Southern and Eastern sub-Saharan Africa. In the context of generalized epidemics, it is often proposed that MSM do not constitute a significant component of the epidemic and that resources should not be diverted from addressing other populations deemed to have higher priority. As a result, in countries categorized as having concentrated epidemics, only a small proportion of HIV

prevention expenditures target the preventive needs of MSM, and an even smaller fraction of funding for HIV prevention supports prevention for MSM. However, recent data highlight the disproportionate burden of HIV among MSM that exists when compared with other men of reproductive age across countries with generalized epidemics.

Fortunately, there has been a recent notable decrease in HIV incidence among several countries with a generalized epidemic, including Malawi, Namibia, Botswana, and Zambia (UNAIDS 2013). However, in a review of 51 countries with generalized epidemics, the burden of HIV was consistently higher among MSM. Data were primarily available for Kenya, South Africa, and Thailand (Baral et al. 2014b). In Kenya, the HIV prevalence among MSM ranges 12.3–43.0% compared with 6.1% among the reproductive-age population. Similarly in South Africa, HIV prevalence among MSM ranges 10.0–40.7% compared with 17.9% among reproductive-age adults. In Thailand, one of the few countries outside of Eastern and Southern sub-Saharan Africa which has had a generalized epidemic, HIV prevalence among MSM ranges 8.2–68.2% compared with 1.1% among adults of reproductive age.

The HIV prevention needs of MSM in generalized epidemics may be different from those in concentrated epidemics. In generalized epidemics, HIV prevalence is higher in the population as a whole and usually disproportionately affects women. Thus, in generalized epidemics, MSM may have higher HIV acquisition risks secondary to their heterosexual partnerships, but some of the relatively higher risks among MSM may reflect their ability to acquire or transmit HIV with both female and male partners. Decriminalization of same-sex sexual practices is important in terms of establishing a facilitating environment for effective HIV programs focusing on MSM in these settings. However, stigma and discrimination, as well as access to effective interventions, will also need to be addressed to reduce impediments for MSM involvement in HIV prevention, treatment, and care. And decriminalization cannot achieve this on its own (Zahn et al. 2016). In

addition, because HIV prevention, treatment, and care services have been designed in a way to not specifically address any at-risk population, there is a common misconception among MSM that HIV transmission is more likely through vaginal intercourse than through anal intercourse (Baral et al. 2014b). A comprehensive agenda to understand who the “general population” is in terms of specific HIV acquisition and transmission risks will be needed in these contexts to inform HIV prevention and treatment response.

West Africa

The dynamics of the HIV epidemic in West Africa are significantly different from what has been observed in neighboring Southern and Eastern Africa. The HIV prevalence among reproductive-age adults is not as high as that in Southern or Eastern sub-Saharan Africa; however, the burden of HIV among key populations including MSM and female sex workers has been significant. West Africa includes both a generalized and concentrated epidemic, with significant transmission in both the general population and in most at-risk groups. In Senegal, a country known for an early and effective response to HIV with scaled-up ART, it is estimated that MSM have 50 times the risk of HIV infection than other reproductive-age men. Similar to Eastern and Southern Africa, homosexual activities are criminalized in a number of West African countries. Decreasing HIV incidence rates among these men will likely necessitate the integration of biomedical interventions such as treatment as prevention, oral PrEP, and eventually rectal microbicides. However, these approaches will have limited effectiveness if these men continue to have limited access to healthcare services as a result of stigma and discrimination (Drame et al. 2013).

Other Key Issues

Role of Community Organizations

Gay men and other MSM have historically led and participated in HIV intervention efforts through advocacy, education, research, and design and delivery of prevention, treatment, and care

programs that have benefited all affected by HIV. In stigmatizing environments, MSM and lesbian, gay, bisexual, and transgender (LGBT) community groups are often the only groups willing to advocate for recognition and rights or to provide HIV-related services to gay men and other MSM. Indeed, gay and MSM advocates have achieved important successes in the response to HIV, but they have faced challenges, including stigma and threats of violence, limited funding, and the need to represent highly diverse populations. Tailored community-based programs led by MSM have resulted in greater feelings of connection, social support, and self-esteem among community members. For example, men living with HIV in Cameroon have been able to obtain greater health services as the result of efforts by a dynamic community-based organization that provided HIV prevention, care, and treatment specifically for the LGBT population (Holland et al. 2015). In addition, MSM community groups have traditionally supported the collection of data that challenge the assumption that gay men and other MSM do not play substantial parts in the HIV epidemic in low-income and middle-income countries.

Protecting and improving personal health require community-level action, and this will continue to be essential in the response to AIDS worldwide. Communities will require increased resources, developmental support, and expanded opportunities to serve and lead the fight against the growing HIV epidemic in MSM (Trapence et al. 2012).

Transgender Women

Transgender women represent a separate population from MSM; they were assigned the male sex at birth but identify as women and are well known to be at exceptionally high risk for HIV acquisition and transmission. Worldwide, the odds for transgender women being infected with HIV is almost 50 times that of adults of reproductive age, with a pooled HIV prevalence of around 19% (Baral et al. 2013b). There are some shared determinants of risk between transgender women and MSM including the high transmission probability of unprotected anal sex. In addition, network-level

(e.g., HIV prevalence in subgroups), community-level (e.g., stigma, social exclusion) and structural-level (e.g., discriminatory laws, economic marginalization) risks contribute to the high burden of HIV among transgender women.

In contrast, transgender men, who were assigned the male sex at birth, have traditionally been considered low-risk for HIV. However, some of these men identify as gay and have sex with other men, sometimes termed trans MSM. Trans men and trans MSM report a range of sexual practices including vaginal or receptive anal sex with other men, which could put them at substantial risk in the context of HIV serodiscordant and viremic sexual partners. HIV prevalence in transgender men ranges from 0% to 2.9% based on two studies conducted in the USA (Reisner et al. 2013). However, there has been such limited programmatic investment and study, ultimately greatly limiting our knowledge of HIV-related risk behaviors, social and structural factors, and sexual health needs of transgender men.

Male Sex Workers

The global burden of HIV among male sex workers is high and in some cases increasing. Data on male sex workers are limited, with most research conducted as part of studies of MSM, female sex workers, or transgender women (Baral et al. 2015). However, available data indicate that male sex workers mostly offer sex to men and rarely identify as sex workers. Male clients sometimes do not identify as gay or bisexual, and many have regular female partners. Because of social exclusion, expulsion from higher education, and limited opportunities for other employment, sexual and gender minorities (including transgender women) are more likely to engage in survival or commercial sex work. In addition, male sex workers may have high numbers and frequencies of male partnerships (many of whom are older than they are), resulting in large sexual networks, which has been established as a risk factor for HIV among MSM. Individual-level behavioral HIV risks are compounded by criminalization and stigma of same-sex practices and commercial sex, leading to deferral of seeking testing, treatment, and prevention services. Other

risks include economic disparities, sexual and physical abuse, drug misuse, and low socioeconomic status. Dedicated advocacy, funding, surveillance, research initiatives, and diverse preventive options for male sex workers are needed to reduce the burden of HIV among male sex workers (Baral et al. 2015).

Internet Use for Finding Sex Partners

Among MSM, the Internet is a popular platform for meeting new sexual partners. Recent data suggest that MSM in low- and middle-income settings utilize the Internet for sex-seeking at rates equivalent to MSM in high-income settings such as North America or Europe. In response to the HIV epidemics among MSM, there has been some pushback against Internet access and other forms of social media – particularly in China but also in several other countries. This is a worrisome trend and is not evidence based. It is currently unclear whether online sex-seeking facilitates HIV transmission. MSM who meet partners online are more likely to report unprotected anal sex and higher numbers of sex partners, which would facilitate HIV transmission, but also with HIV status disclosure and seroadaptive sexual practices, which could protect against HIV transmission (Lewnard and Berrang-Ford 2014). Regardless, increasing evidence is pointing to the Internet as both an acceptable and feasible HIV intervention mechanism to reach MSM worldwide.

Biomedical Improvements in HIV Prevention

Daily oral use of PrEP is an effective HIV prevention intervention for MSM. In 2010, the iPrEx (Preexposure prophylaxis initiative) trial demonstrated a 44% reduced HIV infection rate among MSM in the PrEP arm compared to the placebo arm (Grant et al. 2010), but on average medication adherence was around 50%. In 2015, an open-label randomized trial (the PROUD study) conducted among gay men and other MSM in England ($N = 544$) successfully addressed concerns about real-world effectiveness and risk compensation for PrEP by demonstrating 86% efficacy among MSM who accessed STD clinics who initiated PrEP right away (McCormack et al. 2015). Further, the French and Canadian

Ipergay study found that peri-coital dosing before and after sex was found to be similarly effective (86%) (Molina et al. 2015). Overall, the findings of these studies strongly support the addition of PrEP into combination prevention packages that include behavioral, structural, and biological intervention components. At the time of writing, PrEP is being implemented in the USA, South Africa, France, and Kenya and including MSM in the populations recommended – a remarkably slow rollout for an intervention with 6 years of efficacy data. And indeed, this slow rollout may be further indicative of the limited support for interventions where the primary efficacy data for HIV prevention is among MSM. The coming years will likely introduce new formulations of oral PrEP and even long-acting injectable PrEP which may ultimately represent important components of the package of services for MSM.

Conclusion

There is an HIV pandemic among MSM – it is a global epidemic with more similarities than differences across income levels, HIV epidemic types, and geography. Improved HIV surveillance mechanisms leveraging mathematical modeling, phylodynamics, and meaningful indicators can inform the population attributable fraction of HIV among MSM across countries and will be needed to passively evaluate the success of intervention efforts. Among MSM, individual- and network-level HIV risks are compounded by structural-level risks such as community environments, laws, policies, and program failures. Universal HIV treatment, fourth-generation HIV tests, HIV self-testing, and daily oral PrEP using tenofovir-emtricitabine have emerged as integral to the prevention of HIV transmission, and such efforts should be immediately expanded for MSM and other populations disproportionately affected by HIV. Indeed, the bar for HIV prevention among MSM is extremely high. Only with true respect for human rights and efforts to combat stigma, discrimination, and social exclusion can the levels of coverage needed to change the trajectory of the HIV pandemic among MSM.

Global NeuroAIDS

Bibilola D. Oladeji^{1,2}, Sarah Yosief¹ and Kevin Robertson¹

¹Department of Neurology, University of North Carolina School of Medicine, Chapel Hill, NC, USA

²Department of Psychiatry, College of Medicine University of Ibadan, Ibadan, Nigeria

Definition

The term NeuroAIDS encompasses all the neurological complications associated with HIV. This includes diseases that primarily result from direct infection of the CNS with HIV (HIV-associated neurocognitive disorders [HAND]), secondary conditions resulting either from the effects of associated immunocompromise (neurologic opportunistic infections or tumors) or the effects of treatment (such as the immune reconstitution

syndrome [IRIS]) as well as other diseases that could be influenced but not caused by HIV (e.g., stroke).

Types of HIV-Associated Neurological Syndromes

- Primary HIV neurological diseases
 - HIV-associated neurocognitive disorders (HAND)
 - Asymptomatic neurocognitive impairment (ANI)
 - Mild neurocognitive disorder (MND)
 - HIV-associated dementia (HAD)
 - Aseptic meningitis
 - HIV-associated myelopathy
 - HIV-associated peripheral neuropathies
 - Distal symmetric polyneuropathy (DSP)
 - Inflammatory demyelinating polyneuropathy (IDPN)
- Secondary or opportunistic neurological diseases
 - Opportunistic neurological infections
 - Viral: cytomegalovirus, progressive multifocal leukoencephalopathy, and herpes simplex encephalopathy
 - Bacterial: CNS tuberculosis
 - Fungal: Cryptococcal meningitis
 - Parasitic: Toxoplasmic encephalitis
 - Opportunistic CNS tumor
 - Primary HIV-associated CNS lymphoma
- Treatment-related neurological disease
 - Immune reconstitution inflammatory syndrome (IRIS)
 - Neurotoxic neuropathy
- Non-AIDS-related diseases
 - Stroke

Epidemiology of NeuroAIDS

HIV/AIDS remains a global public health problem with 35.3 million people infected and 2.3 million new infections worldwide in 2012 (UNAIDS 2013). The introduction of antiretroviral therapy (ART) from the mid-1990s led to a gradual reduction in the rates of new infections and increased the life expectancy of people living

with HIV; it also altered the manifestations of HIV disease. The global incidence of new HIV infections has declined by 19% since the peak of the epidemic in 1999. HIV has a wide range of effects on the nervous system, directly on the brain and spinal cord, which create cognitive, central motor, and behavioral abnormalities. In the pre-ART era, neurological disorders were a common presenting feature of HIV infection, with 7–20% of patients having neurological complications at first presentation. Severe cognitive impairment was commonly seen in patients with advanced immunosuppression; HIV-associated dementia was reported in 20–30%, and 39–70% developed opportunistic neurologic infections (Spudich and González-Scarano 2012; Tan et al. 2012).

Currently, in developed countries where there is widespread availability and access to combination antiretroviral therapy (cART), there has been a decline in the incidence of severe HIV-associated neurologic disorders and opportunistic infections by up to 80–90%. For example, between 1996 and 1997, the incidence of opportunistic infections in high-income countries was 13.1 per thousand patient-years; by 2006–2007, this had reduced to 1 per thousand patient-years (Tan et al. 2012). However, the spectrum of disease-causing agents has remained largely unchanged. Despite this reduction in incidence rates, neurologic complications still remain a significant cause of excess morbidity and mortality in people living with HIV. The overall prevalence of HIV-associated neurocognitive disorders (HAND) is on the rise despite satisfactory virologic control; the current prevalence of HAND ranges from 20% to 50% (Brew and Chan 2014).

The picture is somewhat different in low- and middle-income countries where only an estimated 34% of the 28.6 million eligible people in 2012 are receiving ART (UNAIDS 2013). The current picture of HIV neurological disorders appears similar to that of the pre-ART era. The problem in low-resourced areas of the world is further compounded by limited diagnostic capabilities for HIV-associated neurologic disorders and hence a paucity of reliable data on the actual rates of CNS complications in HIV populations in low- and middle-income countries (LMIC)

(Robertson et al. 2010). The little data available suggests that opportunistic infections are still the commonest neurologic complications of HIV.

The type and severity of the neurologic dysfunction related to HIV are influenced by the properties of the HIV virus, disease stage, genetic characteristics of the host, and interactions with the environment. Neurologic manifestations of HIV might be linked to HIV virus subtype. For example, HIV type 2 has less propensity to cause neurologic disease compared to type 1. Even within HIV-1 infection, different subtypes or clades have been associated with different rates of occurrence of neurologic dysfunction in preliminary studies (Sacktor et al. 2007).

Acute HIV infection is usually asymptomatic, but a few patients develop a neurologic illness. Common presentations include aseptic meningitis, facial palsy, Guillain-Barré (GB) syndrome, and transverse myelitis. As the disease progresses, with reduction in the CD4-positive cells, the risk for other conditions such as opportunistic infections, HIV-associated cognitive disorders, and peripheral neuropathies increases (Hogan and Wilkins 2011).

Pathogenesis of NeuroAIDS

HIV is able to infect the nervous system and cause central nervous system (CNS) and peripheral nervous system (PNS) disorders at any stage during disease evolution from seroconversion to late stage HIV disease. The neuropathology of HIV infection is very complex and as yet not fully understood; however, HIV is known to invade the central and peripheral nervous system soon after initial infection. The virus is believed to enter the CNS through HIV-infected macrophages and CD4+ T cells that are able to penetrate the blood-brain barrier. In the CNS, the virus commonly infects perivascular macrophages and the microglia. CNS infection is mediated by CD4 and the chemokine receptor (CCR5) serving as viral receptors (Spudich and González-Scarano 2012).

The mechanism for HIV neurotoxicity is not yet fully understood, but it is thought to result from either direct neurotoxicity from the virus

and its proteins or through sustained chronic immune activation and inflammation. Viral proteins such as glycoprotein 120 (gp-120) and transactivator of transcription (tat) have been shown to be neurotoxic. The chronic immune activation stimulates the microglia and macrophages to secrete neurotoxic products such as pro-inflammatory cytokines (tumor necrosis factor- α , interleukin-1, and interferon- α), quinolinic acid, and arachidonic acid metabolites. This results in disturbance of the blood-brain barrier and further entry of infected cells into the nervous system and eventually to decreased synaptic-dendritic density (Mirza and Rathore 2012). The common end pathway for neurotoxicity is through the excitation of *N*-methyl-D-aspartate (NMDA) glutamate receptors with potential for mediating apoptosis (Spudich and González-Scarano 2012).

HIV-Associated Neurocognitive Disorders (HAND)

HIV-associated neurocognitive disorder (HAND) is a chronic neurodegenerative condition characterized by cognitive, motor, and behavioral abnormalities. HAND is classified into three groups based on the severity of neurocognitive impairment that range from mild to severe: asymptomatic neurocognitive impairment (ANI), mild neurocognitive disorder (MND), and HIV-associated dementia (HAD) (Antinori et al. 2007). ANI is a subclinical decline in cognition, MND is a mild decline in cognition along with mild interference in everyday functioning, and HAD is significant decline in cognition along with significant functional impairment affecting routine activities. These disorders were previously known as AIDS dementia complex (ADC) and minor cognitive and motor disorder (MCMD).

With the introduction of antiretroviral therapy, there has been a substantial change in the epidemiology of HAND with significant decline in the incidence of severe neurocognitive impairment. For example, in the USA, current incidence of HIV-associated dementia is less than 1% compared to 7% in 1989 (Kranick and Nath 2012).

HIV-associated dementia (HAD) is associated with profound immunosuppression with low CD4 counts and the presence of other symptoms of AIDS. In low-resourced countries, where treatment is often delayed, HAD is still quite prevalent. The milder degrees of HAND (ANI and MND), on the other hand, remain common even in ART-treated patients and are no longer associated with the typical HIV disease biomarkers (viral load, CD4, and inflammatory response markers). Compared to patients without any impairment, patients with these milder forms of neurocognitive impairment have worse quality of life, reduced ability to perform everyday tasks, poor medication adherence, and reduced survival time.

The reasons for this persistence of cognitive dysfunction despite good viral control are unknown, but several explanations have been proposed. The host and viral factors that predispose to the development of HAND are also poorly understood. Recent evidence suggests that the subtype of HIV might have effect on disease progression and differ in neuropathogenicity. For example, a study from Uganda, where HIV clades A and D predominate, reported that adults with clade D infection had a more rapid progression and increased risk for dementia compared to clade A (Sacktor et al. 2007). Host factors that affect the occurrence of HAND include aging, substance abuse, and the presence of comorbid diseases such as hepatitis C virus infection (Shapshak et al. 2011).

HAND affects several areas or domains of neurocognitive functioning. The pattern of cognitive impairment observed in classic HAD is a subcortical dementia, more similar to deficits associated with disorders such as Parkinson's disease and Huntington's disease, rather than the pattern for cortical dementia associated with Alzheimer's disease. Cortical deficits were not observed until very late in the disease as the brain became globally affected. There is emerging evidence that HAND has some additional cortical features that are mostly observed in the neuropsychological profile. The most commonly affected domains are attention/working memory, executive functioning, psychomotor speed, memory

and learning, speed of information processing, and motor skills. Other domains less commonly or severely affected by HAND include language fluency and visuospatial domains. Furthermore, there is evidence that HAND is beginning to have more extrapyramidal features, sometimes overlapping with Parkinson's disease. These changes suggest that HAND is probably associated with the accelerated development of some neurodegenerative diseases and accelerated aging (Brew and Chan 2014).

Current "Frascati" criteria for the diagnosis of the milder forms of HAND require formal neurological assessment and neuropsychological testing (Antinori et al. 2007). Neuropsychological impairment is defined by performance below the appropriate normalized group mean on standardized tests. The formal criteria specify that at least five domains of functioning must be included to cover a range of cognitive abilities. ANI and MND impairment is defined as performance one standard deviation or more below the mean on at least two neuropsychological tests of different domains. HAD, however, must have impairment in performance two standard deviations below on two neuropsychological tests in two different domains.

In most clinical settings and in low-resourced settings where facilities for neuropsychological assessments are not readily available, a presumptive clinical diagnosis and use of brief screening tools are advocated. Examples of such brief screening tools include NEU screen, HIV Dementia Scale (HDS) and International HIV Dementia Scale (IHDS), and the ACTG ALLRT Neuroscreen, and even computerized screens such as CogState and CANTAB have also been utilized. However, no single tool is suitable across all practice settings, and these tests are generally not sensitive or specific for HIV-associated neurocognitive dysfunction.

Clinically, HAND presents with difficulties in learning new information, disturbances in attention, slowing of information processing, and disturbances in executive functioning (e.g., planning, abstraction). Motor symptoms include motor slowing, ataxia, incoordination, and tremors and may later progress to weakness, spasticity, and

paraparesis. Behavioral manifestations of HAND include apathy, psychomotor retardation, and irritability. Neuroradiological studies show generalized cerebral atrophy especially in the later stages of the disease; the degree of atrophy on MRI has been correlated with the degree of neurocognitive dysfunction. There is no specific laboratory diagnostic biomarker for HAND; HIV+ patients are diagnosed after ruling out confounding conditions such as CNS opportunistic infections, psychiatric disease, and age-related dementia. ART remains the most important treatment for HAND.

Peripheral Neuropathies

Neuropathy is one of the most common manifestations of HIV disease. Many forms of peripheral neuropathies have been associated with HIV including distal symmetric polyneuropathy (also called distal sensory peripheral neuropathy (DSPN)), mononeuritis multiplex, inflammatory demyelinating polyneuropathy, polyradiculopathy, and autonomic dysregulation. The commonest are distal symmetric polyneuropathy (DSP), acute inflammatory demyelinating polyneuropathy, and neurotoxic neuropathy.

Distal Symmetric Polyneuropathy: HIV-associated DSP is the commonest neurological problem of HIV in developed countries in this era of effective antiretroviral treatment. The rates have not been well studied in developing countries but appear similar to that from developed countries. The current prevalence estimates range from 19% to 66%. This wide variation results from widely varying definitions of HIV DSP used in studies and differences in the cohort studied. Some studies defined DSP as one clinical sign (i.e., reduced ankle reflexes or reduced pinprick sensation or reduced vibration sensation in the feet), others required two clinical signs, and some used validated screening or diagnostic instruments (Schütz and Robinson-Papp 2013). Prior to the introduction of ART, DSP prevalence was 55%, and almost all patients had evidence of DSP on autopsy even those without symptoms during their lifetime. Pre-cART, DSP was related to profound immunosuppression and high HIV

viral load, but recent studies report that the degree of immunosuppression or viral load does not predict the development of DSP. Recent studies report that age is the most important risk factor for DSP; rates are higher in older patients.

DSP is an ascending, symmetric predominantly sensory distal neuropathy. Symptoms typically begin in the distal lower extremities – toes and feet – and may gradually ascend up to the thighs and could similarly involve the hand: glove and stocking distribution of symptoms. Patients present with pain, paresthesia, and numbness. The signs seen on examination include decreased or absent ankle jerks and decreased pinprick and vibration sensation involving the distal lower extremities. Pathological changes may be absent on electromyogram and nerve conduction studies; definitive diagnosis is made on skin biopsy which typically shows a reduction in epidermal nerve fiber density in DSP patients. It is important to rule out other potentially reversible causes of sensory neuropathy such as diabetes mellitus, renal disease, liver disease, infections (syphilis, hepatitis C), and micronutrient deficiency (vitamin B12, folate, and vitamin D). There is presently no effective treatment for DSP.

Inflammatory Demyelinating Polyneuropathy: The true prevalence of this complication is not known. Two forms of inflammatory polyneuropathy have been described in HIV: acute inflammatory polyneuropathy (AIDP) and chronic inflammatory polyneuropathy (CIDP). AIDP typically occurs at seroconversion and may be the presenting symptom of underlying infection with HIV. It is indistinguishable clinically from Guillain-Barré syndrome (GBS); up to 10% of GBS cases are related to HIV. AIDP presents as a rapidly progressive primarily motor neuropathy, most commonly starting in the lower limbs and like GBS can lead to quadriplegia with respiratory failure over days or even hours. The treatment is the same as for non-HIV-associated AIDP. Treatment consists of supportive care, intravenous immunoglobulin, or electrophoresis and possibly starting cART.

CIDP on the other hand occurs in late infection and is associated with low CD4 count. CIDP resembles AIDP, but it is more slowly progressive

and may have a relapsing and remitting course. Electrophysiologic studies show slow or absent nerve conduction. The treatment for HIV-associated CIDPs is identical to that for non-HIV-related disease in addition to antiretroviral medications.

HIV Myelopathy

HIV is associated with a non-inflammatory, subacute vacuolar myelopathy (Previti and Marra 2012). Much of what is known about HIV-associated myelopathy is from the pre-cART era where it was found in up to 30% of autopsies and more commonly in patient with other AIDS-defining conditions. It is likely that the incidence is dramatically reduced in the current treatment era. HIV vacuolar myelopathy (HIV VM) is a diagnosis of exclusion; it has to be differentiated from other causes of spinal cord disease such as direct infections (CMV, HTVL I and II, herpes simplex virus, enteroviruses, varicella zoster, syphilis and mycobacterium tuberculosis), tumors, and nutritional deficiencies (vitamin B12). While vacuolar myelopathy can develop at any stage in the progression of HIV disease, it is more common at lower CD4 levels.

Clinically it presents as a subacute or chronic weakness in the lower limbs, spasticity, hyperreflexia, sensory loss (especially loss of vibration and joint position sense), sexual dysfunction, and sphincter dysfunction. Laboratory and imaging studies are needed to exclude other spinal cord diseases. Histopathological features are prominent vacuolation in the white matter of the dorsal and lateral columns that is most prominent in the thoracic spinal cord. There is no proven treatment for HIV myelopathy, and the condition is irreversible. The treatment is usually symptomatic; however, some patients may improve with ART.

Opportunistic Infections

Most CNS opportunistic infections (OIs) seen in people with HIV are due to reactivation of latent pathogens rather than new infections. The

strongest predictor for the development of opportunistic infections is decreased CD4 count; susceptibility is increased when the CD4 count falls below 200 cell/ μ l. These infections are usually comorbid, with up to 15% of cases having more than one infection (Tan et al. 2011). In the era of cART, opportunistic infections are often unmasked at the initiation of antiretroviral therapy. Many of the OIs that commonly infect the CNS are AIDS-defining conditions; they include toxoplasmosis, cryptococcal meningitis, progressive multifocal leukoencephalopathy (PML), CNS tuberculosis, and CNS cytomegalovirus. CNS OIs are associated with excess mortality. There is wide geographical variation in the occurrence of these infections. For example, the commonest CNS OIs in Asia and Pacific Regions are cryptococcal meningitis, cerebral toxoplasmosis, and tuberculous meningitis, while in Europe and North America, the commonest infections are PML, toxoplasmic encephalitis, and cryptococcal meningitis (Tan et al. 2011).

The diagnosis of CNS OIs is based on the clinical presentation, radiographic features, CSF findings, and isolation of the organism or its antibodies. In resource-rich settings, a battery of investigations which include neuroimaging studies (CT /MRI scans), CSF antibody testing or polymerase chain reactions to identify the organism, and image-guided stereotactic brain biopsy are used to confirm the diagnosis of CNS OIs. In places with limited resources, where diagnoses often depend on clinical presentation and minimal rudimentary investigations, the diagnosis of OIs is often missed or delayed contributing further to increased morbidity and mortality. In such resource poor settings where cART and the resources to manage OIs are not yet widely available, the current medical strategy is the use of prophylactic antimicrobial regimens to reduce the occurrence of OIs.

Primary CNS Lymphoma

Primary CNS lymphoma (PCNSL) is the second most common mass lesion in AIDS; it usually arises in and is confined to the CNS. It is therefore

important to rule out systemic lymphoma with secondary CNS lesions in making the diagnosis. PCNSL affected up to 5% of patients with HIV before the advent of cART, but rates have declined substantially since, and in most developed countries, it is now a rare disease. The major risk factor for PCNSL is a low CD4 count (less than 100cells/ μ l).

Primary CNS lymphoma is a high-grade B-cell non-Hodgkin's lymphoma that is associated with multiple genetic alterations and monoclonal Epstein-Barr virus infection. Factors that contribute to lymphoma development include HIV-induced immunosuppression, impaired immune surveillance, cytokine release and deregulation, and chronic antigenic stimulation. The clinical features of the tumor are usually non-specific and may include headache, lethargy, cognitive changes, seizures, and focal signs which depend on the anatomic site of the tumor. The tumor shows up on neuroimaging (CT or MRI) as contrast-enhancing lesions surrounded by edema and a mass effect. In making the diagnosis, CSF PCR to detect the presence of Epstein-Barr virus is helpful; diagnosis confirmed with brain biopsy. The clinical outcome with current treatments for primary CNS lymphoma in HIV-infected persons remains relatively discouraging; median survival time is about 2 months.

CNS IRIS

Immune reconstitution syndrome (IRIS) is a serious complication related to immune recovery on initiating effective antiretroviral therapy. IRIS can affect any organ system, and it occurs in 15–25% of patients starting ART, but the rates increase to 20–45% in patients with OIs. CNS IRIS is less common, found in only about 1% of patients initiating ART (Kranick and Nath 2012). Even though the rates have not been well documented in low-resourced settings, it is likely to be much higher as patients in such setting usually start ART at lower nadir CD4 levels when many already have an AIDS-defining illness. For example, in a prospective study of neurological disorders

occurring within the first year of starting ART in South Africa, 28% of the sample developed CNS IRIS (Asselman et al. 2010). CNS IRIS is associated with poor outcomes and high mortality rates ranging from 20% to 30% depending on the underlying infection and the immune status of the individual. This excess mortality is related to raised intracranial pressure and risk of brain herniation resulting from the excessive inflammation and swelling in the brain tissue.

The important infections predisposing to CNS IRIS include cryptococcal meningitis, CNS tuberculosis, and progressive multifocal leukoencephalopathy. However, CNS IRIS has been described occasionally with other opportunistic infections and more rarely without an identifiable pathogen. In addition to the underlying OI, other risk factors for developing CNS IRIS are degree of immune suppression prior to initiating ART (indicated by a low nadir CD4 count), rate of immune recovery, and possibly some host genetic factors.

Two forms of IRS are traditionally described: paradoxical and unmasking IRIS. In “paradoxical IRIS,” the individual is already known to have an opportunistic infection but is unable to mount an appropriate immune response against it; on initiating ART, the recovering immune system generates a heightened immune response that results in a worsening of the patients' clinical condition. In “unmasking IRIS,” the presence of a subclinical or occult infection is revealed when the individual commences ART. The exaggerated immune response and clinical deterioration seen in CNS IRIS are mediated by the infiltration of activated CD4+ and CD8+ T cells into the CNS.

The clinical features and time of onset for CNS IRIS vary significantly depending on the underlying OI; this suggests that pathogen-specific disease mechanisms may be responsible for IRIS seen in the context of each OI (Kranick and Nath 2012). CNS IRIS presents as paradoxical worsening of neurologic symptoms within the first 4–8 weeks of starting cART. Neuroimaging shows contrast-enhancing lesions on the MRI scan, indicating a breakdown of the blood-brain barrier. The management of patients who develop CNS IRIS is

guided by the nature of the underlying OI and the severity of presenting symptoms. Since the most important risk for developing IRIS is a low CD4 cell count prior to starting of ART, early initiation of ART will be important in reducing the incidence of CNS IRIS.

Neurotoxic Neuropathy

Some ARTs are known to cause a toxic neuropathy with features similar to and difficult to distinguish from distal symmetric polyneuropathy. The antiretroviral agents classically associated with peripheral neuropathy are the dideoxynucleoside antiretroviral drugs (d-drugs) including didanosine, zalcitabine, and stavudine. These drugs have largely been removed from antiretroviral medication regimens in resource-rich countries but due to their effectiveness and lower cost are still commonly used in resource-limited settings. Toxicity related to the d-drugs is additive, and combination therapy with these drugs should be avoided. Symptoms of ART neurotoxicity usually arise within 2–3 months of initiation of treatment. These drugs are thought to produce nerve damage through their competition with thymidine triphosphate and subsequent mitochondrial dysfunction. Withdrawal of the offending ART and substitution with an alternative that does not include a d-drug is the first step in patient management. Neuropathic symptoms may improve in 1–3 months following the discontinuation of the drug.

Non-AIDS-Related Diseases

The incidence of stroke is higher in HIV populations compared to the general population (Ovbiagele and Nath 2011). This excess risk has been attributed to factors that result directly from HIV infection and others related to complications or treatment of HIV. HIV has been implicated in causing small- and medium-vessel vasculopathy, with dyslipidemia and increased inflammation.

Future Directions

Cure, Eradication, and CNS Latency: Despite the successes achieved in HIV treatment with the introduction of ART, a major limitation of the currently available medications is their inability to eradicate the HIV virus from quiescent reservoirs. Known sanctuaries for latent HIV infection include the central nervous system, the lymphoid tissue, and the testes. Strategies targeted at eliminating persistent HIV from these reservoirs and thereby achieving a cure in patients who are receiving suppressive cART are being evaluated.

Treatment of HAND in Those on ART Who Are Suppressed: Antiretroviral therapy currently is the mainstay of treatment for HAND. However, the use of cART only partially reverses the symptoms or persistence of HAND despite adequate viral suppression. Trials of several adjuvant therapies aimed at attenuating CNS inflammation or acting as putative neuroprotective agents have not yielded much success in reversing neurocognitive impairments till date. Further research is needed to provide more evidence to guide the treatment of HAND in patients whose HIV infection is suppressed on ART.

CNS Penetration: Antiretroviral agents vary in their ability to penetrate the CNS in therapeutic concentrations; the effects of the CNS penetration of cART regimens are an ongoing area of research. While studies have shown that regimens with higher rankings on CNS penetration effectiveness (CPE) are associated with lower CSF viral loads, the effects on neuropsychological performance is as yet inconclusive (Brew and Chan 2014).

Conclusion

Despite advancements in the treatment of HIV, neurologic conditions remain an important cause of morbidity. In developed countries where there is widespread availability and access to combination antiretroviral therapy, there has been a significant decline in the incidence of more severe neurocognitive disorders and opportunistic infections (Sacktor and Robertson 2014); however,

milder forms of HAND are present in up to 50% of HIV-positive adults (Heaton et al. 2010). In low- and middle-income countries especially sub-Saharan Africa where the highest burden of HIV resides, limited resources hinder the diagnosis and treatment of neurological disorders in HIV (Joseph et al. 2013).

Definition

This entry focuses on the therapeutic potential of small molecule inhibitors of two kinases, leucine-rich repeat kinase 2 (LRRK2) and mixed-lineage kinase 3 (MLK3), for the treatment of HIV-1-associated neurocognitive disorders (HAND). In particular, this entry is focused on these small molecule inhibitors as a way of restoring normal synaptic architecture, the key substrate that is damaged by the neuroinflammatory milieu of HAND.

From a signaling perspective, MLK3 is a canonical MAP kinase kinase kinase (MAPKKK) that controls the phosphorylation state of the MAPKs JNK and possibly p38 (Gallo and Johnson 2002). While only relatively recently implicated in the neuropathogenesis of Parkinson's disease (PD), LRRK2 activation

has also been strongly associated with neurodegeneration and neuroinflammation (Kim et al. 2012; Moehle et al. 2012), and studies of its mechanism of action demonstrate that it may also contribute to the phosphorylation of p38 and JNK (Hsu et al. 2010). Further linking the structural and functional relationship of MLK3 and LRRK2, the kinase domain of LRRK2 exhibits a significant amount of homology with the kinase domain of MLK3 (Zimprich et al. 2004). Excessive p38 and JNK activity has been linked to many aspects of neurodegenerative disease, including loss of neuronal processes, increased neuronal apoptosis, and increased inflammatory cytokine production in brain-resident immune cells (Borsello and Forloni 2007; Dhanasekaran and Reddy 2008). These kinases are therefore considered prime targets with the potential for disease modification by small molecule inhibition in chronic neuroinflammatory disease.

Recent work using a commercially available kinase inhibitor relatively specific to LRRK2 demonstrated that inhibition of LRRK2 decreased inflammatory cytokine production by microglia in response to HIV Tat exposure in vitro (Marker et al. 2012). Additional studies using a novel microfluidic-based coculture system in which cultured neurons propagate along microgrooves in contact with cocultured microglial cells further demonstrated that inhibition of LRRK2 protected neuronal axons from destruction and phagocytosis by HIV Tat-exposed microglia (Marker et al. 2012). Using the same in vitro methods

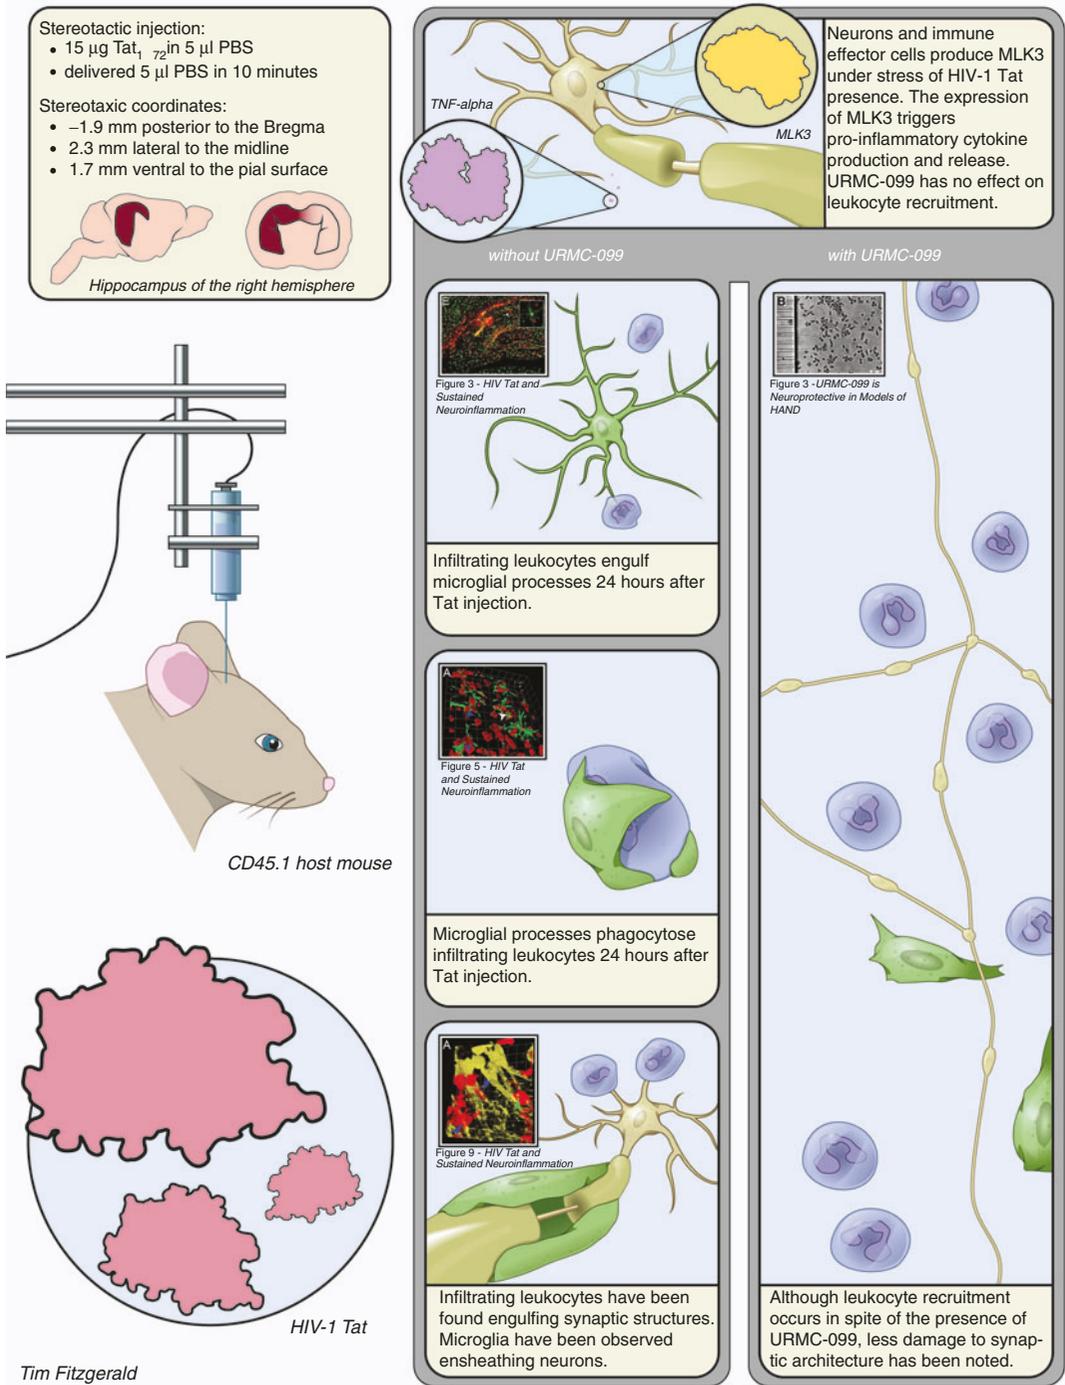

developed for these LRRK2 studies, the efficacy of a novel MLK3 inhibitor named URM-099 was evaluated for *in vitro* and *in vivo* neuroprotection against HIV Tat-induced neurotoxicity (see cartoon, Fig. 1). URM-099 is a kinase inhibitor that has low nanomolar affinity against MLK3 that was designed to be brain penetrant and orally bioavailable (Goodfellow et al. 2013). URM-099 treatment significantly reduced inflammatory cytokine production from cultured microglia in response to HIV Tat (Marker et al. 2013). It also significantly protected primary axons from destruction and phagocytosis by Tat-activated microglia (Marker et al. 2013). Using novel *in vivo* multiphoton imaging techniques in mice with genetically marked neurons and/or microglia, *in vivo* treatment with URM-099 significantly protected neuronal structures in murine cortex from the effects of a single exposure to HIV Tat. In this model, stereotactic injection in the cortex leads to prolonged neuroinflammatory changes that persist for at least 28 days without neuroprotective intervention. URM-099 treatment also altered the morphologic response of microglia exposed to Tat *in vivo* and normalized their interactions with synaptic elements at an ultrastructural level by greatly reducing phagocytosis of a subset of synaptic elements (Marker et al. 2013). These data provide compelling evidence for further study of URM-099 in more comprehensive models of HIV infection, such as the CD34-humanized severe combined immunodeficiency (SCID) mouse model of HAND (Dash et al. 2012), for the purpose of developing it into an adjunctive therapeutic treatment for HAND patients.

Small molecule kinase inhibitors like URM-099 can competitively prevent kinase activity through one of two characterized mechanisms of action: type 1 and type 2 inhibition. Both of these mechanisms prevent the binding of adenosine triphosphate (ATP) in the ATP binding domain of the kinase, and nearly all known kinase inhibitors target this ATP binding site (Liu and Gray 2006). The ATP binding site consists of a number of highly conserved domains: (1) the adenine-binding region, (2) the sugar region, and (3) the phosphate-binding region. Directly adjacent to the

ATP binding site is the “hinge” region, which contains a number of hydrophobic regions as well as “gatekeeper” amino acid residues that prevent ATP binding when the kinase is in an inactive form. Further, all known human kinases contain an aspartate-phenylalanine-glycine (DFG) amino acid sequence that is important for ATP binding in a distant area of the protein known as the activation loop. Type 1 kinase inhibitors form hydrogen bonds with amino acids in the hinge region of the kinase and competitively prevent ATP binding and kinase activity through steric hindrance of the ATP binding domain. In general, type 1 kinase inhibitors bind the active (i.e., phosphorylated) form of the kinase, as the ATP binding site is most accessible in the active conformation, but certain inhibitors can bind the inactive state as well (Liu and Gray 2006).

Type 2 inhibitors work through a different mechanism. They also form hydrogen bonds with the hinge region, but additionally they form hydrogen bonds with the DFG sequence of the activation loop, as well as other allosteric sites on the kinase. All known type 2 inhibitors bind with the DFG sequence in the “out” conformation, meaning these inhibitors bind the inactive form of the kinase (Liu and Gray 2006). These inhibitors may also bind the active form of the kinase in a different conformation or bind to the active form of the kinase and force it into an inactive state, but this has yet to be shown (Liu and Gray 2006). The additional allosteric and DFG binding sites make these inhibitors much more specific than type 1 inhibitors but also make them much more difficult to design.

Quantitative structure activity relationship (QSAR) analysis coupled with kinase activity data of URM-099 performed in cell-free assays has tentatively identified the compound as a type 1 kinase inhibitor that can bind the inactive form of MLK3 (Goodfellow et al. 2013). The data that demonstrate decreased phospho-JNK with URM-099 treatment in cultured BV-2 microglial cells exposed to Tat (Marker et al. 2013) are not inconsistent with this hypothesis. In that experiment, cells with URM-099 showed a reduction in phospho-JNK in response to Tat treatment. This result is consistent with a scenario in which

H

HAND Adjunctive Therapies: Reversing Neuronal Injury, Fig. 1 A cartoon summary of data from Lu et al. (2011) and Marker et al. (2013) depicts in the left-hand panels the in vivo administration of HIV Tat into mice chimeric for either thy1-GFP or CX3CR1-GFP to identify neurons or myeloid cells including microglia, respectively.

The middle and right panels depict the sequence of events that occur after intracerebral inoculation of HIV Tat, including infiltrating inflammatory leukocytes from the peripheral circulation, sustained microgliosis, and amelioration of damage to synaptic structures after treatment with URM-099

URMC-099 binds to the inactive form of MLK3 and prevents activity, although it does not rule out the ability of URMC-099 to inhibit the active form of MLK3, as well.

While URMC-099 was initially designed based on its ability to inhibit MLK3 as the primary target, it was later found to significantly inhibit the LRRK2 in the results of a large-scale kinase screen, the Ambit KINOMEScan (Goodfellow et al. 2013). KINOMEScan measures the activity of potential drug-like small molecules against 456 human kinases, using proprietary methods to determine IC_{50} in a non-ATP-dependent fashion. The off-target effects of URMC-099 against LRRK2 are most likely due to the significant homology between the MLK3 and LRRK2 domains. These results suggest that URMC-099 may have multiple mechanisms for neuroprotection by inhibiting pathologic activation of both MLK3 and LRRK2, but, of course, does not detract from its promise as a therapeutic agent. Thus far, attempts to determine URMC-099's mechanism of action by genetically silencing MLK3 and/or LRRK2 in the microglia *in vitro* have utilized siRNA species using lipofectamine-based methods, but have been hampered by non-specific inflammation. Recent publications have demonstrated significant activation of the JNK pathway in control-transfected microglia (Kim et al. 2012), indicating that lipofectamine-based transfections may also activate cultured microglia. As microglia are a monocyte lineage immune cell that becomes activated in all *in vitro* cultures, it is possible that siRNA treatment further activates innate defense mechanisms normally triggered by infectious agents as well. These confounds make siRNA expression and lipofectamine-based transfection ill-suited for *in vitro* studies directed at elucidating potential signaling pathways relevant to URMC-099's mechanism(s) of action. These results further suggest the need for *in vivo* approaches to address pathologic outcomes of LRRK2 and MLK3 signaling using conditional genetic deletion of one or both of these control points for neuroinflammatory signaling.

Another interesting question raised by studies of HIV Tat-induced neurotoxicity is whether

URMC-099's neuroprotective effects are exerted through kinase inhibition in the microglia, neurons, or both. To answer this question, it will be important to first examine the extent of JNK activation and the effect of URMC-099 treatment in Tat-treated neuronal monocultures. While significant inhibition of the JNK pathway in cultured microglia exposed to HIV Tat occurs (Marker et al. 2013), it remains technically impossible to demonstrate this in neurons exposed to HIV Tat because of the extremely high baseline phosphorylation of JNK in cultured neurons (Barnat et al. 2010). In order to examine Tat and URMC-099's effect on the JNK pathway in cultured neurons, pull-down assays of the individual JNK isoforms may be the most technically feasible way of determining phosphorylation status in neurons exposed to HIV Tat with or without URMC-099. This will demonstrate whether Tat is activating MLK3-controlled pathways in neurons on its own and whether URMC-099 has any effect on these pathways. Efforts to better understand proximate downstream signaling events relevant to MLK3 activation have been hampered by the unavailability of either monoclonal or polyclonal antibodies to phospho-MLK3 since loss of the single commercial source in 2010; thus the effects of URMC-099 treatment on MLK3 phosphorylation using either immunoblotting or immunocytochemistry remain unknown due to the lack of suitable reagents. This also leaves the question as to whether URMC-099 inhibits the active phosphorylated form of MLK3 and/or the inactive form of MLK3 unanswered. However, if Tat alone does not induce MLK3 activity in neurons, it will be necessary to determine if soluble factors produced by Tat-exposed microglia upregulate MLK3 activity. This can be simply tested by exposing neurons to supernatant from Tat-exposed microglia cultures. Finally, it is possible that direct contact between microglia and neuronal elements (such as synapses or axons) is necessary to induce MLK3 activation in neurons. This can only be tested using high-magnification, high-localization ICC, by examining levels and translocation to the nucleus of phospho-JNK (since pMLK3 antibodies are unavailable) in fixed cultures, or by dissociating and sorting the

cultured cells using fluorescence-assisted cell sorting and blotting against the individual isoforms of phospho-JNK in the neuronal fraction.

A previous study demonstrated that the number of synapsin-1-positive puncta at the Tat injection site appeared to decrease between the 7 and 28-day time points (Marker et al. 2013). Because of this progressive loss of synaptic elements, mice were treated with URM-099 at twice daily doses to insure brain levels above the K_i for MLK3 (Goodfellow et al. 2013) and subsequently evaluated by immunocytochemistry for the ability of URM-099 to confer neuroprotection in a chronic model of neural injury like HAND (Marker et al. 2013). This data supports the hypothesis that Tat exposure creates a self-perpetuating inflammatory environment that leads to progressive neurodegeneration (see cartoon, Fig. 1), even after the initial insult is no longer present. It also opens the possibility that delayed URM-099 treatment could still be neuroprotective. Because published data involved pretreatment with URM-099 prior to administration of intracerebral Tat to obtain the maximal degree of neuroprotection, future experiments will investigate the effects of withholding treatment for various periods of time after Tat exposure, to determine the length of the treatment window. If URM-099 is working by breaking an inflammatory feedback cycle, it is also possible that continuous treatment is not needed in the mice for neuroprotection.

Conclusion

Despite initial hopes that the advent of cART would eliminate HIV neurologic disease, over the last decade, it has become clear that this is not the case. In its current form, cART alone simply cannot eradicate the HIV virus from the host, and the low-level production of viral particles and proteins even with efficacious central nervous system-targeted antiretroviral therapy (Ellis et al. 2014) is sufficient to drive HAND in its current manifestations. For the foreseeable future, HIV will remain an incurable but treatable condition, with patients approaching normal life spans. For this reason, the development of an

adjunctive therapy to protect neurologic function in these patients is paramount for their quality of life. Published work using preclinical in vitro and in vivo models of HAND lays a strong foundation for the use of URM-099 in the treatment of HAND. Future studies of this drug concerning safety and efficacy are the obvious next step, but the safety and tolerance of MLK3 inhibition in phase II PRECEPT trials for PD (Parkinson Study Group PRECEPT Investigators 2007) bode well for URM-099's transition to human trials. While CEP-1347, the nonselective MLK3 inhibitor failed to demonstrate efficacy in the PRECEPT trial (Parkinson Study Group PRECEPT Investigators 2007), previously published studies demonstrated that CEP-1347 has a very poor profile of brain penetration and metabolism (Goodfellow et al. 2013) compared to URM-099. This further buttresses the need to address safety, tolerability, and ultimately efficacy of URM-099 for the treatment of HAND.

Harm Reduction for Injection Drug Users

Irene Kuo¹ and Gregory Phillips II²

¹Department of Epidemiology and Biostatistics, George Washington University, Washington, DC, USA

²Department of Medical Social Sciences, Feinberg School of Medicine, Northwestern University, Chicago, IL, USA

Definition

Harm reduction for injection drug users (IDUs) refers to programs designed to reduce or minimize negative health consequences related to substance use among IDUs without the expectation of substance use abstinence. Harm reduction arose as a response to emerging HIV epidemics driven by injection drug use in the mid- to late 1980s. The goal of harm reduction is to reduce individual- and societal-level harms that can result from drug use rather than focusing on stopping drug use altogether. Some harm reduction programs focus on reducing the amount and frequency of drugs used with the eventual goal of abstinence. However, the vast majority of harm reduction programming focuses on the reduction of physical harm to the individual injector, their immediate social network, and the public as a whole, particularly in reducing the transmission of HIV and other infectious diseases. Because the harm reduction approach in dealing with substance use is nontraditional, implementation of harm reduction programs can be controversial and politicized. Despite this, harm reduction strategies have been implemented widely both globally and in the United States. Common harm reduction programs include needle or syringe exchange programs (NEPs or SEPs), supervised injection facilities (SIFs), drug treatment, and provision of condoms and education about sexual transmission of HIV.

Needle and Syringe Exchange Programs (NEPs and SEPs)

History and NEP Coverage

Needle exchange programs (NEPs), also referred to as syringe exchange programs (SEPs) and needle syringe programs (NSPs), provide new sterile syringes to IDUs in exchange for used needles. Use of these programs has been the preeminent form of harm reduction among IDUs both in the United States and internationally and has led to decreases in HIV and hepatitis B and C virus (HBV and HCV) incidence among IDUs.

In 1983, the first NEP was opened in Amsterdam, Netherlands, in order to stem an outbreak of HBV among IDUs. A few years later, driven by the HIV/AIDS epidemic, many new NEPs were established to halt the spread of HIV among IDUs. The first NEPs in the United States were established in the late 1980s. At least 82 countries are known to have one or more operational NEPs (Mathers et al. 2010).

Through 2010, there were 203 known NEPs operating in the United States (Green et al. 2012) – more than triple the number operating in 1995 (Des Jarlais et al. 2009a). American NEPs reported exchanging more than 36 million syringes in 2010 (Green et al. 2012). Along with distributing new sterile needles, the majority of NEPs also provide male and female condoms, have on-site screening for HIV and hepatitis, and offer education on safer sex and injections. Despite these successes, many NEPs cite operational issues in implementation of their programs; foremost among these problems is lack of resources and funding, followed by shortage of staff, and staff burnout (Des Jarlais et al. 2009a).

Evidence for HIV Transmission/Acquisition Reduction

In 2004, the World Health Organization (WHO) released a report stating that there was compelling evidence that NEPs helped to significantly reduce the spread of HIV among IDUs and cited NEPs as a cost-effective method of harm reduction. The WHO report also said, “there is still no persuasive evidence that needle syringe programmes increase the initiation, duration or

frequency of illicit drug use or drug injecting” (Wodak and Cooney 2004).

More recently, researchers have shown that while NEPs are effective at reducing HIV transmission, there is insufficient evidence to conclude that they are associated with reductions in HCV transmission (Palmateer et al. 2010). Reductions in HIV prevalence and incidence among IDUs have been predominantly driven by the use of new sterile needles at each injection, behaviors promoted by NEPs. Use of NEPs has also been shown to be associated with decreases in the frequency of injection and providing used syringes to friends. IDUs who accessed services at NEPs were also more likely to be linked into drug treatment programs.

NEP Policy Issues

In 1988, the US Congress enacted a federal funding ban on NEPs. Ten years later, Lurie and Drucker reported that legalization of NEPs in the United States could have prevented 10,000–20,000 new HIV infections (1997). The 2004 WHO report stated that this legislation on the distribution of injecting paraphernalia was a serious blockade to controlling HIV among IDUs (Wodak and Cooney 2004). The ability to access syringes was hindered by a number of laws, including drug paraphernalia laws in 47 states, syringe prescription laws in eight states, and regulation of pharmacy dispensation of syringes in 23 states. In order to facilitate access to clean syringes, many states enacted legislation to exempt NEPs from these laws. However, the existence of these laws still deterred many IDUs from seeking clean needles due to fear of arrest and incarceration.

In 2009, the Congress voted to overturn the federal funds ban on NEPs in the United States through the Consolidated Appropriation Act. Limited funding was the main concern for most NEPs in the United States (Des Jarlais et al. 2009a), and nearly 80% developed plans to apply for federal funding in 2011/2012 (Green et al. 2012). More than two-thirds of American NEPs received either state or local funding, and increased access to funds would allow them to expand their distribution ability. However, only

2 years after the federal ban was overturned, it was reinstated in December 2011 by the US Congress.

Types of NEPs

There are several different types of NEPs, including those operated through community-based organizations, hospitals, and pharmacies, mobile vans, and vending machines for distribution. In the United States, the majority of NEPs are stationary distribution sites, although more than one-third of all NEPs offers mobile distribution services. While harm reduction is associated with accessing NEPs regardless of type, there are significant differences in those who access specific types. In the United States, mobile-based NEPs attract twice as many high-frequency injectors as a NEP based within a pharmacy. In addition, mobile-based NEPs and syringes dispensed via vending machine were more likely to be accessed by younger IDUs. New and innovative forms of needle exchange, such as backpack exchanges employed in Rhode Island, where individuals roamed high-risk neighborhoods on foot to distribute needles, have been shown to be effective at reaching hard-to-reach injectors.

Supervised Injection Facilities (SIFs)

Supervised injection facilities (SIFs), also called safe injection facilities (SIFs), safe injection sites, drug consumption facilities (DCFs), drug consumption rooms (DCRs), and medically supervised injection center (MSIC), are legally sanctioned sites at which IDUs can inject pre-procured drugs under safe and hygienic conditions under the supervision of medical personnel. SIFs also provide sterile injection equipment, basic wound care, referrals to drug treatment, safer injection education, and access to medical personnel. The availability of a low-stress, safe, and sterile environment for IDUs to inject helps to prevent the transmission of blood-borne infectious diseases, such as HIV, HBV, and HCV, and reduces the risk of development of other negative health consequences, such as endocarditis and abscesses. Because these facilities are medically supervised, overdose deaths can also be averted.

There are more than 60 SIFs globally found in more than two dozen European cities, Sydney, Australia, and Vancouver, British Columbia, Canada (Des Jarlais et al. 2009b). Currently, there are no existing SIFs in the United States, although the acceptability and feasibility of a SIF has been explored in San Francisco, CA (Kral et al. 2010). Among IDUs surveyed, 85% reported they would use an SIF to comply with potential regulations if one opened. Community perceptions in San Francisco were mixed; community stakeholders voiced concerns about whether the burdens from operating a SIF would outweigh the benefits.

SIFs are believed to appeal to more socially vulnerable IDUs, such as those who are homeless or obtained their income from illegal or marginal sources. Previous research in Vancouver revealed that the SIF attracted higher-risk and higher-need IDUs who would benefit the most from a safe, sterile injecting environment (Wood et al. 2006). Extensive evaluation of SIFs has provided evidence of the reduction of overdose mortality as well as the reduction of borrowing used syringes and indirect sharing of injection equipment, increased linkage to drug treatment and detoxification, and the reduction of other medical consequences of non-sterile injection, as well as reductions in public drug use and publicly discarded syringes. In addition, the presence of the SIF has not had an effect on the amount of drug dealing and drug-related crime near the SIF, the rate of transition to injection drug use, or the rate of injection relapse among former IDUs (Wood et al. 2006).

Another feature of SIFs includes the provision of education to help reduce the negative consequences from injecting; in Vancouver, approximately one-third of participants had received safe injecting education from the SIF (Des Jarlais et al. 2009b). SIFs may also act as a gateway to the health-care system which ordinarily may not be as accessible to this highly marginalized population. Furthermore, SIF attendance was found to be positively associated with drug treatment and detoxification entry and a reduction in violence against the women who attended the SIF by allowing the women to avoid gender-related violence

surrounding injection practices norms (Des Jarlais et al. 2009b). Benefits to society have also been examined; one Australian ecological study conducted in New South Wales found that ambulance calls in the vicinity surrounding a SIF had decreased significantly after the SIF opened compared to other areas of New South Wales (Salmon et al. 2010).

The Vancouver SIF was created in response to a sharp increase in overdose mortality in the early 1990s as a result of increasing purity of imported heroin. This SIF has received much local community support and a positive reception from the IDU community. Despite this and extensive evaluation highlighting many individual- and societal-level benefits of the SIF, the SIF in Vancouver has faced many federal legal challenges to close it down (Small 2010). The Vancouver SIF won its latest legislative battle against the Canadian Government on September 29, 2011, when the Supreme Court of Canada ruled unanimously to uphold the SIF's exemption from the Controlled Drugs and Substances Act, allowing it to remain in operation.

Drug Treatment

Drug treatment, in particular opiate substitution treatment, is another component of harm reduction. The use of drug treatment such as methadone maintenance, buprenorphine, and naloxone and naltrexone reduces individual- and societal-level harms resulting from procurement and use of illegal injection drugs by facilitating the engagement of IDUs into a structured treatment program. Being enrolled in a drug treatment program has been shown to effectively reduce the risk of HIV transmission (Metzger et al. 1993). Drug treatment for opiate injectors can be categorized into three main groups: opiate agonist treatment (including use of methadone and buprenorphine), opiate antagonist treatment (including naloxone and extended-release naltrexone), and the use of opiates as drug treatment.

Opiate Agonist Treatment

Methadone maintenance therapy. Methadone hydrochloride is an opiate agonist that has been

utilized as replacement therapy for opiate addiction since the mid-1960s. It has been shown to effectively reduce heroin use and injection behaviors, improve treatment retention, and prevent transmission of HIV and other infectious diseases compared to non-opioid agonist treatments (Metzger et al. 1993). Methadone is dosed on an individualized basis, with an average dose of 80–120 mg used to establish narcotic blockade. It is long acting, with a half-life of 24–36 h, and therefore must be taken on a daily basis. Experimental studies have suggested that higher dose levels result in greater reductions in illicit opioid use.

In the United States, the provision of methadone as opiate substitution therapy is limited to federally approved treatment facilities, which require specific provisions to be met including the use of pre-specified induction dosing schedules, on-site counseling services, and regular urine toxicology. Methadone can either be prescribed as being received on a daily basis at a methadone clinic or, as individuals stabilize on treatment and have sustained drug-free urine toxicologies, as take-home doses. Different approaches toward the use of methadone treatment exist among treatment providers and substance use counselors, with one faction supporting abstinence-based treatment and the other supporting continued substitution treatment.

Globally, methadone maintenance is widely available in Europe and Australia, in which general medicine practitioners are allowed to prescribe methadone to patients, which is then subsequently dispensed through pharmacies (Tetrault and Fiellin 2012). Other regions with large IDU populations, including China, Malaysia, Vietnam, and Ukraine, have recently implemented and expanded the availability of methadone in response to HIV epidemics driven by injection drug use (Mathers et al. 2010). Russia, which has one of the largest HIV epidemics driven by injection drug use, does not allow for any opioid agonist therapy (Mathers et al. 2010).

Other models of methadone maintenance exist, such as low-threshold methadone and interim methadone. Unlike conventional methadone maintenance, in which the ultimate goal is abstinence

from illicit drug use, the goal of low-threshold methadone maintenance is to engage actively using IDUs who may be unwilling or unable to adhere to all necessary requirements of higher-threshold methadone maintenance, such as participation in counseling sessions and abstinence from illicit drug use. These low-threshold programs are designed to engage the highest-risk IDUs to begin the relationship between the consumer and the health-care provider in order to facilitate future engagement in a higher-threshold program.

Several different models of low-threshold methadone exist, including the provision of high-dose methadone without time limitations or requiring abstinence (Torrens et al. 1996). A program in Spain resulted in a 2-year retention rate that was higher than that reported with conventional methadone maintenance treatment. In the Netherlands, low-threshold methadone consists of low doses of methadone dispensed in a variety of settings (including a mobile methadone unit) without the requirement of enrollment into a higher-threshold drug treatment program; other harm reduction paraphernalia are available in these settings including clean injection equipment and condoms (Buning et al. 1990). The philosophy behind the Dutch model of low-threshold methadone is to engage refractory or treatment-resistant drug users who are not ready or willing to enter drug treatment by reducing the harms experienced by continued injection, with the eventual goal of engaging them into a higher-threshold treatment program.

Interim methadone has been used in the United States as a treatment bridge for IDUs who want to enter drug treatment but are on a waitlist for a treatment slot, in which IDUs are given an adequate dose of methadone and emergency counseling as long as they are on a waitlist for drug treatment. A randomized trial found that IDUs engaged in interim methadone maintenance were significantly more likely to enter comprehensive methadone maintenance and reported significantly fewer days of heroin use, reductions in heroin-positive drug tests, and reductions in the amount of money spent on drugs, and self-reported illegal income, compared to those who were on a wait list for treatment but did not receive

interim methadone maintenance (Schwartz et al. 2006).

Buprenorphine and buprenorphine/naloxone. Buprenorphine is a partial opioid agonist that was approved for use as opiate addiction pharmacotherapy in 1996 in France and 2002 in the United States. Because it is a partial agonist, its ability to provide euphoric effects and respiratory depression is dampened compared to that of other pharmacotherapies. Buprenorphine is longer acting and administered every 2–3 days versus methadone which is taken daily. Single formulation of buprenorphine as drug treatment resulted in considerable injection misuse globally, which led to the introduction of a buprenorphine/naloxone combination therapy. Buprenorphine and buprenorphine/naloxone are formulated as either tablets or films for sublingual administration. The buprenorphine/naloxone formulation results in little to no euphoric effects from sublingual administration yet can result in antagonistic effects if injected (Veilleux et al. 2010).

In the United States, as a result of the Drug Addiction Treatment Act of 2000, buprenorphine can be prescribed in primary care office-based settings by certified physicians, which allows for increased access for IDUs who might not otherwise seek treatment at a drug treatment facility. Current research is ongoing to explore the integration of HIV medical care with buprenorphine treatment.

Globally, buprenorphine and buprenorphine/naloxone in combination are widely available in Australia, New Zealand, Western Europe, and most parts of Eastern Europe, with the main exception being Russia. It has some availability as a treatment option in most East, Southeast, and South Asian countries that allow opioid substitution treatment, and there is limited to no availability of buprenorphine in all other parts of the world (Mathers et al. 2010).

Opiate Antagonist Therapy

Naloxone and extended-release naltrexone. Naloxone and naltrexone, which is a longer-acting derivative of naloxone, are opiate antagonist therapies which bind to the μ -opioid receptors in the brain, displacing any exogenously administered

opioids. The successful use of naltrexone as a treatment modality has been met with limited success; because its affinity to opioid receptors is so strong, external sources of opioids are displaced and blocked from the receptors, resulting in the precipitation withdrawal for dependent individuals. The successful initiation of naloxone and naltrexone first requires prolonged abstinence and therefore a long induction period, often resulting in withdrawal, relapse, and early dropout (Veilleux et al. 2010). A systematic review of the literature revealed that oral naltrexone with or without psychotherapy was not more effective in terms of treatment retention or reduction in the use of substance of abuse compared with placebo or no pharmacological treatment (Minozzi et al. 2011). However, some studies have demonstrated beneficial effects of using naltrexone in conjunction with contingency management and among those who are employed and highly motivated (Veilleux et al. 2010).

A recent randomized controlled trial conducted among opiate injectors in Russia comparing injectable, extended-release naltrexone to placebo demonstrated positive reductions in opiate use and craving, longer treatment retention, and a larger proportion of time opiate-free in the extended-release naltrexone group (Krupitsky et al. 2011). Because of the prohibition of the use of methadone and buprenorphine as drug treatment, positive results from this trial may signal a new and viable treatment option for opiate injectors in Russia.

Opiate-Assisted Treatment

Opiate-assisted treatment uses injectable heroin (diacetylmorphine) or other opiates such as morphine or hydromorphone (Dilaudid) as treatment for heroin addiction. In this harm reduction model, heroin maintenance is used as a last-resort treatment among long-term, treatment-refractory IDUs who have failed other conventional forms of drug treatment. The prescription of injectable heroin is used as a means to engage these individuals into a comprehensive treatment program and reduce their need for street-procured drugs.

A review of opiate-assisted treatment studies from six different countries (Switzerland,

Netherlands, Germany, Spain, United Kingdom, and Canada) found that among treatment-resistant individuals with long-term opiate dependence, heroin-assisted treatment compared to methadone resulted in longer treatment retention, better health outcomes, reduced illicit drug use and criminality, and increased social functioning (Ferri et al. 2011). In addition, a cost utility analysis found heroin maintenance to be cost effective. However, adverse events such as respiratory depression and seizure were more frequently reported among the heroin maintenance groups, although no treatment-related deaths were reported. Because of these reasons, heroin-assisted maintenance has been recommended as a last-line treatment option for individuals who have repeatedly failed conventional forms of drug treatment. Availability of heroin-assisted treatment is limited and is currently found in only seven European countries but not on other continents (Mathers et al. 2010).

HIV Testing and Education

Reduction of Sexual Risk

Many programs that target IDUs incorporate HIV testing and/or education about sexual and injection transmission risks into their harm reduction plans. Although injection drug use is the primary mode of HIV transmission for IDUs, IDUs are also still at risk for HIV infection through sexual transmission. HIV prevalence among IDUs who are men who have sex with men (MSM) is more than five times greater than among male IDUs reporting no sex with men, indicating a potential link with sexual behavior. Additionally, among female IDUs, it has been shown that sexual risk, rather than drug use risk, is significantly associated with HIV incidence. Research has also shown that many HIV-positive female IDUs report inconsistent condom use with serodiscordant male partners, providing a risk of sexual transmission to these partners (Latka et al. 2006).

Since risk of HIV acquisition via sexual behaviors is of concern among IDUs, many harm reduction programs seek to target both sexual and drug

use practices. In the United States and Canada, the majority of NEPs provide both male and female condoms to IDUs, along with education on how to prevent transmission and acquisition of HIV through sexual contact (Des Jarlais et al. 2009a). In Vancouver, Canada, an SIF provides safer sex materials to all IDUs who use the facility in order to encourage consistent condom use. Researchers found that HIV-positive IDUs who had been enrolled in the facility's program longer were significantly more likely to consistently use condoms with regular and casual sex partners (Marshall et al. 2009).

Conclusion

Implementation of IDU-focused harm reduction programs has been vital to decreasing the incidence and prevalence of HIV and other blood-borne diseases among IDUs, both in the United States and globally. The foremost method of harm reduction has been the development of needle/syringe exchange programs – providing IDUs with clean, sterile needles and injection equipment significantly decreased the prevalence of sharing syringes and other paraphernalia. Although conventional drug treatment plays a significant role in reducing drug-related harms by focusing on substitution or abstinence, the development of other harm reduction programs such as safe injection facilities and opiate-assisted treatment has helped to expand harm reduction possibilities to injection drug users who may not be ready to cease their drug use. Although NEPs, SIFs, and other more controversial harm reduction programs face a myriad of legal issues and community resistance, especially in the United States, they continue to provide an invaluable service to IDUs.

Health Care Workers, Epidemiology of HIV/AIDS

Erin Graves
Vanderbilt University School of Medicine,
Tennessee Hospital and Health Care, Nashville,
TN, USA

Definition

It is well documented and understood that healthcare personnel are at times at risk for occupational exposure to blood-borne pathogens including human immunodeficiency virus (HIV).

While accurate, and an appropriate concern, this topic deserves to be unpacked and better examined to fully understand the implications of this risk among healthcare workers.

To start, a healthcare worker (HCW) is any healthcare personnel working in the medical or dental fields, or providing related services in an inpatient, outpatient, or community setting. Approximately 7% of the US labor force are health services employees (Bell 1997). These HCWs are employed in a great variety of workplaces which can include emergency departments, inpatient units, urgent care clinics, primary care settings, healthcare facilities in correctional settings, tuberculosis, STD, or substance abuse clinics, outpatient facilities, public health department clinics, skilled nursing facilities, community clinics, etc. There are also over 20,000 provider agencies that deliver home health care in the USA, with thousands of HCWs providing services to patients/clients in these home settings (Siegel et al. 2007).

Perhaps most important to consider is the distinction of which cases of HIV transmission constitute an “occupationally acquired infection?” The Centers for Disease Control and Prevention (CDC) defines an occupationally acquired HIV infection as a case in which “HIV seroconversion [is] temporally associated with an occupational exposure” (Bell 1997).

Possible routes for HIV transmission include blood, semen, pre-seminal fluid, vaginal secretions, rectal fluids (secretions, not feces), and breast milk. Notably, transmission of HIV is not possible via saliva, vomit, sweat, urine, or feces, though especially in healthcare settings, there exists the possibility that any of these materials could also contain HIV-infected blood. While most new HIV infections in the US occur via sexual contact or the sharing of injection needles, occupationally acquired HIV cases are those that occur through percutaneous or mucocutaneous (or both) routes. Percutaneous (through the skin) exposures most commonly occur via punctures from needlesticks or cuts from other sharp medical instruments (e.g., scalpel, glass, etc.). Mucocutaneous (pertaining to mucous membranes or skin tissue) exposures occur if blood or other transmissible bodily fluids come in contact

with the HCW's eyes, nose, mouth, or non-intact skin (CDC 2003).

Risk of HIV Transmission for HCWs

While HIV transmission is possible in healthcare settings, it's important to understand the reasons why occupational HIV transmission is very rare for HCWs.

There are several factors influencing a HCW's risk for occupational transmission, including: (1) the prevalence of HIV infection (in other words, the number of individuals with HIV) in the patient population, (2) the type of exposure(s), (3) the total number of exposures, (4) the amount of blood or other bodily fluid involved in the exposure, and (5) the amount of virus (i.e., viral load) in the infected individual's blood or other bodily fluid at the time of exposure (CDC 2003).

According to the CDC (2003), most occupational exposures (99.7%) do not lead to transmission of the virus. By 1997, US hospital-based HCWs experienced an estimated 500,000 percutaneous blood exposures each year, and of these exposures, about 5,000 involved HIV-infected blood (Bell 1997). Among HCWs with percutaneous exposure (i.e., needlestick or cut) to HIV-infected blood, the average risk of transmission has been estimated to be 0.3% (in other words, about 3 in 1,000), though there are higher risks with different types of percutaneous exposures (e.g., the deeper the needle enters, the more blood transferred, etc.) (CDC 2003, 2013). The average infection risk from mucocutaneous exposure (i.e., eye, nose, mouth, etc.) and exposure of non-intact skin (i.e., open wound, chapped skin, rash, lesions, etc.) to HIV-infected blood is estimated to be 0.09% (or about 1 in 1,000) (CDC 2003). Though it should still be prevented when possible, it's believed that the presence of a small amount of HIV-infected blood on intact skin poses no risk for infection (CDC 2003).

The reporting and documenting of occupationally acquired HIV cases began in 1985. To date, there have been 58 documented cases of US HCWs acquiring HIV through an occupational exposure, with only one confirmed case since

1999 (CDC 2011; CDC 2013; Joyce et al. 2015). There have also been 150 possible cases of occupationally acquired HIV infection in the USA (CDC 2011; CDC 2013; Joyce et al. 2015). These infections were possibly acquired via a workplace exposure, but due to lack of information/documentation regarding a specific exposure incident, these are not confirmed cases (CDC 2005).

Prevention Measures

Infection control experts strongly agree (and a preponderance of evidence strongly supports) that carefully adhering to recommended infection control procedures decreases infection transmission in healthcare occupational settings. As required by OSHA (2011) and recommended by the CDC, HCWs must follow the proper use of safety techniques to prevent exposure to HIV in health care settings (CDC 2003). This includes the proper use of protective practices, safety devices for sharp medical equipment, and personal protective equipment (PPE). PPE includes an array of barrier equipment to protect mucous membranes, skin, airways, and clothes from potential contact with any infectious agents (Siegel et al. 2007). HCWs are advised to act on the assumption that all blood and body fluids are potentially infectious and should follow the most up-to-date safety precautions at all times (CDC 2013).

Of HCWs with documented cases of occupationally acquired HIV, most transmission occurred via percutaneous exposures to HIV-infected blood, and a majority of those involved hollow-bore needles (Bell 1997; Joyce et al. 2015). Motivated in part by these findings, the prevention of percutaneous exposures "has always been an essential element of Universal and now Standard Precautions" (CDC 2003; Siegel et al. 2007). These precaution guidelines address measures that will prevent injury to the user (and others) when handling needles and other sharp objects. These include:

- The use of needles with hands-free recapping systems or other safety devices and injury

prevention equipment. The Needlestick Safety and Prevention Act became a federal law in 2000 and gave OSHA authorization to universally require the use of “safety-engineered sharp devices” in work settings (Siegel et al. 2007). This also requires that HCWs follow precautions by avoiding any recapping of used needles by hand.

- The use of sharp disposal containers for used needles or other sharp patient care equipment.
- The use of gloves. In the event of a needlestick or other puncture, the presence of a glove covering the skin may decrease the amount of blood on the outside (external) surface of the sharp object, though not the inside (lumen) of the needle; thus the amount of protection provided from gloves isn’t certain, but wearing gloves should still be advised when using/handling sharp devices (Siegel et al. 2007).

Guidelines for mucocutaneous protections have been mandated by the OSHA Blood-borne Pathogens Standard and require the use of proper protective barriers for PPE (such as gloves, goggles or other eye protection, face masks with a protective shield, and/or gowns) when anticipating potential contact with blood or other bodily fluids (OSHA 2011). Specifically:

- Gloves are to be used universally to protect the HCW’s hands from having direct contact with blood or bodily fluids, mucous membranes, non-intact skin, other potentially infectious materials (OPIM), or contaminated patient care equipment and surfaces; for nonsurgical patient care, one pair of gloves is adequate (Siegel et al. 2007).
- Isolation gowns and/or other protective apparel must be worn if there is any anticipation that the HCW’s arms and other exposed body parts could possibly have direct contact with blood or bodily fluids, mucous membranes, non-intact skin, OPIM, or contaminated patient care equipment and surfaces (Siegel et al. 2007; OSHA 2011). It should be noted that clinical/lab coats are not considered sufficient PPE protective apparel.

- Masks should be used to protect against sprays or smears of blood or other bodily fluids and may be used in conjunction with eye protection/goggles or a face shield for greater face protection. Personal eyeglasses, sunglasses, or contact lenses are not considered adequate eye protection (Siegel et al. 2007).

It’s also required that healthcare organizations “clean, repair, and replace” all necessary PPE as needed and keep these supplies up-to-date and available for HCWs at no cost to them (OSHA 2011). The CDC advises that all healthcare organizations and agencies create and sustain “an infrastructure to guide, support, and monitor adherence to Standard and Transmission-Based Precautions” (Siegel et al. 2007; CDC 2013). Incorporation of these precautions into their organization’s practice will not only help create an institutional safety culture aiming to keep HCWs and patients safer from the spread of infection, but will also ensure that each organization is working to achieve goals set by the Joint Commission on Accreditation of Healthcare Organization to decrease hospital-acquired infections (Siegel et al. 2007).

Indications for Exposure Occurrence

In the event of an exposure, or a suspected exposure, to a patient’s blood or other bodily fluid(s) capable of transmitting HIV, all HCWs are advised to immediately (1) perform first aid and cleaning to the exposure site, and (2) report the incident to appropriate management personnel. For the purposes of cleaning the exposure site:

- If percutaneous exposure:
 - Wash the exposure area (i.e., site of needlestick or cut) with soap and water.
 - Avoid using a caustic or corrosive agent (e.g., bleach) at exposure site.
- If mucocutaneous exposure:
 - Perform water flushes to the affected mucous membrane (i.e., nose, mouth).
 - Provide irrigation to eyes with saline, clean water, or other sterile irrigants.

-Wash any contaminated skin (intact or non-intact) with soap and water.

For the purposes of reporting and managing the exposure case, healthcare settings and employers are required to have a system in place for HCWs to immediately report possible exposures. Usually HCWs will be encouraged to first report the incident to their manager or supervisor, then to occupational/employee health or infection control personnel, who are then charged with managing the HCW's exposure case (CDC 2003). It is the responsibility of the employer to ensure that as soon after the exposure as possible the HCW (1) is evaluated; (2) receives education about and, if needed, immediate access to postexposure prophylaxis (PEP) medications; (3) is monitored for signs of illness and/or potential PEP side effects; (4) receives appropriate testing to determine if HIV transmission occurred; and (5) is provided ongoing education, support, and/or counseling regarding the situation (CDC 2003). If it is not possible to identify, locate, or provide testing to know the source patient's HIV status, the exposure risk should still be weighed carefully, and employers must immediately follow postexposure procedures and make suitable testing available for the HCW (CDC 2003; Kuhar et al. 2013).

At present day, there exists no vaccine or cure for infection with HIV. However, certain antiretroviral (ARV) drugs have proven effective in reducing the likelihood of HIV infection if taken within a specified time frame after exposure to the virus. The administration of these PEP medications has become the recommended emergency response to certain occupational (and other) exposures that are deemed a risk for HIV transmission. After assessing the exposure risk, if PEP is indicated the HCW must be educated regarding and prescribed the appropriate prophylaxis treatment regimen, ideally starting the medications as soon as possible (but no more than 72 h) after the exposure incident. As of 2013, the US Public Health Service (PHS) recommends a 4-week (28-day) course of three (or more) ARV drugs if the circumstances of the exposure were such that it poses a risk for HIV infection (Kuhar et al. 2013). The PHS no longer recommends choosing

PEP regimens based on severity of exposure, but rather routinely prescribing a 3-ARV drug course for all occupational HIV exposures (Kuhar et al. 2013). Notably, ARV medications are expensive, but if the HCW was exposed in the course of their work, their employer's health insurance or workers' compensation will typically pay for the medications and care management.

There exists several combination options for the three-drug PEP regimens, and these drugs come from six classes of ARVs: nucleoside and nucleotide reverse-transcriptase inhibitors (NRTIs), non-nucleoside reverse-transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), a fusion inhibitor (FI), an integrase strand transfer inhibitor (INSTI), and a chemokine receptor 5 (CCR5) antagonist (Bartlett et al. 2009; Kuhar et al. 2013). For most PEP regimens, the PHS currently recommends a fixed-dose combination pill of tenofovir (TDF) and emtricitabine (FTC) (both NRTIs, which when combined is known as Truvada), plus the INSTI raltegravir (RAL) (Bartlett et al. 2009; Kuhar et al. 2013). The PHS PEP recommendations may be modified on an as-needed basis, depending on the specifics of each exposure case, and/or the HCW's response to the medications prescribed (CDC 2003, 2013). Ideally, a medical provider with expertise in HIV and/or ARVs (e.g., an infectious disease specialist) should be consulted for proper and effective PEP regimen management (CDC 2003; Kuhar et al. 2013).

It's worth reiterating that occupational exposure to HIV should be considered a medical emergency, and if indicated, PEP ought to be started as soon as possible, ideally within only hours of the exposure. PEP is most effective when the recommended 28-day treatment course is adhered to, and the exposed HCW should notify their managing provider immediately if they need to stop/change their regimen for any reason (Roland 2005; CDC 2013). Though the optimal time interval in humans has not been well studied related to ethical concerns and small sample populations, animal studies have suggested that PEP treatment becomes less effective with the more time that elapses from the exposure (CDC 2003). Even when taken as advised, PEP is still not 100% effective (Gerberding 2003; Roland 2005).

Worldwide there are 21 known cases in which HCWs became HIV-infected despite timely PEP treatment (Gerberding 2003). Of the 58 confirmed US cases of occupationally acquired HIV infections, in six of these cases, the HCWs had started the recommended PEP regimen within 2 h of being exposed (Bartlett et al. 2009).

Unfortunately, all ARV medications used for HIV treatment and PEP are associated with some type of potential side effects, the most commonly experienced being nausea, vomiting, diarrhea, fatigue, and headache (CDC 2003; Gerberding 2003). The most serious side effects reported from PEP treatment include kidney stones, hepatitis (inflammation of the liver), and decreased blood cell production (CDC 2003). According to CDC surveillance data, almost 50% of exposed HCWs who received PEP treatment reported adverse side effects (Gerberding 2003). It's imperative that the managing physician discusses with the exposed HCW the risks, benefits, and potential side effects of PEP prior to starting the medications and, if needed, addresses management for any other medications being taken. The exposed HCW should receive lab testing (including complete blood count, renal, and hepatic function testing) at baseline and 2 weeks after starting PEP to monitor for drug toxicity and other possible adverse side effects (CDC 2003; Gerberding 2003). And perhaps most importantly, the HCW should also be closely monitored for any possible signs or symptoms of HIV infection, such as sudden or severe flu-like illness including fever, rash, aches, etc. The HCW should be encouraged to contact the managing provider immediately with any questions or concerns.

Baseline HIV antibody testing should occur as soon as possible after the occupational exposure, and then follow-up testing should occur periodically for a minimum of 6 months following the date of exposure to detect and ideally rule out HIV infection. As their status will be unknown during this follow-up period, to prevent possible further HIV transmission, the HCW should follow considerable precautions, including refraining from donating blood, semen, or organs, engaging in sexual intercourse, and if lactating, women should consider alternative infant feeding methods (CDC 2003).

It should be noted that PEP is not indicated if blood or bodily fluid contact was only to HCW's intact skin, or if the source patient is found to be HIV-negative (Gerberding 2003). If PEP was started in such instances, it may be safely discontinued after consulting with the managing provider. In all circumstances, if the occupational exposure is not deemed a risk for HIV infection, PEP should not be taken, as serious side effects can result, and risk for these should also be avoided when possible (CDC 2003).

Dispelling Myths

While there is some risk of infection from their work practices, the vast majority of HIV infections contracted by individuals who work as HCWs are in fact not related to their occupation. Most HCWs who contracted the HIV infection in the 1980s and 1990s did so via sexual intercourse, not from occupational exposures (CDC 2003). According to CDC data from 1995, of adults with AIDS who had worked as HCWs, 94% reported that they had acquired HIV via risks not related to their occupational setting, and the other 6% reported having "undetermined risk" (Bell 1997).

Though the majority of this chapter has been devoted to discussing the rarity of HIV transmission from patients to HCWs, it's worth noting that there are cases, however even more rare, in which HCWs with HIV have infected their patients. These more anecdotal cases of HIV transmission, whether intentional or inadvertent, deserve to be better understood as well.

The first documented case in the US in which a HCW spread the HIV infection to his patients was that of Dr. David J. Acer (Altman 1993). Dr. Acer was a Floridian dentist who had contracted HIV in 1986 (via sexual intercourse), and between then and his death from AIDS in 1990, he continued to practice dentistry. Though a great deal of unknowns surround the circumstances of the infections, it's been confirmed that within those 4 years Dr. Acer infected six of his patients with HIV, four women and two men, ranging in age from 15 to 65. Dr. Acer denied ever intending to

hurt his patients, but law enforcement and public health surveillance officials still remain uncertain if these were accidental or deliberate cases of transmission (Ciesielski et al. 1994).

A significant outbreak of HIV infections was discovered in 1989 among Romanian infants and young children who were cared for in various orphanages and pediatric hospitals. It's now believed that these infections occurred inadvertently as a result of policies and practices that encouraged injection transfusions of small volumes of unscreened blood to malnourished and anemic children, as well as inadequate sterilization procedures and reuse of injection syringes at these underfunded and understaffed facilities (Dente and Hess 2006). By 2002, there were 12,559 documented cases of HIV infection in Romania, of which 9,936 were among Romanian children, which at the time equated to 60% of Europe's pediatric HIV/AIDS cases (Dente and Hess 2006). Though initially slow to recognize and respond to the outbreak, the Romanian government eventually sprung to action and by 2003 was the first Eastern European country to provide free universal ARV coverage to all persons infected with HIV (Dente and Hess 2006).

From 1997 to 1998, more than 400 Libyan children were infected with HIV while being treated at Al-Fateh Hospital, Benghazi's public pediatric hospital. Community and international outrage fueled Libyan government and prosecutors to charge five Bulgarian nurses and one Palestinian doctor who worked at the hospital with intentionally infecting the children, over 60 of whom have died to date. However, experts who investigated the outbreak have reported the HIV strains involved in the outbreak were already present in the hospital prior to the arrival of the six foreign HCWs, and the likely cause of the massive spread of HIV infection was poor hygienic standards and inappropriate sterilization of medical equipment (Ahmad 2004; De Oliveira et al. 2006). Though initially convicted and sentenced to death, the six HCWs, themselves not HIV-positive, were extradited to Bulgaria in 2007 and released.

As recently as December 2014, a man named Yem Chrin, a local medical practitioner in Roka,

Cambodia, had been charged with causing an HIV outbreak among more than 100 community members, both adults and children. Chrin, who was charged by a provincial court with (1) spreading HIV, (2) cruel murder, and (3) violating medical ethics, admitted to reusing syringes between patients (Al Jazeera 2014).

Despite these extremely rare examples of transmission based on either substandard care or harmful practices, the majority of HIV-infected HCWs are eager and capable of continuing to provide safe and effective care to their patients. In the US, the 2010 SHEA guidelines recommend that HIV-positive HCWs should "not be prohibited from participating in patient-care activities solely on the basis of their HIV infection" (Henderson et al. 2010). The SHEA guidelines state that the HCW should be freely permitted to participate in/perform procedures in which HIV transmission is either extremely miniscule or "theoretically possible but unlikely" (Henderson et al. 2010). To perform procedures that do present a "definite risk" of transmission, the HCW should have their clinical status and lab data reviewed every 6 months by a managing physician, have a reduced viral load, and seek prior approval from an expert review panel (Henderson et al. 2010). The guidelines also state that if the HCW is compliant with all other SHEA guidelines, they should not be required to disclose their HIV-infection status to patients as part of the informed consent process prior to performing procedures, though there is nothing in the guidelines that prevents them from doing so (Henderson et al. 2010).

Exposure Management Resources

In the US, it's required that employers report cases of suspected (and confirmed) occupationally acquired HIV infection to the local and/or state health department, who in turn are required to report the cases to the CDC (Bell 1997). Still, it can be difficult to track all such cases since accurate surveillance relies on voluntary reporting to health department and CDC officials (Bell 1997; CDC 2013). As summarized by Ippolito et al., "surveillance and research programmes of

occupational exposures are needed to monitor the risk of exposure to and transmission of bloodborne pathogens, the efficacy and tolerability of post exposure treatments, and the effectiveness of safety devices and safety practices” (Ippolito et al. 1999). Though today there exists a far greater body of knowledge regarding occupational exposures, including best prevention and treatment practices, this statement rings as true as it did then, and active surveillance efforts must continue in earnest to continue monitoring HCWs’ risks.

For reporting suspected or confirmed cases of occupationally acquired HIV and/or possible PEP failure:

1. Report to state health department HIV surveillance personnel.
2. Report to CDC Coordinator for “Cases of Public Health Importance”: 404-639-0934 or 404-639-2050 (<http://www.cdc.gov/hiv/risk/other/occupational.html>).

For questions regarding possible or confirmed occupational exposure to HIV:

- Clinical Consultation Center (CCC) Post-Exposure (PEP) Consultation: 888-448-4911 (<http://nccc.ucsf.edu/clinician-consultation/post-exposure-prophylaxis-pep/>)
- Division of Healthcare Quality Promotion: 800-893-0485 (www.cdc.gov/ncidod/hip)
- National Institute of Occupational Safety & Health: 800-356-4674 (www.cdc.gov/niosh)
- National AIDS Hotline: 1-800-342-2437

Conclusion

Though this chapter has focused mostly on US HCWs and their risk, the international community is increasingly collaborating to better protect all HCWs against workplace HIV transmission. Addressing the issues of occupational safety at a global scale, the International Labor Organization (ILO) is a special division of the United Nations (UN) that focuses on HIV/AIDS in workplaces around the world (ILO 2015). The ILO acts to

leverage support and mobilize action by international governments, Ministries of Labor, employers, labor organizations, and employees in efforts to protect workers’ rights, combat discriminatory practices and/or policies against HIV-infected employees, and improve occupational safety and health (ILO 2015). Such collaborative efforts by the international community will ideally foster greater support for and commitment to evidence-based safety precautions in global healthcare occupational settings, which can ultimately reduce risk for HIV transmission in the workplace.

In conclusion, while risk of HIV infection from occupational exposure is low, and lowered further by proper adherence to an appropriate PEP regimen, it’s impossible to guarantee that an exposed HCW will not become infected with HIV, which only highlights the importance of ensuring that all HCWs follow the recommended safety precautions to prevent exposure (Siegel et al. 2007).

Healthcare Workers, Shortage and Task Shifting of

Laura J. Edwards

Division of Health and Environment,
Abt Associates, Atlanta, GA, USA

Definition

A robust health workforce, one that is capable of providing effective, efficient, and high-quality services, is a vital component of health system functioning and plays a critical role in addressing the global HIV epidemic. Extensive challenges persist in the recruitment, distribution, and retention of healthcare workers. Current figures estimate a worldwide shortage of nearly 7.2 million physicians, nurses, and midwives, a scarcity most acute in sub-Saharan Africa, which already has some of the world's weakest health systems. Brain drain, or the migration of healthcare workers away from low-resource settings, is one of the many complex contributing factors to healthcare worker shortages. Brain drain can be internal or external to national health systems; both types must be addressed in order to improve the availability, accessibility, acceptability, and quality of the health workforce.

Task shifting is an approach to rapidly scale-up the overall health workforce and mitigate the effects of brain drain by systematically delegating responsibilities from highly qualified health workers to those who are less qualified. There are two basic forms of task shifting – one that reassigns responsibilities from highly skilled to less skilled workers, such as the WHO-promoted method in which trained nonphysician clinicians, midwives, and nurses are responsible for conducting HIV testing, prescribing and/or dispensing ART, and clinical monitoring and side effects management for patients who are positive for HIV. The second form of task shifting moves tasks from generalized workers to those who have been narrowly trained to fulfill particular duties, as is done when responsibilities are standardized

and delegated from healthcare professionals (e.g., nurses) to a new cadre of lay workers (e.g., community health workers). The efforts of such community health workers, especially those living with HIV who are successfully managing their condition, have demonstrated an increased uptake of HIV services, more timely diagnoses, enhanced adherence to treatment, and reduced loss to follow-up. Task shifting is an essential component of the WHO's coordinated strategy, called "Treat, Train, Retain," for addressing specific challenges related to shortages in the health workforce.

A robust health workforce, one that is capable of providing effective, efficient, and high-quality services, is a vital component of health system functioning. Health workers, the individuals "whose primary intent is to enhance health," are responsible for protecting and improving the lives and well-being of members of their communities through preventive, promotional, or curative health services (World health report 2006b). Traditional examples of human resources for health include nurses, midwives, pharmacists, physicians, and dentists, but auxiliary staff, such as community health workers, practitioners of traditional medicine, technicians, and other paraprofessional personnel, are just as important in the achievement and sustainment of local, national, and global health-related goals. Global health differs from general community health in that it emphasizes difficult to reach populations over wider geographic areas and prioritizes health equity for people worldwide.

Health workers play a seminal role in addressing the healthcare needs of a population, yet extensive challenges persist in their recruitment, distribution, and retention. Recent modeling formulas suggest a higher deficit in the global health workforce than previously estimated. Worldwide, 100 countries fall below the minimum density of 34.5 skilled health professionals/10,000 persons, a threshold delineated in the context of establishing universal health access. Amounting to a current estimated shortage of nearly 7.2 million physicians, nurses, and midwives, this scarcity is expected to surge to 12.9 million health workers by 2035. In most nations, the rate at which new

workers are trained and added to the workforce is not commensurate with the accelerating demands of growing populations (A universal truth: no health without a workforce 2014). If not immediately addressed, this issue will lead to serious consequences for the health of billions of people across the globe.

These workforce shortages constitute a public health emergency, and the extent of the problem is grossly imbalanced across the globe; in many places, the dire situation demands immediate action. Countries with the lowest relative need and the strongest health systems have the highest numbers of health workers, while, conversely, those with the greatest burden of disease and the most fragile systems must cope with significantly fewer personnel. For example, the WHO Region of the Americas contains only 10% of the global burden of disease, yet employs approximately 37% of the world's health workforce; in contrast, the African Region bears more than 24% of the global burden of disease but has access to only 3% of health workers (World health report 2006b). Even within national borders, the availability of healthcare workers typically exhibits considerable geographic variation, with significantly better availability within cities and urban centers.

Although parts of Asia have the greatest projected deficits over the next two decades in absolute terms, worker shortages are expected to be most acute in sub-Saharan Africa, which already has some of the world's weakest health systems. Current training facilities are insufficient to meet the growing needs, as there are a mere 168 medical schools in the 47 countries that comprise sub-Saharan Africa. Of those countries, 11 have no medical school at all, and 24 have only one medical school (Mullan et al. 2011).

These disparities between the supply and demand of healthcare workers have led to crippling effects on poorer countries' prospects for development. Efforts to achieve the health objectives of the Sustainable Development Goals set by the United Nations in 2015 have been thwarted due to the lack of healthcare staff in many countries. As a result, human resources for health have received significant attention in the global health policy realm in recent years.

The causes of this health worker crisis are multidimensional. In addition to unprecedented world population growth, an ageing workforce, whereby staff retire without being replaced, is occurring alongside an inadequate number of young people newly entering health professions. The workforce shortage, particularly in low- and middle-income countries, is a major barrier to the prevention and treatment of HIV. These workers comprise the frontline efforts to combat this disease, and there is a direct correlation between a greater number of health providers and higher rates of access to antiretroviral therapy (ART) (World health report 2006b). At the end of 2015, 36.7 million people worldwide were living with HIV. Globally, only 18.2 million of these people were accessing in ART treatment, which is key to extending life expectancy, preventing and reducing morbidity, reducing transmission, and halting AIDS-related deaths. The WHO's recommendation in late 2015 was revised to a "test and treat" strategy, whereby everyone with HIV should be offered ART as soon as they are diagnosed. (Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection 2013). This increased eligibility, coupled with the fact that people with the virus are living longer as the disease transitions to one that can be successfully managed on a long-term basis, makes the demand on healthcare workers even more prominent. A strong health workforce is critical to attaining, sustaining, and accelerating progress toward universal access to ART for the half of eligible persons, or roughly 18.5 million people, currently lacking access to this lifesaving treatment (UNAIDS 2016).

Brain Drain

While the causes of the ongoing health worker scarcity are multifaceted, the perpetual migration of trained health workers, colloquially known as "brain drain," is widely recognized as a primary contributory factor. Brain drain occurs both when members of the workforce in resource scarce countries migrate to wealthier nations, and when workers leave the public health sector for other

jobs within domestic borders. Heavy workloads stemming from an already limited workforce and high disease burdens mean losses due to brain drain are particularly costly to health systems. Not only does the continuous efflux of health workers negatively affect continuity of care, but it also increases the potential for further turnover of existing employees who suffer from stress and burnout as they take on additional workloads.

External Brain Drain

The migration of healthcare workers from low-resource settings with immense need ("source" countries) to resource-abundant locations with better living and working conditions ("destination" countries) is the consequence of a complex set of decisions and contextual factors. Since the era of modern globalization, many poor nations have been losing up to half of their newly trained health workforce to the rich world on an annual basis. Such external brain drain, or out-migration, has precarious consequences on the national health systems of poor nations. When developing nations pay to educate health workers who in turn decide to temporarily or permanently settle abroad, the poorer countries are, in essence, subsidizing the health systems of wealthier nations (Kuehn 2007). The International Organization for Migration (IOM) estimates that low-income countries spend US \$500 million per year to train healthcare workers who eventually migrate to high-income countries. Moreover, these poor countries' already limited supply of skilled labor, often considered the brightest of the bunch, is even further reduced (Lopes 2008).

Internal Brain Drain

Internal brain drain, or the migration of workers away from the public health sector and toward opportunities within private institutions or non-government organizations, further intensifies these workforce imbalances. Additionally, the maldistribution of the health workforce, characterized by urban concentrations and rural deficits, is an inherent challenge in many countries, irrespective of their level of economic development. In most nations, health workers move from lower resource, rural settings to higher resourced,

urban areas at a faster rate than the general population, leaving these locations understaffed in comparison to wealthier regions and cities. About half of the global population lives in rural and remote areas, yet they are served by less than one quarter of the world's doctors and fewer than one third of the world's nurses (A universal truth: no health without a workforce 2014).

Push and Pull Factors in Brain Drain

At face value, it may seem that workers are simply moving toward jobs with better pay. While issues surrounding employee remuneration and compensation are critical, many studies have shown that financial compensation alone does not explain the brain drain predicament. Both "external" and "internal" brain drain phenomena are the result of a multitude of complex, interrelated "push" factors encouraging workers to leave. Low-resource health systems frequently have poor working conditions, including unrealistic or unsafe workloads, deteriorating physical environments, and inadequate or faulty supplies and equipment. Issues surrounding human resource management, including insufficient opportunities for professional development or continuing education, limited prospects for career advancement, and weak performance monitoring are also important contributory factors. Many of the countries with the most fragile health systems and extensive brain drain are those with the highest levels of social tension, gender discrimination, and political instability, creating a climate which further pushes health workers away from employment within the public sector.

Simultaneously, numerous "pull" factors in wealthier nations entice workers to migrate there. Such factors in developed countries include growing ageing populations and an increasingly technology-driven healthcare system, which creates a high demand for employees. Poor planning and underinvestment in health worker education has left many developed nations with too few domestic workers to meet this demand, causing them to rely on immigrants, many of whom migrate from developing nations (Kuehn 2007).

The dynamic interplay of such "push" and "pull" forces that perpetuate the asymmetric shifts

in skilled human resources is a central part of the discourse surrounding health workforce development (Tankwanchi et al. 2013, 2014, 2015). The human resource crisis stemming from these forces must be approached holistically, in which political, technical, and economic aspects of the problem are taken into account. This process is political in that it requires deliberate coordination on the part of various sectors and constituencies in society at different levels of government; it is technical in that it necessitates expertise in human resource planning, education, and management; and it is economic in that it entails substantial investments in workers and institutions. Meanwhile, it is important that any strategies confronting these arenas maintain a delicate balancing act whereby healthcare workers maintain their individual rights to migrate. Plans to attract, retain, and motivate healthcare workers must address both financial and nonfinancial incentives, and governments must increase the number of healthcare training institutions (Sales et al. 2013).

The health worker shortage has too often been addressed through fragmented initiatives or temporary, simplistic solutions. As this problem is projected to grow significantly in the coming decades, it is imperative for governments to do away with piecemeal efforts and take immediate action toward long-term, comprehensive workforce planning. Such steps must align with overarching national development efforts. Consequently, it is essential to rethink traditional models of education, structure, deployment, and remuneration for the health workforce.

Task Shifting as a Response to the Global Shortage of Workers

The roots of the health workforce crisis are multifaceted; therefore, one solution alone cannot singlehandedly resolve this challenge in all of its complexities. Efforts to globally increase the number of physicians, nurses, midwives, pharmacists, and technicians are imperative, but such recruitment and training requires considerable time. Training takes at least 6 years for doctors, 3–4 years for nurses, and 4 years for midwives. Waiting for enough new workers to enter public

health systems through conventional education streams will result in lengthy delays in the provision of urgently needed services, a situation which can devastate the response to current and emerging crises such as the HIV epidemic. Instead, the roles of healthcare workers need to be reexamined, reassigned, and decentralized.

The conversation surrounding global human resources for health is shifting from a focus exclusively on the *number* of health workers to more explicitly considering their availability, accessibility, acceptability, and quality. *Availability* means having a sufficient supply of workers with skills to match a community's healthcare needs, whereas *accessibility* indicates members of a population, including those living in remote and underserved areas, have equitable access to workers. *Acceptability* is the ability of the workforce to create a sense of trust and treat everyone with dignity, while *quality* refers to the skills, knowledge, and behavior of health personnel, evaluated in the context of professional norms and perceptions from the recipients of health services (A universal truth: no health without a workforce 2014).

When implemented as a component of overall community development and poverty alleviation strategies, task shifting is a viable method capable of enhancing the availability, accessibility, acceptability, and quality of the healthcare workforce. Task shifting is an approach in which certain responsibilities are systematically delegated, where rational and appropriate, from highly qualified health workers to those who are less qualified. The task shifting strategy aims to redesign roles in a way that aligns to local health needs while creating a more streamlined chain of care, relieving pressure on individual workers, and rapidly scaling up the overall health workforce.

Historic Examples of Task Shifting

Though only a recently coined term, task shifting is not a new phenomenon but has been practiced for centuries with varying levels of formality. In France, the medical credentialing system was abolished in the late nineteenth century during

the French Revolution, and the absence of teaching and licensing institutions left the medical system in a state of chaos. Second-tier doctors known as *Officiers de Sante* served to increase the country's medical manpower, eventually becoming a formally recognized cadre of non-physician healthcare workers.

In mid-twentieth century China, peasants were selected for an intensive 3- to 6-month course in medical training to bring healthcare to rural areas of the country. Known as "barefoot doctors," these workers provided basic services to underserved populations, including immunizations, family planning, first aid, preventative care, and health education. The barefoot doctors were widely utilized across the country and eventually incorporated into the national health system.

Overview of Task Shifting

In healthcare, task shifting has similar principles to the lean model used in industry and production, where the goal of any process is to use less to do more. By minimizing waste (in this case, the time of highly skilled workers), lean thinking standardizes tasks and processes in ways that maximize the duties each worker performs at his or her highest skill level. The goal of this practice is to redistribute and decentralize the health workforce to more efficiently utilize available human capital while rapidly expanding the overall talent pool to cope with growing patient loads. There are two basic forms of task shifting – one that reassigns responsibilities from highly skilled to less skilled workers, and one that moves tasks from generalized workers to those with narrow but specialized training.

The first form of task shifting involves delegating responsibilities from workers with higher levels of education and skill to those in lower cadres within the existing health workforce, where workers have fewer qualifications. This model is predicated upon the notion that experts with highly specialized abilities are too scarce to waste on jobs others can do, including primary care, general management, and administrative duties. Instead, roles are redefined in such a way

that experts spend more time on tasks only they can perform. For example, since doctors are in such short supply, WHO promotes a method in which trained non-physician clinicians, midwives, and nurses are responsible for HIV testing, ART prescribing and/or dispensing, and clinical monitoring and side effects management (Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection 2013). Only complicated cases are referred to specialists or senior clinicians, and, as a result, these physicians are able to dedicate more time to the management of a greater number of complex cases across a wider geographic region.

The second type of task shifting occurs when specific duties are transferred from workers with generalized medical training to those who have been narrowly trained for a particular task. This model most commonly occurs when explicit responsibilities are standardized and delegated from health professionals (e.g., nurses) to a new cadre of lay workers (e.g., community health workers). In rural areas where scarcities of doctors and nurses are particularly severe, many countries successfully utilize a lay health worker strategy. These lay health workers must perform their duties according to strict protocols, as they lack the broad education, experience, and professional judgment required to make competent decisions when complications arise or protocol deviations occur. Levels of community health worker responsibility vary considerably, but WHO guidelines support a model whereby trained and supervised community health workers care for patients already initiated in ART by preliminarily assessing for new signs or symptoms, providing adherence monitoring and support, and dispensing medication between regular clinical visits (Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection 2013). Depending on the competencies required, it takes between 1 week and 1 year to train a community health worker in contrast to the 3–4 years needed to obtain a nursing certification. These workers are typically recruited from local communities and are often HIV-positive themselves.

Community members, especially people living with HIV who are successfully managing their

condition, have the potential to be an important resource in the delivery of ART, yet are often underutilized. Community health workers are able to improve the accessibility of HIV services, particularly across remote and underserved regions. Numerous studies have confirmed that appropriately trained and supervised staff of lower-level cadres are not only capable of carrying out shifted tasks but may even perform certain duties better than physicians (Penazzato et al. 2014). In addition to providing more manpower for the workforce and creating employment opportunities, the community health worker model is advantageous in that it can build important bridges between health facilities and surrounding populations. These health workers can be especially supportive in reducing HIV-related stigma and providing support for ART adherence within defined locations. Care that is localized, decentralized, and delivered by community-based workers has been shown to bring positive health benefits, including an increased uptake of services, more timely detection, enhanced adherence to treatment, and reduced loss to follow-up. For example, community members called adherence counselors have helped many remote clinics outperform hospitals in the retention of patients in ART treatment, a result attributed to the close relationship between the adherence counselors and the patients at the village level (Kredo 2014). The acceptability of HIV services is improved when the profile of the health workforce – its age and sex composition, language, skill mix, and level of cultural awareness – meets the expectations of its recipients, which is more likely when workers and patients are from the same communities.

Current Status of Task Shifting

In May 2006, WHO launched a coordinated global plan addressing specific challenges related to shortages in the health workforce and its consequences in delivering HIV care and treatment. This strategy, called *treat, train, retain* (TTR), explores both the causes and effects of health worker shortages, and delineates a three part solution within the context of HIV – first, increase the

delivery of HIV treatment, prevention, care, and supportive services for health workers infected or affected by the epidemic (treat); second, empower workers to deliver comprehensive and universal access to HIV services (train); and third, retain clinical and public health employees through improved working conditions, financial compensation, and other incentives in effort to reduce migration and mitigate brain drain (retain) (Taking stock: health worker shortages and the response to AIDS 2006a).

Embedded within the “train” step of the TTR framework, task shifting is an essential component of the strategy to expand HIV services while providing an important new opportunity for strengthening human resources for health more generally. Under the umbrella of the TTR model, WHO, UNAIDS, and PEPFAR jointly released 22 recommendations for task shifting in HIV care in 2008 (Task shifting: global recommendations and guidelines 2008). These important guidelines promote a formalized framework that supports task shifting under the auspices of national priorities for holistically organizing and reinforcing the health workforce. As such, TTR is considered a strategic approach to health worker mobilization, rather than a program, meaning it requires substantial in-country leadership, ownership, and direction in order to avoid parallel systems and duplicated efforts (Task shifting to tackle health worker shortages 2007).

It is important for countries to professionalize the task shifting process and formally recognize new cadres of the health workforce. Task shifting is most successful when employees have clearly defined roles and responsibilities, which requires standardized training and examination criteria. Training culminating with formal credentialing further legitimizes this process. As such, the certification of previously nonprofessional cadres (for example, volunteer community health workers), should be prioritized, with salaries commensurate to their added responsibilities. As these employment levels are legitimized, opportunities for continuing education should be available to staff and occur at an appropriate frequency.

Additionally, as responsibilities are downshifted, employees must have clearly delineated

avenues for patient referral. It is essential to have adequate mentoring and supervision so employees do not step outside of their roles, which should involve implementing employee performance monitoring and evaluation systems.

Conclusion

Reaching 18.5 million people with universal access to HIV care and treatment depends on effective and efficient health systems capable of delivering services at a scale much larger than that at which they are currently operating. There is no denying that the absolute number of healthcare workers must grow, and coordinated efforts to increase the quantity and quality of health training institutions in the developing world, as well as the retention of workers who graduate from them, are imperative. Task shifting is a process which empowers those in the health workforce by utilizing them more efficiently, thereby promoting teamwork, improving worker morale, reducing burnout, and increasing employment retention. When coupled with national strategies for health system strengthening and poverty reduction, task shifting is a viable option for responding to crippling health worker shortages and ensuring there is more human capital available to address the health needs of people living with HIV.

Hepatitis C Virus Infection and HIV

Andri Rauch¹ and Jürgen Kurt Rockstroh²

¹Department of Infectious Diseases, Inselspital, Bern University Hospital, University of Bern, Bern, Switzerland

²Department of Medicine, University Hospital Bonn, Bonn, Germany

Definition

Hepatitis C virus (HCV) infection in HIV-infected patients is frequent since both viruses share common routes of transmission. HIV/HCV coinfection is associated with higher HCV viral loads and accelerated liver fibrosis progression particularly in those with low CD4 T cell counts, compared to HCV infection alone. While AIDS-related mortality dramatically decreased since the introduction of antiretroviral therapies (ART), there is an increasing impact of chronic viral hepatitis on hospital admissions and mortality among HIV-infected patients. Hepatic decompensations and HCCs are among the most common causes of death in HIV/HCV-coinfected patients. However, the recent major advances in HCV treatments have the potential to substantially reduce HCV-related morbidity and mortality among HIV-infected patients.

Hepatitis C in HIV-Infected Patients: A Frequent and Complex Coinfection

It is estimated that worldwide two to three million HIV-infected patients are coinfecting with HCV (Rockstroh 2015). The clinical manifestations of this coinfection are extremely diverse and range from asymptomatic HCV infection to life-threatening complications including liver cirrhosis, hepatic decompensation, and hepatocellular carcinoma (HCC) ► [Hepatocellular Carcinoma in HIV-Positive Patients](#). Moreover, HCV infections cause a wide range of extrahepatic complications which include highly unspecific

Hepatitis C Virus Infection and HIV, Table 1 Characteristics of three exemplary HIV/HCV-coinfected patients

Characteristic	Patient A	Patient B	Patient C
Sex	Male	Male	Female
Age	45	55	35
Mode of HCV transmission	IDU (currently in opioid substitution program)	MSM	IDU (short period 5 years ago)
HCV genotype	1	3	4
Time since HCV transmission (years)	15	2	5
Liver stage (Metavir scale)	F4 (child B)	F2	F0
Symptoms/complications	Jaundice, esophageal varices, thrombopenia	Severe fatigue	None
CD4 count (/μl)	150	550	450
Antiretroviral treatment	Tenofovir, zidovudine, lamivudine, darunavir/ritonavir	None	Tenofovir, emtricitabine, efavirenz
Further problems and comorbidities	Alcohol abuse	None	Planned pregnancy

Abbreviations: *IDU* intravenous drug use, *MSM* men who have sex with men

symptoms such as chronic fatigue or typical HCV-related diseases such as mixed cryoglobulinemia (MC) vasculitis. In this overview, key aspects of screening, diagnosis, and treatment of HIV/HCV-coinfected patients will be reviewed by discussing the clinical management of three exemplary patients (Table 1).

Epidemiology and Screening

The three patients described in Table 1 are very different with regard to their social situation, risk behavior, and mode of HCV transmission. For many decades, HCV infections occurred almost exclusively in people who inject drugs (PWID) or in hemophiliacs. Most PWID acquired HCV before HIV, and, accordingly, up to 90% of HIV-infected PWID are coinfecting with HCV (Rauch et al. 2005). In this context, it is not surprising to diagnose HCV coinfections in HIV-infected PWID (**patients A and C**). In countries with effective drug substitution and harm reduction programs, there was a marked decline in HCV incidence in recent years. However, in other areas including Eastern Europe and Southeast Asia, HIV/HCV coinfection incidence is increasing and affects up to 50% of PWID.

Screening for HCV is recommended in all HIV-infected patients at the time of HIV diagnosis. In case of HCV seropositivity, an HCV RNA has to be ordered and the genotype determined. The status of liver damage has to be assessed including staging of liver fibrosis. In recent years, most clinicians preferred noninvasive tests such as transient elastography (FibroScan) or serum biomarkers to assess the stage of liver fibrosis. The APRI and FIB-4 scores are commonly used noninvasive tests of liver fibrosis. These scores have been well validated including in HIV/HCV coinfection and can be calculated in almost all patients based on age, transaminases, and platelet levels. Liver biopsies are ordered if noninvasive assessments do not provide conclusive results or to exclude other liver pathologies. More detailed recommendations for the care of HIV/HCV-coinfected patients are available from the European AIDS Clinical Society (EACS) guidelines (www.eacsociety.org/guidelines/eacs-guidelines/eacs-guidelines.html).

Patient A suffers from liver cirrhosis. His 5-year risk of hepatocellular carcinoma (HCC) is about 10% (Hill 2015). Because early detection of HCC improves survival, this patient should be screened 6-monthly with liver ultrasound for HCC ► [Hepatocellular Carcinoma in HIV-Positive](#)

Patients. In addition, the patient needs regular surveillance and treatment for esophageal varices, hepatorenal syndrome, and encephalopathy. Furthermore, the patient needs support to reduce his alcohol consumption. Before starting HCV treatment, zidovudine should be substituted with another antiretroviral drug due to the increased risk of severe anemia when combined with ribavirin (RBV) (see below for HCV treatment options).

Patient B is an MSM with a recent HCV transmission. Incident HCV infections were very rare until 12 years ago. However, in the last decade, there has been a new epidemic of incident HCV infections among men who have sex with men (MSM). Unprotected anal sex, use of sex toys, and recreational drugs have been associated with incident HCV infections among MSM. The “classic” HCV epidemic among PWID (**patients A and C**) differs in many ways from the “new” epidemic among MSM (**patient B**). In the PWID epidemic, nearly all HCV infections occurred before HIV infection. In contrast, in the MSM epidemic, HCV infections occur in a host with at least some degree of HIV-mediated immune deficiency. This might partially explain the relatively low (approximately 20%) spontaneous clearance rates after incident HCV infections in HIV-infected patients. Another marked difference between the two epidemics is in treatment uptake. HCV treatment uptake has been low in most cohorts of HIV-infected PWID. Typically, less than 20% of patients started therapy due to multiple barriers to treatment including contraindications to interferon, comorbidities, and uncontrolled addiction. In contrast, the majority of HCV-infected MSM start HCV therapy early after infection (Boesecke et al. 2012).

Worldwide, the large burden of HCV disease is still within the PWID population. However, in Western Europe, the majority of incident HCV infections among HIV-infected patients occur in MSM ► [Men who have sex with men \(MSM\)](#), [Epidemiology of HIV/AIDS](#). It is important to note that these epidemiological features differ substantially in other countries. As an example, in Eastern Europe and Southeast Asia, the large majority of incident HCV infections still occur in PWID.

Because of the frequency and the clinical relevance of HCV infections, the European guidelines

recommend yearly HCV screening in all HCV seronegative HIV-infected patients.

HIV Infection Adversely Affects the Natural Course of HCV Infection

Acute HCV infection induces a wide range of innate and adaptive immune responses. Despite these immune responses, the virus is able to establish a chronic infection in most infected individuals. HCV specific immune responses are severely impaired in HIV-infected patients. Accordingly, spontaneous clearance rates are lower and HCV RNA levels higher in HIV/HCV-coinfected compared to HCV-monoinfected patients (Fig. 1).

Coinfection with HIV accelerates liver fibrosis progression. A landmark study with repeated biopsies estimated that the median time from infection to cirrhosis was 12 years shorter (26 years vs. 38 years) in HIV/HCV-coinfected compared to HCV-monoinfected patients (Benhamou et al. 1999). HIV coinfection has also been associated with higher rates of hepatic decompensation and with shorter survival times in patients with HCC. Accordingly, HCV-related complications are among the leading causes of death in HIV/HCV-coinfected patients (Weber et al. 2006).

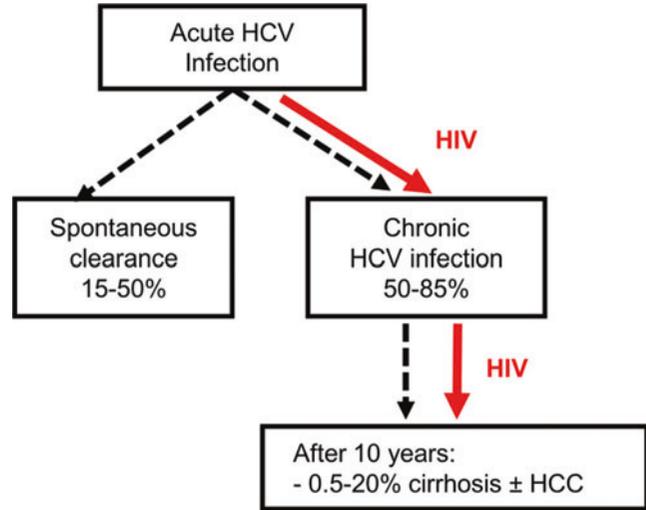

There are several reasons for the harmful effects of HIV on the natural history of HCV infection. First, cellular immune responses to HCV antigens are severely impaired in HIV-infected patients. Second, untreated HIV infection causes chronic immune activation with upregulation of pro-inflammatory cytokines which can accelerate fibrogenesis. Third, the HIV-associated damage of gut mucosa and bacterial translocation to the portal system increase hepatic inflammation ► [Microbial Translocation](#). And finally, HIV can infect and activate hepatic stellate cells promoting fibrogenesis in the liver (reviewed in Rockstroh et al. (2014)).

ART in HIV/HCV-Coinfected Patients

Given the detrimental effects of HIV on the natural course of HCV infection, it is logical to postulate

Hepatitis C Virus Infection and HIV,

Fig. 1 Natural course of HCV infection and impact of HIV

that an effective ART should partially revert the harmful effects of untreated HIV infection ► [Anti-retroviral Medications, Adult Care and Treatment](#). And indeed, several studies demonstrated that ART is beneficial with regard to viral control and liver damage (Rohrbach et al. 2010; Thein et al. 2008). However, even patients with successful ART remain at increased risk for liver-related complications, in particular those with ongoing HIV replication during ART or with CD4 T cell counts below 200/μl (Lo Re et al. 2014; Qurishi et al. 2003). The beneficial effects of ART on HCV related complications support recent recommendations to start ART in all patients irrespective of CD4 counts.

The choice of ART is mainly driven by HIV-related factors, further comorbidities, and comedications. Drugs with hepatotoxic potential should be avoided. In the era of direct-acting antiviral agents (DAAs), the choice of ART should also consider potential drug-drug interactions between HIV and HCV drugs (see below).

HCV Therapy in HIV-Infected Patients

Eradicating HCV infection dramatically reduces HCV-related complications. The benefits include improvements in extrahepatic manifestations such as chronic fatigue or MC vasculitis, as well as an approximately tenfold reduction in

the risk of hepatic decompensation and a three-fold reduction in the risk of HCC (Hill 2015). In coinfection studies SVR also reduced non-liver related deaths, suggesting that cure of HCV infection decreases systemic inflammation. Furthermore, eradicating HCV eliminates infectiousness. Modeling studies suggest that treating HCV could be a very effective measure to reduce HCV incidence and prevalence by preventing HCV transmissions through needle sharing or high-risk sexual behavior (Martin et al. 2013).

The recent improvements in HCV treatments are a major breakthrough in the care of HIV/HCV-coinfected patients. For many years, treatment uptake and outcomes were unsatisfactory. The previous standard of care treatments consisted of weekly injections with pegylated interferon alpha (IFN) combined with daily doses of ribavirin (RBV). The typical treatment duration for coinfecting patients was 48–72 weeks. These therapies were often poorly tolerated, and the cure rates between 30% and 70%, depending on the HCV genotype, were unsatisfactory. Multiple contraindications to treatment and the fear of side effects were important barriers to HCV therapy. Furthermore, IFN-based therapies in those with the most urgent need (such as **patient A**) could lead to life-threatening hepatic decompensations. Therefore, in most settings, only a minority of patients started therapy.

The new era of IFN-free DAA treatments has revolutionized the management of hepatitis C in HIV-infected patients. Compared to interferon-based therapies, these treatments are more effective and eradicate infection in the large majority of patients. Importantly, patients who would not have tolerated interferon have now excellent treatment options. Previously reported treatment barriers for IFN/RBV therapy do not apply anymore in the large majority of cases. Sustained virological response (SVR) rates were typically lower in HIV-infected patients with traditional IFN-based therapy compared to HCV-monoinfected patients. Fortunately, treatments including DAAs are equally effective in patients with and without HIV coinfection. This has led guidelines (EASL, EACS, AASLD) to no longer separate between HCV-mono- and HIV-coinfected subjects. Indication and choice of DAAs is now the same for all patients. The only remaining issue is the need to check for drug-drug interactions between HIV and HCV drugs.

Treating HCV Infection from 2015: The Future Is Bright

The hepatitis C treatment options and recommendations change rapidly. As an example, first-generation HCV protease inhibitors were approved 4 years ago but have already been replaced by better tolerated and more effective compounds. It is therefore crucial to consult regularly the updated treatment recommendations. The joint guidance by the Infectious Diseases Society of America (IDSA) and the American Association for the Study of Liver Diseases (AASLD), the European Association for the Study of the Liver (EASL) and the European AIDS Clinical Society (EACS) guidelines updates online detailed recommendations and includes a specific guidance for HIV/HCV-coinfected patients (www.hcvguidelines.org, www.eacsociety.org/guidelines/eacs-guidelines/eacs-guidelines.html and www.easl.eu/research/our-contributions/clinical-practice-guidelines).

The rapidly evolving HCV treatment options make it difficult to maintain a good overview.

However, some basic principles which are very familiar to HIV physicians facilitate the oversight in this changing field. JM Pawlotsky has proposed in a recent review three requirements for an HCV cure which can be applied to any DAA combination treatment (Pawlotsky 2014). To understand this concept it is important to remind the two main phases of HCV RNA decline during HCV therapy. The first-phase decline is the result of the direct antiviral effect of DAA treatments and characterized by a steep decline in HCV RNA within days of starting therapy. DAAs block almost immediately the production of new virions and reduce HCV RNA by at least three logs within 3–5 days of therapy. However, as in HIV, monotherapy leads to rapid selection of resistance variants causing a rapid rebound of HCV viremia. Therefore, DAA needs to be combined with other antiviral agents (IFN, ribavirin, or preferably a second DAA). Combination of two DAAs results in a significant increase in the barrier to resistance, and thus the decline in HCV RNA is sustained. The second-phase decline is characterized by the clearance of infected cells through the host immune response and the progressive degradation of HCV RNA. To achieve cure, HCV treatment has to be sustained until all infected cells are eliminated. The approved DAA combination treatments fulfill the requirements of potency and high barrier to resistance. Nevertheless, several factors need to be considered when discussing the optimal treatment choice. Key parameters are summarized in Table 2.

HCV DAAs in 2015

Effective DAA combinations inhibit different steps of the HCV life cycle. The three main DAA targets are the HCV protease, the NS5A protein, and the NS5B polymerase. Only approved compounds will be discussed here. Many other agents are in clinical development and will partially replace the currently available drugs.

HCV Protease Inhibitors

The first approved protease inhibitors (PIs) were boceprevir and telaprevir. When combined with

Hepatitis C Virus Infection and HIV, Table 2 Factors to be considered in DAA therapy

Parameter	Examples	Consequence
HCV genotype	The first-generation HCV protease inhibitors telaprevir and boceprevir are only active against HCV genotype 1; simeprevir is not active against HCV genotype 3 Some DAA combination treatments (e.g., ombitasvir-paritaprevir + dasabuvir) are not active against HCV genotype 3	DAA choice needs to consider HCV genotype
Liver fibrosis stage	Relapse rate is higher in cirrhotic patients	Prolong treatment duration and/or maximize potency (e.g., by adding a third antiviral agent)
Treatment experience	Nonresponse to previous IFN-based therapy is associated with higher relapse rates	Prolong treatment duration and/or maximize potency (e.g., by adding a third antiviral agent)
Comedication	Drug-drug interactions (DDIs) between HCV and HIV protease inhibitors Increased tenofovir exposure together with sofosbuvir	Choose DAA treatment without relevant DDIs or adapt ART before DAA therapy Adapt ART or frequent monitoring for renal toxicity

IFN and ribavirin, the addition of these first-generation PIs increased cure rates from about 40% to 70% in treatment-naïve HCV genotype 1-infected patients. However, IFN-related side effects, a high pill burden, and multiple side effects were major drawbacks of these first DAA-based therapies. Therefore, most guidelines do not recommend the use of first-generation PIs anymore.

In 2013, the second-wave PI simeprevir was approved in the USA and subsequently in Europe. This PI is active against HCV genotypes 1, 2, and 4 and is combined with either IFN/RBV or the NS5B inhibitor sofosbuvir (see below). The simeprevir/sofosbuvir combination has been widely used in clinical routine including in HIV-infected patients, and cure rates above 80% have been reported. One limitation is that due to drug-drug interactions, simeprevir cannot be combined with HIV protease inhibitors, etravirine or efavirenz.

NS5A Inhibitors

These drugs inhibit the HCV NS5A protein and block viral replication, assembly, and release. Daclatasvir has been approved in Europe in combination with either sofosbuvir or IFN/RBV. The combination of daclatasvir and sofosbuvir is an important treatment option for HCV genotype 3-infected patients with cirrhosis as other currently

available DAAs are not sufficiently active against this genotype. In this context it is interesting to note that HCV genotype 3 was considered as “easy to treat” in the IFN/RBV era but is now considered as “hard to treat,” as many currently approved DAAs have poor antiviral efficacy against this genotype.

NS5B Polymerase Inhibitors

The first approved NS5B inhibitor is sofosbuvir. This nucleotide analogue inhibitor has already been used extensively together with IFN/RBV or in combination with other DAAs. Sofosbuvir exhibits pangenotypic activity, has a high barrier to resistance, and has few drug-drug interactions. One exception is an increase in tenofovir exposure which warrants caution especially in those with impaired renal function.

Of note, there has been a recent report on significant arrhythmias during treatment with sofosbuvir and daclatasvir together with the anti-arrhythmic drug amiodarone. This unexpected side effect exemplifies the importance of continued monitoring for unexpected adverse events as the new DAAs are introduced into clinical routine.

Fixed Combinations

In 2015, two fixed-dose DAA combinations were approved. Sofosbuvir/ledipasvir has been approved for the treatment of HCV genotypes

1, 3, and 4. This combination results in cure rates above 90% in both HCV-monoinfected and HIV/HCV-coinfected patients. Ombitasvir-paritaprevir-ritonavir plus dasabuvir is another combination therapy (approved for HCV genotypes 1 and 4) which achieved cure rates above 90% in HIV/HCV-coinfected patients.

Drug-Drug Interactions

HIV-infected patients are at particular risk for significant drug-drug interactions, as nearly all patients start ART before commencing HCV therapy. In addition, many HIV-infected subjects are treated for comorbidities that increase the number of drugs and the potential for significant drug-drug interactions. Therefore, HIV-infected subjects are at risk for inadequate drug levels of both HCV and HIV drugs. Drug-drug interactions occur between many antiretroviral and HCV drugs that are substrates, inhibitors, or inducers of different cytochromes, UDP-glucuronyltransferase, or efflux pumps. It is therefore crucial to check for drug-drug interactions before starting DAA treatments. Regularly updated databases such as www.hepdruginteractions.org are of great help in this context. In some cases, therapeutic drug monitoring can be helpful to tailor ART and HCV treatments. In most patients, drug-drug interactions are manageable and should not be a barrier to starting HCV therapy.

Who and How to Treat HCV Infection

In light of the current knowledge, how should the three patients described above be treated?

Patient A suffers from decompensated liver cirrhosis and has an urgent indication for HCV treatment. Curing HCV would dramatically reduce his risk of liver-related complications. Several studies have demonstrated that HCV therapy can achieve high success rates in opioid substitution programs. A key advantage is that treatment can be supervised daily during the opioid substitution. Reinfection rates are low in this

population, and, therefore, a history of intravenous drug use must not be a reason for not starting therapy. As outlined above, zidovudine should be replaced in this patient because of increased mitochondrial toxicity when combined with ribavirin. Interferon-based treatments should be avoided because of the risk of hepatic decompensation. In this situation, the current guidelines recommend either fixed-dose combination ledipasvir/sofosbuvir and RBV for 12 weeks or in those with anemia or RBV intolerance ledipasvir/sofosbuvir without RBV for 24 weeks. Further combinations including ombitasvir-paritaprevir-ritonavir plus dasabuvir and ribavirin are currently tested in clinical trials but are not recommended yet in decompensated cirrhosis.

Patient B has a relatively recent HCV infection with significant liver fibrosis but no signs of cirrhosis. Even without therapy, the risk of a severe liver-related complication within the next 5 years is below 10% (Macias et al. 2015). However, he suffers from severe fatigue which is a very common complaint that can be relieved by eradicating HCV infection. Furthermore, recent modeling work suggests that deferring treatment until advanced fibrosis (Metavir stage F3) could increase the lifetime risk of liver-related deaths even after eradicating HCV infection. HCV clearance is often associated with fibrosis regression, but some individuals may also experience liver fibrosis progression after SVR. This is plausible considering that many risk factors associated with fibrogenesis including drug toxicity, alcohol use, coinfections, or metabolic liver disease persist. Furthermore, the time of infectiousness could be shortened substantially if treatment would start immediately instead of deferring therapy until F3. Taken together, there are several arguments to start therapy immediately in this patient. Unfortunately, the very high current treatment costs (above 50,000 USD/treatment course) led to reimbursement restrictions to patients with at least advanced fibrosis in many countries. If HCV treatment was reimbursed, DAA treatment would almost certainly permanently eradicate HCV infection in this patient. To avoid drug-drug interactions, the start of ART could be deferred until HCV treatment has terminated. Currently

available treatment options would include combinations of sofosbuvir/ribavirin, sofosbuvir/daclatasvir, or sofosbuvir/IFN/RBV in this HCV genotype 3-infected patient.

Patient C has no liver fibrosis and is asymptomatic. However, the treating physicians should discuss the options of eradicating HCV infection before pregnancy. In the IFN/RBV era, a planned pregnancy was a contraindication to HCV therapy because of the teratogenic effects of ribavirin during therapy and 6 months thereafter. However, with the new DAA therapies, HCV infection could be eradicated within 3 months and before conceiving. An HCV regimen without ribavirin should be chosen in this patient. Current recommendations for HCV genotype 4 infections in non-cirrhotic patients include combinations with sofosbuvir with either ledipasvir, simeprevir, or daclatasvir for 12 weeks. These interferon- and ribavirin-free treatments achieve cure rates above 90%. Curing HCV infection before pregnancy would eliminate the risk of a vertical transmission which is 10–20% in the setting of HIV/HCV coinfection.

Conclusions

The new advances in HCV treatments offer unprecedented opportunities to improve the health of HIV/HCV-coinfected patients and to reduce horizontal and vertical HCV transmissions. However, to achieve a major impact on the hepatitis C disease burden at the population level, treatment uptake has to be increased substantially. It is now possible to dramatically reduce the risk of HCV-related complications in the large majority of HIV/HCV-coinfected patients. However, to make this affordable for healthcare systems worldwide, the prices for DAA treatments need to be lowered substantially. Until recently, the most urgent problem in the field of HIV/HCV coinfection was to improve efficacy and tolerability of HCV therapies. To date, nearly all patients can be cured with very well-tolerated and safe treatments. The most urgent priority today is to massively increase treatment uptake. If this can be achieved, the future is bright, and

millions of HCV-infected patients will benefit from a true breakthrough in medicine.

Definition

Hepatocellular carcinoma (HCC) is a primary tumor of the liver that arises from hepatocytes. The principal factors that increase the risk of HCC include infection with hepatitis B virus (HBV), infection with hepatitis C virus (HCV), alcoholism, and aflatoxin. Patients with HIV infection also have an increased risk of HCC, but the role of HIV and immunosuppression is unclear, and much of this risk appears to be because of coinfection with HBV and/or HCV. Whether HIV plays a direct role in HCC pathogenesis remains to be established, but it can increase the risk of HCC in individuals coinfecting with HBV and/or HCV. The clinical course of HCC depends on the stage of cancer disease, performance status, and comorbidities. Therapeutic options include liver transplantation, local antitumor chemotherapy,

and biological agents. In the HIV setting few data are available about treatment options. The increased longevity of patients with HIV appears to be contributing to an increased incidence of HCC in this population and imposes new strategies for prevention and therapeutic management of patients.

Introduction

HIV has been linked to malignancies since the beginning of the AIDS epidemic in 1981, when Kaposi's sarcoma was reported for the first in young never-married men. Soon thereafter, aggressive non-Hodgkin lymphoma (NHL) was found to be linked to HIV, and these two tumors were considered AIDS defining when they occurred in an HIV-infected patient. Subsequently, invasive cervical cancer was also noted to be more common in HIV-infected patients and became the third AIDS-defining tumor. Since that time, numerous studies have shown that HIV infection raises the risk of a number of other tumors that do not confer a diagnosis of AIDS; these are called non-AIDS-defining cancers (NADCs). NADC cancers include carcinoma of the anus, testis, lung, skin (basal cell skin carcinoma and melanoma), Hodgkin disease, and hepatocellular carcinoma (HCC) (Dal Maso et al. 2009; Polesel et al. 2010; Pantanowitz et al. 2006).

The advent of highly active antiretroviral therapy (HAART) has dramatically extended the survival rates of patients with human immunodeficiency virus (HIV), leading to effective suppression of HIV and prolongation of life (Nunnari et al. 2005; Polesel et al. 2010). Most patients receiving HAART have an increase in their CD4 counts and a decrease risk of AIDS-defining tumors associated with severe immunosuppression, such as Kaposi sarcoma or central nervous system lymphoma. However, as these patients live longer, we are seeing a rise in a wide range of other cancers, and cancer is an increasing cause of morbidity and mortality in HIV patients; in fact, in some recent studies, cancer is the most common cause of death in

HIV-infected individuals (Bonnet et al. 2004; Simard et al. 2010, 2011; Meijde et al. 2013; Centers for Disease Control and Prevention 1992).

Zucchetto et al. evaluated the mortality for NADCs among 10,392 Italian patients with AIDS, who were diagnosed between 1999 and 2006, compared with the general population of the same age and sex. NADCs were the underlying cause of death for 7.4% of HIV-infected patients. The authors found a 6.6-fold elevated risk of death for NADCs among persons with AIDS. Most of these cancers with significantly elevated standardized mortality rates (SMRs) have a viral etiology, including anal cancer, which is associated with a human papilloma virus (SMR 270); Hodgkin lymphoma, which is associated with Epstein-Barr virus (SMR 174); and HCC, which is associated with chronic hepatitis B and C virus infections (SMR 11.1). In absolute terms, the most common cause of death for NADCs was lung cancer (24.6%), followed by liver cancer and Hodgkin lymphoma (both with 11.9).

The particularly enhanced risk for infection-related cancers could be explained by the fact that the altered immune system in HIV-infected persons may reduce its ability to control and suppress the oncogenic viral process or tumors expressing foreign antigens (Dubrow et al. 2012). This mechanism is supported by Grulich et al. who compared, in a meta-analysis, the cancer risk for HIV-positive patients and organ transplant recipients. These populations had a common risk factor for cancer: immunosuppression. Indeed, most of the cancers seen with a higher frequency in both populations had a known infectious cause. The exact role of HIV-induced immunosuppression in the pathogenesis of NADCs remains controversial and may vary from tumor to tumor: certain tumors appear to be associated with low CD4 counts, while in other tumors this relationship is less clear or nonexistent. Silverberg et al. analyzed a cohort of 19,280 HIV patients, followed from 1996 to 2007 and matched for age and sex with 202,303 HIV-negative persons. The authors found that the risk of mouth-throat cancer, anal cancer, colorectal cancer, lung cancer, and Hodgkin

lymphoma rose as recent CD4+ cell count fell, even after adjusting for other cancer risk factors such as age, smoking status, substance use, and viral hepatitis. Longer duration of HIV infection and a history of repeated opportunistic or other infections are also considered as relevant risk factors for development of various NADCs. It has been suggested based on animal studies that some anti-HIV drugs may contribute to one or more NADC, but this has not been shown in humans.

Focusing on HCC, it is known that the major risk factor for HCC is liver cirrhosis, and in many countries, the most common cause of cirrhosis is infection with HCV or HBV. Other causes of cirrhosis and HCC include alcoholism and, especially in part of Asia, aflatoxin exposure. HCC usually develops only after several decades of HCC or HBV infection. The role of HIV in the development of HCC is not clear; most HIV-infected patients who develop HCC re-coinfected with HBV and/or HCV, and these are the major risk factors for the development of HCC. Evidence seems to suggest that HIV by itself is not a risk factor for HCC. It is not known whether HIV infection alone is a risk factor for HCC, and indeed, evidence from several large retrospective studies suggests it is not. There is some, although conflicting, evidence that among patients coinfecting with HIV and either HBV or HCV, HCC is more common in patients with low CD4 counts, suggesting that HIV or HIV-induced immunosuppression may be a contributory factor in the development of HCC. HIV coinfection also seems to accelerate disease progression of HCC. The ability of HAART to reduce HIV-associated immunosuppression may thus be beneficial in reducing the risk of HCC. At the same time, patients receiving HAART have a prolonged survival, and in countries where HAART is widely used, the HIV-infected population is increasing in number and becoming more aged. These latter trends are contributing to a substantially increased overall burden of HCC in HIV-infected or AIDS patients. In addition to potential indirect effects on HCC risk through improvements in immune reconstitution and survival, HAART is known to have some direct

hepatotoxic effects, which might be amplified among HIV-positive patients chronically infected with HBV or HCV. Whatever the contributory causes of the increased number of cases of HCC in the HIV-infected population, this is an increasingly important problem, and there is an urgent need for more effective preventive, diagnostic, and therapeutic approaches.

HCC: A Rising Problem Among Patients with HIV

Epidemiology and Risk Factors

HCC is the commonest primary cancer of the liver and, according to the WHO report, the fourth commonest cause of cancer-related death. The estimated incidence of new cases worldwide is about 500,000–1,000,000 per year, causing 600,000 deaths globally per year. Although there are large areas of the world where the incidence of HCC is still unknown, several regions including parts of East Asia and sub-Saharan Africa are affected by a very high incidence of HCC (over 20 cases/100,000 population). Areas with moderately high risk (11–20 cases/100,000 population) include Italy, Spain, and Latin America; France, Germany, and the United Kingdom have instead an intermediate risk (5–10 cases/100,000 population). A relatively low incidence (less than 5 cases/100,000 population) is found in the United States, Canada, and Scandinavia. The incidence of HCC has been rising in developed Western countries in the last two decades, driven in part by the increased prevalence of HCV infection and the rise of immigration rates from HBV-endemic countries. In addition, even though the incidence of HCC reaches its highest peak among persons over 65 years, an increased incidence among younger individuals has been noted in the last two decades both in the United States and Europe.

In HIV-positive patients, the incidence of HCC is substantially higher (82/10,000 according to the Data Collection on Adverse Events of Anti-HIV Drugs) than in the general population. Overall, HCV infection is the strongest predictor for liver-related death, followed by HBV; many studies have confirmed this datum. The role of HIV is

less clear. A large retrospective cohort study on US veterans demonstrated that HIV-positive persons had a higher risk to develop HCC than HIV-negative persons, but, after adjusting for HCV and alcohol abuse, HIV status was not independently associated with cancer. The 2001 French Mortavic study (Rosenthal et al. 2003), a prospective 1-year cohort study involving 25,178 HIV-positive patients, showed a significant increase in death from end-stage liver disease (ESLD) and HCC, as compared to similar cohorts in 1995 and 1997; death due to ESLD rose from 1.5% to 14.3% of all deaths, whereas deaths due to HCC rose fivefold, from 4.7% to 25% of all deaths; interestingly, essentially all deaths from HCC were in patients with HCV coinfection. Throughout the same period, deaths directly due to AIDS fell from 91.6% of all deaths (in 1995) to 48.7%, suggesting that the increased longevity in the HAART era could be a reason for the increased HCC rate in the 2001 cohort. In a prospectively followed cohort of HIV-infected individuals in France, HCC deaths related to HCV infection also increased during the period from 2000 to 2005 (Bonnet et al. 2004). By contrast, the incidence of HCC development and related deaths among HIV-HBV-coinfecting individuals seemed to be relatively stable (Bonnet et al. 2004). A retrospective study conducted on a cohort of US veterans with hepatitis C between 1991 and 2000 showed that the incidence of HCC did not differ between HIV-/HCV-coinfecting and HCV mono-infected patients in the HAART era, whereas it was significantly lower among HIV-/HCV-coinfecting individuals previously to HAART introduction. This datum supports the premise that, in the pre-HAART era, HIV patients did not survive enough to develop HCC. Other retrospective studies examining cohorts from countries where HAART is largely unavailable found the incidence of HCC to be lower or equal to average population rates, also supporting this conclusion.

In 2004, the Italian Cooperative Group on AIDS and Tumors (GICAT), while collecting data on malignancies occurring in HIV patients since 1986, identified a total of 41 consecutive patients with HCC (from a joint Italian and

Spanish database) and retrospectively investigated the main epidemiological characteristics of these patients as compared to a control group comprised of 384 HIV-negative patients diagnosed over the same period. The GICAT study emphasized the younger age of HIV-positive patients at the diagnosis of HCC (age 40–46 vs. 60–70 in HIV negatives). HCV infection was the main risk factor for HCC development in both HIV-positive and HIV-negative subjects. The median time to develop HCC after HCV infection was found to be around 22 years in HIV-positive patients: 10 years shorter than that reported among HIV-negative patients who acquired HCV infection with transfusion. Alcohol abuse (which is often associated with HIV risk behaviors) and insulin resistance (which causes non-alcoholic fatty liver disease and frequently occurs in HIV-infected individuals in part from certain antiretroviral drugs) are other potential risk factors for the earlier development of HCC among HIV-positive patients.

HIV-HBV and HIV-HCV Coinfection: Prevalence and Significance of a Complex Interaction

Coinfection with HCV and/or HBV is common among HIV-infected persons, because of shared routes of transmission, although the prevalence of coinfection varies markedly according to the geographic origin and demographic characteristics of infected patients. Approximately 25% of HIV-positive persons in the Western world have HCV coinfection. In a study of 3,048 patients in the European SIDA cohort, the prevalence of HIV/HCV coinfection was 33% overall but 75% in injection drug users (IVDUs). In the United States, the highest rates of HIV/HCV coinfection were also seen among IVDUs. As regards HBV, up to 9% of HIV-positive patients in Europe are coinfecting with HBsAg (Konopnicki et al. 2005). In Italy, between 3% and 4% of HIV-infected individuals are chronic carriers of HBsAg. The recorded prevalence is likely to be inaccurate, however, because of the large number of patients with occult HBV infection, associated with detectable HBV DNA on quantitative PCR.

HCV usually leads to the development of HCC through the stage of cirrhosis, which can

take 28–30 years to occur. Cirrhosis is almost a prerequisite for the development of HCV-related HCC: HCV is not able to integrate into the host genome, and the major hypothesis to explain hepatocarcinogenesis in patients with HCV is related to immune-mediated inflammation and hepatocellular injury. HBV chronic infection is another major cause of HCC, but, differently from HCV, HCC may occur in HBsAg carriers without cirrhosis, because of the direct involvement of a number of viral-related factors (viral proteins, BCP mutation in the viral genome, pre-S deletion mutants). Furthermore, HBV has a retroviral intermediate stage in its replication and can integrate its DNA into the host genome. This can lead to a variety of mutagenic consequences, including large inverted duplications, deletions, amplifications, and translocations, resulting in chromosomal instability. As expected, patients with HCV-HBV coinfection have yet a higher risk of developing HCC than those infected with just one or the other, and vaccination against HBV should be proposed to all patients with chronic hepatitis C who are not infected with HBV.

A number of studies have examined the role of HIV in the pathogenesis of HCC. In vivo studies in murine models have shown a potential role of the HIV *Tat* gene in liver tumorigenesis. In transgenic mice expressing this gene, a greater incidence of hepatocellular carcinoma and extrahepatic malignancies has been found, suggesting that the potential oncogenic effect of *Tat* gene is not liver specific. There is suggestive evidence that *Tat* may have oncogenic activity because of its anti-apoptotic activity, pro-angiogenic activity, and ability to induce expression of growth factors, cytokines, and transcription factors. Although murine experiments suggested a direct role of *Tat* in HCC, a number of epidemiological studies have not shown a clear role of HIV itself on HCC development; in a large retrospective study by Giordano et al., for instance, the rate of HCC was not higher in HIV mono-infected patients without HCV or HBV infection than in general population. At the same time, however, there is a clear evidence that HIV can accelerate the progression of HCV- and

HBV-liver disease to cirrhosis and HCC. In this regard, the presence of HIV alters the natural history of HCV infection, increasing the likelihood of chronicity (over 90%) due to the lack of CD4+ T-cell responses against HCV. Moreover, once chronic HCV infection is established, liver disease progression is much faster in HIV-infected patients, resulting in a higher frequency of cirrhosis and its complications compared to HCV mono-infected patients.

The molecular mechanisms of accelerated fibrosis in coinfecting patients are not fully understood. The studies of Galastri et al. suggest that HIV gp120 may play a role by exerting multiple effects on human hepatic stellate cells (HSCs), modulating their phenotype in a profibrogenic way. Incubation of HSCs with gp120 significantly increased the migration of HSCs and their expression of proinflammatory cytokines, including monocyte chemoattractant protein-1 (MCP-1) and type 1 procollagen. Recent data suggest that the binding of HIV gp-120 to the CXCR4 coreceptor, which is expressed on the surface of hepatocytes and HSCs, is able to upregulate tumor necrosis factor (TNF)-related apoptosis, inducing ligand (TRAIL) R2 expression. By this mechanism, HIV infection may make hepatocytes more susceptible to liver injury. During HIV coinfection, increased liver damage may also be mediated by the effects of antiretroviral drugs and indirectly by immune reconstitution syndrome (Bonnet et al. 2004; Puoti et al. 2012).

Further prospective studies are needed to better evaluate the role of HIV in subjects coinfecting with HCC. It will be important to control for potential confounding factors in epidemiologic studies. In some studies, for example, not all HCV-HBV patients had been tested for HIV, thus implying the possibility to underestimate the prevalence of coinfecting persons. Also, since time of infection with HBV or HCV is often missing, it is hard to calculate the effect of HIV coinfection on the development of HCC. For example, if patients with isolated HCV or HBV acquired this infection earlier than HIV-coinfecting patients in a study, this variation in the duration of infection could contribute to an apparent effect of HIV infection. Given these considerations, key points

of an ideal prospective study should include cross-testing for coinfections before individual allocation to groups, standardized screening for HCC, and regular evaluation of HIV viral load in the coinfecting cohort, in order to evaluate the potential effect of HAART-induced viral suppression on HCC pathogenesis.

Clinical Characteristics

During its initial stages, HCC is generally asymptomatic. In more advanced phases, hepatomegaly, jaundice, and abdominal pain may appear. Overall, the clinical presentation and prognosis considerably vary according to the number and size of tumor lesions. Liver cancer may appear either as a single nodular or infiltrating lesion with an eccentric growth or as a multinodular widespread tumor *ab initio*. In some patients HCC lesions have a slow growth rate, with a twofold increase in 20 months, while in others it can double in less than 1 month. Multinodular HCC is more often found in patients with more than one risk factor and needs to be classified as primitive multicentric HCC or metastatic cancer from a primitive HCC. This distinction has important clinical implications because primitive multicentric HCC are less aggressive and recur less frequently after ablation than metastatic cancers from a primitive HCC.

Among HIV-infected patients, cumulative clinical data suggests a more aggressive course of HCC. Patients with HIV from the HIV-HCC Italo-Spanish group showed a more advanced and infiltrating HCC (also with extranodal metastases), a more advanced stage of cirrhosis at presentation, and a reduced survival rate in comparison with HIV-negative patients. A 2007 US-Canadian multicenter retrospective study identified 63 HIV-infected patients with HCC from 1992 to 2005 and compared them to 226 HIV-negative HCC patients. Patients with HIV not only were younger and more frequently symptomatic than HIV-negative patients but also showed higher median α -fetoprotein levels. By contrast with other studies, tumor staging and survival were similar between cases and controls in this study. In untreated HCC cases, the presence of undetectable HIV-RNA was an independent

predictor of a better survival. In a recent, large, multicenter, observational study, Berretta et al. (2011) confirmed that HIV-positive HCC subjects tend to be younger and to have a shorter survival time after treatment than HIV-negative patients.

HCC: Treatment Options

HCC treatment is usually classified as curative or palliative. The curative treatments are surgical resection, orthotopic liver transplantation (OLT), and local ablative therapies, including percutaneous ethanol injection (PEI) and radiofrequency ablation (RFA). Surgical resection is the treatment of choice in solitary tumors less than 5 cm in diameter that are without vascular invasion or extrahepatic spread, developing in patient with preserved hepatic function who does not have portal hypertension; in this setting, the 5-year survival rate is about 50%. OLT is the best option for cirrhotic patients with a solitary lesion less than 5 cm in diameter that is not a candidate for resection or with up to three lesions smaller than 3 cm and where there is no vascular invasion or metastasis according to the Milan criteria. In these cases the 5-year survival rate can be as high as 70%. In patients that are not eligible for resection or transplantation, owing to comorbidities, liver dysfunction, or limited surgical resources, PEI and RFA are a potential treatment for small tumors, usually less than 3 cm in size. For early stage HCC, RFA has been reported to induce a complete response in about 80% of patients, with a 5-year survival of 50% and recurrence rates comparable to surgical resection.

Unfortunately, however, most patients with HCC have advanced disease at diagnosis. They are candidates for palliative treatments that include transarterial chemoembolization (TACE), chemotherapy, hormonal compounds, and immunotherapy. TACE has been shown to improve survival when applied to carefully selected patients. It is indicated for unresectable multinodular HCC, without vascular invasion or extrahepatic spread. To date, durable remission has rarely been reported with chemotherapy, and no significant survival benefits have been conclusively demonstrated with this approach, probably

because of the chemoresistance of HCC cells. More recently sorafenib (an oral multikinase inhibitor of the vascular endothelial growth factor receptor) prolonged median survival time as compared to placebo as well as time to radiologic progression in patients with advanced HCC, and it has been approved for advanced disease.

Other antiangiogenic therapies that may have some utility in HCC are sunitinib and the combination of bevacizumab and erlotinib; unfortunately, no data are available concerning their use in HCC patients infected with HIV. Also, mammalian target of rapamycin (mTOR) inhibitors have shown a certain rate of efficacy in small cohorts of patients with HCC, but these data need to be validated in wider clinical settings. The presence of sexual hormone receptors on HCC cells raised the possibility of using antiestrogens like tamoxifen against those HCC cases not amenable to resection: unfortunately, several trials failed to demonstrate any benefit either in terms of response or in terms of overall survival in patients with advanced HCC treated with tamoxifen.

HCC in patients with HIV is often advanced at presentation, not allowing curative therapeutic strategies. Until a few years ago, HIV infection was an exclusion criterion for liver resection or transplantation. An important concern was the risk of HIV progression after OLT, a poor post-transplantation prognosis, and eventually the waste of graft (Di Benedetto et al. 2008; Terrault et al. 2012). Ettore et al. (2003) showed that almost half of HIV-positive patients affected with end-stage liver disease were not suitable for surgical treatment and comprehensively only 28% of them had the opportunity to receive a successful surgical treatment. An analysis of the GICAT cohort showed that in a series of 41 HIV-positive patients affected by HCC, 15 (35%) of them fulfilled the Milan criteria and could potentially have been treated with OLT as a curative intent. However, none of them underwent liver transplantation; only two underwent surgical resection with a 2-year survival of 41% in treated patients and 0% in untreated cases.

Since the introduction of HAART, the outcome of HIV infection has dramatically changed.

Patients with HIV have a substantially better long-term survival, and as a consequence, liver transplantation needs to be considered to treat HCC. Several studies found that most HIV-positive patients who undergo a liver transplant have a good long-term survival (Di Benedetto et al. 2008). Di Benedetto et al. (2008) reported on a series of 7 HIV-positive patients with HCC that, by fulfilling the Milan criteria, underwent OLT. After a mean follow-up of 232 days, the overall survival rate was 85.7%, and only one patient died; this individual had a functioning graft and no HCC recurrence and died of a myocardial infarction. Radecke et al. reported that out of five cases of OLT in HIV-infected cirrhotic subjects, two had stable liver function and non-progressive HIV infection under HAART, 61 and 23 months after OLT, respectively; unfortunately, in this report, three out of five patients died due to graft failure. Clinical posttransplant management of OLT in HIV-positive patients is doubtless more complex than in the HIV-negative counterpart. The main reported problem in these patients has been an earlier and more aggressive HCV recurrence (experienced in about 33% of patients), faster occurrence of hepatic fibrosis, a greater rate of rejection (from 33% to 38%) (Di Benedetto et al. 2012), and a higher incidence of tacrolimus toxicity.

The outcome of HIV-positive liver recipients depends in part on the immunological status of the patient at the time of OLT. There is a considerable agreement about the necessity of a full virological control of the underlying HIV infection before OLT: in fact, transplanted patients with higher CD4+ cell counts and undetectable HIV viral load display clinical courses similar to HIV-negative recipients. Di Benedetto et al. proposed some criteria to select HIV-positive patients with HCC for OLT: firstly, patients must completely fulfill the Milan criteria. They should also have an undetectable HIV viral load (<50 copies/mL) and a CD4+ cell count more than 200/mL. After OLT, HAART needs to be reinstated as soon as clinically possible, with the input of a multidisciplinary transplant team (surgeons, infective disease specialists, and oncologists) with great experience in the management of pharmacologic

Hepatocellular Carcinoma in HIV-Positive Patients, Table 1 Criteria for considering liver transplantation in HIV-infected patients (according to Di Benedetto 2008)

Liver disease criteria	
Child-Turcotte-Pugh score \geq B7; MELD score \geq 14	
<i>Milan criteria</i> ^a	
No more than three tumor nodules	
No nodule greater than 5 cm in diameter	
Absence of macroscopic portal vein invasion	
Absence of recognizable extrahepatic disease	
HIV infection criteria	
<i>Immunological criteria</i>	
None of AIDS-defining opportunistic infections in the previous year	
CD4 cell count >200 cells/ μ L or >100/ μ L in case of therapy intolerance	
<i>Virological criteria</i>	
Undetectable HIV viral load (<50 copies/mL) in the last 12 months or effective therapeutic options for HIV infection during the posttransplant period	
General criteria	
Favorable psychiatric evaluation	
Social stability	
No alcohol abuse for at least 6 months	
No drug consumption for at least 2 years (patients who are on stable methadone maintenance programs can be included and can continue on the maintenance program after the procedure)	
No extrahepatic malignancy	
No pregnancy	

^aPatients with HCC who are being considered for liver transplantation should not have a needle biopsy due to the significant rate of needle-track seeding leading to recurrence posttransplant

interactions between HAART and immunosuppressive agents (see Table 1). In conclusion, the latest evidence suggests that OLT should be considered as a possible therapy for patients with HIV and HCC. Accurate selection protocols for this approach that take into account HIV status, HCC stage, and other factors are essential (Wood 2012). At the present time, the key question is not *if* but *who* should be referred to liver transplantation.

In the palliative setting, recent data on the use of sorafenib in unresectable HCC/HIV-positive patients showed that this treatment along with concomitant HAART is safe and feasible and that the response rates are similar to general population (Berretta et al. 2013). Unfortunately the

number of HCC/HIV-positive patients analyzed is small, and prospective and randomized trials are necessary to draw further conclusions.

HCC: Primary, Secondary and Tertiary Prevention

Prevention and early diagnosis are key points to the management of HCC, but, at present, there are no universal guidelines, especially when it occurs in HIV-positive patients (see also Table 2). Primary prevention in subjects with HIV should entail efforts to promote alcohol avoidance and when appropriate include strongly HBV. In fact, HCC was the first human cancer that was shown to be amenable to prevention using mass vaccination.

Secondary prevention should include regular exams aimed at early detection of HCC. The European Association for the Study of the Liver (EASL) has proposed guidelines describing patient selection and surveillance intervals for HCC screening in HIV-HCV and HIV-HBV-coinfecting individuals. Six monthly ultrasonography and alpha-fetoprotein (AFP) level measurements are the two methods most commonly used to screen cirrhotic patients for HCC. The use of AFP alone for early diagnosis of HCC in HIV-coinfecting patients is not recommended and may be suggested only where and if ultrasonography is unavailable. In fact, even though AFP values higher than 400 ng/ml are usually considered as diagnostic of HCC, false-positive AFP results can occur in HIV-infected patients as a result of HAART inducing substantial increases of AFP levels. The GICAT group observed a more advanced HCC at diagnosis in HIV-positive patients, apparently unrelated to a true delay in

diagnosis, and suggested shortening the interval for HCC screening in this patient population as hepatocarcinogenesis can be a more-rapid process in HIV-positive cirrhotic subjects.

Another point to consider in patients coinfecting with HIV is the treatment of HCV and/or HBV. Treatment with IFN and ribavirin may induce a persistent clearing of HCV viremia in 27–40% of HIV-HCV-coinfecting individuals and seems to reduce the risk of HCC in these cases. Moreover, HCV eradication in HIV-coinfecting patients results in a definitive improvement of liver function, and it seems to improve tolerance to antiretroviral agents. In particular, therapy with pegylated-IFN alpha plus ribavirin appears able to slow down the rate of liver disease progression, although the likelihood of achieving a sustained virological response (SVR) is lower in coinfecting persons than in those with HCV mono-infection. Based on available clinical results, 48 weeks of ribavirin and pegylated-IFN therapy at doses used for HCV mono-infected patients seems to be advisable. Unfortunately HCV therapy in HIV patients is not as well tolerated as in other patients; side effects include relatively more severe and frequent myelosuppression, more frequent anemia (especially in patients taking zidovudine), an increased risk of lactic acidosis, and a poorer response in patients with low CD4+ cell counts. HBV treatment also appears to substantially reduce HCC incidence in patients with severe cirrhosis, and there are reasons to suspect the same effect in HIV-coinfecting patients. Patients in whom treatment for both HBV and HIV is planned should receive therapies that are effective against both viruses, and regimens such as lamivudine plus tenofovir or emtricitabine plus tenofovir are preferred. As far as we know, no relevant data on tertiary prevention (which aims to reduce HCC recurrence after resection) are available in HIV-positive individuals.

Conclusion

Currently, in areas where HAART is available, a rapid increase of HCC incidence is occurring

among HIV-positive individuals. It is reasonable to hypothesize that in a few years, the burden of HCC in HIV-infected patients will increase in developing countries as well. Considering the more aggressive clinical behavior and progression of HCC in coinfecting patients, there is an urgent need for effective prevention programs, screening techniques, and specific management guidelines. Large, multicenter, randomized clinical trials are needed, in order to better define the criteria for surveillance and the effect of early diagnosis on outcome. In addition, important needs for future research include a further evaluation of the feasibility of liver transplantation and efficacy of new therapeutic agents.

HIV "Auxiliary" Proteins

Cécile Hérate, Serge Benichou and Marie Lambelé
 Inserm U1016, Institut Cochin, Paris, France
 CNRS, UMR8104, Paris, France
 Sorbonne Paris-Cité, Université Paris-Descartes, Paris, France

Definition

In addition to *gag*, *pol*, and *env*, HIV and SIV genomes contain additional genes (*tat*, *rev*, *vif*, *vpr*, *vpx*, *vpu*, and *nef*) encoding for regulatory proteins. While Tat and Rev are required both in vitro and in vivo for virus replication, the Vif, Vpr, Vpx, Vpu, and Nef "auxiliary" proteins are

usually dispensable for virus growth in vitro, but these auxiliary proteins play essential roles in vivo for virus replication and AIDS pathogenesis through interaction and perturbations of cellular pathways and functions in HIV target cells.

Introduction

The genome of human lentiviruses (HIV-1 and HIV-2) contains more genes than the usual *gag*, *pol*, and *env* genes common to all retroviruses. Indeed, HIV-1 contains additional open reading frames called *tat*, *rev*, *vif*, *vpr*, *vpu*, and *nef* encoding for small regulatory proteins, while the HIV-2 genome has an additional *vpr*-related *vpx* gene but usually no *vpu*. While Tat and Rev proteins are absolutely required both in vitro and in vivo for virus replication, expression of Vif, Vpr, Vpx, Vpu, and Nef proteins is usually dispensable for efficient virus growth in several in vitro virus-replication systems and these proteins were thus first referred to as accessory or auxiliary proteins. However, their primordial role for virus infectivity and replication as well as in AIDS pathogenesis during the course of the natural infection was rapidly established. In spite of their small size, a plethora of effects and functions have been attributed to these regulatory proteins in vitro during virus replication in the target cells of HIV, CD4⁺ T lymphocytes, macrophages, and dendritic cells. It was known for many years that these proteins utilize and perturb basic cellular pathways leading to optimization of early or late essential steps of the virus life cycle. More recently, accessory proteins have progressively been shown to be involved in the counteraction of different innate antiviral cellular restriction factors that partially inhibit virus infectivity and dissemination in the target cells. Recent studies highlighted some cellular proteins targeted by the viral auxiliary proteins to perform their different tasks and counteract restriction factors, such as the apolipoprotein B mRNA-editing enzyme 3G (APOBEC3G), the bone marrow stromal cell antigen 2 (BST-2) also called tetherin, and the recently identified sterile-alpha motif and HD domain protein (SAMHD1). Their real roles and

functions during the course of natural infection are still largely enigmatic.

Here, an overview of the established knowledge concerning the multifunctional activities of HIV auxiliary proteins in focusing particularly on their interaction with restriction factors is presented.

Nef: An Essential Virulence Factor

Nef, abbreviated from negative factor, is a myristoylated protein of 27–35 kDa encoded by all HIV and SIV primate lentiviruses that is expressed early during the viral life cycle, suggesting an important role in creating a favorable environment for virus replication. Nef was initially so called as early *in vitro* studies showed its propensity to reduce HIV replication in established cell line, but subsequent *in vitro* and *in vivo* studies realized in macaques infected with Nef-deleted SIV as well as in transgenic mice expressing Nef and HIV-1-infected "humanized" mice identified Nef as a key factor for AIDS pathogenesis and unraveled its ability to promote virus spread. Despite its lack of enzymatic activity, Nef acts as an adapter to bind cellular factors and exert pleiotropic functions. Nef affects vesicular trafficking and signal transduction leading to prevention of superinfection, protection of infected cells from recognition by the immune system, reduction of the motility of infected T lymphocytes, and enhancement of the infectivity and replication of released virus particles (Malim and Emerman 2008; Abraham and Fackler 2012; Strebel 2013; Basmaciogullari and Pizzato 2014). Nef is a multifunctional protein able to interact directly with cellular components involved (i) in vesicular transport between endosomal membrane compartments of the endocytic pathway and (ii) in the control of several signaling pathways in HIV-1-infected cells. These Nef-induced alterations of intracellular trafficking and cell signaling pathways are related to the presence of specific motifs, reminiscent of interaction motifs found in cellular proteins, within the primary sequence of HIV-1 Nef. Two motifs of Nef have been extensively characterized:

a leucine-based motif (E/D₁₆₀xxxLL₁₆₅), found in a C-terminal flexible loop of HIV-1 Nef, and a poly-proline (P₇₂xxP₇₅) motif. While the leucine-based motif allows recruitment of clathrin-associated adaptor protein (AP) complexes that participate in the vesicular transport within the endocytic pathway, the poly-proline motif is required for interactions with cellular proteins containing SH3 domains, such as tyrosine kinases of the Src family (Abraham and Fackler 2012). AP complexes are heterotetramers constituted of two large subunits, a medium chain and a small subunit that play important roles in the selection of the cargo proteins, formation of clathrin-coated vesicles (CCVs), and vesicular transport between the different membrane compartments of the endocytic pathway. Therefore, some functions of Nef, such as cell surface downmodulation of certain membrane receptors, are specifically dependent of the Leu-based motif, whereas the integrity of the poly-proline motif is required for some other Nef effects, regarding alteration of signaling pathways observed in HIV-1-infected T cells and macrophages. Interestingly, Nef-mediated enhancement of HIV-1 infectivity and replication depends on the integrity of both Leu-based and poly-proline motifs.

It is now well documented that Nef acts on the endocytic pathway to disturb the intracellular trafficking and cell surface expression of several membrane receptors, including CD4, major histocompatibility class I and II (MHC-I and MHC-II) molecules, the CD28 co-stimulatory molecule, the DC-SIGN lectin expressed on dendritic cells, and the CCR5 and CXCR4 chemokine receptors involved in virus entry. The current molecular model for Nef-induced CD4 endocytosis suggests that Nef acts as a connector between CD4 and the clathrin-associated AP-2 complex at the plasma membrane. This connection results in the targeting of CD4 to clathrin-coated pits for rapid internalization via CCVs to reach internal early endosomes where CD4 is then rerouted to the lysosomal degradation pathway (Tokarev and Guatelli 2011). Whereas the recruitment of AP complexes is mediated by the leucine-based motif of Nef, the putative CD4-binding site is found in the N-terminal part of the protein. This

mechanism prevents cell superinfection and more surprisingly is required to maintain the full infectivity of the viral particles released.

Nef also downregulates the cell surface expression of MHC-I molecules, thus overcoming the antiviral cytotoxic T-lymphocyte response and the lysis by natural killer cells. Cell surface MHC-I downmodulation relies on the ability of Nef to connect MHC-I to the AP-1 complexes involved in the transport between the trans-Golgi network (TGN) and the early endosomes. Interestingly, two other Nef motifs are involved in MHC-I downregulation: the poly-proline motif and an acidic cluster-based sequence (EEEE), both motifs located in the N-terminal region of Nef. Although not fully understood, it was proposed that upon Nef binding, a putative tyrosine-based sorting motif found within the cytoplasmic tail of MHC-I is exposed allowing the interaction with AP-1 resulting in the retention of MHC-I in the TGN followed by its degradation in the lysosomes (Tokarev and Guatelli 2011).

Along Nef's potency to modulate cell surface protein expression, Nef can also alter signal transduction such as decreasing the threshold of T-cell activation creating a favorable environment for HIV-1 replication in CD4-positive T lymphocytes. By decreasing the cell surface expression of both CD4 and the CD4-associated lymphocyte-specific tyrosine kinase Lck, Nef induces a narrow T-cell antigen receptor (TCR) response at the plasma membrane while redirecting it to the TGN, resulting in the activation of the Ras-Erk pathway. Nef reroutes host cell signal transduction machinery away from the plasma membrane to assemble active intracellular signalosomes and fine-tune T-cell activation states via association with at least two independent signalosomes, the Nef-associated kinase complex (NAKC) and the complex formed by direct interaction between Nef and the serine/threonine kinase PAK2. In the context of the Nef-PAK2 complex, the viral protein associates with highly active PAK2 and alters the substrate specificity of the kinase. Phosphorylation of novel substrates such as the actin-severing factor cofilin allows Nef to reduce host cell actin dynamic and thus motility of infected T cells. The NAKC is a multiprotein complex

including kinases, the polycomb protein Eed, and protein interaction adaptors. Functionally, NAKC assembly triggers signaling events reminiscent of inside-out integrin signals leading to upregulated virus transcription as well as secretion of extracellular vesicles. Recent findings illustrate that these processes involve the PAK2-dependent phosphorylation of paxillin, thus providing a physical and functional link to the formerly established Nef-PAK2 complex. In the context of this complex, Nef recruits the proteases ADAM10 and ADAM17, and this results in the secretion of activated ADAM proteases in extracellular vesicles, leading to processing of the ADAM substrate TNF α in the target cells of these vesicles and contributing to the apoptosis of bystander T cells (Abraham and Fackler 2012). In macrophages, Nef's poly-proline motif interacts with high affinity with the SH3 domain of the protein tyrosine kinase Hck, an enzyme specifically expressed in myeloid cells such as monocytes and macrophages, thus activating the kinase activity, leading to alterations of the phagocytic and migration functions of infected macrophages (Basmaciogullari and Pizzato 2014). However, both poly-proline and leucine-based motifs of Nef are required for alterations of these macrophage functions, indicating that the Nef-induced perturbations of both intracellular trafficking and signaling pathways play additional roles in these processes.

A decade after HIV-1 discovery, the stimulation of Nef on virus infectivity and replication was revealed. The magnitude of this Nef-mediated enhancement of virus infectivity varies depending on the producer and target cell types and is comprised between 3- and 40-fold with the strongest effect observed when viruses are produced in lymphoid cell lines suggesting that a potential as yet to be discovered restriction factor may be present in these specific cells. Indeed, Nef effect on virus particle infectivity can only be observed if the regulatory protein is present in the producer cells during virus particle biogenesis. To date, though the exact molecular mechanisms remain largely unknown, it is admitted that Nef helps during the early phases of the viral life cycle. Following fusion with the plasma membrane of

the target cell, HIV-1 encounters a barrier consisting of the cortical actin network, and several lines of evidences suggest that Nef affects the actin cytoskeleton by controlling the incorporation of host factors, i.e., dynamin-2 and ezrin, to facilitate the viral penetration. Dynamin-2 is a GTPase responsible for the clathrin-dependent endocytosis and is required for viral infectivity. Ezrin belongs to the ERM family proteins and serves as a connector between the plasma membrane and the actin cytoskeleton. In the target cells, Nef has been documented to enhance cDNA synthesis by promoting the generation of reverse-transcription products suggesting that either the uncoating or the reverse-transcription steps are involved in this activity (Malim and Emerman 2008; Basmaciogullari and Pizzato 2014).

Vpr: An Essential Player of the Early Steps of Virus Replication

The viral protein R (Vpr) is a small regulatory protein (14 kDa) of 96 amino acids. As for Nef, its importance has been initially reported in vivo in rhesus macaques infected with SIV lacking the *vpr*, and the related *vpx* (see below) genes. These infected animals displayed a lower virus burden and did not consistently develop immunodeficiency disease in the absence of Vpr/Vpx expression (Guenzel et al. 2014; Planelles and Benichou 2009). Interestingly, Vpr is the only auxiliary protein specifically incorporated into viral particles via a direct interaction with the C-terminal p6 domain of the Pr55Gag precursor, indicating that Vpr plays critical roles during the early steps of the virus life cycle. In this regard, Vpr has been shown to influence the accuracy of the reverse-transcription process. The HIV-1 reverse transcriptase is an error-prone RNA-dependent DNA polymerase, and Vpr is able to modulate the mutation rate in both dividing and nondividing HIV-1 target cells, even if this activity is more pronounced in terminally differentiated infected macrophages. This role of Vpr was related to the recruitment of the nuclear form of uracil-DNA glycosylase (UNG2), an enzyme of the DNA

repair machinery able to remove the misincorporated uracil in DNA, into virus particles. Recent results suggest that incorporation of UNG2 into virions has a positive impact on HIV-1 infectivity and replication and positively influences the reverse-transcription process. However, several conflicting findings have been reported regarding the role of UNG2, arguing that the protein has rather a detrimental impact on virus replication and may act as a restriction factor. In this model, UNG2 could introduce a-basic sites in place of deoxyuridine created by the well-characterized HIV restriction factors of the APOBEC3 family (see below), leading to the degradation of the neo-synthesized viral DNA. The Vpr protein should induce the proteasomal degradation of UNG2 in virus-producing cells in order to prevent its recruitment into virus particles. The Vpr-induced degradation of UNG2 was related to the ability of Vpr to interact with the DCAF1 subunit of the Cul4a/DDB1 E3 ubiquitin ligase complex containing the damage-specific DNA-binding protein 1 (DDB1), Cullin-4A (Cul4A), and Cul4-associated factor 1 (DCAF1) as well as Rbx1, which would be responsible for targeting UNG2 to the proteasome for degradation (Guenzel et al. 2014; Romani and Cohen 2012).

Once the viral DNA is synthesized, Vpr could be involved in its transport toward the nucleus in association with other viral and host cell proteins to form the so-called preintegration complex (PIC). It was proposed that the PIC moves along the cytoskeletal microtubule filaments using the dynein/dynactin complex as a motor, leading to its accumulation in the perinuclear region close to the centrosome. It is not known whether Vpr plays an active role in the intracytoplasmic transport of the PIC or is only associated with the complex and plays a role later for nuclear membrane anchoring and translocation of the viral DNA into the nucleus (Guenzel et al. 2014). The nuclear envelope (NE) contains two concentric membranes in which are embedded nuclear pore complexes (NPC) consisting of aqueous channels allowing for selective transport between the cytoplasmic and nuclear compartments. The NPC corresponds to a 125 MDa structure consisting of 30 distinct

proteins, named nucleoporins (Nups). Through interaction with some nucleoporins (Guenzel et al. 2014), Vpr docks and accumulates at the NE and may be involved in active nuclear import of the PIC in nondividing cells, such as macrophages. Vpr may thus be responsible for the first step of viral DNA import by targeting the PIC to NPC, while other components of the PIC could trigger the next step of the nuclear translocation. In addition, it has been reported that this high affinity for components of the NE could be responsible for the induction by Vpr of herniations and dissociations of lamina and NE. These herniations provoke a blend of nuclear and cytoplasmic proteins suggesting that Vpr could impact nuclear membrane stability and consequently also facilitates the entry of the PIC through a non-conventional pathway (Planelles and Benichou 2009).

Finally, the best-characterized activity of Vpr is related to its ability to induce a cell cycle arrest in the G2 phase in infected cells. This cytostatic function of Vpr could be a strategy used by HIV to improve viral replication and protein expression. The biological significance of this cell cycle arrest during the natural infection is not well understood, but the HIV-1 LTR seems to be more active in the G2 phase, implying that the G2 arrest may confer a favorable cellular environment for efficient transcription of HIV-1 and viral replication in human CD4 T cells. Different and multiple interactions with cyclins and other key enzymes of the cell cycle have been described to explain the Vpr cytostatic effect. The first studies proposed a Vpr-dependent accumulation of the hyperphosphorylated form of the cyclin-dependent kinase CDC2 (the p34 cdc2/cyclin B complex) that would block the cell cycle prior to mitosis. As mentioned above, Vpr is present in the nucleus and at the NE where it can induce envelope bursting and disturb the nuclear lamina. The modification of the membrane structure would perturb the distribution of several nuclear factors and redistribute them to the cytoplasm, which would alter the cell cycle. In this nuclear context, Vpr could interact with the chromatin and also target and activate two critical sensors of the cell cycle (ATM/ATR, ataxia telangiectasia-mutated and

ataxia telangiectasia and Rad3-related proteins). The upstream events of the signaling pathway activated by Vpr, specifically how Vpr induces activation of the ATR/ATM kinases, were recently highlighted. It was first clearly established that Vpr connects the DCAF-1 (DDB1- and Cul4-associated factor) adaptor of the Cul4A ubiquitin E3 ligase for proteasomal degradation of a cellular target factor leading to G2 arrest. In this model, Vpr recruits both DCAF1 and this factor, which is ubiquitinated and degraded (Guenzel et al. 2014; Romani and Cohen 2012). Then, proteomic analysis finally allowed the identification of a new key target of Vpr, the SLX4 structure-specific endonuclease regulator complex playing a role in nucleic acid metabolism and in DNA repair. It was shown that Vpr activates this SLX4 complex through direct interaction with SLX4, leading to the recruitment of DCAF-1 and the PLK1 kinase. The activated form of the SLX4 complex will then cleave the DNA in association with the MUS81-EME1 endonucleases. Consequently, the activation of SLX4-bound MUS81-EME1 induces the cleavage of DNA intermediates and replication stress, leading to an arrest in the G2 phase in dividing cells (Brégnard et al. 2014). It is interesting to note that Vpr is also able to induce apoptosis in dividing cells and could be responsible, at least in part, for the drastic and critical depletion of CD4 T lymphocytes during the disease progression. Depending on the authors, this cytotoxic effect has been related to the direct consequence of the prolonged cell cycle blockage in the G2 phase induced by Vpr or to the recruitment of the mitochondrial transmembrane adenine nucleotide transporter (ANT) that leads to the classical apoptosis pathway (Guenzel et al. 2014).

Vpx: An Essential Protein for Virus Replication in Nondividing Target Cells

In addition to Vpr expressed by all primate lentiviruses, members of the HIV-2/SIV_{sm}/SIV_{mac} and SIV_{rsm}/SIV_{mnd-2} lineages also express Vpx, probably originated from gene duplication of the *vpr* gene, a 12 to 16 kDa protein, known to

outcome the restriction of HIV-2 and SIV infection in nondividing cells such as macrophages, dendritic cells, and resting CD4-positive T cells. Like Vpr, Vpx is also specifically incorporated into virions and was proposed to participate in the nuclear translocation of the newly synthesized viral DNA within the PIC in nondividing cells such as terminally differentiated macrophages. However, subsequent evidences indicated that Vpx could counteract and induce proteasomal degradation of a cellular restriction factor expressed in myeloid cells through interaction with the CUL4A E3 ubiquitin ligase. Using proteomic approach, SAMHD1 (sterile-alpha motif and HD domain protein I) was finally identified as a target of Vpx for the proteasome machinery (Laguette and Benkirane 2012). SAMHD1, an interferon (IFN)-induced factor in primary monocytes, was already known as associated with the genetic Aicardi-Goutières syndrome characterized by an elevated secretion of IFN- α and an abnormal activation of the immune system. SAMHD1 is an enzyme mainly displaying a deoxynucleoside-triphosphate (dNTP) phosphohydrolase activity and thus maintains low levels of the cellular dNTP pool below the levels required for productive reverse transcription leading to restriction of virus replication. The restriction activity of SAMHD1 is dependent on the phosphorylation status of the protein, and only the dephosphorylated form seems able to efficiently restrict virus replication. Since SAMHD1 is a substrate for phosphorylation by the cyclin-dependent kinase (CDK), such as CDK1, this could explain why SAMHD1 restriction is only efficient in differentiated nondividing cells (Strebel 2013). However, recent studies indicate that SAMHD1 also displays an exonuclease activity, not regulated by phosphorylation, for both single-stranded DNA and RNA and thus can restrict virus replication through damage of viral nucleic acids (Yang and Greene 2014). So far, it is still not clearly established which SAMHD1 enzymatic activity is required or whether both enzymatic activities participate in virus restriction (Yang and Greene 2014). Of note, in some SIVs devoid of a *vpx* gene but containing a single *vpr* gene, such as SIV_{agm}

and SIV_{mus}, the Vpr protein can counteract the restriction activity of their natural host, but Vpr from the HIV-1/SIV_{cpz} cannot.

In addition to SAMHD1, several lines of evidence suggest that other IFN-inducible antiviral factors might be counteracted by HIV-2/SIV Vpx proteins in myeloid target cells. Interestingly, the APOBEC3A, a member of the cytidine deaminase APOBEC3 family, is induced by IFN treatment, may display restriction activity for HIV-1 replication in myeloid cells, and is able to interact with Vpx. It seems that APOBEC3A stability is negatively affected by Vpx through targeting to proteasomal degradation. However, the exact role of Vpx for the control of APOBEC3A activity remains unclear (Schaller et al. 2014). Finally, the Vpx protein of HIV-2/SIV_{sm}/SIV_{mac} lineage certainly plays other functions during virus replication in other cell types than differentiated myeloid cells and resting CD4 T cells, such as activated primary T cells in which the lack of Vpx expression also leads to replication defects (Schaller et al. 2014).

Vif: An Essential Factor for Virus Replication

The viral infectivity factor (Vif) is a 23 kDa protein encoded by all primate HIV and SIV genomes but also by most of other lentiviruses. As evidenced in the SIV-infected macaque model, Vif expression is absolutely required for virus spreading *in vivo*. *In vitro*, it was revealed early that Vif was required for efficient HIV-1 replication in some established lymphoid and myeloid CD4-positive human cell lines, whereas some other cell lines are permissive for *vif*-deleted virus replication. However, the CD4-positive T lymphocytes and myeloid cells are non-permissive to HIV infection in the absence of Vif. Early studies also revealed that the requirement of Vif expression is primordial in virus-producing cells leading to release of virus particles defective for efficient replication in the target cells (Jónsson and Andrésdóttir 2013).

It was finally documented that Vif is essential for virus replication in primary target cells

because it prevents incorporation into released virions of the cellular restriction factors of the apolipoprotein B mRNA-editing enzyme catalytic polypeptide-like 3 (APOBEC3) family (Jónsson and Andrésdóttir 2013). The seven members of the APOBEC3 family (APOBECA-H) are cellular cytidine deaminase enzymes that catalyze sequence-specific cytidine deamination of single-stranded DNA. While APOBEC3G and APOBEC3F display the most potent restriction activity against primate lentiviruses, other members of the family could also exhibit antiviral activity against *vif*-deleted HIV. All the members of the APOBEC3 family are able to remove the amino group from the cytosine bases creating uracil residues in DNA that lead to the insertion of mutations in HIV DNA (Jónsson and Andrésdóttir 2013). By mutating cytosine into uracil in reverse transcribed (minus strand) HIV DNA, the enzyme induces G to A hypermutations in the second HIV DNA synthesized (plus strand) and makes the virus unable to replicate in the target cells. Furthermore, the newly appearing deoxyuridine in viral DNA could also enhance the cellular DNA repair machinery and simply provoke the definitive fragmentation of the viral DNA. As mentioned above, the uracil-DNA glycosylase (UNG2) could introduce a-basic sites in place of deoxyuridine created by the cytidine deaminase activity of APOBEC3 proteins leading to the degradation of the neo-synthesized viral DNA. Even if the restriction activity of APOBEC3 proteins is mainly related to their cytidine deaminase activity, some studies reported that APOBEC3G and 3F proteins may also exert antiviral activity independently of cytidine deamination through direct action on the reverse-transcription process (Strebel 2013).

It is now accepted that Vif counteracts APOBEC3G through the proteasomal machinery. Vif interacts both with APOBEC3G and the Cul5-based E3 ubiquitin ligase complex to target APOBEC3G for poly-ubiquitination and proteasomal degradation. The E3 complex involved in the proteasomal degradation contains the ElonginB, ElonginC, Cullin-5, and Rbx2. Other cellular factors, such as CBF β , a cellular transcription forming a heterodimer with the RUNX

transcription factors, also interfere with the Vif-induced APOBEC3 degradation mechanism. However, it is still unclear whether CBF β stabilizes the Vif protein folding or triggers Vif conformational changes in order to stabilize the interaction between Vif and the Cul5 E3 complex (Strebel 2013). Interestingly, there is also emerging evidence indicating that Vif can counteract APOBEC3G in a proteasome-independent mechanism. This alternative mechanism of Vif to block APOBEC3G encapsidation without degradation is supported by identification of APOBEC3G mutants that cannot be targeted to the proteasome for degradation but are still counteracted by Vif. In contrast, some Vif mutants with differential efficiency for APOBEC3G degradation still retain the same capacity to block APOBEC3G. Taken together, these observations indicate that Vif uses at least two different ways to hijack APOBEC3 proteins: a degradation-dependent and a degradation-independent mechanism (Strebel 2013).

Vpu: An Essential Protein for Virus Budding

Vpu, standing for viral protein unique, is a transmembrane type I protein of 16 kDa encoded exclusively by HIV-1 and its related SIVs, i.e., SIVcpz, SIVgsn, and SIVmon, but absent from HIV-2 and most of the SIVs. It is expressed later during the viral life cycle suggesting that it is playing a role during the late stages. Indeed, the two main functions assigned to Vpu are the down-regulation of the CD4 expression through proteasomal degradation of the receptor and the enhancement of virion release from the plasma membrane (Malim and Emerman 2008).

In cooperation with Nef (see above), Vpu-induced CD4 degradation is believed to block interaction of CD4 with envelope glycoproteins insuring the release of infectious viruses. Vpu interacts with neo-synthesized CD4 molecules and acts by retention and accumulation of CD4 in the endoplasmic reticulum (ER) followed by its targeting to the ER-associated degradation pathway. While the retention of CD4 requires the

interaction between the transmembrane domains of CD4 and Vpu, the determinants needed for its degradation by the proteasomal pathway are localized within the first alpha helix of the Vpu cytoplasmic domain. Proteasomal degradation of CD4 requires phosphorylation of Vpu on two serine residues situated in the conserved DSGxxS motif localized in the cytoplasmic tail of the viral protein. This phosphorylation induces the recruitment of the cellular beta-transducin repeat containing protein (β -TrCP) that belongs to the Skp1-Cullin-1-F-Box (SCF) E3 ubiquitin ligase complex. β -TrCP recognizes the phosphorylated substrate, here Vpu, allowing the recruitment of the SCF E3 ubiquitin ligase complex that mediates poly-ubiquitination of lysine and serine/threonine residues found in the cytoplasmic tail of CD4 for proteasomal degradation (Malim and Emerman 2008; Tokarev and Guatelli 2011; Strebel 2013).

Similarly to the CD4 downregulation activity, the Vpu-induced viral release has been observed early after HIV-1 discovery but remained uncharacterized during the first 20 years. A major finding was the identification of the cellular restriction factor counteracted by Vpu implicated in this block, the so-called tetherin as this host protein tethers the viral particles to the plasma membrane. Tetherin, also known as the bone marrow stromal antigen 2 (BST-2), is expressed in B cells, dendritic cells, T cells, and macrophages. Remarkably, tetherin is upregulated in response to type I IFN and shows a broad activity by inhibiting the release of various enveloped viruses such as retroviruses; hence, it belongs to the innate immune response against viral infection. Tetherin/BST-2 is a transmembrane protein that presents an unusual topology with a transmembrane anchor near its N-terminus and a glycosylphosphatidylinositol (GPI) lipid anchor at its C-terminus (Strebel 2013; Roy et al. 2014). The accepted scenario of viral particles entrapment provoked by BST-2 suggests that dimers of the protein anchored their N-termini into the cell membrane and their C-terminus GPI domains in the virion envelope. Of note, in HIV-2 and SIVs that do not contain a *vpu* gene, BST-2 is antagonized by determinants found in the HIV-2

surface envelope glycoprotein and in the SIV Nef protein (Strebel 2013).

The mechanism of Vpu antagonism appears to rely on misdirection of BST-2 from the plasma membrane to intracellular compartments followed by its degradation. However, in the CD4-positive T lymphocytes and macrophage primary target cells of HIV-1, the cell surface level of BST-2 is not decreased by Vpu, suggesting that the antagonism relies on the displacement of the restriction factor from the site of viral budding at the cell surface (Tokarev and Guatelli 2011; Roy et al. 2014). Similarly to CD4, Vpu induces the ubiquitination of BST-2 through phosphorylation of its conserved DSGxxS motif in a β -TrCP-dependent manner, but instead of targeting BST-2 to the proteasomal pathway, it redirects it to the lysosomal degradation pathway. Upon BST-2 ubiquitination, Vpu binds to the hepatocyte growth factor receptor-regulated tyrosine kinase substrate (HRS), a component of the endosomal sorting complexes required for transport (ESCRT) machinery involved in the generation of the multivesicular body late endosomal compartment and hijacked by HIV-1 during the budding process. Ubiquitinated BST-2 is recognized by the ESCRT machinery and misrouted to late endosomes for degradation in lysosomes (Roy et al. 2014).

In addition, recent evidence suggests that BST-2 is also able to sense HIV-1-infected cells, and it is hypothesized that Vpu counteracts this innate immune activity via interference with the BST-2 signaling cascade in a β -TrCP-dependent manner (Roy et al. 2014; Sauter 2014).

Conclusion

HIV auxiliary proteins play essential roles during the virus life cycle by rendering the cellular environment favorable to HIV-1 replication, dissemination, and persistence. Indeed, Vif, Vpu, and Vpr counteract restriction factors belonging to the innate immune response, and Nef has evolved to also affect the adaptive immune response ultimately leading to the evasion of the virus from the immune system. Since HIV discovery, lots of

efforts have been devoted to the development of therapeutics conducting to the design of the highly active antiretroviral therapy (HAART). Unfortunately, HAART can limit viral replication but neither completely eliminates the virus from infected patients nor avoids the deleterious depletion of CD4⁺ T cells. Hence, the need to unveil new potential targets seems obvious, and based on their preponderant role, the “essential auxiliary” proteins represent attractive targets for the development of novel antiviral strategies.

HIV and Sexual Violence

- Brooke E. E. Montgomery¹ and Katharine E. Stewart²

Definition

Like HIV, sexual violence is a worldwide public health concern due to the extent of the problem and its multiple consequences to physical and mental health. Sexual violence occurs in all countries, to people of all ages and genders. Published rates of sexual violence from law enforcement and research are rough estimates since most occurrences are not reported due to fear, shame, and guilt on the part of the victims (Jewkes and Abrahams 2002). Researchers, service providers, policymakers, and law enforcement define sexual violence in multiple ways, and attempts have been made to decide upon uniform definitions (Saltzman et al. 1999). The World Health Organization (Krug et al. 2002) defines sexual violence as

Any sexual act, attempt to obtain a sexual act, unwanted sexual comments or advances, or acts to traffic, or otherwise directed, against a person's sexuality using coercion, by any person regardless of their relationship to the victim, in any setting, including but not limited to home and work. (p. 149)

Coercion includes all forms of unwanted aggression including psychological threats and physical intimidation to a person who can provide consent or taking advantage of a person who cannot provide consent due to intoxication or other form of mental incapacitation (Krug et al. 2002). As a result of this broad definition, a wide range of experiences can be classified as sexual violence including rape, attempted rape, sexual harassment, sexual coercion, sexual abuse, forced marriage, forced abortion, forced sexual initiation, denial of contraception or STD protection, genital mutilation, and sexual exploitation and trafficking (Krug et al. 2002; Stockman et al. 2010).

Additionally, sexual violence can occur in tandem with other forms of physical and psychological violence that are also associated with HIV risk and acquisition (Kouyoumdjian et al. 2013; Montgomery et al. *in press*; World Health Organization [WHO] 2001; Krug et al. 2002). Sexual violence can occur in a variety of settings by a variety of perpetrators. Frequent settings include the home, school, work, local neighborhood, health-care settings, and conflict settings. Likewise, perpetrators can range from strangers, intimate partners, relatives, colleagues, law enforcement, health-care providers, teachers, and fellow or opposing soldiers. Regardless of the setting or perpetrator, the mental and physical repercussions of sexual violence can be devastating and long lasting. Sexual violence can even result in death through HIV transmission, traumatic injuries, subsequent infections, suicide, and “honor” murders (Krug et al. 2002).

Intersection with HIV/AIDS

Many of the factors that increase risk for HIV are also associated with greater risk of experiencing sexual violence including alcohol and drug use, societal norms and beliefs about female oppression and male superiority, previous or childhood sexual violence, multiple sexual partners, poverty, and commercial, survival, and transactional sex work (Krug et al. 2002). The World Health Organization (2001) and extensive

peer-reviewed literature have examined the intersection between HIV and different forms of sexual violence including sexual assault (Draughon 2012), intimate partner violence (Gielen et al. 2007; Campbell et al. 2008; Kouyoumdjian et al. 2013), violence against women (Montgomery et al. *in press*; García-Moreno and Watts 2000; Maman et al. 2000; Manfrin-Ledet and Porche 2003; Meyer et al. 2011), and childhood sexual abuse (Senn et al. 2008). Across these reviews, several direct and indirect pathways between HIV and sexual violence have been identified. Sexual violence is directly related to HIV transmission through forced sexual intercourse with a person living with HIV. Risk of HIV exposure during unprotected nonconsensual sex is estimated to be higher than unprotected consensual sex because the likelihood of genital trauma is greater (Draughon 2012). HIV risk during sexual violence depends on the amount of physical force used, the extent and severity of the genital lacerations and abrasions, the location of the penetration (i.e., oral, anal, or vaginal), the amount of exposure to the virus through bodily fluids, and the age and gender of the survivor of the violent attack (World Health Organization 2004; Draughon 2012). Survivors of unprotected receptive anal rape are the most vulnerable to HIV transmission. Likewise, the vaginal tract of prepubescent girls can tear easily, which also puts them at increased risk for HIV transmission (Draughon 2012).

There are also several indirect pathways between sexual violence and HIV risk and acquisition (World Health Organization 2010). Survivors of sexual violence are more likely than individuals who have not experienced sexual violence to participate in HIV risk behaviors, including abusing alcohol and drugs, having multiple partners, having riskier sexual partners, participating in sex while using drugs or alcohol, engaging in transactional sex, and having unprotected sex with a partner who has an unknown or positive HIV status (World Health Organization [WHO] 2001; Krug et al. 2002; Manfrin-Ledet and Porche 2003; Koenig et al. 2004; World Health Organization [WHO] 2004; Senn et al. 2008). Furthermore, surviving sexual violence is associated with

higher sexually transmitted infection rates, which is associated with increased HIV risk (Gielen et al. 2007). Hypothesized reasons for this relationship include less sexual autonomy and poorer sexual risk negotiation skills. Additionally, survivors of sexual violence are more likely to report poorer mental health and psychological symptoms related to chronic anxiety, depression, and post-traumatic stress disorder (Senn et al. 2008). However, few studies have been able to test the temporality of these relationships, and therefore, causality has not been well-established (Campbell et al. 2008; Senn et al. 2008).

Implications

Given how HIV and sexual violence intersect, the World Health Organization suggests synergistically addressing sexual violence and sexual risk at multiple levels to amplify the effectiveness of HIV prevention programs (World Health Organization 2010). Behavior change interventions have taken place to assist HIV-positive and HIV-negative survivors of sexual violence and those at high risk for sexual violence (García-Moreno and Watts 2000; Sikkema et al. 2007; Senn et al. 2008; World Health Organization 2010; Chin et al. 2014). These interventions aim to reduce sexual risk by improving sexual risk negotiation skills, increasing consistent and correct condom use, and increasing HIV knowledge and awareness. Some concurrently aim to reduce drug and alcohol use, increase medication adherence, improve coping skills, address further risk of violence, and reduce traumatic stress.

Additionally, training on the intersection between sexual violence and HIV for law enforcement and health-care providers is recommended as an opportunity to aid survivors of sexual violence. For example, Sexual Assault Nurse Examiners are trained to deal with sexual assault and may be an avenue for reducing HIV risk through HIV-related counseling and education as part of post-rape care (Tufts et al. 2010). Another avenue is the use of post-exposure prophylaxis

immediately after potential HIV exposure (World Health Organization 2010). Screening for HIV or conversely for sexual violence during primary care visits or voluntary HIV-testing and counseling is another option that has not received much attention (World Health Organization 2010). Another option that may be especially effective is the use of programs that address the societal beliefs and norms about gender oppression and superiority which frequently support sexual violence, particularly against women (World Health Organization 2003, 2004).

Lastly, experiencing poverty and living in impoverished areas increase the risk of experiencing sexual violence and acquiring HIV (Goodman et al. 2009; Latkin et al. 2013). As a result, multi-level interventions that improve public awareness of the problem, economically and socially empower those most at risk for sexual violence, and promote legislation and policies that severely punish perpetrators of sexual violence regardless of the setting are all essential to address the devastating intersection between HIV and sexual violence (World Health Organization 2004).

Conclusion

Sexual violence and HIV intersect in many different ways on many different ecological levels. This intersection makes survivors of sexual violence a population at high risk for acquiring HIV. In addition to addressing the HIV-related and other health needs of survivors of sexual violence, national and international health agencies should make preventing both sexual violence and HIV top priorities. Public policymakers and HIV researchers should combat these co-occurring and mutually enhancing health and social problems in a comprehensive manner that addresses their multifaceted nature.

HIV and SIV, B-Cell Responses to

Susan Moir

Laboratory of Immunoregulation, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, MD, USA

Definition

Humoral immunity refers to the component of an immune response that is mediated by circulating antibodies. B cells secrete antibodies following differentiation into either short-lived plasmablasts, which can circulate, or long-lived sessile plasma cells that reside primarily in the bone marrow, but can also be found in mucosal tissues and the spleen. Classic memory B cells refer to cells that have encountered antigen, responded by undergoing somatic hypermutation

in the variable regions of their immunoglobulin genes with or without class switching (to IgG, IgA, or IgE) and returned to a resting state (Tarlinton and Good-Jacobson 2013). Upon reencounter with cognate antigen, memory B cells will rapidly respond by differentiating into plasma blasts/cells. HIV infection leads to numerous perturbations of the B-cell compartment that affect several developmental stages of maturation and differentiation. In the absence of antiretroviral therapy (ART), the resting memory B-cell compartment becomes depleted, and altered/activated memory B cells and plasmablast predominate. In advanced disease, there is an overrepresentation of immature/transitional B cells. The impact of these alterations on the humoral immune response to HIV is not completely understood, although recent advances in the investigation of antibodies derived from infected individuals have provided more insight into the dysregulation of this arm of the immune system.

Animal Models Used to Investigate HIV Infection and Associated Humoral Immunity

Studies on SIV in nonhuman primates, either in the setting of natural or induced infection, have helped advance the understanding of HIV infection and disease progression. Nonhuman primates offer several advantages, including being closely related to humans while providing the opportunity to study infection in natural and unnatural hosts that can be manipulated and followed from a known time point. However, there are also several limitations associated with SIV models for HIV disease (Brenchley and Paiardini 2011). Among these limitations are important differences between human and nonhuman primates that relate to immunophenotyping and functional attributes of B-cell subsets. For example, CD10 is one of the most useful markers to identify human immature/transitional B cells as well as germinal center B cells, yet there is no commercially available antibody to evaluate the expression of CD10 in nonhuman primates. Alternative markers of

immaturity such as CD24 and CD38, the latter of which is expressed in a complex and tightly regulated manner during human B-cell development, have not been well characterized in non-human primates. Furthermore, the reduced expression of the complement receptor CD21, an indication of B-cell abnormalities in HIV infection and other human disease settings (Moir and Fauci 2013), is a normal feature of a substantial fraction of memory B cells in uninfected healthy nonhuman primates. In contrast, memory B cells in SIV but not in HIV infection express significantly increased levels of PD-1, a marker of exhaustion that when blocked has been shown to improve the antibody response in treated animals. Finally, plasma blasts/cells, which are overrepresented in both HIV and SIV infection and associated with hypergammaglobulinemia, a hallmark of HIV/SIV infection, bear immunophenotypic features that are distinct to each species. These distinctions hamper the ability to compare differences in tissues and peripheral blood between the species, especially in the setting of SIV or HIV infection and disease progression. Finally, several HIV envelope proteins that are being used as probes to identify HIV-specific B cells with potent HIV-neutralizing potential have thus far not been extended to SIV infection. As an alternative, humanized mouse models have been developed and have provided important insight into the capacity of various HIV-specific antibodies to block HIV infection and/or restrict viral replication *in vivo* (Klein et al. 2013). As detailed below, the concept of passive immunization with recently described HIV-neutralizing antibodies has now been extended to SHIV models in nonhuman primates and HIV-infected individuals.

Early Phase of HIV Infection

It is very difficult to identify and investigate humans immediately upon HIV infection. However, a few studies have succeeded in describing early events following HIV infection with protocols that involve extensive and frequent screening of plasma in order to identify individuals who become positive for HIV RNA while negative

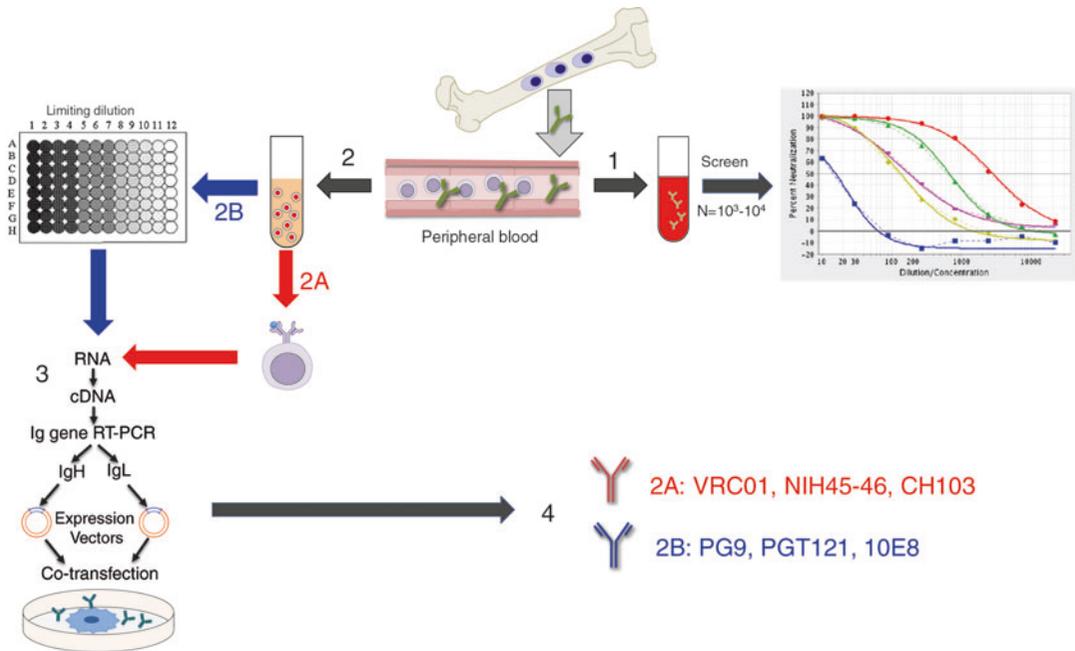

for HIV-specific antibodies. There is a ~12-day window between the time HIV RNA becomes detectable at ~10 days after transmission and the induction of humoral immunity against the virus, which begins with low affinity antibodies against structural proteins such as p24. During most acute viral infections, a strong innate immune response will precede and fuel the adaptive responses and generate a cytokine “storm,” of which the one induced by HIV infection is particularly strong (Cohen et al. 2011). Several of the cytokines induced during the acute phase of HIV infection target B cells; they include IP-10, IL-10, and IL-6. One of the corresponding early events of acute viral infections, as well as immunizations, is the transient appearance of plasmablasts in the peripheral blood at ~7 days postexposure, of which a variable percentage is pathogen-/immunogen-specific (Fink 2012). While there are no studies that have captured this burst of plasmablasts during acute HIV infection, these differentiated B cells are overexpressed in the peripheral blood during the early months of HIV infection.

Most of the plasmablasts found in circulation in acute/early HIV infection are not specific for the virus, likely reflecting the heightened level of nonspecific immune activation. The increased frequencies of plasmablasts in early as well as chronic phases of HIV infection are associated with hypergammaglobulinemia, suggesting that circulating plasmablasts are a source of these immunoglobulins. In this regard and despite the low frequencies of HIV specificity, circulating plasmablasts have been shown to be a source of antibodies against gp41, the transmembrane component of the HIV envelope, that appear in the blood a few weeks after transmission (Bonsignori et al. 2012). These early antibodies, which first appear complexed with virions, are non-neutralizing and do not drive escape mutations in the virus. Analysis of the gp41-reactive antibodies derived from circulating plasmablasts, as well as bone marrow plasma cells of recently HIV-infected individuals, revealed that they were highly mutated. However, these mutations are unlikely to reflect a response to HIV itself and more likely indicative of a polyreactive response

that arose from cross-reactivity with preexisting memory B cells, possibly against gut-derived antigens (Bonsignori et al. 2012). Polyreactivity is a common feature of HIV-specific antibodies, especially those directed against gp41, and it remains uncertain whether this feature is a desired or detrimental feature for neutralization (Klein et al. 2013; Bonsignori et al. 2012). Nonetheless, there is overwhelming evidence that the early antibody response against HIV is ineffective, and furthermore, once strain-specific neutralizing antibodies appear at approximately 80 days post-infection, escape mutations rapidly enable the virus to evade the autologous antibody response (Mascola and Haynes 2013). Paradoxically, it is the ongoing cat and mouse game that is thought to drive the induction of a broadly and potent neutralizing antibody response in approximately 20% of HIV-infected individuals, although the response provides limited clinical benefit to these individuals. However, it should be noted that while the antibody response is unlikely to contribute to long-term non-progression of disease, as has been shown for the CD8⁺ T-cell response in a certain percentage of ART-naïve individuals, there is nonetheless a possibility that antibodies can suppress viral replication and slow disease progression. In this regard, the majority of the highly potent and broadly HIV-neutralizing antibodies that have recently been identified were isolated from slow progressors (Mascola and Haynes 2013). As discussed below, passive immunization with such antibodies can significantly suppress viremia in HIV and SIV pre- and post-infection.

Chronic Phase of HIV Infection

The appearance of HIV strain-specific neutralizing antibodies coincides approximately with the transition to the chronic phase of infection. In the majority of ART-naïve individuals, this phase is associated with detectable viremia, accompanied by genetic diversification of HIV. At least a portion of this diversification is driven by antibody-mediated pressure. In turn, the heterogenic nature of the virus appears to also drive diversification of

HIV and SIV, B-Cell Responses to, Fig. 1 Strategies for isolating HIV-neutralizing antibodies. (1) Serum antibodies, most likely produced by plasma cells in the bone marrow, are screened for HIV-neutralizing activity. (2) Peripheral blood B cells are submitted to either (A) HIV-specific single B-cell sorting or (B) limiting dilution culturing. (3) The variable regions of immunoglobulin

heavy and light chains are amplified and cloned into vectors containing respective constant regions. The vectors are co-transfected into 293T cells, and supernatant containing the secreted antibodies is collected for analysis or purification. (4) Examples of HIV-specific antibodies and methods used to obtain the antibodies listed

the antibody response, which in a certain percentage of individuals (ranging from 10% to 30% depending on cohorts) leads to a broad and potent neutralizing antibody response (Klein et al. 2013; Mascola and Haynes 2013). Those individuals with the strongest responses, typically the top ~5% of cohorts, are referred to as “elite” neutralizers. It is important to note that this term refers to serologic activity and not to the clinical definition of elite non-progressors who are capable of maintaining aviremia in the absence of ART (Perreau et al. 2013). In addition, the HIV-neutralizing activity measured in the serum does not distinguish between an antibody response of single specificity and a response comprised of multiple specificities that in combination exhibit broad and potent neutralizing activity against the virus. With the advent of high-throughput technologies designed to screen large numbers of serum samples for neutralizing

activity against large panels of HIV isolates and advanced computational methods, there is now the capability of deciphering the components of neutralizing antibody responses without having to isolate each constituent (Kwong et al. 2013). However, monoclonal antibody reconstitution from single B cells remains the method of choice for definitive characterization of antibody activities. As described in more detail below, most of these single-cell analyses have been performed on memory B cells isolated from the peripheral blood of HIV-infected individuals whose serum had been prescreened for HIV-neutralizing activity.

High-throughput approaches that combine serum screening with single-cell dilution or isolation schemes have yielded a trove of new highly potent and broadly HIV-neutralizing antibodies (details in section “[Insight into Vaccine Development and Passive Immunization](#)” and Fig. 1). However, there appears to be few clinical

indicators, whether immunologic or virologic, that are predictive of individuals who are most likely to develop a potent and broad HIV-neutralizing antibody repertoire. Furthermore, even strong HIV-neutralizing antibody responses identified in elite neutralizers appear to be ineffective against their own virus. Nonetheless, the knowledge gained regarding the evolution of antibody responses in HIV-infected individuals and, most importantly, the identification of the germline antibodies that potentially initiated these responses are thought to be critical for the development of immunogens that could elicit similar response in uninfected individuals (Kwong et al. 2013). Such schemes could involve successive immunizations with different viral proteins, each designed to drive the memory B-cell response towards an increasingly more diverse and potent antibody response against HIV. This scenario would most likely involve memory B cells that had been elicited by the first immunogen being recruited to undergo further diversification in response to the next immunogen in the series. There is evidence from other pathogens, including influenza, that diversification and strengthening of virus-specific B-cell responses can occur over time, either from exposure to the pathogen itself or repeated vaccination with modified immunogens (Chiu et al. 2013).

There are several caveats to consider when developing an HIV vaccination scheme that is guided by the evolution of antibody responses in infected individuals. In a majority of ART-naïve individuals, their chronic phase of infection, while clinically asymptomatic, is accompanied by persistent immune activation that is manifested by several systemic alterations, including increased levels of inflammatory cytokines and other soluble factors. B cells are affected by chronic HIV viremia, as evidenced by persistent hypergammaglobulinemia and changes in circulating B-cell subsets, including antigen-experienced subsets. The circulating B-cell populations are quite distinct in HIV disease. Typically, resting memory B cells are depleted in HIV-infected chronically viremic individuals, whereas exhausted and activated memory B cells as well as short-lived plasmablasts are enriched when

compared to uninfected individuals (Moir and Fauci 2013). In addition, the presence of a persisting pathogen, such as HIV, is also associated with changes in secondary lymphoid tissues, including perturbations in the gut-associated lymphoid tissues (GALT) that likely fuel immune activation (Brenchley 2013). One of the more obvious consequences of HIV-induced immune activation is lymphoid tissue hyperplasia that is characterized by the presence of prominent germinal centers. While these histological observations were made decades ago on lymph nodes (Tenner-Racz and Racz 1995), it is only recently that hyperplasia in lymph nodes of HIV-infected individuals has been associated with increased numbers of CD4⁺ T follicular helper cells and germinal center B cells. Similar observations have been made in SIV-infected macaques. While there is some debate as to whether these conditions are helpful or harmful to the development of HIV-neutralizing antibodies (Ma and Deenick 2014), the persistence of virus is responsible for these changes and unlikely to be elicited and/or sustained following vaccination. Despite these differences, the advances made in understanding the antibody response in HIV-infected individuals and potential implications for vaccine development far outweigh the caveats mentioned here and elsewhere.

Advanced HIV Disease

Our understanding of B cells and the antibodies they secrete in response to HIV has advanced greatly over the past few years as it relates to the early and chronic clinically asymptomatic phases of infection. What has received less attention, and for good reason, is how such responses are affected by advanced HIV disease. Given the widespread availability of ART, even in developing countries, relevant observations on the effects of HIV disease progression on the antibody response to the virus are generally restricted to stored specimen or reinterpretation of earlier findings. The systemic changes that occur with advancing HIV disease would suggest a waning of immunity against the virus. Hyperplastic lymph

nodes become fibrotic, and the cell-cell interactions involved in maintaining immunity become restricted and impeded by increased collagen deposits (Zeng et al. 2012). These changes in lymphoid tissues are accompanied by notable systemic changes, including a reversal of hypergammaglobulinemia and increased levels of other soluble factors that are associated with hyperactivation. These declines are accompanied by increasing levels of factors associated with lymphopenia and loss of homeostasis, IL-7 being the most studied example. The paucity of memory B cells that begins in the early phase of HIV infection is exacerbated with advancing disease. As generalized lymphopenia progresses, immature/transitional B cells become more prominent in the peripheral blood and can be the major subset in individuals with CD4⁺ T-cell counts below 50 cells/ μ l. These B cells respond poorly to stimulation and are highly susceptible to intrinsic apoptosis (Moir and Fauci 2013). In this context, where CD4⁺ T-cell help is severely curtailed, B cells are unlikely to generate adequate responses against all pathogens, including HIV. At this stage of advanced disease, the circulating antibodies against HIV are most likely to originate from plasma cells that were seeding in the bone marrow in the years prior to disease progression. Despite these extreme alterations, recent studies conducted in SIV-infected monkeys indicate that even under conditions of severe lymphopenia, both cellular and humoral immunity can be enhanced by certain immunomodulatory interventions (Kulpa et al. 2013), suggesting that similar outcomes may be achieved in humans. In this regard, studies in advanced HIV disease suggest that the vast majority of individuals in advanced disease respond well to ART and can regain significant immunologic function (Deeks et al. 2013).

Effect of ART-Mediated HIV Suppression on B Cells

The vast majority of studies have shown that the reduction of HIV viremia by ART leads to a full or partial normalization of the B-cell compartment,

including an increase in resting memory B cells and a decrease in the more activated and differentiated subsets (Moir and Fauci 2013). However, there is also evidence that the reduction of HIV viremia by ART leads to decreased frequencies of HIV-specific B cells, indicating that at least part of B-cell immunity is sustained by ongoing viral replication. Nonetheless, there are several indications that it is not simply ongoing viral replication that drives HIV-specific B-cell responses, and little is known regarding the effect of decreased viremia on long-lived plasma cells, the cells in the bone marrow that are thought to be largely responsible for the antibodies that circulate in the blood. Furthermore, both the quantity and quality of B-cell responses are influenced by stage of infection and timing of ART. When ART is initiated in the early phase of infection, the resting memory B-cell compartment, both in terms of numbers and functional attributes, is better able to reconstitute itself than when ART is initiated during the chronic phase of infection (Moir and Fauci 2013). There are also indications that decreases in HIV-specific B-cell responses are not as precipitous in early treated individuals than in those individuals who initiate ART during the chronic phase of infection. Furthermore, whereas a majority of the HIV-specific response is contained within activated and exhausted memory B cells in untreated individuals, once HIV viremia is reduced by ART, these B cells disappear, whereas resting memory B cells, some of which are HIV-specific, are maintained or even expanded, especially in individuals who initiate ART early. However, these are preliminary observations that require further confirmation with analyses involving large and diverse cohorts of HIV-infected individuals. Nonetheless, these observations have implications for the overall immune competency of infected individuals and also for achieving sustained virologic remission where individuals would be able to stop ART and rely on their own immune system to prevent disease progression. While the antibody response alone is unlikely to prevent plasma viral rebound, a combination of humoral and cellular immunity with or without intermittent passive immunization may provide long-term “virologic remission” in

the absence of ART. It is in this unlikely yet possible future scenario that the maintenance of a competent memory B-cell repertoire against HIV would be very important.

Insight Into Vaccine Development and Passive Immunization

There are numerous virus- and host-related factors that have been identified as potential obstacles to the development of an effective HIV vaccine. While most of these factors are beyond the scope of this chapter, B cells of HIV-infected individuals and their derived antibodies have been a major focus of the renewed interest in an antibody-based vaccine. Prior to 2009, only a handful of HIV-neutralizing monoclonal antibodies had been characterized, all were derived from infected individuals, and all possessed unusual properties that were considered impediments relative to vaccine strategies (Kwong et al. 2013). Since 2009, several technical and computational advances have enabled the identification and synthesis of hundreds of HIV-specific monoclonal antibodies, many of which with breadths and potencies superior to the previous ones. The more recent crop of HIV-specific antibodies has been derived from circulating memory (IgG⁺) B cells of HIV-infected individuals, most of whom were identified by the screening of serum from a large number of individuals to identify those with broad and potent HIV-neutralizing antibody responses. These high-throughput screens, which test serum samples against panels of diverse HIV reporter strains, have led to the observation that approximately 20% of untreated HIV-infected individuals will develop a broad HIV-neutralizing antibody response during the chronic phase of infection.

Two approaches have been used to derive monoclonal antibodies from memory B cells of HIV-infected individuals (Fig. 1). One approach involves single-cell sorting and makes use of fluorochrome-labeled HIV envelope protein probes that bind to the B-cell receptor (BCR) of HIV envelope-specific B cells. One caveat to this approach is that the HIV envelope is known to bind non-BCR receptors on B cells. The variable

regions of the heavy and light chain immunoglobulin genes are then amplified, cloned into vectors that contain the constant elements of the human IgG1, and expressed/secreted in the human 293T cell line (Moir et al. 2011). Examples of antibodies derived with this approach include CD4 binding site-specific antibodies VRC01 and NIH45-46. The second approach involves performing limiting dilution followed by *in vitro* expansion of memory B cells isolated from pre-screened HIV-infected individuals. The end result is similar to that of the single-cell sorting approach in that monoclonal antibodies are derived from the clonally expanded B cells. Examples of such antibodies include PG9 and PG16 that recognize epitopes in the V1/V2 loops of gp120, the PGT series of antibodies that recognize peptidoglycan epitopes within the variable loops of gp120, as well as 10E8 that recognizes the membrane-proximal region of gp41.

A number of factors need to be considered when isolating HIV-specific antibodies from B cells of HIV-infected individuals. In the initial screening process, the antibodies being measured in serum likely originate from plasma cells that reside in tissues, either bone marrow or secondary lymphoid organs. However, the immunoglobulin genes that are isolated in the subsequent steps originate from memory B cells that circulate in the peripheral blood. There is an inherent assumption that the immunoglobulins secreted by plasma cells are related to those expressed on the surface of memory B cells as part of their BCR. This relationship remains largely unknown for HIV, whereas a direct link between antibodies secreted by plasma cells and the BCR of memory B cells has been observed for some pathogens, such as influenza, but not others (tetanus). Furthermore, current single-cell sorting strategies are somewhat limited by the nature of the probes and the ability of these probes to bind to HIV-specific BCRs at intensities that are clearly above background. Probes that identify CD4 binding site-specific B cells have been used with much success, but not all desirable epitopes, especially quaternary ones, within the HIV envelope can be targeted with this approach. Conversely, those antibodies derived from clonal dilution and *in vitro*

expansion will select those B cells that can survive and expand under the culture conditions used. In this regard, several subsets of B cells that are overrepresented in HIV-infected individuals and account for most of the HIV-specific response, including activated and exhausted memory B cells, are less likely to survive and expand during the *in vitro* selection process than resting memory B cells (Moir and Fauci 2013). Finally, there are concerns that the best neutralizing antibodies that have been derived from memory B cells of HIV-infected individuals involve an induction and maturation process that may be difficult to elicit in uninfected individuals following vaccination (Mascola and Haynes 2013). Several of the antibodies derived from infected individuals have properties that are not normally observed during an immune response, including polyreactivity and/or autoreactivity; long complementarity determining regions (CDR), especially CDR3 in the heavy chain; and extensively mutated variable regions in both heavy and light chains. There are also indications that mechanisms of tolerance and anergy are responsible for the rarity of certain antibodies that have potent neutralizing activities, including those directed against the membrane-proximal region of gp41 and antibodies that have long CDR3s. Nonetheless, the knowledge gained by investigating HIV-specific antibodies and B-cell responses in infected individuals has proven invaluable to the field and has prompted a search for vaccine strategies that would overcome the limitations described herein. As described above, one such strategy involves administering successive immunogens designed to direct the antibody response towards a desired outcome, whereas other strategies involve adjuvants and other immunomodulating agents designed to amplify responses or to overcome the negative selective forces of tolerance and/or anergy (Mascola and Haynes 2013).

The recent success in identifying highly potent and broadly HIV-neutralizing antibodies from infected individuals has also led to a renewed interest in passive immunization. The concept of preventing infection was first illustrated over a decade ago in the SIV model using relatively

large doses of neutralizing antibodies that were available at the time (Mascola and Haynes 2013). More recently, HIV viremia in infected individuals was decreased transiently, although again, this was with the older HIV-neutralizing monoclonal antibodies that were more weakly neutralizing when compared to the most recent ones described above. Over the past year, several studies performed in nonhuman primates and humanized mice have demonstrated that infection can be prevented, and viremia significantly reduced following infection, with relatively low concentrations of potent bNAbs, especially when several are administered in combination (Klein et al. 2013). In HIV-infected individuals, safety trials are being conducted with the latest generation of potent and broadly neutralizing antibodies, including VRC01. These trials are also designed to determine whether viremia can be decreased with these broad and potent HIV-neutralizing antibodies. The main purpose of these studies is to ultimately determine whether passive immunization can be used as a means of prevention or as a component of a combination strategy for maintaining HIV-infected individuals in remission.

Conclusions

Since 1983 when B-cell perturbations were first described in HIV-infected individuals, much has been learned regarding B-cell pathogenesis and hypergammaglobulinemia following infection. However, it is only with the recent emphasis on the antibody response to HIV in infected individuals that much progress has been made to better understand HIV-specific humoral immunity and to apply such knowledge towards the development of an effective antibody-based vaccine. While there is much to learn and much to do, this task does not seem as daunting and impossible as it did just a few years ago. As research efforts continue in this area, the outcomes are likely to provide new insight into the fundamentals of human immunology and possibly translate into new and ultimately successful approaches towards an effective HIV vaccine.

Definition

Immune responses to infections are a multifaceted interplay between different specialized cell types. These arms of the immune system are broadly divided into innate immunity, which is a rapid first line of defense that has limited specificity toward a particular pathogen, and adaptive immunity, which is delayed but develops with high specificity for pathogens, and once it is established, it has the potential for strong recall responses (immunological memory) (Abbas et al. 2012a). Successful cross talk between innate and adaptive immunity leads to effective immune responses and pathogen clearance. In HIV infection, however, defects in the function of both systems lead to ineffective immune responses that result into lack of viral control and chronic immune activation (Mandell et al. 2010).

CD4 T cells also known as T-helper cells (T_h) are cells of the adaptive immune system, and their main role is to orchestrate immune responses by fine tuning the cross talk between the innate and the adaptive immune systems (Abbas et al. 2012b). CD4 T cells are a subset of lymphocytes that develop and mature into the thymus, where a wide diversity in T-cell receptors (TCR) is generated. A given CD4 T cell expresses a single type of TCR, and it is the specificity of this TCR that determines what antigen the T cell can respond to. Naïve T cells then spread throughout the body and locate preferentially into lymphoid tissues, such as lymph nodes. CD4 T cells get activated when their TCR efficiently binds to an antigen presented on a major histocompatibility complex (MHC) class II molecule by an antigen-presenting cell (APC). This stimulation

of T cells by the TCR (primary signal) is modulated by a wide array of stimulatory or inhibitory secondary signals, including co-signaling surface molecules and cytokines (Abbas et al. 2012b). Upon antigen recognition and activation, CD4 T cells secrete cytokines that modulate function of other cells that contribute to innate immunity such as monocytes/macrophages, NK cells, and dendritic cells, which are highly effective antigen-presenting cells that bridge innate to adaptive immunity, as well as cells of the adaptive immune system such as B cells and CD8 T cells. When activated, undifferentiated interleukin-2 (IL-2)-secreting CD4 T cells will differentiate into several CD4 subsets that are categorized according to the cytokine they produce (Abbas et al. 2012a; Abbas et al. 2012b). The two main subsets that were initially described are the Th1 CD4 T cells, which secrete interferon- γ (IFN γ) and tumor necrosis factor- α (TNF- α) and modulate cell-mediated responses, and the Th2 lymphocytes, which predominately produce IL-4, IL-5, and IL-13 and regulate humoral immune responses. Another CD4 T-cell subset is the Th17 cells that secrete IL-17 and are important in regulating antibacterial and antifungal functions in the tissues. More recently, a new CD4 T-cell subset has been identified that resides in the lymph nodes and produces among others high levels of IL-21. This CD4 T-cell subset, also known as T-follicular helper (Tfh) CD4 T cells, modulates germinal center formation and provides help to B cells for the generation of antibodies (Abbas et al. 2012b). Newer data have challenged the traditional model of stably defined and separate CD4 T-cell lineages. CD4 T-cell differentiation appears to have a higher plasticity than initially thought, with many CD4 T cells presenting mixed phenotypes and functions and being influenced by their environment in body tissues.

CD4 T-Cell Depletion in HIV Infection

One of the first immunologic disorders characterized in HIV infection is the marked reduction in CD4 T-cells counts that leads to impaired immune functions and progression to AIDS. The loss of

CD4 T cells has been the focus of intense research that so far indicates a multifactorial basis: (1) direct destruction of HIV-infected CD4 T cells, (2) viral proteins that cause apoptosis of uninfected CD4 T cells, (3) abnormally high levels on immune activation that leads to activation-induced cell death of CD4 T cells, and (4) impaired renewal of the established pool of CD4 T cells (Levy 2007; Porichis and Kaufmann 2011). Recent studies have identified a novel mechanism of uninfected CD4 T-cell depletion where CD4 T cells that are abortively infected by HIV proceed to programmed cell death that is triggered by the abortive infection (Levy 2007). A massive destruction of memory CD4 T-cell populations, in particularly of those located in the gut-associated lymphoid tissue (GALT), occurs at the time of acute HIV infection, and this defect is only partially corrected by antiretroviral therapy (ART) (Mandell et al. 2010). Detailed tissue studies in nonhuman primates such as rhesus macaques infected by the simian immunodeficiency virus (SIV) have been particularly revealing in this regard. It is very likely that this extensive damage also cripple the HIV-specific CD4 T cell very early in infection. This defect in mucosal CD4 T-cell immunity is thought to play an important role in the ongoing translocation of bacterial products observed in HIV infection (Haase 2010). This phenomenon contributes to chronic immune activation with deleterious effects on the immune system and other complications such as accelerated cardiovascular disease (Mandell et al. 2010).

Consistent with this critical role played by the damage to the CD4 T-cell compartment in HIV pathogenesis, it was shown that elite controllers, who are rare individuals that achieve spontaneous control of HIV infection in the absence of ART, have the ability to maintain persistent functional memory T cells that are critical for long-lasting protection after exposure to pathogens, in contrast to individuals with progressive chronic HIV infection (chronic progressors or CP). Elite controllers preserve central memory (T_{cm}) CD4 T cells that have higher expression of IL-7 receptor. IL-7 is a critical cytokine that regulates T-cell homeostasis

and progressive, HIV infection is correlated with lower responsiveness to IL-7. Therefore, the higher expression of IL-7 receptor in CD4 T cells from elite controllers favors maintenance of these cells in contrast to chronic HIV-infected subjects that have CD4 T cells with low IL-7 receptor, which leads to reduced sensitivity to IL-7 and increased CD4 T-cell loss. Additionally, it was shown that in chronic HIV infection, deposition of collagen in lymphoid tissues resulted in reduced accessibility of T cells to IL-7 on the fibroblastic reticular cell network leading to enhanced CD4 T-cell depletion in these tissues. Administration of IL-7 in ART-treated subjects suggested a possible benefit of this cytokine as treatment to restore CD4 numbers in individuals whose immune system shows suboptimal restoration in spite of effective antiviral therapy, but clinical gains remain to be demonstrated.

Class II Recognition of CD4 T Cells

CD4 T cells utilize a heterodimeric cell surface protein, the T-cell receptor (TCR), to recognize foreign antigens bound to the human leukocyte antigen (HLA) class II molecules on antigen-presenting cells. The antigens parts presented on HLA molecules, or epitopes, are typically small chains of amino acids (peptides) that derived from proteins (Abbas et al. 2012a, 2012b). HLA class II molecules can accommodate larger peptides, 12–24 amino acids long, than class I molecules that are recognized by CD8 T cells and typically bind to epitope that are 8–11 amino acid long. The HLA molecules are highly diverse in human populations and genetically inherited from both parents. Their structure determines which antigen they can present which in turn can influence the ability of an individual to mount an effective T-cell immune response to a given pathogen or to develop specific diseases, e.g., the risk to develop certain types of autoimmune diseases. In the setting of HIV infection, some specific HLA class I alleles, in particular HLA-B*2705 and HLA*B5701/03, have been shown to be

associated with better outcome. In contrast, data on HLA class II alleles have been far less conclusive, although some studies suggest that some HLA class II molecules such as HLA-DRB1*13, HLA-DRB1*1502, and HLA-DQB1*06 are associated with immune control and/or more robust and functional HIV-specific CD4 T-cell responses (Porichis and Kaufmann 2011). This lack of strong association does not prove a weaker role for HIV-specific CD4 T-cell responses in viral control, as many CD4 T-cell epitopes can be presented by multiple HLA class II molecules, contrasting with a more specific binding repertoire for HLA class I molecules and CD8 T-cell responses. The fact that the same HIV epitopes can be broadly recognized by CD4 T cells in genetically diverse human populations may be useful for future development of an HIV vaccine with a broad population coverage.

Function of HIV-Specific CD4 T Cells

Although a number of studies in animal infectious disease models and humans suggest that effective HIV-specific T-helper responses will be critical both for control of viral replication in infected people and for development of an effective preventive vaccine, knowledge is currently still largely lacking on which specific functions are required for protective immunity (Porichis and Kaufmann 2011). Like in many other human studies, when investigations identify differences in characteristics of HIV-CD4 T-cell-specific responses in subjects who are able to maintain low levels of viremia as compared to people with progressive disease, it is difficult to tell apart factors that can contribute to better disease outcome from consequences of a better preserved immune system (Younes et al. 2003). In most infected individuals, HIV-specific CD4 T-cell responses are impaired early in the course of HIV infection. Some studies demonstrating preferential infection of HIV-specific CD4 T cells by HIV as compared to T-helper cells from other specificities, such as CMV, raised the concern that eliciting HIV-specific CD4 T-cell responses

by vaccines or immunotherapeutic strategies could fuel viral replication and have detrimental consequences for infected individuals (Douek et al. 2002). However, the initial notion that HIV-specific CD4 T cells are preferentially infected and as a consequence are depleted from the circulation is now being revisited since the large majority of HIV-specific CD4 T cells are not infected *in vivo*. Even though CD4 T-cell depletion is indeed a major reason for the collapse of the immune system at the later stages of HIV infection, it was shown that CD4 T cells lose their functionality before substantial CD4 T-cell depletion. The proliferative capacity of HIV-specific CD4 T cells was one of the first functions shown to be diminished in chronically HIV-infected subjects. It was later shown that the reduced proliferative capacity was a consequence of reduced IL-2 secretion by HIV-specific CD4 T cells. HIV-specific CD4 T cells in elite controllers have a greater capacity to proliferate *in vitro* compared to subjects with progressive HIV disease, suggesting a stronger capacity to mount secondary immune responses. Even though the magnitude of HIV-specific CD4 T cells as measured by IFN γ secretion did not correlate with viremia, elite controllers were found to have more HIV-specific CD4 T cells that are polyfunctional, i.e., are capable to produce multiple cytokines at the same time, than those of subjects with progressive HIV disease. However, detailed studies comparing HIV-specific CD4 T-cell responses in untreated individuals and people efficiently treated with ART showed that the functional profiles of the T-helper responses get closer to those of elite controllers once viremia is suppressed by therapy, suggesting that most of these differences are a consequence, rather than a cause, of viral control (Harari et al. 2004). Of note, a significant proportion of elite controllers maintain robust HIV-specific CD4 T-cell responses in spite of undetectable viral load (Ferre et al. 2010), whereas an attrition of these responses is seen once chronic progressors are put on therapy. This antigen dependence is classical of dysfunctional T-cell responses in chronic infection and has also been well described in animal models of chronic infection (Virgin et al. 2009).

Cytolytic CD4 T Cells

The majority of HIV-specific CD4 T cells in the blood produce IFN γ , TNF α , and IL-2, suggesting dominant antiviral Th1 responses in the absence of detectable Th2 cytokine secretion such as IL-4 or IL-13. Even though the main function of CD4 T cells is to orchestrate immune responses through cytokine secretion, recent studies have highlighted the ability of some CD4 T-cell subsets to kill infected cells either through direct cytolytic activity mediated by perforin or through Fas/Fas ligand-induced apoptosis. Cytolytic CD4 T cells have been observed in many chronic viral infections such as Epstein-Barr virus (EBV), hepatitis C virus (HCV), influenza virus, and cytomegalovirus (CMV). The most compelling data were derived from the lymphochoriomeningitis virus (LCMV) mouse model where LCMV-specific CD4 T cells with cytolytic activity killed virally infected cells *in vivo* and contributed to control of LCMV infection.

Cytolytic CD4 T cells have also been reported in HIV infection, although their importance in controlling the infection and the actual targets are still not well understood. Some of the first studies identified HIV-specific CD4 T-cell clones that showed potent killing capacity of HIV-envelope pulsed B cells *in vitro*. However, the fact that these cells were cultured for a long time *in vitro* in conditions that may favor certain functions raised the question whether HIV-specific CD4 T cells exist and could play a role *in vivo*. Ex vivo killing assays showed that both HIV- and SIV (simian immunodeficiency virus)-specific CD4 T cells have the ability to kill target cells pulsed with HIV or SIV peptides. Studies in SIV infection of nonhuman primate models suggested a preferential killing of macrophages over infected CD4 T cells that may arise by the high expression of HLA class II molecules on the surface of macrophages (Sacha et al. 2009). Infected CD4 T cells downregulate class I HLA molecules as a result of expression of viral proteins such as NEF and may therefore be more resistant to killing by cytotoxic CD4 T cells. Thus, cytolytic CD4 T cells might complement the activity of their CD8 T-cell counterpart for

specific infected cell subsets. A more recent study showed that cytotoxic activity of CD4 T cells, as measured by granzyme A, correlated with slower disease progression in HIV-infected subjects (Soghoian et al. 2012). This may suggest a role of cytolytic HIV-specific CD4 T cells in controlling infection or, as discussed above, may reflect a better preservation of some immune functions in subjects with favorable outcome.

T-Follicular Helper CD4 Cells

Another CD4 T-cell population that has gained focus in recent years is the T-follicular helper CD4 T-cell subset. Tfh cells reside in lymphoid follicles within lymphoid organs and exert their function within the germinal centers (GCs), which are the anatomic compartment where B cells and Tfh cells come in contact. Tfh cells are specialized CD4 T cells that provide help to antigen-specific B cells to support their differentiation and antibody class switching and secretion. They were initially identified by their high expression of B-cell zone homing CXC chemokine receptor 5 (CXCR5) (Abbas et al. 2012a). Subsequent studies characterized Tfh cells by the combined expression of CXCR5 with co-stimulatory molecules such as ICOS, CD40L, and the inhibitory receptor programmed cell death protein-1 (PD-1). Tfh cells in the germinal centers express high levels of the transcriptional repressor B-cell lymphoma 6 (BCL-6), and they secrete the cardinal cytokine IL-21.

T-follicular helper cells have drawn a lot of attention in the past few years due to their critical role in antibody development. Broadly neutralizing antibodies, whose generation is thought to be critical for any effective HIV vaccine, exist only in a small number of HIV-infected individuals. Their development requires the accumulation of a series of amino acids mutations during antibody maturation that occurs over an extended period of time. It is therefore very likely that vaccines aiming at eliciting broadly neutralizing antibodies need to accommodate strong, long-lasting Tfh responses that will help create functional germinal centers and provide constant help to B cells until

the generation and maturation of broadly neutralizing antibodies is achieved (Abbas et al. 2012a).

In HIV and SIV infections, a number of studies showed an accumulation of Tfh cells in the lymph nodes during chronic HIV and SIV infections. The increase in Tfh frequency was correlated with plasma viremia, the number of GCs, the frequency of plasma cells, and the onset of hypergammaglobulinemia suggesting a direct functional impact of Tfh cells on humoral responses during chronic HIV and SIV infection (Lindqvist et al. 2012; Petrovas et al. 2012). A recent study showed that even though Tfh cells frequencies are increased in chronic infection, they are dysfunctional, leading to deregulated help to B cells (Cubas et al. 2013). The increase in Tfh CD4 T-cell numbers contrasts with the general depletion of CD4 T-cell subsets occurring in HIV infection. Tfh cells were found to be susceptible to infection with HIV and SIV, and human Tfh were shown to support high levels of viral replication and contained more copies of HIV DNA than other CD4 memory subsets, suggesting that they may serve as preferential reservoir of the virus (Perreau et al. 2013). One of the explanations for the expansion of Tfh cells is that ongoing viremia may drive a Tfh cell differentiation of CD4 T cells. This hypothesis is supported by the fact that antiretroviral therapy reduces the frequency of HIV-specific Tfh cells. The effect of viral persistence could be further augmented by changes in cytokine levels that include increased IL-6 and reduced IL-2 production in chronic progressive HIV disease. Tfh cells express high levels of IL6 receptor and therefore are sensitive to IL-6 signaling that is one of the most potent inducers of Tfh differentiation. At the same time, IL-2 is a major negative regulator of Tfh differentiation, and the lack of IL-2 due to T-cell exhaustion along with high levels of IL-6 and ongoing antigenemia may be driving CD4 T-cell responses toward a Tfh phenotype.

The capacity to identify memory Tfh cells in the periphery (pTfh) is a golden fleece of current research since it would be an extremely valuable measurement to monitor responses to candidate vaccines. Many research groups have used several markers to identify pTfh, but there is currently no

consensus in the field, resulting in sometimes contradictory results in published studies. In HIV infection, a recent study identified PD-1⁺CXCR5⁺CD4⁺ T cells to be the population in peripheral blood most closely related to germinal center Tfh. The authors further subcategorized this subset and found that PD-1⁺CXCR5⁺CXCR3⁻ CD4 T cells have a transcriptional profile close to GC Tfh and provided better help to B-cell differentiation in *in vitro* assays than the other CD4 T-cell subsets tested. More importantly, they showed that this population correlated with development of broadly neutralizing antibodies against HIV in subjects with chronic infection (Locci et al. 2013). However, this correlation was established with the total frequencies of PD-1⁺CXCR5⁺ CXCR3⁻ CD4 T cells, not HIV-specific CD4 T cells within this population, whose detection appears very challenging with currently available assays. Thus, the contribution and the functional characteristic of peripheral HIV-specific Tfh CD4 T cells to foster development of broadly neutralizing antibodies remain unclear.

Regulatory T Cells

As discussed above, the main role of CD4 T cells is to orchestrate immune responses. Most CD4 T-cell subsets secrete cytokines to activate cells of the innate and adaptive immune system. However, an important function of CD4 T cells is not only to stimulate immune responses but also to regulate immune activation. The balance of immune activation and immune inhibition is critical in order to prevent excessive immune activation and thus protect the host tissues from immune-mediated damage. Regulatory T cells (Tregs) are CD4 T cell with suppressive effects (Chevalier and Weiss 2013). Their main role is to inhibit effector function of innate and adaptive immune cells (Abbas et al. 2012b). Tregs are characterized by high expression of IL-2 receptor alpha (IL-2R α or CD25) and transcription factor FoxP3. Although Tregs have been shown to play a critical role in suppressing autoreactive responses, their role in HIV infection is still controversial. Tregs could potentially be beneficial by inhibiting

excessive immune activation and the generation of new activated CD4 T cells that are vulnerable targets for the HIV virus. Conversely, they could be detrimental by inhibiting HIV-specific immune responses, thus contributing to ineffective viral clearance. Studies in the SIV macaque model indicated that early Treg response was associated with persistent inhibition of T-cell responses enhanced viral replication and disease progression (Chevalier and Weiss 2013). Tregs were shown to inhibit HIV-specific T-cell responses *ex vivo*. More recently, HIV-specific Tregs were identified using class II tetramer staining and flow cytometry, although their frequency was extremely low. Further studies are needed to specify their function. Initial work looking at the frequency and numbers of Tregs in the periphery of HIV-infected subjects also showed sometimes contradictory results. More recent studies rather suggest an increase in the frequency of Tregs in peripheral blood. However, the main anatomic compartment where Treg exert their function is in tissues, in particular in the gut-associated lymphoid tissues (GALT), where a tight control of inflammation is critical given the constant exposure to the gut bacterial flora (Nilsson et al. 2006). Studies in the SIV macaque model and subsequently in HIV-infected human subjects showed enhanced frequencies of Tregs in the lymph nodes and tonsils. Whereas specific modulation of Treg responses by therapeutic interventions in HIV infection might have a beneficial effect is currently unknown.

T-Cell Exhaustion

In HIV infection, like in other chronic viral diseases, there is a progressive loss of T-cell functions, also known as T-cell exhaustion, which leads to ineffective immune responses and defective viral clearance. Virus-specific T-cell proliferation and IL-2 secretion are among the first functions to be impaired, whether other effector functions such as IFN γ secretion are lost at later stages of the disease (Wherry 2011). T-cell dysfunction is a result of extrinsic negative regulatory pathways, such as immunoregulatory cytokines, e.g., IL-10, and cell-intrinsic inhibitory pathways,

such as inhibitory receptors on the surface of CD4 T cells.

One of the first inhibitory pathways implicated in CD4 T-cell dysfunction was the PD-1 receptor. PD-1 is an inhibitory molecule of the B7:CD28 family and modulates the signal given by the TCR. It is upregulated on HIV-specific CD4 T cells, and its expression was correlated with markers of HIV disease progression, positively with the viral load and negatively with the CD4 count (Day et al. 2006; Porichis et al. 2011). Blockade of the PD-1 pathway *in vitro* using blocking antibodies restored proliferation and cytokine secretion by HIV-specific CD4 T cells. Interestingly, blockade of the PD-1 pathway was found to be effective, although to a lesser extent, in ART-treated subjects suggesting a potential role of immunotherapeutic interventions targeting this pathway as an adjuvant to antiviral treatment to improve HIV-specific immune responses (Porichis et al. 2011). More recently, PD-1 was shown to regulate function of Tfh cells, and blockade of the PD-1 pathway restored HIV-specific Tfh help to B cells resulting to enhanced HIV-specific immunoglobulin production *in vitro* (Cubas et al. 2013).

Besides PD-1, a complex network of inhibitory receptors has been identified as contributing to HIV-specific CD4 T-cell dysfunction. At the same time, as PD-1 was identified as one of the major inhibitory pathways, another member of the B7:CD28 family, the inhibitory receptor CTLA-4, was also shown to play a critical role in CD4 T-cell dysfunction. Similar to PD-1, CTLA-4 is upregulated on HIV-specific CD4 T cells and mediated a reversible T-cell dysfunction (Kaufmann et al. 2007). However, in contrast to PD-1 that regulates both CD4 and CD8 T-cell responses, CTLA-4 was shown to be specific for CD4 T-cell responses as it had lower expression on HIV-specific CD8 T cells and had minimal impact on their dysfunction. Further studies identified showed that coexpression of PD-1, CTLA-4, and another co-inhibitory receptor, TIM-3, was linked to more exhausted HIV-specific CD4 T cells. Further investigations confirmed that the HIV-specific CD4 and CD8 T-cell subsets are regulated by different set of inhibitory coreceptors: in contrast to HIV-specific CD8

T cells, CD4 T responses do not express significant levels of the inhibitory molecules CD244, LAG-3, and CD160 (Porichis et al. 2011).

Chemokines and cytokines are also major immunoregulatory pathways and in combination with the inhibitory receptors form a complex network that regulates HIV-specific CD4 T-cell function. IL-10 is a cytokine shown to play a critical role in immunopathogenesis of HIV infection. IL-10 plasma levels are increased in HIV infection and correlate with markers of disease progression. Even though IL-10 is produced by multiple cell subsets, monocytes appeared to be the major producers in the setting of HIV infection. Blockade of IL-10 pathway *in vitro* restores proliferation and cytokine secretion by HIV-specific CD4 T cells. However, IL-10, through dampening of chronic immune activation, may also have positive effects in HIV infection. Recent studies showed a link between IL-10 and the PD-1 pathway, where triggering of PD-1 on the surface of monocytes resulted in enhanced secretion of IL-10 (Said et al. 2010). It is important to note that inhibitory pathways can have qualitatively different effects on CD4 T-cell functions. As a consequence, combining PD-1 and IL-10 blockade *in vitro* has a strong additive impact on some HIV-specific CD4 T-cell functions but not others. In the cancer field, tremendous progress has been made in the clinical use of inhibitory pathway blockade (such as PD-1 and CTLA-4) to restore T-cell functions of exhausted cells and combat tumors. Clinical trials will be needed to assess whether such interventions could be a useful adjunction to standard antiviral therapy in HIV-infected patients, in particular to improve CD4 T-cell functions or help reduce viral reservoirs.

Conclusion

Effective HIV-specific or SIV-specific CD4 T-cell responses are likely important for long-standing control of viral replication once infection is established and will likely be critical to elicit protective immune responses by a preventive HIV vaccine. HIV-specific CD4 T-cell responses have been the focus of renewed research efforts after early hopes that vaccine trials emphasizing

generation of virus-specific CD8 T cells failed to show efficacy. Although important research efforts are still needed to identify protective components of the T-helper response against HIV, progress has been made to characterize in-depth these responses and their link to evolution of HIV disease. It is very likely that potent HIV-specific CD4 T-cell responses will need to act in concert with other arms of the adaptive immune responses such as antibodies and CD8 T cells as well as effective stimulation of innate immunity will be required to design effective preventive vaccines and, possibly, therapeutic vaccines to achieve HIV cure in infected people.

²Howard Hughes Medical Institute, Chevy Chase, MD, USA

Definition/Introduction

HIV infection is associated with widespread infection of both circulating and tissue CD4 T cells,

with initial viral loads peaking at five to ten million HIV RNA copies/ml plasma within weeks of exposure. This is followed by a rapid decline in plasma virus to a median “viral set point” of around 30,000 HIV RNA copies/ml. Importantly, studies in humans infected with HIV and monkeys infected with SIV indicate that CD8 T lymphocytes are pivotal to this dramatic decline in viral load, yet the progressive dysfunction of the CD8 T lymphocyte population over time leads to a subsequent increase in viral load and progression to AIDS. CD8 T lymphocytes are a white blood cell subset of the adaptive immune system, which recirculate between the blood and peripheral lymphoid organs. The main role of CD8 T lymphocytes is to recognize and kill infected target cells that harbor intracellular pathogens; therefore, those targeting HIV are defined as HIV-specific CD8 T cells. Understanding the potent antiviral function of HIV-specific CD8 T cell responses and the factors that lead to their dysfunction has important implications for the development of therapeutic and prophylactic HIV/AIDS vaccines.

Frequency of HIV-Specific CD8 T Cells

The emergence of HIV-specific CD8 T cells is strongly associated with the initial decrease of HIV viral load to set point, and several studies have shown that HIV-specific CD8 T cell responses can also control HIV replication during chronic infection. Yet, the correlates of a protective HIV-specific CD8 T cell response remain poorly defined (Walker and McMichael 2012). Early studies focused on the quantity of CD8 T cell responses in HIV-infected persons. Importantly, in vitro assays analyzing their lytic function (including chromium release assays, viral suppression assays) or ex vivo binding to HLA class I tetramers (tetrameric complexes of peptide-HLA, bound to a labeled streptavidin bead) consistently detected robust CD8 T cell responses in the peripheral blood of HIV-infected individuals. In some HIV-infected individuals, the percentage of HIV-specific CD8 T cells could be 10–20% or more of the total CD8 T cell population, yet

control of virus was not consistently observed in these individuals. Collectively, these studies were in general agreement that there are no significant differences in the frequencies of HIV-specific CD8 T cells between “HIV controllers” (chronically infected individuals who can spontaneously control HIV in the absence of antiretroviral drugs) and “HIV progressors” (chronically infected individuals who progress to AIDS in the absence of antiretroviral drugs) (Walker and Yu 2013). Furthermore, detailed characterization of the specificity of CD8 T cell targeting of different HIV peptides (using IFN γ ELISPOT assays) has also failed to correlate the magnitude or breadth of HIV-specific CD8 T cell responses with better control of viremia. Together, the findings from numerous laboratories indicate that HIV-specific CD8 T cell activity is influenced by quality rather than merely the quantity of the response alone. Consequently, efforts have focused on the search for the key qualitative determinants of HIV-specific CD8 T cell efficacy.

Function of HIV-Specific CD8 T Cells

Cytotoxic T Cells

A key function of CD8 T cells is to recognize pathogen-derived peptides presented by HLA class I molecules on the surface of infected cells and kill those infected cells by cytolytic/cytotoxic mechanisms, thereby eliminating the intracellular pathogen. Therefore, CD8 T cells are often referred to as “cytotoxic T lymphocytes” (CTL) in the scientific literature. In order to kill the infected cell, CTL cells must adhere tightly to the infected cell, with the formation of an “immunological synapse” at the site of contact. Activated CTL then release their granule contents by exocytosis, which induces cell death of the infected target cells. The two main types of granule protein released by activated CTL are granzymes and perforin. In the setting of HIV infection, several studies have suggested that CTL in “HIV controllers” demonstrate a superior ability to upregulate perforin (ex vivo after antigen stimulation and in vitro proliferation) and that lytic granule loading and delivery of granzyme B from CTL into

infected target cells were statistically more pronounced (Migueles et al. 2008). This is concordant with studies demonstrating that CTL from “HIV controllers” are better able to inhibit HIV replication. However, it is worth noting that many of these studies are conducted in in vitro culture conditions, which may not represent the ex vivo activity of these cells. Direct measures of cytotoxic activity have been difficult to achieve, especially in a physiologically relevant setting. Further research is required, but the ability of CTL from HIV controllers to upregulate perforin and enhance their cytotoxic capacity may represent the functions most clearly associated with immune control.

Polyfunctionality

Another important attribute of HIV-specific CD8 T cell antiviral activity is the mixture of cytokines and chemokines released. The ability of HIV-specific CD8 T cells to proliferate upon antigen encounter, a property allied to the production of the cytokine IL-2, has been associated with HIV control. In addition, it has been shown that HIV-specific CD8 T cells secreting TNF α and IFN γ cytokines in tandem, rather than IFN γ alone, have enhanced cytolytic activity. Recently, several investigators have used multiparameter flow cytometry to analyze multiple effector functions simultaneously and have thus identified “polyfunctionality” as a strong correlate of CTL antiviral efficiency (Betts et al. 2006). “Polyfunctionality” typically describes the capacity of these cells to degranulate (CD107a) and simultaneously produce multiple cytokines and chemokines including IFN γ , TNF α , IL-2, and MIP-1 β . These studies found that polyfunctional secretion by HIV-specific CD8 T cells was significantly more frequent in “HIV controllers” than in “HIV progressors,” whose CD8 T cells largely secreted only IFN γ . Thus, these groups recorded an inverse correlation between polyfunctionality and viral load. However, it is not clear whether polyfunctionality is a cause or consequence of immune control. More recent studies comparing chronically infected HIV individuals (with prolonged antigenic exposure in the absence of antiretroviral drugs) and HIV individuals on

antiretroviral treatment (with drug-suppressed viral loads and consequently low antigen levels) have suggested that polyfunctional HIV-specific CD8 T cell profiles may simply reflect the consequence of a better-preserved immune system, rather than the cause.

Functional Avidity and TCR Usage

Another CD8 T cell effector function that has received much attention is “functional avidity,” the affinity of the TCR for peptide presented by HLA. Several authors have demonstrated a correlation between enhanced functional avidity of HIV-specific CD8 T cell responses and a reduction in HIV viral load. It has been theorized that high levels of antigen sensitivity enable HIV-specific CD8 T cells to recognize peptide-HLA complexes at low density, readily triggering effector functions such as perforin, granzymes, and cytokines, which correspond to rapid and effective killing capacity against infected target cells. However, this remains controversial with many others finding no correlation between functional avidity and functional output. Other factors may also be important, including the specific TCR clonotype usage, with some TCR clonotypes associated with enhanced effector functions and superior HIV control.

CD8 T Cell Exhaustion

During the course of HIV infection, like in other chronic viral infections, CD8 T cell functions such as cytokine secretion, cytotoxicity, and proliferation diminish gradually. This progressive loss of CD8 T cell effector functions is referred to as “immune exhaustion.” These dysfunctional HIV-specific CD8 T cells were described early in the HIV epidemic and have been associated with the inability of the immune system to clear HIV infection.

Programmed death-1 (PD-1) was one of the first inhibitory receptors to be implicated with immune exhaustion. PD-1 is an inhibitory molecule of the B7:CD28 family that is expressed on both CD8 and CD4 T cells, among other immune cells. PD-1 expression on HIV-specific CD8 T cells is positively correlated with HIV viral load and progression to disease (Day

et al. 2006), although observations suggest that these phenotypic changes are the end result of persistent antigenic stimulation, rather than the direct cause of high viral loads. Importantly, blockade of the PD-1 pathway (in rhesus macaque monkeys chronically infected with SIV) resulted in the recovery of virus-specific CD8 T cell responses, including improved cytokine secretion and enhanced proliferation. These studies not only demonstrated that blockade of PD-1 signals can reverse immune dysfunction but also demonstrated the potential efficacy of blocking inhibitory pathways in future immunotherapeutic approaches to restore T cell function. Further research on inhibitory pathways such as PD-1, in addition to immunoregulators LAG-3 and TIM-3, is needed to better understand how immune exhaustion contributes to HIV pathogenesis and whether blocking of such pathways could be useful in addition to standard antiretroviral therapy in HIV-infected individuals.

CD8 T Cells and HLA Class I

CD8 T cells recognize and kill cells that harbor nonself proteins and thus are a major defense mechanism against invading viruses. To initiate antiviral activity, CD8 T cells first require a signal from the infected cell. This signal is a virus-derived peptide displayed by a major histocompatibility molecule (MHC) class I molecule on the infected cell surface. Each T cell expresses a unique T cell receptor (TCR) capable of recognizing viral peptide bound to MHC molecules. Classically, the T cell paradigm dictates that CD8 T cells recognize short viral peptides of 8–11 amino acids in length bound to MHC class I molecules (while CD4 T cells recognize longer peptides of 12–24 amino acids bound by MHC class II molecules). In humans, MHC molecules are referred to as human leukocyte antigens (HLA). The HLA locus is the most polymorphic region of the human genome. HLA molecules are genetically inherited from both parents, which each individual inheriting up to six different HLA class I molecules (two HLA-A, two HLA-B, and two HLA-C; homozygosity can be

present, making the total number of distinct class I molecules less than six).

Interestingly, numerous cohort studies have shown strong associations between the expression of certain HLA class I molecules and disease outcome (Walker and Yu 2013). In particular, some HLA class I genes are linked with individuals who succumbed quickly to AIDS, while other HLA class I genes are associated with individuals called “HIV controllers” who spontaneously maintain low viral loads, in some cases for decades, without requiring antiretroviral drug treatment. Most of these associations are in HLA-B alleles, most notably with expression of HLA-B*57 and/or HLA-B*27 associated with better control of HIV in “HIV controllers” and expression of HLA-B35 variants associated with faster progression to AIDS-like disease (Goulder and Walker 2012). In particular, a large-scale genome-wide association study (GWAS) enrolling nearly 1,000 “HIV controllers” and almost 3,000 “HIV progressors” detected four single-nucleotide polymorphisms (SNPs) that are associated with HIV control or lack of control (International HIV Controller Study 2010). All four SNPs were located in the HLA region of chromosome 6. In-depth analysis of this region has revealed that the SNPs are tagging specific amino acids in the HLA-B binding groove that influence the binding of viral peptides for recognition by HIV-specific CD8 T cells, in addition to tagging other amino acids that influences regulation of HLA-C expression.

Overall, these strong associations between HLA class I expression and viral control implicate an important role for HLA class I-restricted HIV-specific CD8 T cells in the setting of HIV infection. However, it is important to note that these data suggest that even in persons with so-called “protective” HLA-B alleles (such as B*57 or B*27) and with favorable amino acids in the HLA-B peptide-binding groove, the majority of these individuals will become “HIV progressors,” rather than “HIV controllers.” Indeed, host genetics can currently explain only 23% of the variation in HIV viral load at the population level.

Specificity of HIV-Specific CD8 T Cells

The ability of T cells to distinguish between different viral proteins or viral peptides is defined as the “T cell specificity.” The specificity of HIV-specific CD8 T cell responses varies greatly between HIV-infected individuals (due to genetic differences in HLA molecules), yet is highly predictable once the HLA type of the individual is known. The specificity of HIV-specific CD8 T cell response also differs during the stage of viral infection. In the earliest stages of acute HIV infection, the HIV-specific CD8 T cell response in the blood is narrowly directed against only a handful of HIV peptides, predominantly derived from Env and Nef (which are among the most variable HIV proteins) (McMichael et al. 2010). These HIV-specific CD8 T cell responses are linked with the dramatic decline in HIV viral load to set point, indicative that these narrowly directed responses are at least partially effective. The HIV-specific CD8 T cell response then broadens over time, with a median of 14 peptides simultaneously targeted by HIV-specific CD8 T cells in chronic infection.

In chronic infection, multiple studies have shown that CD8 T cells dominantly target peptides derived from Gag (which is a highly conserved HIV protein), which has been associated with lower HIV viral load. In particular, a large study of chronically infected individuals found that broader Gag-specific CD8 T cell response was associated with lower HIV viral load, while conversely broader Env-specific CD8 T cell responses were found in persons with higher HIV viral load (Kiepiela et al. 2004). In addition, studies of HIV controllers expressing “protective” HLA alleles (such as HLA-B*27 and B*57) have shown that CD8 T cell targeting of specific peptides in the structurally important Gag protein can result in the selection of viral escape mutants with reduced viral fitness, facilitating immune control. Collectively, these studies repeatedly suggest that the specificity of the CD8 T cell response plays a key role in chronic HIV infection, with responses to the highly conserved Gag protein associated with superior immune control.

Viral Escape from HIV-Specific CD8 T Cells

During the acute and chronic phases of HIV infection, the targeting of HIV-infected cells by HIV-specific CD8 T cells exerts a strong inhibitory effect on viral replication. The strong CTL-driven selective pressure on HIV may consequently induce the emergence of mutations in the initial infecting virus, termed “escape mutants,” that enable the mutant virus to escape CTL recognition. The first example of escape was proposed in 1991, yet this was not generally accepted until further examples of CTL escape in natural infection were demonstrated (Borrow et al. 1997). Numerous papers have subsequently been published identifying HIV and SIV escape mutants and also evaluating the underlying mechanisms of escape.

The most well-established mechanism of HIV escape is mutation of amino acids within the targeted peptide that binds to MHC class I. Mutations within the epitope can result in a loss of binding between the peptide and MHC complex and/or impair the interaction of the TCR for its peptide-MHC complex. In addition, mutation within a peptide and also in the flanking region of the peptide may result in altered peptide processing and presentation. The propensity of HIV to mutate in response to CTL selection pressure is not random but rather occurs at specific positions in the viral sequence. This strongly suggests that there are functional and structural constraints on virus sequence variability, with some escape mutations imparting a detrimental “fitness cost” on HIV replication resulting in less-fit viruses (as commonly observed in Gag protein in “HIV controllers”). In contrast, other escape mutations may confer a “selective advantage” allowing the virus to effectively escape the host immune response. Importantly, many of these mutations become unstable upon transmission from an HIV-infected donor to a new recipient, with the virus frequently reverting to the original “wild-type” sequence in the recipient (in the absence of ongoing immune selection pressure). The timing of escape may vary greatly, with some

escape variants detected within days of acute HIV infection, while others occur late in chronic infection and may be associated with clinical decline.

Overall, there is considerable evidence of viral escape during acute and chronic HIV infection, which is driven by HIV-specific CD8 T cell selection pressure. Although some mutations result in a less-fit virus with impaired replicative ability (particularly mutations occurring in Gag), other mutations may have no fitness cost on the virus and may actually help to drive global HIV sequence evolution.

Immune Activation of Nonspecific and HIV-Specific CD8 T Cells

One of the hallmarks of HIV disease progression is chronic immune activation. Chronic immune activation refers to an overtly overactivated state of the immune system, which is characterized by increased expression of activation markers on T cells, hyperactivation of B cells (often in conjunction with hypergammaglobulinemia), and increased levels of proinflammatory cytokines. Immune activation of T cells is defined by the expression of specific activation markers on T cells (most notably CD38 and HLA-DR), increased T cell turnover, and spontaneous T cell death referred to as “apoptosis.”

Importantly, immune activation of memory CD8 T cells is one of the strongest predictors of how quickly an HIV-infected individual will progress to AIDS (in the absence of antiretroviral treatment). Numerous studies have shown that high frequencies of activated CD8 T cells (expressing CD38) are associated with faster disease progression. However, this does not imply that CD8 T cells are detrimental in the setting of HIV infection; instead, it suggests a paradoxical role. The majority of highly activated cells are not HIV-specific CD8 T cells, but rather represent CD8 T cells of undetermined specificity, most likely CD8 T cells specific to other microbes or self-proteins that are vulnerable to bystander immune activation. HIV-specific CD8 T cells clearly play a major role in limiting viral spread,

but after years of continued HIV replication and repeated antigenic stimulation, a proportion of these HIV-specific CD8 T cells will be driven to a state of hyperimmune activation, irreversible exhaustion, and T cell death by apoptosis. Immune activation and the resulting loss of some of these HIV-specific T cells therefore likely accelerate the onset of disease progression to AIDS, even though the majority of HIV-specific T cells remain functionally active, albeit less effective against HIV.

The cause of immune activation is still largely unknown; yet it is likely multifactorial. For activated CD8 T cells, one favored explanation is “microbial translocation,” whereby the destruction and depletion of CD4 T cells from the mucosal lymphoid tissue during primary HIV infection lead to increased “leakiness” of the gut membrane, allowing for microbial products to translocate from the gut, thus enhancing the amount of antigenic stimuli that both CD8 and CD4 T cells are exposed to (Brenchley et al. 2006). In addition, HIV may mediate a direct negative effect on T cell activation (by accessory proteins such as Nef), and coinfection or reactivation of pre-existing viruses and bacteria such as cytomegalovirus, CMV, is also likely to play a role. Understanding the mechanisms that give rise to immune activation represents an area of continued investigation that has important implications in the clinical treatment of HIV-infected individuals (to limit disease progression) and in the setting of prophylactic and therapeutic vaccines where the focus is to induce beneficial T and B cell responses that remain effective against HIV.

Importance of CD8 T Cells in Controlling HIV and SIV

It is widely believed that HIV-specific CD8 T cells play a key role in controlling HIV and SIV infection. Strong evidence for this stems from several key observations (Walker and McMichael 2012):

1. The rapid drop in plasma HIV viral load very early in acute infection coincides with the initial detection and expansion of the

HIV-specific CD8 T cell response, which may exceed 10% of all circulating CD8 T cells.

2. Detection of viral escape mutations in the first days and weeks following acute HIV infection implies that CD8 T cells are mounting strong selective pressure on the virus. Furthermore, the detection of viral escape mutants that can evade HIV-specific CD8 T cells is frequently linked to disease progression in HIV-infected individuals.
3. The expression of particular HLA class I alleles restricting HIV-specific CD8 T cell responses is associated with different clinical outcomes. Most notably, a delay in AIDS progression in infected individuals carrying HLA-B27 and HLA-B57 is observed, while the accelerated onset of AIDS is associated with HLA-B35.
4. Arguably, the most compelling evidence for the importance of CD8 T cell responses in controlling HIV has come from animal models. In the rhesus macaque model, the depletion of CD8 cells (by anti-CD8 antibody infusion) during acute SIV infection resulted in high viral loads and rapid progression to AIDS-like disease and death. In animals in which the infusion of monoclonal antibody was halted, CD8 T cell numbers rebounded, and a resulting decline in viral load was observed, thus attributed to immune control mediated by SIV-specific CD8 T cells.
5. Interestingly, while the vast majority of HIV-infected individuals progress to disease in the absence of antiretroviral drug treatment, a very small percentage of HIV-infected individuals (~1%) are able to spontaneously control HIV viral loads to almost undetectable levels in the absence of antiretroviral drugs for many years and do not progress to AIDS-like disease (Walker and Yu 2013). These HIV-infected individuals have been termed “HIV controllers” or long-term nonprogressors (LTNPs). (The definition of “HIV controllers” can also be subdivided into “elite controllers” who have viral loads of less than 50 HIV RNA copies/ml and “viremic controllers” who have viral loads of 50–2,000 HIV RNA copies/ml.) Importantly, multiple studies suggest that the

superior immune control observed in “HIV controllers” may be linked with improved functions of their HIV-specific CD8 T cells (such as proliferation and cytotoxicity) and the HLA class I alleles that restrict these HIV-specific CD8 T cell responses.

Importance of CD8 T Cell Responses in Prophylactic HIV Vaccines

Although the CD8 T cell response to HIV infection is often considered to be “too little, too late” to control HIV infection, there is significant hope in the HIV research field that CD8 T cells elicited by a prophylactic vaccine may be able to suppress viral load to such low levels that it would confer a strong beneficial effect in the HIV-infected individual, limiting immunopathogenesis and/or reducing the risk of transmission (in the absence of antiretroviral drugs). Vaccine-induced T cell responses would not be expected to prevent initial HIV infection. Instead, strong vaccine-elicited responses could potentially intercept HIV infection near the site of entry to prevent systemic viral spread to other areas, or eradicate HIV particles “hiding” in viral reservoirs. Toward this goal, T cell responses have been evaluated in depth in the development of prophylactic HIV vaccines (both in the context of T cell-inducing vaccines and also for T cell- and B cell-eliciting vaccines).

Initial tests of HIV vaccines are conducted in nonhuman primate (NHP) models, typically rhesus macaque monkeys, who are challenged with the simian equivalent of HIV called SIV. Although studies vary greatly (in the species of monkeys used, the SIV strain, the route of viral challenge, the vaccine regimen, and the vaccine constructs used), several key observations have emerged. Firstly, vaccines can induce SIV-specific CD8 T cells, which upon viral challenge can rapidly expand up to tenfold in magnitude and frequency. Secondly, in some (but not all) studies, vaccine-induced CD8 T cell responses can reduce the peak viral load and/or reduce viral set point (by up to two logs), which is likely to limit progression to AIDS-like disease and prolong the survival of the animals. Thirdly, at least one

study has demonstrated that vaccine-induced CD8 T cells can progressively clear SIV infection from the blood and tissues, although it should be noted that the HLA restriction and recognition characteristics of vaccine-induced CD8 T cells appear to be highly unconventional (Hansen et al. 2013; Ranasinghe and Walker 2013). Collectively, there is wide variation in the results of these NHP studies, and arguably, the critical question remains whether the vaccines tested in NHP models with SIV challenge are going to be more or less effective in protecting humans from HIV infection.

To date, only three HIV vaccines have been tested in phase 2b or phase 3 efficacy trials in humans (with numerous others failing to demonstrate sufficient safety at phase 1 or sufficient immunogenicity at phase 2, or currently awaiting testing). The first of these HIV vaccines, VAX003, was not designed to elicit CD8 T cell responses; instead, it was designed to elicit only antibodies and showed no efficacy in HIV-negative individuals at high risk of HIV acquisition. In contrast, the second trial, phase 2b Merck STEP trial using adenovirus 5 (Ad5) vectors with HIV Gag, Nef, and Pol inserts was designed to induce HIV-specific CD8 T cells in HIV-negative individuals at high risk of HIV acquisition. The vaccine elicited detectable HIV-specific CD8 T cells in 73% of vaccinated individuals, yet there was no evidence of vaccine-induced protection (either in preventing HIV acquisition or reducing post-acquisition viral load at peak or set point) (Buchbinder et al. 2008). Post hoc analysis suggests that the magnitude and breadth of these CD8 T cell responses may have been too weak, potentially still “too little, too late,” to achieve protection in this vaccine, although the vaccine did show some evidence of exerting selection pressure on the virus in those who became infected. The STEP trial was a clear negative result in the pursuit of an HIV vaccine. Yet, it serves to shed more clues on the different strategies that could be used for future HIV vaccines, such as the use of different vectors (adenovirus, canarypox, cytomegalovirus, etc.) to modulate the CD8 T cell responses induced, and a renewed focus on developing vaccines that induce both T cells and antibodies.

Importantly, in addition to these two efficacy trials, a third trial did suggest vaccine-induced protection from HIV acquisition. The US Military HIV Research Program (MHRP) RV144 phase 3 efficacy trial in Thailand involved a combination regimen of a recombinant canarypox virus with booster doses of a clade A/E gp120 glycoprotein vaccine in HIV seronegative persons at low risk of HIV acquisition. The vaccine group showed a 31% reduction in HIV acquisition when compared to the placebo group. This demonstrates for the first time that an HIV vaccine can reduce HIV acquisition. However, the observed reduction in HIV acquisition was modest and only just above the borderline of statistical significance ($p = 0.04$, with a $p = 0.05$ statistical cutoff), and no significant difference in HIV viral load was observed between vaccinees who became infected and placebo groups. This vaccine was primarily designed to elicit antibodies, which are likely to have mediated the prevention from acquisition in almost a third of vaccinees, yet investigations are still ongoing to determine precise immune correlates of protection (Kim et al. 2015).

The next scheduled efficacy trials in the HIV/AIDS vaccine field are primarily focused on building on the results of the Thai RV144 trial. The MHRP is currently running RV305 in Thailand, which seeks to evaluate the effects of re-boosting the volunteers who participated in the initial RV144 study. In addition, a consortium known as the Pox-Protein Public-Private Partnership (P5) was formed to coordinate further clinical tests of RV144-like vaccine strategies in Thailand and South Africa. A new phase III efficacy trial using a clade B/E boost is expected to start in Thailand in 2016/2017. Trials in South Africa testing the original clade A/E boost, and separately a new ALVAC/protein clade C boost, are also expected to start in 2016/2017. In addition, other vaccine constructs including NYVAC, DNA, and protein will also be tested by P5 in multiple locations across Southern Africa. The results of these trials are not expected for several years; however, there are also over 20 other HIV/AIDS vaccine trials at earlier stages of development (phase 1 and 2 and preclinical testing),

including several that aim to elicit only T cells, only antibodies, or both T cells and antibodies. Collectively, the highly varied design and implementation of these vaccine trials will be instrumental in discerning the most efficacious vaccine-induced immune responses and vaccine strategies required for preventing HIV acquisition.

Conclusions

As with other viral infections, the host immune response mounts a vigorous adaptive immune response to HIV, with clear evidence that HIV-specific CD8 T cells exert an antiviral effect that contributes to lowering viral load to a quasi set point (Walker and McMichael 2012). Unfortunately, there is no clear evidence that this T cell response ever completely eradicates natural infection. A combination of progressive CD8 T cell dysfunction in response to ongoing viral replication, together with immune escape through mutations, leads to a gradual increase in viral load in untreated persons. However, the finding that some persons known as “HIV controllers” are able to maintain low to undetectable viral loads for years in the absence of antiviral therapy suggests that CD8 T cell responses might be meaningfully enhanced in infected persons and might contribute to protection from disease progression if induced by immunization (Walker and Yu 2013). Intriguingly, the finding that a CMV vector expressing SIV proteins was able to induce potent and persistent effector memory CD8 T cell responses that protected macaques from infection (Hansen et al. 2013) suggests that CD8 T cells may also have an important role in preventive HIV vaccines.

Definition

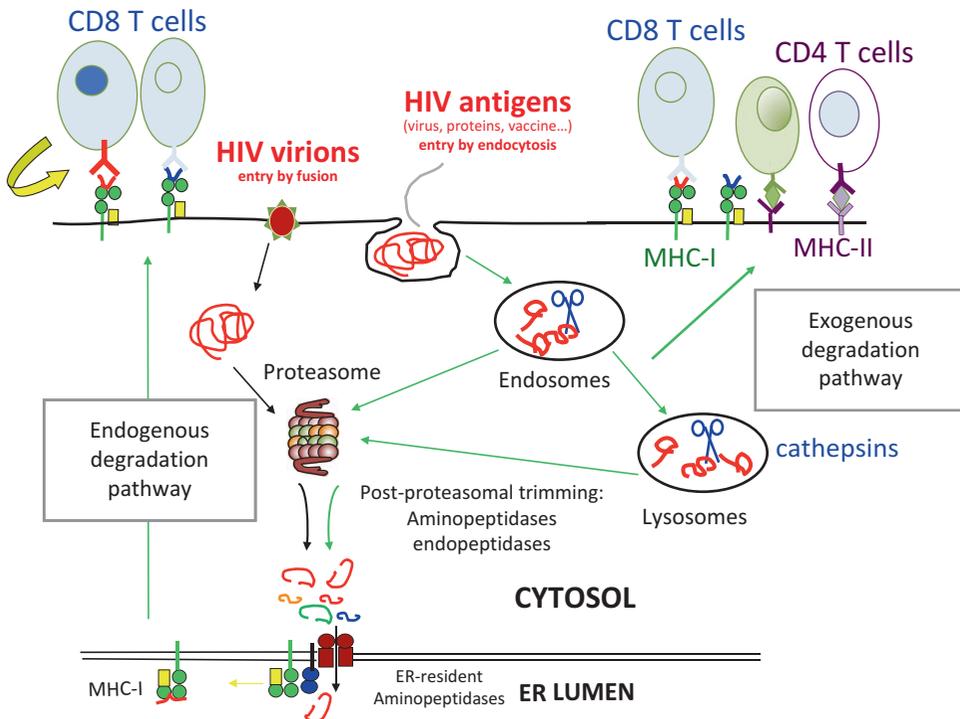

Immune T cells detect and clear cells infected by pathogens such as bacteria or viruses, because infected cells present peptides derived from the intracellular degradation of the pathogen. Antigen processing consists of the multi-step intracellular degradation of self- and pathogen-derived proteins into short peptides loaded onto major histocompatibility complex (MHC) molecules and displayed at the cell surface. MHC-I complexes display peptides mostly 8–11 amino acids (aa) long to CD8 T cells and MHC-II display longer peptides (mainly 12–18 aa) to CD4 T cells. While pathogen-specific CD8 T cells are cytotoxic T cells killing infected cells, CD4 T cells primarily provide help to maintain CD8 T cell responses and antibody responses against pathogens. The processing of pathogen-derived antigens into epitopes and their presentation by dendritic cells is the first step leading to the priming of pathogen-specific CD8 and CD4 T immune responses in the context of infection or vaccination. Antigen processing and presentation enables the immune system to monitor the intracellular content of cells, detect pathogens, and fight infection. Understanding antigen processing and presentation in the context of HIV infection is critical to identify epitopes presented by HIV-infected cells, to define protective immune responses, to elucidate the mechanisms of immune escape, and to improve the design of vaccine immunogens.

Overview of the Protein Degradation Pathways

Protein degradation constantly occurs in healthy or infected cells as it allows for the regulation of cellular activities through the removal of specific proteins, to eliminate misfolded or defective proteins, and to recycle amino acids to make new proteins and display peptides at the cell surface for immune monitoring (Blum et al. 2013; Yewdell 2007).

The endogenous processing pathway refers to the degradation of proteins located inside cells, mostly endogenous proteins but also proteins from pathogens entering in the cytosol or newly synthesized pathogens (Fig. 1). Polyubiquitinated proteins or misfolded proteins are degraded intracellularly by proteasomes located in the cytosol and nuclei. Proteasomes are the only proteases that can both unfold and degrade proteins and are therefore the first involved in protein degradation. They produce peptides ranging from 2 to

30 aa and often define the C-terminus residue of epitopes due to frequent cleavage sites after hydrophobic residues, the most frequent C-terminal anchor residues of MHC-I epitopes. 20S proteasomes are barrel-shaped proteases made of four rings of seven subunits each, where the two central rings each contain three catalytic subunits cleaving after hydrophobic, acidic, or hydrophilic residues. The core can be capped with two lids forming the 26S proteasome. In the presence of interferon gamma, the constitutive catalytic subunits can be replaced by immunocatalytic subunits leading to immunoproteasomes (Blum et al. 2013). Lymphoid cells such as T cells or dendritic cells contain mostly immunoproteasomes and some constitutive proteasomes; in other tissues, the majority of proteasomes are constitutive proteasomes. Whereas in other tissues constitutive proteasomes are the major type of proteasomes. Immunoproteasomes tend to produce longer peptides with more hydrophobic C-termini (fitting most MHC molecules)

HIV Antigen Processing and Presentation, Fig. 1 Processing and presentation of MHC-I and MHC-II epitopes to T cells

that may be better suited for the production of epitopes. Thymic tissues contain proteasomes with unique catalytic subunits forming thymoproteasomes that may permit the production of a variety of peptides suitable for positive and negative selection during thymic education. After proteasomal degradation peptides can be further degraded in the cytosol by endopeptidases and aminopeptidases (cleaving from the N-terminal side of peptides). Peptides of at least 8 aa long and usually shorter than 16 aa that bear adequate anchor residues for the transporter associated to antigen processing (TAP) will translocate into the endoplasmic reticulum (ER), where they can be further trimmed by ER-resident aminopeptidases (ERAP1 and ERAP2) before or after loading onto MHC-I. MHC-I-peptide complexes released from the ER traffic to the cell surface and are displayed for immune monitoring. Although many peptidases have been identified and involved in the processing, the number of peptidases involved in degradation and order in which they cleave a given substrate is not well defined.

In addition to the endogenous pathway, the exogenous pathway leads to the degradation of extracellular proteins, pathogens, or fragments of dead cells taken up by phagocytosis, endocytosis, or macropinocytosis (Yewdell 2007) (Fig. 1). Exogenous substrates are degraded by cathepsins in endosomes and lysosomes (Blum et al. 2013). Degradation products can transfer back in the cytosol for further degradation and cross-presentation by MHC-I. In professional antigen-presenting cells constitutively expressing MHC-II (macrophages, dendritic cells, and B cells), degradation products reach a specialized phagocytic compartment called MIIC containing MHC-II molecules bound to an invariant chain Ii and where cleavage of Ii and loading of peptides onto MHC-II trigger the traffic of MHC-II-peptide complexes to the cell surface. MHC-II can also present endogenous antigens such as membrane proteins degraded in lysosomes or during autophagy when cytosolic and nuclear antigens are engulfed in autophagosomes fusing with lysosomes for degradation and MHC-II presentation. The distinction between endogenous and exogenous

pathways is becoming more tenuous as the processing of some MHC-II epitopes of exogenous and endogenous antigens involves lysosomal enzymes and proteasomes, and the processing of MHC-I epitopes from exogenous and endogenous antigens sometimes involves peptidases from several compartments.

Factors Driving the Efficiency of HIV Epitope Production

HIV can enter cells through fusion at the plasma membrane or be phagocytosed, while after integration of the provirus, newly synthesized HIV proteins will assemble in the cytosol into new virions (Fig. 1). Thus peptidases in multiple compartments may contribute to degrading HIV during its replication cycle. So far proteasomes, TPPII, TOP, nardilysin, and ERAP1 have been involved in the processing of some HIV epitopes. There is no extensive knowledge of all peptidases involved in the processing of HIV epitopes due to the lack of throughput tools to follow epitope production and presentation. Immunoproteasomes and proteasomes are likely to be the starting point of degradation of HIV proteins and be involved in the processing of most MHC-I epitopes. However, the contribution of post-proteasomal peptidases in the cytosol and in the ER is less well defined and probably variable according to peptide lengths and sequences. Each category of post-proteasomal peptidases has catalytic specificities defining cleavable substrates. For instance, aminopeptidases cleave peptides shorter than 16 aa from the N-terminal side and cleave only 10 residues with good efficiency. TPPII is an endopeptidase that cleaves longer peptides up to 32 aa and could cleave long peptides released by proteasomes. Peptidases are involved in producing peptides for loading onto MHC but can also destroy peptides and limit epitope presentation (Blum et al. 2013). Thus the sequence of the antigen and cellular peptidases encountered by antigens will define the pool of peptides available for loading onto MHC molecules and shape the specificity of immune responses during infection.

HIV proteins are unevenly immunogenic; Gag, specifically p24, and Envelope contain the highest density of T cell or antibody immune responses while proteins such as Tat or Vpr contain fewer responses (Llano et al. 2013). Searches for potential MHC-I epitopes throughout the HIV proteome are performed by identifying potential anchor residues in HIV proteins allowing binding to specific MHC complexes and show many more potential epitopes than known T cell responses in HIV-infected persons. One possible early bottleneck limiting the diversity of immune responses is the degradation patterns of HIV proteins and the subsequent limited production of peptides compatible with loading onto MHC molecules. In vitro degradation of HIV Nef with purified proteasomes showed production of a larger number of fragments in epitope-rich areas with many containing hydrophobic C-terminal residues. Degradation of long HIV peptides of 24–35 aa or full proteins in cytosolic extracts also showed variability in fragments with some protein areas producing mostly 8–11 aa long peptides (compatible with MHC-I loading), some producing mostly longer fragments (possibly indicative of slower degradation rates), and some producing mostly peptides <7 aa too short to be loaded onto MHC-I. The higher proportion of 8–18 aa long fragments produced in epitope-rich areas and the complete degradation of some other protein areas suggest that degradation patterns contribute to shaping the immunogenicity of proteins by providing selected protein fragments that may be displayed by MHC molecules.

Complete or incomplete proteins are degraded in fragments eventually trimmed into epitope precursors and epitopes. Both production and degradation of fragments will define peptide availability for MHC-I and MHC-II peptide presentation. Degradation experiments of proteins or long peptides by purified peptidases (Tenzer et al. 2009) or cellular extracts (Le Gall et al. 2007) showed that HIV epitopes within a given protein (even for overlapping epitopes) are sequentially and unevenly produced. Computational analysis of motifs flanking epitopes showed that the efficiency of epitope production is driven by surrounding motifs creating good or poor

cleavage sites for peptidases that will impact the time at which an epitope is produced. Mutating residues flanking poorly processed epitopes toward motifs enriched around efficiently processed epitopes (as long as they are processed by the same categories of peptidases) accelerated the production of the epitope (Le Gall et al. 2007; Tenzer et al. 2009). In addition to the efficiency of epitope production, the sensitivity of a peptide to degradation before binding to MHC may affect the amount of peptides available for T cell recognition. Whereas it was thought that short peptides are quickly degraded in the cytosol, a study on HIV peptide stability in the cytosol highlighted variability in peptide half-lives (<10 s to >60 min), a property that extends beyond HIV peptides (Lazaro et al. 2011). Whereas most HIV peptides were unstable, about 15% of them displayed unusually high stability in the cytosol. Distinct motifs were enriched in stable and unstable peptides, and exchanging motifs between peptides switched their stability ranking. Intracellular peptide stability contributed to the amount of peptides available for display by MHC-I and T cell recognition. Altogether, in vitro degradation data of HIV proteins by purified peptidases or cellular extracts have provided a wealth of information on steps and sequence signatures linked to efficient or inefficient epitope production. In conjunction with studies on peptide affinity for HLA molecules or T cell receptor (TCR) and the identification of TCR repertoire, unveiling the mechanisms of HIV protein degradation into epitopes will define factors underlying the variable immunogenicity of HIV proteins. Nonetheless several questions remained to be answered. CD4 T cells and monocytes present different levels of antigen processing activities that affect the kinetics and amount of epitope production. The relative hydrolytic activities of all HIV-infectable cell subsets (CD4 T cells, monocytes, macrophages, dendritic cell subsets) have not yet been compared in primary cells from the same donors. However, if they are heterogeneous as demonstrated for CD4 T cells and monocytes in humans, this may affect the production and display of HIV epitopes. The diversity of degradation pathways and peptidases in these cells might increase the diversity of

peptides presented by HIV-infected cells, either the diversity of HIV peptides presented or the relative amount of each peptide. The direct and unbiased identification of epitopes presented by MHC-I or MHC-II after HIV infection has not yet been achieved due to technical difficulties related to the cytopathic effect of the virus on cells and the very high number of cells required for MHC-bound peptide isolation by mass spectrometry. One group identified self-derived peptides in HIV-infected cells secreting MHC molecules (Hickman et al. 2003), an important first step toward the identification of peptides presented by cells. It will be critical to expansively identify peptides naturally presented by MHC molecules of HIV-infected cells in order to identify immune responses able to efficiently recognize and clear infected cells.

HIV Antigen Processing and Hierarchy of HIV-Specific Immune Responses

HIV-specific T cell responses are extensively studied with regard to peptide and HLA specificity (i.e., specific subtypes of MHC-I or MHC-II molecules), frequency and magnitude of interferon gamma production by T cells in HIV-infected persons, proliferation and cytokine production, killing capacity, TCR sequence, and specificity, but much less in terms of HIV epitope processing and presentation. Numerous HIV-specific CD8 and CD4 T cell responses have been identified in large populations of HIV-infected persons. Immunodominant responses correspond to the most frequent T cell responses in a population sharing the restricting HLA or, when defined at the individual level, as the T cell response producing the most interferon gamma. Narrow immunodominance of CD8 T cell responses in acute HIV infection contrasts with broader immune responses in chronic infection. The association of certain HLA with spontaneous control of HIV and the presence of multifunctional T cell responses indicate an important role of T cell responses in the outcome of HIV infection. However, factors driving the elicitation of immune responses associated with

control or progression of the disease or driving immunodominance are not well defined. The most detailed studies on immunodominance come from mouse models using artificial antigens such as ovalbumin or pathogens with little genetic variability and show that immunodominance is multifactorial and depends on either of these factors alone or in combination: protein degradation, affinity of peptides for TAP binding leading to peptide transfer into the ER, binding to MHC or the TCR, as well as TCR repertoire in the human population (Yewdell 2006). The presentation of a peptide by its cognate HLA is the earliest and mandatory step required to trigger an immune response. Thus both timing and amount of peptides presented by cells will likely play an important yet understudied role in the hierarchy of T cell responses established during infection or vaccination. Degradation of long HIV peptides or proteins with purified proteasomes or cytosolic extracts containing cytosolic peptidases identified a link between efficiency of epitope production and immunodominance of the corresponding T cell response. However these studies have been performed on a limited number of epitopes, and other factors such as binding affinity to MHC or to the TCR may be more influential in shaping immunodominance of certain epitopes. Since subdominant rather than dominant CD8 T cell responses correlate with lower viral loads in HIV-infected persons, and since immunodominance hierarchy naturally established during infection never leads to clearance of infection, it is now accepted that a HIV vaccine should elicit immune responses breaking natural immunodominance. Assessing the contribution of antigen processing to immunodominance is therefore important to manipulate immunogen design and to orchestrate epitope presentation in such way that natural immunodominance of HIV-specific immune responses will be broken.

Immune Escape Through Impaired Epitope Production

HLA-restricted mutations in HIV genome (i.e., mutations found only in persons sharing a given

HLA) induced by immune pressure are observed during the acute and chronic phases of infection. They can be found within and outside epitopes throughout most of the HIV proteome except a few highly conserved areas. HLA-restricted mutations in HIV can impact viral fitness, either reducing replicative capacity of the virus or compensatory mutations reestablishing viral fitness. They can also prevent immune recognition through mutations at anchor residues of epitopes either preventing or reducing binding to MHC molecules or reducing binding to the TCR of CD8 T cells. Additionally mutations outside epitopes can modify the degradation patterns of protein into epitope precursors and epitopes. Mutations within epitopes can create cleavage sites and destroy epitopes before presentation. Identifying factors driving viral evolution and predicting upcoming mutations for given combinations of HLA will permit to better design vaccine eliciting immune responses driving viral evolution toward unfit variants. However the high number of mutations and HLA combinations in the population preclude testing all mutations and assessing their potential role in immune escape. Recent studies took an indirect approach by first determining motifs that can be cleaved or not by families of peptidases involved in epitope processing to identify signatures of impaired epitope presentation (Zhang et al. 2012). Ten poorly cleavable motifs and ten well cleavable amino acids by aminopeptidases, which trim peptides from the N-terminal side, were identified. The presence of a poorly cleavable residue flanking an epitope reduced epitope production measured by mass spectrometry in *in vitro* degradation assays increased the production of N-extended peptide less well suited to be loaded onto MHC, and accordingly diminished its endogenous processing and presentation to epitope-specific CD8 T cells measured by killing assays. Conversely, switching a flanking residue toward a more cleavable flanking residue enhanced epitope production and presentation to epitope-specific CD8 T cells. Interestingly, the analysis of all HLA-restricted mutations in a population of 1,200 HIV-infected persons showed a significant

enrichment – at the population level – in residues poorly cleavable by aminopeptidases flanking several HIV epitopes. Another study showed that the intracellular stability of peptides prior to loading onto MHC-I contributes to defining how much peptide is available for display to T cells. The analysis of 167 HIV peptides showed highly variable intracellular stability, and the computation analysis of combinations of residues in stable and unstable peptides identified motifs in either category of peptides. Again natural HLA-restricted mutations found in HIV-infected persons tend to evolve toward more cleavable motifs reducing peptide presentation. Thus mutations outside epitopes leading to modified degradation patterns and reduced production of optimal epitopes are probably occurring more frequently than originally thought during viral evolution under immune pressure.

Altogether, these results show that the combined experimental and computational analyses of HIV protein degradation and epitope production, a better understanding of the specificity of cellular peptidases, and the capacity to analyze binding affinity of peptide variants to MHC molecules will permit the prediction of mutations leading to impaired peptide presentation and the contribution of various mechanisms of immune escape to viral evolution at the population level.

HIV Antigen Processing and Vaccine Immunogen Design

The ultimate goal of HIV research is to develop vaccines that will protect from infection (prophylactic vaccines) or to boost immunity in HIV-infected persons to clear infection or at least reduce viral load to undetectable levels (therapeutic vaccines). A commonly accepted approach to vaccine design would combine a potent antibody response to prevent establishment of infection and sustainable T cell responses to control viral replication (Burton et al. 2012). Challenges faced by vaccinologists include the genetic diversity of HIV, our lack of understanding of protective immunity (since there is no case

of natural clearance of infection), the establishment of viral reservoirs that cannot be eliminated with antiretroviral therapy, and our inability to induce B cells making specific neutralizing antibodies (Picker et al. 2012). Various types of immunogens (proteins, peptides, nucleic acids), viral vectors (non-replicative or attenuated persistent), vector-less system (nanoparticles carrying immunogen), and adjuvants are being tested in cellular studies, preclinical studies in animals, or in clinical trials (Johnson et al. 2013; Parks et al. 2013). The most encouraging results in recent preclinical studies used either chimeric SIV immunogens expressed by an adenoviral vector (Barouch et al. 2013) or an attenuated rhesus CMV viral vector expressing complete SIV proteins (Hansen et al. 2013). These two successful approaches may have provided immunization conditions that deeply differ from those established by natural infection, breaking immunodominance and broadening immune responses. The mechanisms underlying priming of immune responses leading to clearance (CMV study) or protection (chimeric immunogen study) are unknown. We still do not comprehend how the viral vector selected to express the immunogen (or the use of vector-less nanoparticles carrying HIV peptides or proteins), the design of the immunogen, the choice of adjuvants, and modes of vaccination impact the elicitation, hierarchy, specificity, and functionality of immune responses elicited by HIV/SIV vaccines. A shared goal of all vaccination approaches is the elicitation of sustainable immune responses clearing infected cells or blocking viral spread. Studies on HIV antigen processing and presentation will be instrumental to identify epitopes presented by infected cells, to rationally design immunogens leading to the presentation of adequate epitopes (for instance, by defining the optimal order of selected SIV/HIV fragments for chimeric immunogens, the addition of linkers facilitating the liberation of peptides from the immunogen), and to test epitope processing from immunogens prior to *in vivo* studies in relevant cells. Regardless of the vector used for vaccination, the immunogen will be processed in APC for priming of immune

responses. It is necessary to ensure through in-depth studies of antigen processing that – in the context established by the specific vaccination strategies discussed above – the immunogen will be degraded into MHC-I and MHC-II epitopes corresponding to sustainable protective immune responses able to recognize infected cells.

Conclusion

The degradation of HIV proteins into MHC-I or MHC-II epitopes is the earliest event leading to immune recognition. Compared to the wealth of knowledge on HIV-specific immune cells, little is known about HIV antigen processing and presentation. These early events will define the timing and amount of epitopes presented by HIV-infected cells. The identification of HIV peptides presented by infected cells should be an important goal of the current HIV antigen processing research as it will permit the complete definition of the landscape of peptides during infection, possibly leading to the identification of additional immune responses efficiently recognizing and clearing infected cells. Various motifs within and outside epitopes define the sensitivity of a given sequence to degradation, the kinetics of epitope production, and the overall efficiency of epitope presentation. Conversely, studies on HIV antigen processing also allowed a better understanding of the mechanisms of immune escape and highlighted the multiple ways HIV evolves to block or limit epitope presentation through mutations affecting various steps of epitope processing. Understanding the contribution of various mechanisms to viral evolution (viral fitness, compensatory mutations, drug resistance, antigen processing mutations) will inform how to identify immune responses of the virus toward unfit variants while allowing efficient recognition of infected cells. Finally, uncovering mechanisms of HIV peptide processing presentation may provide ways to check proper processing of vaccine immunogens into epitopes in relevant cells and if necessary to modify sequences to optimize presentation of HIV epitopes during vaccination.

HIV Cancers in Resource-Limited Regions

Sam M. Mbulaiteye

Infections and Immunoepidemiology Branch,
Division of Cancer Epidemiology and Genetics,
Department of Health and Human Services,
National Cancer Institute, National Institutes of
Health, Bethesda, MD, USA

Definition

About 29 of 33 million persons living with human immunodeficiency virus (HIV) or the acquired immunodeficiency syndrome (AIDS) (PLHA) worldwide in 2009 reside in resource-limited countries. The burden of cancer in this population is substantial, although there is much we still do not know about the epidemiology of various HIV-associated tumors in these regions. Access to life-extending combination antiretroviral therapy (cART), which has been rapidly expanding since 2000, has improved survival to nearly normal life expectancy, including in resource-limited countries where about 30% of PLHA are receiving cART. The improvements in survival with HIV, however, are occurring at the expense of increased incidence of chronic comorbidities including cancer in PLHA on cART. Sparse data about the risk of cancer in PLHA in resource-limited countries complicates efforts to evaluate this concern. Cancer is diagnosed in about 30% of PLHA in developed countries. Cancers in PLHA are historically categorized as “AIDS-defining” cancer (ADC) or “non-AIDS-defining” cancers (NADCs). ADCs include Kaposi sarcoma (KS); aggressive non-Hodgkin lymphoma (NHL), including Burkitt lymphoma (BL); and invasive

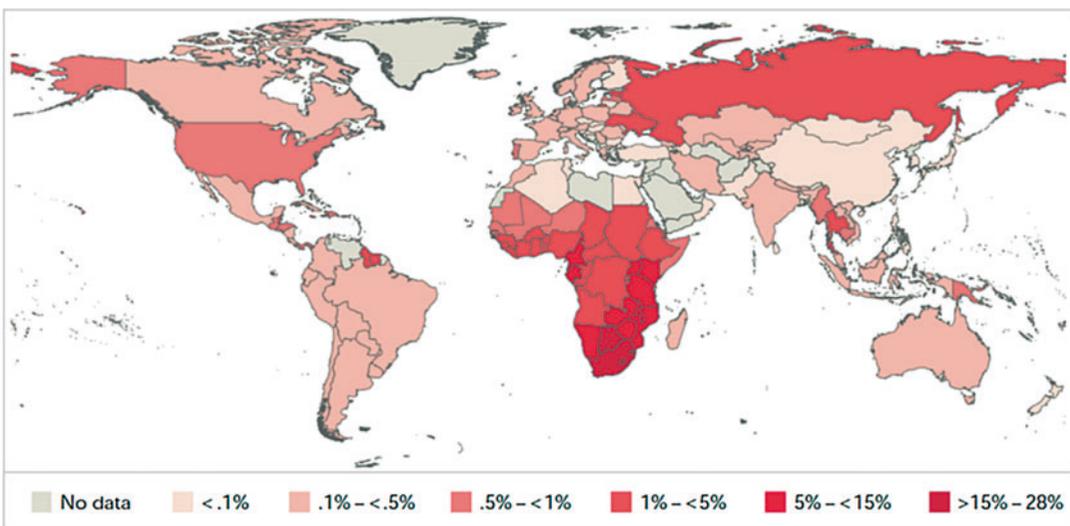

cervical cancer. These cancers have a viral etiology and are more likely to be associated with the degree or duration of immunosuppression. NADCs include Hodgkin lymphoma and anogenital, liver, and lung cancer. Most of these cancers have a viral etiology or are associated with lifestyle factors, e.g., cigarette smoking or injection drug use, which are more prevalent in PLHA. These cancers often occur in spite of sustained immune restoration. Thus, NADCs have assumed greater importance as PLHA survive longer and ADCs proportionately decrease. Cancer is diagnosed in fewer than 5% of PLHA in resource-limited countries. This rate is likely a gross underestimate and is also affected by competing mortality from endemic infectious diseases such as malaria and tuberculosis. The low access to diagnostic services in low-resource settings may also mean that a notable fraction of cancers remain undiagnosed in PLHA. Increasing access to affordable cART in resource-limited settings is likely to rapidly reduce infectious comorbidities such as tuberculosis and thus amplify the importance of cancer in PLHA. Studies of PLHA in resource-limited countries are needed to characterize the additional cancer burden in PLHA to inform public health policy and knowledge about cancer etiology in different populations.

Introduction

In 2009, 28.8 million PLHA were living in resource-limited countries, including 22.5 million in sub-Saharan Africa and 6.3 million in countries in South Asia, Southeast Asia, East Asia, and Central and South America (History of the AIDS Epidemic) (Fig. 1) (2009). The risk for cancer in PLHA in resource-limited countries has not been well described, with fewer than 5% of PLHA in resource-limited countries being diagnosed with cancer (► [Cancers Related to HIV](#)). This low rate is most likely a gross underestimate because of competing mortality due to common infections like malaria and tuberculosis and because of lack of specialized hospitals that can diagnose and treat cancer and cancer registries that can collect and analyze incidence data on various cancers that are seen in the region. For example, only four countries in sub-Saharan Africa had registries of high quality sufficient for inclusion in the *Cancer Incidence in Five Continents* monograph published by IARC in 2002. Thus, the relationship between HIV and cancer in the resource-limited countries remains poorly described.

Understanding the impact of HIV on cancer in populations residing in resource-limited countries is important for public health and science

H

HIV Cancers in Resource-Limited Regions, Fig. 1 Global prevalence of HIV in 2009 (UNAIDS Report)

(► [Cancers Related to HIV](#)). In 2008, the International Agency for Research on Cancer (IARC) estimated that 12.7 million new cancers were diagnosed worldwide, 56% – or seven million new cases – were in resource-limited countries, and about 23% of those cancers could be attributed to infections (de Martel et al. 2012). Also, the profile of cancers occurring in resource-limited countries varies considerably from region to region, in part, because these regions span a broad range of prevalent infections; lifestyle factors; genetic, environmental, and dietary backgrounds; and different demographic distributions. No prospective studies have been conducted to investigate cancer risk in PLHA in resource-limited countries. In developed countries, the evaluation of cancer burden in PLHA has been facilitated by linking the records of population-based HIV/AIDS registers to population-based cancer registers, but this is difficult to implement in most resource-limited countries because of the lack of electronic registries. Some data has accumulated from case series reports and a few case-control studies that have been published. The case series suggest an increase in the number of cases or a change in the clinical pattern of disease, but they are not useful in quantifying risk or identifying cofactors associated with cancer in PLHA. Case-control studies have provided some insights into risk, but they are few and often have been small. The results from the studies are described in detail below. For these reasons, more quantitative and accurate studies of HIV-associated cancers in resource-limited regions are urgently needed.

AIDS-defining Cancers

Kaposi Sarcoma

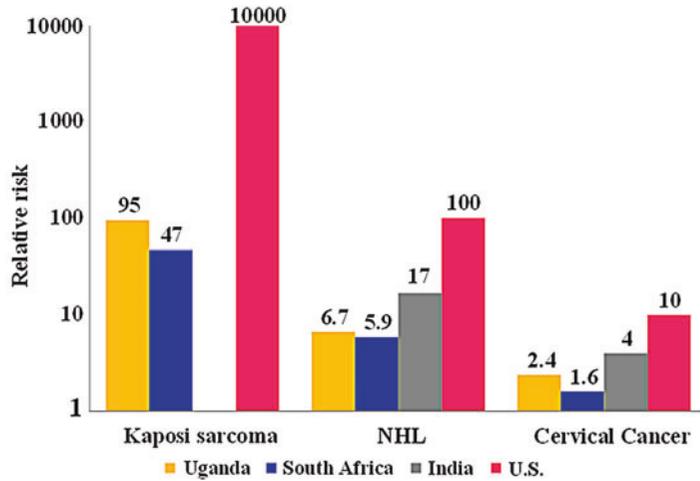

KS was endemic in sub-Saharan Africa before the onset of the AIDS epidemic. The epicenter of KS was around the Congo-Nile Watershed in Equatorial Africa, and the incidence fell with distance away from this epicenter. In the early 1980s, clinicians working in Uganda and Zambia noted an increase in the number of KS cases attending their clinics and a change in the clinical course of the

disease (1988). The changes in the clinical picture and epidemiology resembled the pattern of epidemic KS cases that had recently been described in men who have sex with men in the USA and Europe (► [Epidemiology of AIDS-Related Malignancies](#)). Subsequent studies on site in Africa confirmed that epidemic, but not endemic, KS in Africa was associated with AIDS. In contrast to patients with endemic KS, whose clinical course was indolent and who developed lesions mostly on the feet or hands, patients with epidemic KS often developed widely disseminated lesions almost anywhere on the body, including internal body organs and mucosal surfaces, and often had a rapidly fatal course (► [Presentation and Pathogenesis of Kaposi Sarcoma](#)). The median age of patients with epidemic KS was also lower, corresponding the median age of patients with AIDS, and the male-to-female sex ratio was close to 3:1, in contrast to 10:1 reported for endemic KS.

The incidence of KS has increased in the general population of countries in sub-Saharan Africa with a substantial HIV epidemic. For example, in Uganda, one of the first countries to be touched by the HIV epidemic, KS incidence rate per 100,000 increased 12-fold in men and 218-fold in women during 1995–1997 as compared with 1960–1966 (Mbulaiteye et al. 2011). It is currently the first or the second commonest cancer in men, women, and children in Uganda. Similar changes have been reported in other countries in Equatorial Africa, including Zimbabwe, Zambia, and Tanzania, although precise estimates of the change in the incidence are not available. The risk of KS is increased 22–95 times in persons with HIV compared to unaffected persons (Fig. 2) (Mbulaiteye et al. 2011). For example, in Rwanda, close to the epicenter of endemic KS, the risk of KS is increased 35 times in persons with HIV compared to unaffected persons. Similarly, elevated risks have been reported in South Africa (22–47 increased risk with HIV). The impact of HIV on KS risk appears to be higher in children. One study conducted in Uganda reported that the risk of KS was 95 times higher in children (≤ 15 years) with HIV compared to unaffected children. While the fold increases in the risk of KS in Africa are

HIV Cancers in Resource-Limited Regions,

Fig. 2 Relative risk of AIDS-defining cancers (Kaposi sarcoma, non-Hodgkin lymphoma, and cervical cancer) in people living with HIV in three different resource-limited countries and in the USA as compared to unaffected populations in the same countries (Mbulaiteye et al. 2011)

lower in PLHA than in the USA, these estimates probably grossly underestimate the impact of HIV because of premature mortality due to more common illnesses, such as malaria and tuberculosis, due to underdiagnosis, and higher background incidence rate of KS in the general population in Africa.

An essential risk factor for KS is infection with Kaposi sarcoma-associated herpesvirus (KSHV) (► [Kaposi's Sarcoma Associated Herpesvirus](#)), which was discovered by Moore and Change in 1994 (Boshoff 2000). Serological studies conducted in Africa, where KS is endemic, have confirmed, as expected, that KSHV is common, with antibodies detected in 20–80% of persons tested. The highest prevalence is found in populations residing in the Congo-Nile watershed, the epicenter of endemic KS, where 50–90% of adults have KSHV antibodies. The risk of KS is associated with the presence of KSHV antibodies or DNA in peripheral blood and with severe T-cell immunosuppression. In resource-limited countries, the use of cART is associated with a substantial reduction in the risk of KS (► [Management of Kaposi's Sarcoma](#)). The globally coordinated efforts aimed at interrupting the spread of HIV/AIDS and the reducing mortality from AIDS in sub-Saharan Africa have dramatically increased access to cART, from a few hundreds a few years ago to close to four million PLHA in 2009 (2009), mostly using the more affordable regimens based on non-nucleoside

reverse transcriptase inhibitors (NNRTIs). Significant increase in life expectancy has already been reported among PLHA using cART in sub-Saharan Africa, and the incidence of KS is falling, although less precipitously than was observed in developed countries. The reasons for the apparent lower protection of cART against KS in patients in Africa are unclear, but they may include poor adherence, the effects of coinfections on immunosuppression, or other unknown factors. There is some evidence suggesting that anti-HIV regimens containing NNRTI may provide less protection against KS than regimens containing protease inhibitors, although some retrospective studies suggest there is no difference and this remains a controversial area. KS has also been reported to develop shortly after the initiation of cART, suggesting that KS may occur as a complication of the immune reconstitution syndrome (Jaffe et al. 2011). These observations suggest that unlike in developed countries, where KS has become less of a concern with the introduction of cART, KS is likely to continue to be a major problem of PLHA in sub-Saharan Africa because of the significant overlap of KSHV and HIV infections in the population. Thus, public health messages in Africa should stress the link between HIV and KSHV and highlight the opportunity for screening and early detection of KS and linkage to HIV care.

While KS can occur in Asian PLHA, it is distinctly uncommon. Only a handful of cases

have been reported in India, although the country has more than 1.5 million PLHA who include a substantial proportion of men who have sex with men. KS was not observed among 137 HIV-positive patients with cancer treated from 2001 to 2005 at the Tata Memorial Hospital in Mumbai, the largest tertiary cancer referral medical center in India (Biggar et al. 2009). The reasons for the low rate of KS in India are unclear. KS also is uncommon in Thailand. Since KSHV infection is required for KS to develop, the low rate of KS suggests low prevalence of KSHV. However, there is little known about KSHV seroprevalence; in one study, the seroprevalence was about 7% in India (Ablashi et al. 1999). Why KSHV would be uncommon in India is unclear. In Africa, KSHV infection occurs in early childhood, and prevalence increases rapidly with age in both sexes, particularly in poorer households without access to clean water. Transmission is probably via saliva exchange. Why KSHV has not spread in India or other areas of Asia, despite a large population living in poor socioeconomic conditions and lacking access to clean water, raises interesting questions about the biology of the virus versus human hosts in Asia. KSHV infection can occur among Asians because infection and KS have been reported in populations on the west coast areas of India, which have had many centuries of immigration and trade interaction with east and central Africa. Although data are sparse, there is evidence that half or more of adults in those regions are KSHV-infected and KS is also endemic. Studies conducted in PLHA and in the general population to confirm the low prevalence of KSHV and KS in Asia could provide insights about virus-host pathobiology. These studies might reveal, for example, pockets of KSHV infection in remote rural areas of India or Asia, which when they overlap with HIV might be associated with increased risk of KS.

In contrast to India, KS is diagnosed frequently in men who have had sex with men in Latin American countries, including Brazil, Columbia, and Argentina. In these countries, one-quarter of KS cases are AIDS defining, and three-quarters are diagnosed after AIDS onset (Yoshioka et al. 2004). The risk of KS has been linked to

infection with KSHV, which can be transmitted through male-male sexual contact (Boshoff 2000).

Non-Hodgkin Lymphoma

The risk for NHL in resource-limited countries is considered to be lower than in resource-limited countries, with notable exceptions. For example, Burkitt lymphoma (BL), which was first described by Denis Burkitt in 1958 in African children and linked to Epstein-Barr virus (EBV) (► [Epstein-Barr Virus](#)), is endemic in sub-Saharan Africa (► [Burkitt and Burkitt-Like](#)). In 1982, BL was one of the aggressive lymphomas that heralded the AIDS epidemic (► [Epidemiology of AIDS-Related Malignancies](#)). Not surprisingly, scientists wondered whether all or some of endemic BL cases might also be AIDS associated. Studies conducted on site in Africa dispelled this notion. Those studies demonstrated, as has been shown by studies conducted since, that most instances of BL in sub-Saharan Africa are HIV negative. The prevalence of NHL was 2.8% (compared to 6% in developed countries) in a necropsy study of among 247 persons aged 14 years or older who died of HIV-related disease and underwent post-mortem diagnosis at a hospital in Abidjan, Côte d'Ivoire, during 1991–1992 (Lucas et al. 1994). This included 1.6% with visceral NHL and 1.2% with primary cerebral lymphoma. Childhood BL was not observed among 78 autopsies performed on children in the same study. In the absence of well-conducted prospective studies, the results from this autopsy study provide the best data about the impact of HIV on NHL in Africa, where underdiagnosis may contribute to the low rates of NHL. A study of 26 NHL cases among persons aged 16 years or older diagnosed between 1992 and 1996 in Kenya found that 19 of the cases were diagnosed in HIV-positive persons. This number was higher than the investigators had expected, based on historical patterns before the HIV epidemic. The median age of the HIV-positive BL cases was 35 years, which is higher than the peak age of 5–9 years observed in endemic BL.

Data from population-based cancer registries comparing the incidence of NHL before and after

the onset of the AIDS epidemic support the notion that the NHL incidence may be increasing during the AIDS era. The incidence increased about three times for all NHL and about four times for pediatric BL, in the general population covered by the Kampala Cancer Registry between 1961 and 1971 and 1997 (Mbulaiteye et al. 2011). While these results support the notion of a positive impact of HIV on NHL, the lack of HIV status results on the NHL cases prevents firm conclusions.

Data from case-control studies conducted at large tertiary hospitals have provided a mixed picture. The results are compatible with a null or a modest impact of HIV with the estimates of increased risk ranging from 2.2 to 46.2 times compared to unaffected populations (Fig. 2). The largest study conducted in South Africa looked at 154 histologically confirmed adult NHL cases and compared them to 4,399 adult hospital controls drawn from cancers unrelated to HIV among the men or vascular conditions among the women. This study reported a fivefold increase in HIV infection in the NHL cases (95% CI 2.7–9.5) (Mbulaiteye et al. 2011). The results from an HIV/AIDS-cancer record linkage study conducted in Uganda observed that NHL incidence was increased seven times in persons with HIV compared to the general population (SIR 6.7, 95% CI 1.8–17) (Mbulaiteye et al. 2006), but no independent histological verification of NHL was done. The impact of HIV on BL varies from 2.1 to 46. The uncertainty about the degree of impact of HIV on BL is due to the inclusion of cases diagnosed clinically or with local histopathology without confirmation by expert hematopathologists. The possible exception is the result from a study conducted in South Africa, where the BL subtype observed is sporadic. Compared to children with other cancers, children with BL were 46 times more likely to be HIV positive, based on the finding that 13 of 33 cases were positive. The impact of HIV on BL in South Africa is more similar to the impacts reported in developed countries than in Africa (Mbulaiteye et al. 2011). The contrasting impacts of HIV on BL according to the subtype of BL are intriguing and prompt the question whether the association with HIV is different

between endemic and sporadic BL (► [Burkitt and Burkitt-Like](#)). Some of the reasons for the relatively low impact of HIV on BL include premature mortality from competing causes like malaria or tuberculosis or due to underdiagnosis of BL. If HIV increases the risk of BL, then the success in reducing mortality from preventable infections like tuberculosis and malaria may more clearly reveal the impact of HIV on BL. If the risk for BL is increased, approaches to increasing surveillance may have to be considered. In addition, questions about the proper treatment of HIV-positive children with BL will have to be considered.

Studies in Asia and Latin America also suggest that NHL risk is increased in persons with HIV. In India, the proportional incidence of NHL in persons infected with HIV was increased 17 times in men and ten times in women, based on a study conducted at Tata Memorial Hospital. NHL was the most common type of cancer reported in this study, accounting for 38% of the cancers seen in HIV-infected males and 16% of all cancers in HIV-infected women. The apparently lower risk of NHL in women than men is due to a large proportionate contribution from cervical cancer. Data from population-based cancer registries in Thailand suggest that the incidence of NHL has almost tripled from 1989–1991 to 1999–2001 (Sriplung and Parkin 2004). The incidence increased most steeply (11% per year) for diffuse/high-grade lymphoma, which is an ADC (Sriplung and Parkin 2004). The risk of NHL was elevated 34 times among 3,554 PLHA in Hubei Province in China followed from 2004 to 2007 compared to the general population.

Data from Latin America are scanty, but NHLs have been reported in persons with HIV and show a strong association with EBV in different countries, including Brazil (Sampaio et al. 2007). The low rates of NHL in PLHA from resource-limited countries are likely due to the gross underestimate of the real risk due to competing mortality (Access to Care). Under-ascertainment and/or misclassification of cases likely contributes. Conclusions about the impact of HIV on NHL await results from studies using sound epidemiological and laboratory design.

Cervical Cancer

Cervical cancer is the leading cancer and cause of cancer death in women in the resource-limited countries (► [Cervical Cancer](#)) (Sylla and Wild 2012). The principal cause is infection with carcinogenic human papillomavirus (HPV) via sexual contact (► [Human Papillomaviruses](#)). Thus, an association between HIV and invasive cervical cancer might be expected in populations where there is significant overlap of both infections because of shared routes of transmission (► [Epidemiology of AIDS-Related Malignancies](#)). An additional biological association might be expected because immunosuppression by HIV would impair the women's ability to clear their HPV infection, and it might act synergistically with HPV oncoproteins E6 and E7 to facilitate progression to invasive cervical cancer in HIV-/HPV-coinfected women. Consistent with this expectation, the prevalence of cervical intraepithelial neoplasia (CIN), which reflects infection of the cervical epithelium with HPV, with or without cellular abnormalities, is increased with HIV infection, and the prevalence or incidence of HPV or CIN is inversely associated with CD4 counts. However, the evidence for the association between invasive cervical cancer with HIV infection in resource-limited countries is controversial. The incidence of invasive cervical cancer in the general population in Uganda increased about threefold from 1960–1966 to 1991–2006 (Mbulaiteye et al. 2011), based on data from the Kampala Cancer Registry, but this magnitude of increase is small and could be due to effects of temporal changes, e.g., urbanization, better access to medical care, or improved case reporting. In Zimbabwe, which has also been severely affected by the HIV epidemic, no significant change in the incidence of invasive cancer in the general population was seen between 1990–1992 and 1993–1995 despite a sharp increase in the HIV prevalence among women during the same period. Moreover, the clinical presentation of invasive cancer has not dramatically changed during the AIDS era. The null or small increase (1.6–8-fold) in the risk of invasive cervical cancer in HIV-infected women has been confirmed by findings from case-control studies.

In Uganda, HIV was associated with a nonsignificant 1.6-fold increase in invasive cervical cancer in a hospital-based case-control study conducted in five hospitals in Kampala, the capital city of Uganda (Fig. 2). The risk was similar but statistically significant in a hospital-based study on Johannesburg in South Africa. A record linkage study of the women registered in the AIDS Support Organisation in Uganda with a local cancer registry reported a 2.4-fold increase in invasive cervical cancer incidence in HIV-infected women compared to women in the general population (Mbulaiteye et al. 2006). The highest risk of invasive cancer was reported in a case-referent study conducted in referral hospitals in Côte d'Ivoire and Benin from October 2009 to October 2011. The prevalence of HIV was eight times higher in women with invasive cervical cancers compared to other cancers.

Because African countries have only begun implementing cervical screening programs, the small impact of HIV on the risk of invasive cancer in sub-Saharan Africa may be largely due to competing causes of mortality in HIV-infected women. This explanation would be consistent with reports of elevated risk of CIN in HIV-infected women, but small impact with invasive cervical cancer, which takes up to 10 years to progress from initial lesion to invasive cancer. Despite the small impact, the prevention of invasive cervical cancer must remain a priority in many African countries. Recently established HIV treatment cohorts provide suitable opportunities to not only gather information about cancer risks but also introduce innovative approaches that link HIV services to cancer screening, early detection, and treatment services (► [HIV Prevention and Women](#)).

The impact of HIV on cervical cancer in India, the country with the world's highest number of cervical cancer cases, was slightly stronger (Biggar et al. 2009). The prevalence of HIV was four times higher in women with invasive cervical cancers compared to other cancers. The impact might be 68-times higher in HIV-positive women compared to unaffected women in other countries, based on results from one study in Hubei Province in China during 2004–2008

(Mbulaiteye et al. 2011). These results, while not confirmed yet, justify continued concern about the potential association between invasive cervical cancer and HIV in resource-limited countries.

Non-AIDS-Defining Cancers

Squamous Cell Carcinoma of the Conjunctiva

The diagnosis of squamous cell carcinoma of the conjunctiva (SCCC), a rare cancer of the ocular surface linked to exposure to ultraviolet light, has been linked to HIV infection in African countries close to the equator (► [Conjunctival Carcinoma](#)). This association was first reported in Uganda, where a curious doctor noticed an increase in the number of cases presenting with SCCC at eye clinics in Kampala. A formal study of 48 patients with SCCC and matched to 48 patients with benign conditions attending the eye clinics at Mulago Hospital revealed HIV infection in 75% of the cases compared to 19% among the controls (Mbulaiteye et al. 2011). Studies conducted in Uganda and Malawi suggest a tenfold higher risk of SCCC in HIV-infected individuals than in the unaffected individuals (Mbulaiteye et al. 2011). Consistent with this high risk, the SCCC incidence rates have increased 15 times in the general population between 1960 and 1997 (Mbulaiteye et al. 2011). This increase corresponds to the increase in the fraction of eye tumors that are due to SCCC, which increased from 23.5% to 71% among the men and from 0% to 85% among the women between 1960 and 1997. The strong association between SCCC and HIV has prompted a search for infectious etiology, focusing on mucosal high-risk and cutaneous HPV. However, in spite of the initial excitement about the possibility of discovering a novel infection or association, no clear etiologic agent has yet emerged.

An increase in the risk of SCCC has not been observed in South Africa (Mbulaiteye et al. 2011), despite a substantial HIV epidemic in that region and advanced medical services. The absence of impact in South Africa, which lies in the southern hemisphere far away from the equator, suggests that the HIV impact may be mediated by

ultraviolet light-mediated damage to the surface of the eye.

The risk for SCCC in other resource-limited countries has not been quantified, but reports of cases in HIV-infected people in India suggest that it occurs (Biggar et al. 2009).

Hodgkin Lymphoma

While studies conducted in developed countries suggest an excess risk of Hodgkin lymphoma in HIV-infected persons (► [Hodgkin Lymphoma](#)), the association with HIV in sub-Saharan Africa is less clear (Mbulaiteye et al. 2011). In Uganda, Newton et al. found that two of the four adults with HL (50%) were HIV seropositive compared to the (21%) HIV seropositivity observed among other cancers not known to be related to an infectious etiology. The risk of Hodgkin lymphoma was increased 1.4-fold in a case-referent study conducted in Johannesburg in South Africa (OR 1.4, 95% CI 1.0–2.7), and it was 1.6-fold when follow-up analysis was conducted with larger numbers (95% CI 1.0–2.7). The risk was increased 5.7-fold in a record linkage study conducted in Kampala in Uganda (OR 5.7, 95% CI 1.2–17) (Mbulaiteye et al. 2006), which is compatible with an adverse impact of HIV on Hodgkin lymphoma risk. Similar to other cancers, the risk of Hodgkin lymphoma may be grossly underestimated because of the lack of pathology diagnosis in most countries in sub-Saharan Africa. It is interesting that some studies, but not all, conducted in resource-limited countries suggest that the risk of Hodgkin lymphoma may be increasing in patients who are started in cART. If this pattern is confirmed, then studies conducted in sub-Saharan Africa patients who are initiated on cART may reveal an increase in risk in patients started on cART.

In India, a study of cancer patients at the Tata Memorial Hospital observed a fourfold increase in the proportional incidence of Hodgkin lymphoma among HIV-positive men and twofold increase in women, which was not statistically significant.

Liver Cancer

Hepatocellular carcinoma (HCC) is one of the most common cancers in sub-Saharan Africa (Sylla and

Wild 2012), with most cases attributed to hepatitis B and/or C virus infections. Studies conducted in sub-Saharan Africa have confirmed the expected high frequency of coinfection between HIV and chronic HBV and HCV infections in many countries in sub-Saharan Africa (Sutcliffe et al. 2002). However, an impact of HIV on liver cancer has not been demonstrated (Mbulaiteye et al. 2011) in the studies conducted in South Africa (OR 0.8, 95% CI 0.4–1.7) or Uganda (OR 1.2, 95% CI 0.3–4.2) (Mbulaiteye et al. 2011). Data from population-based cancer registries have demonstrated continuing stable rates during the HIV epidemic, consistent with the lack of an impact from HIV. Recently, a case-referent study conducted in referral hospitals in Côte d’Ivoire and Benin has reported an increased risk of liver cancer in their series including 1,017 cancers (OR 2.7, 95% CI 1.1–7.7). Liver cancer has a long induction period, and the observed risk may be low because of competing causes of mortality in HIV-infected patients in Africa. Thus, conclusions about the associations with HIV will have to wait for better data coming from the new consortia established to provide treatment in sub-Saharan Africa and may also increase as more HIV-infected patients get access to anti-HIV therapy.

A study of cancers in a cohort of HIV patients at the Zhongnan Hospital of Wuhan University in Hubei Province in China observed an elevated risk of liver cancer (SIR 6.0, 95% CI 2.6–12.2) (Mbulaiteye et al. 2011). While these results must be confirmed, they suggest that the risk of liver cancer may be significantly increased in HIV-positive patients in China, perhaps because of coinfection with HBV and/or HCV (Mbulaiteye et al. 2011).

The Role of Infections as Drivers of Cancer in PLHA

The onset of the HIV epidemic, heralded by cancers with suspected infectious etiology, focused attention on the role of infections and immunity on cancer risk. Although it was initially suspected that HIV might directly influence the risk of some cancers, it is now well established that HIV lacks oncogenes, which are needed to directly influence the risk of cancer in PLHA. The consensus is that

HIV primarily influences the risk of cancer indirectly via suppression of T-cell immunity (► [CD4 T Cell Depletion](#)), which then permits reactivation of latent oncogenic infections such as KSHV and EBV. This indirect mechanism has been supported by studies showing both the degree and the duration of immunosuppression measured by deficit in CD4 T cells correlate with the risk of KS and aggressive NHLs. However, not all cancers associated with infection show this expected pattern, suggesting that the relationship between HIV and cancer risk is multifactorial. The studies are limited in number and duration and have few outcomes, precluding any confident comment on risk factors, which might affect cancer risks in PLHA. The patterns of diagnosed cancer in resource-limited countries differ from those in the developed countries. Thus, the cancer profile and the risk factors for cancer in PLHA in resource-limited countries will differ from those in developed countries (Table 1). More than 50% of the 12 million cancers diagnosed globally are in resource-limited countries and about 30% are attributable to infection. The overlap between cancer and HIV among the 29 million PLHA in resource-limited countries is unknown, but even a small relative risk increase of cancer among PLHA has important public health consequences. The study of PLHA in the resource-limited countries could lead to the discovery of novel infections or novel associations with cancer. The discovery of KSHV and of a polyomavirus associated with Merkel cell carcinoma in patients with HIV/AIDS demonstrates the potential for such discoveries (► [Merkel Cell Virus](#)).

Conclusions

While cancer is not currently considered a common clinical problem in PLHA in resource-limited countries, this is likely to change as access to affordable cART improves and premature mortality from other causes is reduced (Access to Care; ► [cART and Supportive Care](#)). In the West, cancer is responsible for up to one-third of deaths in PLHA. The burden of cancer has increased in spite of the reduction in risk of

HIV Cancers in Resource-Limited Regions, Table 1 Summary of associations with selected cancers among people living with HIV/AIDS (PLHA) in developed and resource-limited countries

Cancer sites with increased risk	Relative risks in developed countries	Correlated with duration or degree of CD4 loss in PLHA	Tumor-associated co-viral infections	Incidence in developing relative to developed countries	Fold increase in PLHA in developing countries	Additional comments
AIDS-defining cancers						
Kaposi sarcoma	>1,000	++++	KSHV	Varies by region; very high in Africa	20–600 in Africa	Reported occasional in Asia
Non-Hodgkin lymphoma	20–350	+++	EBV	Low	2–46	
Cervical cancer	2–20	–	HPV	Very high	2–68	
Non-AIDS-defining cancers						
Squamous carcinoma of the conjunctiva	10–15	–+	?HPV	Very high	10	Reported in Africa, rare elsewhere
Hodgkin lymphoma	3–18	Inverse	EBV	Low	2–7	
Liver					<1	
Anus	20–50	–	HPV	Low	?	Little information
Vulva and vagina	4–8	–	HPV	High	?	

ADCs in PLHA principally because of a shift from ADC to NADCs. Projecting the future impact of HIV on cancer in resource-limited countries is fraught with difficulty given the lack of reliable data on cancer and HIV, but the negative aspect of the increasing risk of cancer in PLHA is a real concern. New efforts are needed to quantify the risk and identify opportunities to implement early cancer detection and treatment programs through linkage of HIV services to cancer care ([► Observational Cohorts Highlights of Evidence and Research](#)).

HIV Compartments and Viral Rebound During Treatment Interruption

Sol Aldrete and Vincent C. Marconi
Division of Infectious Diseases, Emory
University School of Medicine, Atlanta, GA,
USA

Definition

One of the main challenging characteristics of HIV is its extensive genetic diversity. This diversity is apparent across geography as represented by differing clades, but on a smaller scale exists within an individual. Viral phylogenetic studies within the same individual have shown diversity and divergence of the HIV virus in the multiple cell types and tissues analyzed. These subpopulations are known as viral quasispecies (Blackard 2012). The local environment present in the tissues influences the evolution of the quasispecies and subsequently impacts cellular tropism (i.e., higher affinity to macrophages from brain-derived virus), affects the response to antiretroviral therapy (ART), and ultimately, could affect eradication strategies.

A compartment has been defined as an anatomical site in which the virus is present, and there is limited exchange of viral genetic information with

other sites and may contain compartment-specific viral sequences (Eisele and Siliciano 2012). A reservoir, on the other hand, is characterized by cells or tissues that restrict viral replication and preserve replication-competent virus for a long period of time. It has more stable kinetics than the main pool of actively replicating virus. A sanctuary site is a compartment defined by limited penetration of ART (Nickle et al. 2003). These terms are not mutually exclusive, and some anatomic sites might function as one or more of these at the same time.

Introduction

The introduction of ART has dramatically changed the survival and prognosis of people living with HIV (Rodger et al. 2013). Initial analysis of the viral dynamics after initiating ART identified an initial rapid decay phase (half-life of 0.5–2 weeks) and a second slower decay phase (half-life of 1–4 weeks); early estimates based on these decay characteristics estimated that 2–3 years of therapy would be necessary to eliminate HIV from all its compartments (Perelson et al. 1997). We now know that there are two additional decay phases; a third one with a half-life of approximately 39 weeks and a fourth one with an estimated infinite half-life (Coffin and Swanstrom 2013). Recent estimates predict that close to 73.4 years of therapy might be necessary to eradicate the HIV reservoir within an individual (Siliciano et al. 2003), and new direct sequencing studies suggest that the size of the reservoir could be 60 times greater than initially proposed based on data from quantitative viral outgrowth assays (Q-VOA) (Ho et al. 2013).

It has been apparent that despite being on suppressive therapy, most patients have detectable plasma viremia when using more sensitive tests (i.e., HIV-RNA single-copy assay [SCA]). The significance of this is still unclear, but it has been shown to be a predictive factor of future virological failure and HIV drug resistance (Santoro et al. 2014; Maggiolo et al. 2012).

The source of these virions remains controversial summarized by two main hypotheses. The

first one posits that residual viremia stems from a low degree of ongoing viral replication. The second hypothesis proposes that the viremia represents a release of virions from the latent cellular reservoir, without infecting new cells owing to the presence of ART. Intensification of therapy, such as adding an integrase inhibitor, seems to have had no demonstrable reduction in residual viremia. This finding supports the theory that residual viremia might originate from the latent reservoir and not from ongoing viral replication (Gandhi et al. 2010), although there are two reports contradicting these findings (Hatano et al. 2013; Buzón et al. 2010).

The stability of this latent reservoir, mainly in resting memory CD4 T cells, allows the virus to persist despite potent ART and rebound after discontinuation of therapy.

Viral Rebound During Treatment Interruption

Treatment interruption leads almost invariably to viral rebound regardless of ART duration (Davey et al. 1999). Once therapy has been discontinued, time to detectable viral rebound is determined by two main factors; initially, the time to initiate viral replication by the latent reservoir (influenced by drug washout and time to viral reactivation), and second, the time from replication to viral load detection (Pinkevych et al. 2015). Several studies have shown a median time of 4 weeks to viral rebound (using a threshold of 200–400 copies/ μ L) after stopping ART and a median of 50 weeks to achieve pre-ART viral load levels (Li et al. 2016; Hamlyn et al. 2012).

The length of this period is influenced by several factors such as time of initiation of ART (acute vs. chronic HIV infection) (Steingrover et al. 2008), duration of ART prior to treatment interruption (Marconi et al. 2008), cd4 nadir (Hamlyn et al. 2012), and reservoir size (Li et al. 2016).

There is a small proportion of patients (5–15%), called posttreatment controllers (PTC), who remains virologically suppressed for several years after treatment interruption. Usually, they

have received very early and effective ART for several years before treatment interruption. These patients have been described in several studies (Hocqueloux et al. 2010; Sáez-Cirión et al. 2013; Sthör et al. 2013) and differ from elite controllers in several ways: there is not an overrepresentation of protective HLA class I alleles (HLA B*27 or HLA B*57), and they have ineffective HIV-specific CD8+ T-cell responses and low levels of T-cell activation. The exact mechanism has not been fully elucidated, but factors associated with PTC are a longer duration of ART, a female gender (Sthör et al. 2013), and a small viral blood reservoir (Sáez-Cirión et al. 2013).

Sources of Viral Rebound

Analyses of structured treatment interruption studies (STI) after long-term suppressive ART have shown that the origin of the rebound virus seems to be from long-lived latently infected resting CD4 T cells (Joos et al. 2008). More in-depth analyses have shown no significant changes in diversity, divergence, or phylogenetic structure on the HIV subpopulations when comparing pre-therapy to post-therapy virus, further supporting the idea that the reservoir becomes established before ART initiation and persists in long-lived cells that are subsequently the source for the rebound virus (Kearney et al. 2014, 2015). A recent study showed that the origin of this rebound virus seems to be from reactivation of many latently infected cells from multiple sites (Rothenberger et al. 2015).

HIV Compartments

As described above, viral compartments are characterized by a restriction of the viral gene flow between cells or tissues. The different factors thought to influence the establishment of a compartment are the following: cell types susceptible to HIV infection, immune pressure, local concentration of antiretroviral drugs, levels of inflammation/immune activation, and coinfections, among others (Blackard 2012).

To date, the most well-established HIV tissue compartments are the central nervous system (CNS), genital tract, gut-associated lymphoid tissue (GALT), and lymph nodes. Despite our extensive knowledge of viral dynamics in peripheral blood, there are limited studies on the dynamics existent in these different tissue compartments (Svicher et al. 2014).

CNS

The CNS represents an anatomic compartment as well as a pharmacologic sanctuary with very distinct characteristics. Its relative immune-privileged state permits an immunologic selective pressure on the virus that is distinct from lymphoid tissues. Additionally, viral quasispecies adapt within this compartment in order to replicate efficiently in macrophages further diverging these populations from peripheral blood (Gonzalez-Perez et al. 2012). The compartmentalization of the CNS is apparent when comparing HIV viral sequences between the blood and the brain; changes have been noted in the envelope (*env*) (Dunfee et al. 2006), *pol* (Dahl et al. 2014), *nef* (Olivieri et al. 2010), and long terminal repeat (LTR) sequences (Ait-Khaled et al. 1995). Certain variations in the HIV *env* sequences have shown relationship with HIV-associated dementia (HAD); this is believed to be due to increased neurotoxicity of these brain-derived variants (Power et al. 1998).

In the CNS, HIV replicates primarily in macrophages. There are four types of macrophages: the perivascular macrophages, meningeal macrophages, and macrophages of the choroid plexus and the microglia. The perivascular macrophages and microglia have been found to be the major reservoir for HIV, as well as the primary source of persistent inflammation in the brain (Zayyad and Spudich 2015). The role of astrocytes as a reservoir in HIV infection is less clear. HIV-infected astrocytes have been identified, but it is unclear if these cells can reactivate and produce infectious virions. Nonetheless, these cells produce tat protein, a potent neurotoxin associated with neuronal damage (Churchill and Nath 2013).

Regarding antiretroviral (ARV) penetration of the blood–brain barrier, a CNS penetration

effectiveness (CPE) rank was developed in order to categorize the current ARVs based on the ability to achieve optimal concentrations in the CNS. These categories were established after evaluating each ARV's chemical properties, concentration in the cerebrospinal fluid (CSF) from clinical studies, or effectiveness in mitigating HIV-associated neurocognitive disorders (HAND). The three categories are those with (1) the lowest CNS penetration, (2) an intermediate penetration, and (3) the highest penetration. Individual drugs are then assigned a value of 0, 0.5, or 1, respectively (Letendre et al. 2008). Evidence regarding the utility of this score to target CSF viral escape or HAND remains controversial, with some studies advocating for a benefit (Canestri et al. 2010), while others showing no benefit of an ART regimen with a high CPE score (Caniglia et al. 2014).

Lymph Nodes (LN)

Within lymph nodes, the majority of HIV-infected CD4⁺ T cells are found in the follicular mantle of the germinal center (GC) and the paracortex. The germinal center itself mainly contains follicular dendritic cells (FDC) that bind free virions via their complement and antibody receptors (Haase 1999).

HIV infection within the LN gets established in the very early stages of infection and, in untreated individuals, represents the main source of virus production and storage (Pantaleo et al. 1991). Unfortunately, despite the initiation of ART and suppressed plasma viremia, LN contain higher titers of viral RNA than other tissues (Horiike et al. 2012), and they are likely a key reservoir that contributes to viral rebound after treatment interruption (Rothenberger et al. 2015).

It is possible that LN could also represent a viral sanctuary, as ART (TDF, FTC, ATV, DRV, EFV) drug penetration is lower in lymphoid tissues compared to the blood cells (Fletcher et al. 2014), although this remains to be confirmed.

Genital Tract

HIV is transmitted predominantly via the sexual route, and semen is considered the major vehicle for transmission in both women and MSM

(Svicher et al. 2014). Current ART has significantly decreased the risk of sexual transmission by decreasing the HIV RNA in plasma and seminal fluid to undetectable levels. Nonetheless, HIV shedding in semen has been detected in some men receiving suppressive ART, highlighting the importance of the genital tract as a distinct compartment (Gianella et al. 2013).

It has been shown that HIV characteristics between the blood and semen differ in aspects such as the envelope and protease genes, drug resistance, and lack of correlation between the blood and seminal plasma RNA viral loads. Besides, there is evidence of different HIV quasi-species between seminal leukocytes and seminal plasma (Craig and Gupta 2006). The mechanism for compartmentalization within this site is not known, but higher levels of cytokines and chemokines and therefore inflammation and T-cell activation have been found in the seminal compartment (Politch et al. 2012). This inflammation and T-cell activation increases HIV replication and infection of new cells through several mechanisms. Cytokines such as IL-6 result in an increase of HIV transcription and post-transcription steps, a proliferation of HIV-infected cells, and a reduction in HIV immune response. Expression of CCR5 on CD4⁺ T cells leads to an increased susceptibility of these cells for HIV infection and traffics these cells to areas of highest HIV infection within tissues (Golden et al. 1992; Blackard 2012). The genital female tract has documented compartmentalization as well, and factors such as a higher CD4 count are associated with a higher degree of compartmentalization and changes in the density of gp120 glycosylation (Craig and Gupta 2006; Kemal et al. 2003).

Elevated levels of genital pro-inflammatory or chemotactic cytokines (MIP-1 α , MIP-1 β , IP-10, IL-8, MCP-1, IL-1 α , IL-1 β , IL-6, and TNF- α) have been associated with an increased risk of HIV acquisition (Masson et al. 2015). A major source of elevated inflammatory cytokines in the genital female tract seems to be sexually transmitted infections (STI) and bacterial vaginosis (BV) even if they are asymptomatic (Masson et al. 2014).

Herpes simplex type 2 (HSV-2) infection has been demonstrated to have an important synergy with HIV as both increase the risk of acquiring the other. It is believed that HSV-2 increases the risk of HIV-1 infection through disruption of the epithelial barrier and recruitment and persistence of inflammatory cells that are susceptible to HIV-1 (CCR-5 expressing CD4 T cells, dendritic cells) in the genital tract (Barnabas and Celum 2012).

GALT

Within weeks after primary HIV infection, there is massive depletion of CD4⁺ memory T cells in the lamina propria of GALT; this significant depletion likely reflects the high frequency of lamina propria CD4⁺ T cells that express CCR5 and are in an activated state (Eisele and Siliciano 2012). The initiation of ART does not rapidly reverse this process, and higher frequencies of HIV-proviral DNA are detected in this compartment compared to blood despite long-term suppressive therapy (Chun et al. 2008).

The role of GALT as a compartment is still controversial. Several studies have shown no genetic differences or viral evolution between the HIV-1 sequences in the blood compared to the gut (Svicher et al. 2014).

HIV Reservoir

The reservoir has been recently redefined as an HIV-infected cell population that allows the existence of replication-competent HIV-1 in patients on optimal ART in the order of years (Eisele and Siliciano 2012). This new definition emerged to reflect the increasing efforts toward identifying a cure and eradication of the reservoir. However, the reservoir is already present in a small fraction of resting CD4⁺ T cells (<0.05%) before ART initiation. The reservoir is extraordinarily stable, and it seems to have minimal decay after several years of suppressive therapy (Siliciano et al. 2003).

Latency

Viral latency is a state of reversible, nonproductive HIV infection of individual cells. HIV establishes latency in cells through two different

mechanisms: pre-integration and post-integration latency. Pre-integration latency usually happens when the virus infects resting CD4⁺ cells; however, due to blocks on the cell cycle in this state, the viral genome is unable to migrate to the nucleus and integrate to the host genome. This reservoir is considered to be very labile, with a half-life of 1–6 days. Post-integration latency occurs when HIV infects activated CD4⁺ T cells and integrates into the host DNA and the cells survive long enough to revert back to a resting state as memory cells (Blankson et al. 2002). This reservoir gets established very early during the primary HIV infection and remains stable despite viral suppression with ART (Finzi et al. 1999).

The most well-characterized cellular reservoir in HIV-1 infection is the small pool of latently infected resting memory CD4⁺ T cells; among which, the subset of central memory (T_{CM}) and transitional memory (T_{TM}) CD4⁺ T cells are infected in higher proportion compared to effector memory (T_{EM}) or naïve (T_N) T cells (Chomont et al. 2009). During treatment, the frequency of these latently infected cells has been noted to be low, between the ranges of 0.03–3 infectious units per million (IUPM) (Siliciano et al. 2003). The factors that contribute to the stability of this latent reservoir have not been fully elucidated, but are thought to be due to the intrinsic stability of the resting memory CD4⁺ T cells, cryptic (cell-to-cell) transfection, and homeostatic proliferation (Chomont et al. 2009; Rong and Perelson 2009). More recently, another mechanism has been postulated for the persistence of this reservoir and involves clonal expansion of HIV-infected T cells influenced by insertion of the provirus in specific genes (i.e., MKL2 and BACH2) contributing to the expansion and persistence of the host cell (Maldarelli et al. 2014).

Other proposed cellular reservoirs are the monocyte–macrophage cell lineage, dendritic cells (DCs) and follicular dendritic cells (FDCs). These cells have been shown *in vitro* to support HIV replication and have long half-lives permitting an ideal candidate for composing part of the reservoir.

The monocyte–macrophage cell lineage could represent an important second reservoir for HIV

given their longevity and limited cytopathic effects in these cells. Monocytes (Sonza et al. 2001) and macrophages (Cribbs et al. 2015) have been shown to harbor HIV-proviral DNA despite undetectable plasma viremia. However, their role in latency and as a reservoir is still being studied.

Measuring the HIV Reservoir

One of the greatest challenges to eradicating HIV is detecting changes in the reservoir after experimental interventions. Measuring the HIV reservoir generally refers to quantifying the pool of latently infected T cells in the body. To date, there is no perfect method to measure this reservoir, as the latently infected T cells are disseminated throughout the body and concentrate differently in the lymphoid tissues (Rouzioux and Richman 2013). Each technique will give us different information about the reservoir.

Viral outgrowth assay (VOA): currently considered the gold standard assay for measuring the size of replication-competent HIV reservoir, but with a number of drawbacks. This measures the frequency of resting CD4⁺ T cells that produce infectious virus after a single round of maximum *in vitro* T cell activation. Limiting dilutions of resting CD4 T cells are stimulated with the mitogen phytohemagglutinin (PHA); released viruses are expanded by addition of CD4⁺ T lymphoblasts from healthy donors. Afterwards, the number of culture wells at each dilution that are positive for HIV-1 p24 antigen (via ELISA) is determined. These results are extrapolated to calculate the number of latently infected cells per million resting CD4⁺ T cells (infectious units per million, IUPM) (Ho et al. 2013; Eisele and Siliciano 2012). The main disadvantages of this assay are that it is labor-intensive and time-consuming, requires a large volume of blood (120–180 ml), and relies on the number of resting CD4 T cells isolated.

Molecular Measure of the Reservoir

HIV genetic sequences can be found within infected cells (i.e., the reservoir) in a variety of forms: HIV DNA (integrated, nonintegrated, and

circular) and HIV RNA (spliced and unspliced) (Lewin et al. 2011).

Total cell-associated HIV DNA (CA-DNA): CA-DNA (integrated, nonintegrated, and circular) is detected through PCR. The PCR-based assays are far cheaper and faster than the VOA. However, the main problem with this assay is that it cannot differentiate between cells infected with defective virus and viable provirus, overestimating the size of the reservoir when compared to the VOA. Furthermore, it cannot distinguish between integrated and nonintegrated HIV DNA.

Integrated HIV DNA: for this assay, an *Alu*-LTR PCR is used with the capacity to quantify only integrated HIV DNA.

2-LTR circles: 2-LTR circles are episomal forms of nonintegrated HIV DNA and a marker of recent infection. PCR is also used to detect them.

CA HIV RNA: viral RNAs transcribed from the integrated provirus give origin to multiply spliced RNAs (ms), unspliced RNAs (us), and incompletely spliced (is) RNAs. The origin of these transcripts in patients on suppressive ART can be from latently infected cells, reactivated cells, or newly infected cells. This CA-RNA is considered to be a biomarker of the “active viral reservoir” (Pasternak et al. 2013). Similar to HIV-DNA measures, this assay cannot distinguish between replication-competent and replication-incompetent virus.

RT-PCR for poly(A) tail of HIV-1 mRNA: this assay targets specifically the viral mRNA generated only after host transcription via downstream primers consisting of oligo dTs followed by nucleotides complementary to the last few nucleotides before the poly(A) tail (Shan et al. 2013). It is also used to detect residual viremia. The advantage of this technique is to eliminate the host read-through of HIV DNA.

Tat-/Rev-induced limiting dilution assay (TILDA): this assay measures the frequency of cells with multiply spliced HIV RNA in unstimulated and stimulated cells.

SCA: a very sensitive PCR assay that detects the presence of residual viremia with a limit of detection as low as 0.2 copies/ml plasma depending on the input volume (Eriksson et al. 2013).

Conclusion

Our inability to eradicate HIV from its compartments and reservoir represents the major impediment to an HIV cure. During acute HIV infection, the virus disseminates via the blood stream to various organs and tissues within weeks. It also establishes latency in a small pool of long-lived CD4⁺ T memory cells, which has precluded early initiation of ART from completely eradicating infection and explains viral rebound after stopping ART. In addition, HIV compartmentalization represents a unique opportunity for the virus to grow in environments with different immune pressures, drug concentrations, and levels of inflammation/immune activation that further drive its diversity and divergence.

A better understanding of these interactions might permit the development of more targeted therapeutic strategies.

Definition

For *Retroviridae* like human immunodeficiency viruses (HIV), the latent reservoir consists of inactive forms of the provirus that is the DNA version of the viral genome integrated at a random position in the host genome. After infection, HIV rapidly disseminates through the body and HIV reservoir is consisted of one or multiple viral reservoirs (cell types or tissues). Despite the development of successful treatment of HIV-infected individuals and the capacity to reduce HIV in the blood to undetectable levels, it has not been yet possible to eradicate HIV from the body due to the persistence of viral reservoirs. CD4+ T cells are thought to be the most significant cellular reservoir for HIV-1, but other reservoirs can contribute to virus persistence (Brenchley et al. 2004). Furthermore, the

establishment of viral persistence and latent reservoirs could also depend on the HIV tropism and differential expression of coreceptor on the surface of cells.

HIV-1 entry into CD4+ T cells is a multiple step process. First, the external envelope glycoprotein (gp120) of HIV-1 binds to the CD4 receptor on the surface of the CD4+ T cell. Binding of the coreceptor leads to conformational changes in HIV-1 gp41, followed by fusion of the viral membrane and the host cellular membrane and the release of the viral particle contents into the cytoplasm. The HIV-1 infection is then limited mostly to cells that express CD4 (a member of the immunoglobulin superfamily) and appropriate coreceptors. The identification of CCR5 and CXCR4 as main HIV-1 coreceptors for entry of HIV-1 into target cells was one of the most important discoveries in the HIV-1 field that significantly advanced the understanding of virus-host interactions. The human receptors CCR5 and CXCR4 are members of (or closely related to) the chemokine receptor family. These receptors are expressed on a wide range of cells that circulate in the blood, but the primary target for HIV-1 infection is the proliferating CD4+ T cell.

The regions of gp120 implicated in the interaction with coreceptors are variable V1/V2 and V3 loops. Coreceptor selectivity is mainly determined by genetic sequences within gp120, particularly on a highly variable and structurally flexible region termed “V3” involved in coreceptor binding (Jensen and van't Wout 2003). This V3 loop of HIV-1 gp120, a disulfide-linked loop of approximately 35 amino acids, makes direct contact with the coreceptor and plays a dominant role as determinant of coreceptor usage. Several amino acid substitutions in V3 loop (e.g., at positions 11 and 25) and total net charge of V3 loop frequently determine viral coreceptor usage. The V3 loop has now long been known to be a major determinant of cell tropism and now receptor use. The HIV viruses were then categorized as R5-tropic (ability to interact with R5 coreceptor) or X4-tropic viruses (ability to interact with X4 receptor). The R5X4-tropic viruses have the ability to use both coreceptors.

There is an increasing interest in the coreceptor tropism implication, including in reservoirs, in the HIV disease progression, to better understand the physiopathology of the disease and also because an antiretroviral class uses a novel mechanism of action by blocking attachment between HIV-1 gp120 and the human CCR5 receptor.

Tropism in PBMCs (Peripheral Blood Mononuclear Cells)

Proviral DNA in PBMCs may be considered as a potential alternative source of viral genetic material for tropism testing in patients with low or undetectable viral load (Soulie et al. 2012). The percentage of R5-tropic viruses determined in DNA varied between approximately 48% for multi-treated patients with undetectable or detectable HIV-1 viral load and 92% for non-treated patients in primary infection (Soulie et al. 2011; Frange et al. 2009; Bon et al. 2015). This proportion was similar to that previously evidenced for HIV-1 tropism in plasma. In some studies, tropism determination was performed both in proviral DNA and plasma RNA (at the same time or delayed time), and discordance rate ranged from 4.8% to 10%. Thus, there is a relatively high concordance of HIV tropism in RNA and DNA (Soulie et al. 2012). Some studies suggested that the composition of HIV-1 quasi-species in patients with sustained undetectable viral load on antiretroviral treatment can evolve with an increase of CXCR4 virus in DNA (Delobel et al. 2005).

The presence of X4-tropic viruses in PBMCs in chronically infected patients, with an R5-tropic variant in plasma, could represent the emergence of an archived virus (distinct env sequences in compartment and plasma) (Rozera et al. 2009). This is consistent with the presence of archived proviruses which might not correspond to the most prevalent variant in plasma as distinct resistance patterns were found in PBMCs and plasma.

Tropism in the Central Nervous System

The macrophages in the central nervous system, and other tissues, are an important cellular reservoir for HIV infection. R5 viruses are

predominant in tissues in which monocytes/macrophages lineage cells are prevalent like in brain tissue (Peters et al. 2007). Indeed, most HIV strains isolated from individuals with HIV encephalitis and AIDS dementia are R5-tropic viruses, which are consistent with the central role of macrophage in brain infection (Soulie et al. 2009). X4-using viruses mainly infect T lymphocytes, although some X4-tropic isolates could also infect macrophages and microglia.

The ability of drugs to cross the blood-brain barrier is a limitation for HIV treatment. An antiretroviral treatment with a low penetration in the central nervous system (CNS) can allow a residual HIV replication in the compartment; this can be related to cognitive impairment and HIV genetic variation including tropism changes. It has been shown that maraviroc (a CCR5 antagonist) achieved concentrations within the EC(90) range in cerebrospinal fluid (Tiraboschi et al. 2010). Another way to improve the drug penetration could be new drug delivery technologies.

Tropism in the Male and Female Genital Compartment

The male genital secretions are implicated in the majority of HIV transmission. Viruses present in the seminal fluid include X4 or R5 strains that preferentially infect lymphocytes and macrophages according to their coreceptor usage, respectively (Curran and Ball 2002). Several genetic studies have predicted viral tropism in the genital mucosae or secretions with a viral genetic compartmentalization between blood and this compartment associated with different coreceptor usage (Andreoletti et al. 2007). The mechanism for coreceptor switching in women's secretions is not known, but assumptions are made that X4-infected cells are originated from peripheral blood. The R5-tropic viruses are more readily transmitted than X4-tropic viruses, probably due to the selective expression of the R5 cell-surface protein on the target cells in the genital mucosa. This compartmentalization for the male or female genital tract could have an impact on transmission and could be due to divergent immune responses in these compartments.

Tropism in the Gut-Associated Lymphoid Tissue

The gut-associated lymphoid tissue is the largest lymphoid tissue in the body and contains a high level of CD4 cells that express CCR5 coreceptor (van Marle et al. 2007). It was evidenced that HIV persists in the gut-associated lymphoid tissue even in the presence of successful antiretroviral therapy. A recent study used sequence analysis of the *env* C2-V3 region to clearly demonstrate a lack of compartmentalization of HIV-1 quasi-species between blood and gut. This argues that the gut mucosa does not appear to serve as a sanctuary site for HIV-1 replication and that free exchange of HIV-infected cells takes place between gut and blood (Imamichi et al. 2011). Then, the tropism should be similar between these two compartments.

Conclusion

It is now unquestionable that the evolution of R5-tropic to X4-tropic strains occurs in vivo in HIV patients (about 50% of symptomatic individuals illustrate the capacity of HIV-1 to switch coreceptors) and that the presence of X4 viruses clearly increases the risk of disease progression. Furthermore, compartmentalization of the viruses has been shown in some cases, evidenced by HIV-1 tropism, genetic evolution, or distinct patterns of resistance. Depending on the compartment, the presence of the coreceptors and the immune selective pressure could be different. Independent HIV variation in different body compartments has been now well documented and also suboptimal drug penetration in tissue that can participate in HIV replication within compartments. In this way, there is a need to develop drugs with a good penetration into compartments to have a good pressure on HIV and to avoid viral evolution.

Definition

HIV testing and counseling (HTC) is the process that individuals and couples undergo to learn if they are infected with the human

immunodeficiency virus (HIV). A blood, saliva, or urine sample is taken from the person and tested for HIV antibodies or antigens, depending on the type of test being used. Counseling is an interactive and personalized dialog between the person or couple seeking the test and the provider. Certain kinds of HTC, such as voluntary counseling and testing (VCT), provide counseling before and after an HIV test. Other models of HTC, such as provider-initiated testing and counseling (PITC), offer pretest information and posttest counseling based on the test result and are integrated with routine clinical services. In addition to the diagnostic value of HIV testing, learning one’s HIV status through HIV testing and counseling has been shown to motivate behavior change among people who test negative for HIV to prevent acquisition of the virus and among those who are positive to reduce their risk of transmission of the virus. It is also critical to know one’s HIV infection status in order to appropriately link individuals who test positive with HIV care such as antiretroviral therapy (ART) and also triage preventative interventions such as medical male circumcision, antenatal prophylaxis, and pre-exposure prophylaxis. The World Health Organization emphasizes that mandatory or coerced HIV testing is never appropriate and that the provision of HIV testing and counseling must adhere to what is known as the five Cs – consent, confidentiality, counseling (at a minimum, pretest information and posttest counseling), correct test results, and linkages to care (WHO 2012a).

Introduction

At the time the first licensed HIV test became available in 1985, there were no treatments for HIV available and learning one’s HIV status was viewed as a virtual death sentence. During the years immediately after HIV testing became available, positive test results diagnosed within the health system were frequently reported to insurance companies, government agencies, and employers resulting in significant social harm to those tested. These social harms amplified the already existing stigma surrounding HIV and

toward the groups initially most affected, including men who have sex with men and injecting drug users. As a result, there were concerns that people at heightened risk of HIV would donate blood in order to learn their status through blood banks rather than through the health-care system. Given that the HIV test could often not detect the virus during the 6-month window period when an infected person is developing antibodies, people seeking an HIV test result through blood banks could have jeopardized the safety of the US blood supply. The US government responded to this dilemma by supporting the development of HIV testing sites where individuals could learn their HIV status anonymously. Shortly afterwards, the US Centers for Disease Control and Prevention (CDC) and the World Health Organization (WHO) developed official guidelines on HIV testing. These guidelines emphasized that HIV testing needs to be a confidential process and should always occur together with HIV prevention counseling (CDC 1985, 1987; WHO 1990). Ultimately, voluntary counseling and testing (VCT) emerged as a model of HTC that includes pre- and posttest client-centered counseling focused on HIV prevention (CDC 1994; Divine et al. 2001; WHO 1993). VCT rapidly became the HTC model promoted internationally as an HIV prevention tool in the mid-1990s (UNAIDS 1997, 2000).

Since then, multiple developments in HIV testing technologies, effective HIV treatments, and HIV prevention approaches have changed the HIV testing landscape. When rapid HIV diagnostic tests became available, clients no longer had to return to the clinic weeks after a blood draw to learn their results. Instead clients could receive their results on the same day during the same visit, thus increasing the number of people learning their test result, especially among marginalized populations (Pottie et al. 2014). The development of effective ART in the mid-1990s also expanded the value of HIV testing and counseling from a preventive measure with psychological benefits, to a necessary step to entering care and accessing treatment. In response to such developments, new models of HTC emerged.

These models include provider-initiated HTC and, more recently, based on advances in testing technology, self-testing for HIV. These evolving approaches have also allowed HIV testing and counseling to be offered beyond clinic settings and could then be expanded to community settings. Furthermore, the importance of knowing one's HIV status has only intensified as a critical step for engaging in newer prevention tools that offer increased protection from the virus, including medical male circumcision (see “► [Circumcision and AIDS](#)”) and preexposure prophylaxis (PrEP) (see “► [Preexposure Prophylaxis \(PrEP\)](#)”).

Evolving Models of HIV Testing and Counseling

HIV Voluntary Counseling and Testing (VCT)

One of the first models of HIV testing and counseling that emerged was VCT. VCT is client-initiated, meaning that the person who wants to know his or her HIV status actively seeks the test. VCT also includes both pre- and posttest counseling. Pretest counseling is an opportunity for the counselor and client to review the test process, discuss the client's risk behaviors, review prevention options, reaffirm the decision to take an HIV test, and assess coping strategies if found to be living with HIV (Divine et al. 2001; UNAIDS 2000). During posttest counseling clients receive their HIV test results and discuss personalized risk-reduction and disclosure strategies as well as receive referrals for care and support. VCT was first promoted as a way for individuals to learn their HIV status and then expanded to include couples counseling and testing. Couples VCT involves two people undergoing VCT together and learning each other's status through mutual disclosure (WHO 2012b). VCT is often offered in a stand-alone location, separate from other health-care services, although VCT was being integrated into some existing services such as antenatal care (ANC) and sexually transmitted infections (STI) clinics even prior to the

shift toward provider-initiated testing and counseling.

Provider-Initiated Testing and Counseling (PITC)

In the PITC model, HIV testing is offered as part of routine clinical care with an emphasis on identifying and linking people living with HIV with care and treatment. Unlike VCT, which relies on individuals and couples to actively seek an HIV test, PITC emphasizes the health-care provider offering HIV testing to their clients as part of routine care. PITC guidelines require less counseling than VCT, with a focus on the provision of pretest information, which can be didactic, as compared to pretest counseling, which is client-centered and interactive (Branson et al. 2006; WHO and UNAIDS 2007). Pretest information may be provided using an opt-in or opt-out approach. In the opt-in approach, the patient must explicitly agree to have an HIV test when offered by the provider. Conversely, in an opt-out approach, the HIV test is routinely performed with the patient's awareness unless the patient explicitly declines to take the test (UNAIDS 2007). WHO/UNAIDS recommends opt-out testing except when working with vulnerable populations who may have limited freedom to refuse a test (e.g., prison populations) (WHO and UNAIDS 2007). Following the test, all PITC clients should receive posttest counseling tailored to their HIV test result. Such counseling focuses on HIV prevention for people who test either negative or positive. For those who test positive, HIV status acceptance and linkages to HIV care and treatment are also emphasized (WHO and UNAIDS 2007). WHO/UNAIDS provides further guidance to recommend PITC for all patients who exhibit signs and symptoms of HIV infection in any setting and as a standard part of medical care for all patients in settings where HIV prevalence is greater than 1%. In epidemics where the HIV prevalence is high among defined subpopulations but less than 1% among the population at large, WHO/UNAIDS recommends more selective implementation of PITC only in facilities reaching

groups at higher risk (e.g., tuberculosis (TB) and STI clinics).

HIV Self-Testing

Self-testing for HIV occurs when an individual collects a saliva or blood specimen themselves, performs an HIV rapid diagnostic test, and interprets the results in private (WHO 2014a). Self-testing differs from home specimen collection, which was approved by the US Food and Drug Administration (FDA) in 1996, and allows individuals to collect a sample of blood that is sent to a laboratory for testing. A self-testing kit developed by OraSure Technologies was approved for use by the FDA in 2012 (FDA 2012). US-based studies have demonstrated the acceptability and feasibility of self-testing among key populations, including men who have sex with men, and studies from low- and middle-income countries show promising results regarding the uptake, feasibility, and acceptability of self-testing (Krause et al. 2013).

Potential benefits of self-testing include expanded access to HIV testing, especially for high-risk populations, increased convenience and privacy, user empowerment, and the potential for mutual partner testing prior to sex (Wood et al. 2014). Concerns regarding self-testing include inequitable access due to its relatively high cost, the potential for user error and failure to seek confirmatory testing, a lack of counseling and linkage to care for infected individuals, and the potential for forced or coerced testing (Wood et al. 2014). HIV self-testing is a promising new approach to HTC, but questions remain about the logistical, regulatory, and policy implications of its implementation.

Service Delivery Approaches to HIV Testing and Counseling

The World Health Organization outlines different service delivery approaches for providing HTC in both facility and community settings (WHO 2012a).

Facility-Based

Facility-based HTC approaches consist of HTC conducted in a health-care facility. Most facility-based HTC consists of PITC in specialized clinics, including ANC, TB, STI clinics, and in general medical practice clinics. Facility-based HTC also encompasses stand-alone VCT centers serving the general population, as well as drop-in centers targeting key groups at heightened risk of HIV such as sex workers, people who inject drugs, and men who have sex with men.

Community-Based

Community-based HTC approaches include home-based testing, mobile and outreach testing, and testing that takes place in institutional settings such as schools and workplaces. Self-testing is also included as a community-based approach. Home-based testing consists of both HTC being offered door-to-door in a community and the targeted provision of HTC in the homes of index cases who are already identified as living with the virus. Mobile HTC involves the use of mobile vans or tents and may be offered in connection with specific public gatherings or events. Finally, HTC can be conducted in institutional settings such as workplaces and schools, either as a one-time event or a regular component of institutional health and wellness services.

Effectiveness

HTC has multiple goals, including people learning their HIV status to facilitate uptake of appropriate care and treatment as well as to reduce HIV-related risk behaviors. Several review articles and meta-analyses have examined whether HTC is successful at achieving these goals. Meta-analyses use statistical techniques to combine results across different studies in order to quantitatively assess the impact of the intervention. Below are brief summaries of review articles and meta-analyses to date that examined the preventive benefits of HTC – as a way to change sexual risk behaviors or as a way to increase HIV serostatus awareness and linkages to HIV care and treatment.

Changing Sexual Risk Behaviors

The earliest review articles on HTC focused on the effects of VCT on sexual risk behaviors among populations, mainly in high-income settings (Higgins et al. 1991; Wolitski et al. 1997). These reviews found that results varied by the populations studied, such as men who have sex with men and people who inject drugs, with the most consistent findings showing increased condom use and safer sexual practices among couples where at least one partner was HIV positive. In 1999, the first meta-analysis of the impact of HTC on sexual risk behavior was published (Weinhardt et al. 1999). Analyzing data from 27 published studies, the findings supported HTC as a secondary prevention method with the greatest changes in behavior occurring among individuals or couples living with HIV.

In 2008, the first meta-analysis focusing on studies from low- and middle-income settings was published. Data from seven studies showed that people who received VCT were significantly less likely to engage in unprotected sex when compared to their behaviors before receiving VCT, or as compared to people who have not received VCT [OR 1.69; 95% CI 1.25–2.31]. VCT was not found to have a significant effect on the number of sex partners [OR 1.22 95% CI 0.89–1.67] (Denison et al. 2008). A 2012 Cochrane Review updating these data found 19 eligible studies (Fonner et al. 2012). This meta-analysis found that study participants who received VCT, when compared to those who did not, were less likely to report an increased number of sexual partners [OR = 0.69 95% CI 0.53–0.90]. The odds of protected sex/condom use as a result of HIV testing was also significant when data across studies were pooled, but only among people who were living with HIV [OR 3.24 95% CI 2.29–4.58].

Only one review article to date has looked at behavioral outcomes following provider-initiated testing and counseling in low- and middle-income countries (Kennedy et al. 2013). This article provides a qualitative review of existing data as heterogeneity among intervention approaches and outcomes precluded meta-analyses. The majority of articles (12 out of 19) focused on PITC offered

in ANC, family planning, and postpartum/child health clinics. The rest of the studies took place in TB, outpatient, STI, or methadone maintenance clinics. Trends from these studies indicate an increase in condom use after PITC.

These review articles and meta-analyses highlight several trends, including growing evidence over time for desirable behavior change among people who test positive for HIV compared to their HIV-negative counterparts. Most reviews have focused on VCT, with newer reviews considering the impact of newer models of HTC on risk behavior outcomes, reflecting the history in the evolution of HTC.

Increasing Knowledge of HIV Status and Access to Care

Globally, more than half of all people living with HIV are unaware of their HIV infection status (UNAIDS 2014). Multiple reviews and meta-analyses document that HIV testing using rapid tests, conducted in clinical settings with a PITC model, and HIV testing offered in community settings all have been shown to increase the uptake of HIV testing and the number of people who learn their HIV status (Hensen et al. 2012; Sabapathy et al. 2012; Kennedy et al. 2013; Suthar et al. 2013; Pottie et al. 2014). In particular, community-based HIV testing strategies can reach groups who do not typically access routine medical care (Pottie et al. 2014). For example, a meta-analysis of home-based voluntary HIV testing found that men, who in many settings test for HIV much less frequently than women, were just as likely as women to accept the test with home-based testing (Sabapathy et al. 2012). This review of home-based HIV testing also presented a pooled estimate that 83.3% of participants (95% CI 80.4–86.1%) accepted to undergo home-based testing and 76.7% (95% CI 73.4–80.0%) received their HIV test results. Less is known, however, about how people identified as living with HIV through the different approaches to HTC link with HIV care and treatment. A review of community-based testing approaches found that 80% (95% CI 75–85%) obtained a CD4 cell count test result after learning their HIV status and 73% (95% CI 61–85%) eligible participants initiated ART

(Suthar et al. 2013). Another review of self-testing for HIV found that 96% of participants who tested positive reported they would seek posttest counseling, although none of the studies in the review published data on linking to care after the test (Pai et al. 2013). Overall, while the different models of HTC are increasing people's awareness of their HIV status, a better understanding of how these HTC strategies can connect people newly diagnosed with HIV to care and treatment is needed.

Continuing Challenges and Emerging Issues

Quality Assurance/Quality Control

Many HTC programs, particularly in low- and middle-income settings, rely on testing algorithms composed of several rapid diagnostic tests. Rapid diagnostic tests approved by the World Health Organization have shown high levels of sensitivity and specificity based on field studies conducted in low-income settings (WHO 2014b). Despite the very good quality of these tests, errors could result in the misclassification of HIV status. Inaccuracies during rapid testing can result from operator error and improper testing procedures, faulty test kits (e.g., use past expiration), using an improper test sequence, and potential cross-reactivity due to certain population characteristics (Klarkowski 2014). WHO has created guidelines to help countries determine which specific rapid diagnostic tests and algorithms are most appropriate to use (WHO 2012a). To cope with the rapidly expanding number of HTC programs and facilities, having adequate quality assurance and opportunities for confirmatory testing is critical in ensuring HTC clients are provided with accurate HIV test results.

Task Shifting

Countries have different regulations for who can conduct HTC. Only licensed nurses or doctors are allowed to conduct HTC in some countries, while in other countries, trained lay people (lay health providers) are allowed to perform HTC. With many countries experiencing health workforce

shortages, task shifting – or the rational redistribution of tasks from higher-trained providers to less well-trained providers – may help expand the reach of HTC services. Existing research, while limited, suggests that lay providers can conduct high-quality HTC and may even be better than more highly trained providers. For example, a US-based randomized trial comparing HTC provision in an emergency department setting by trained HIV counselors versus regular emergency department health-care providers found higher rates of HTC uptake in the counselor arm (57%) compared with the provider arm (27%; $p < .001$) (Walensky et al. 2011). Studies from South Africa (Jackson et al. 2013), Malawi (Molesworth et al. 2010), and Cambodia (Kanal et al. 2005) have also shown that lay providers can conduct HTC with high rates of sensitivity and specificity (over 98%). Lay providers conducting HTC may be particularly important for reaching key populations and may provide an important source of support and information to these populations as self-testing becomes more common.

Role of Risk-Reduction Counseling

The importance, nature, and extent of counseling as part of HIV testing have long been a source of debate. Extensive counseling requirements may pose human resource and financial limitations to the scale-up of HTC, and the impact of prevention counseling on individuals who test HIV negative in particular remains unclear. One reason that the independent effect on risk behaviors of counseling linked to HTC is unclear is because it has been considered unethical to randomize subjects to HIV testing without counseling. Thus, no studies that directly compare the differential effects of the testing versus counseling with HTC have been conducted. In 2006, the US Centers for Disease Control and Prevention (CDC) recommended not requiring prevention counseling during provider-initiated or diagnostic testing in health-care settings. These guidelines emphasize that HIV diagnostic testing in health care – to identify people living with HIV in order to link them with HIV care – is distinct and separate from HIV testing and counseling which is conducted mainly for prevention purposes among uninfected persons

at increased risk of HIV (Branson et al. 2006). Several trials have assessed the impact of patient-centered risk-reduction counseling as part of HTC. In 1998, Project RESPECT reported that brief, patient-centered counseling in the context of HIV testing reduced subsequent STI risk (Kamb et al. 1998), while in 2013, the AWARE trial reported that such counseling did not result in any reduction in STI risk (Metsch et al. 2013). The discrepant findings of these two trials may reflect changes over the past two decades, including the development of rapid HIV testing (and consequently a single visit for HTC) and the changing epidemiological, clinical, and social context of HIV.

Types of HIV Tests

Many types of tests exist to identify HIV. Rapid diagnostic tests use a blood or oral fluid specimen to screen for HIV-1/2 antibodies and/or antigens (WHO 2013). Results from these tests are available 10–20 min after performing the test. Enzyme immunoassays (EIAs) are laboratory-based tests that require a blood specimen to screen for HIV antibodies and/or antigens. Western blotting and line immunoassays, often used for confirmatory testing, are also laboratory-based assays that detect certain HIV-specific proteins. Molecular-based technologies, such as polymerase chain reaction (PCR), can detect HIV viral nucleic acid. These types of tests, although expensive, can help monitor the progression of HIV infection and are particularly useful in diagnosing HIV-exposed infants who carry HIV antibodies from their mothers during their first months of life which eventually disappear if infants remain HIV uninfected. New technologies, known as fourth generation assays, are currently being developed that detect both HIV antibodies and antigens and can identify HIV infection earlier than previously possible, including during the window period (WHO 2013).

Conclusion

While models of HTC have expanded and changed over time, HTC remains a critical

approach to helping people learn their HIV serostatus, access HIV care and treatment services if positive, access HIV prevention services if negative, and consider behavior change. The importance of HIV testing as a critical element in the HIV care and treatment armamentarium has grown as the epidemic has grown and as prevention and care options have increased. Virtually all of the most highly effective HIV control, prevention, and mitigation efforts rely heavily on HIV testing. These include HIV testing as a key strategy for primary prevention through risk reduction, screening and diagnosing clients to assure that they receive appropriate care and treatment, prevention of mother-to-child transmission programs, medical male circumcision, pre- and post-exposure prophylaxis, and many others. Perhaps one of the most salient, and maybe less recognized, benefits of the wide-scale availability of HIV testing is that because large number of people now know that they are infected with HIV, there has been the emergence of constituencies of people living with HIV who now advocate for rights and services. As new generations develop in a world where HIV is well established and the personal threat of HIV has been lessened with effective treatments, new challenges in the prevention, care, and treatment of HIV are arising. With half of the people living with HIV worldwide unaware of their status, combined with the positive advances being made in treatment and prevention options, it remains vitally important that innovative ways are devised to sustain and scale-up HTC service provision.

HIV Infection, Immune-Based Interventions for

Guislaine Carcelain and Brigitte Autran
 Laboratory Immunity and Infection, UPMC
 University Paris VI, Paris, France
 Laboratory Immunity and Infection, INSERM
 U1135, Paris, France

Definition

The overwhelming and continuous success of combination antiretroviral therapy (ART) is undermined by the inability to completely eradicate the HIV virus, requiring lifelong treatment, which is associated not only with side effects for the patients but also with substantial costs for the society. Immune-based interventions (IBTs) were developed during the last 15 years along two distinct paradigms. The first paradigm proposed during the late 1990s and early 2000s suggested either (1) using IBTs to help restore CD4 counts, in cases of failed immune reconstitution, or (2) using therapeutic vaccines to allow for prolonged treatment interruptions (TIs) and prevent disease progression by better controlling virus replication in the absence of treatment (Autran et al. 2004; Carcelain and Autran 2013; Pantaleo and Levy 2013). However, the SMART study, which demonstrated deleterious consequences of treatment interruptions, halted these TI-based strategies. The greater efficacy of new antiretroviral drugs, together with the “Berlin patient” demonstrating the first case of successful HIV eradication, suggested that a cure for HIV is an increasingly realistic objective (Richman et al. 2009; Trono et al. 2010). The current paradigm for IBTs, termed the “shock and kill”

approach, is to develop strategies in which therapeutic vaccines would be administered in combination with latency-reversing agents, including cytokines, that reactivate virus production from latently infected cells (International AIDS Society Scientific Working Group on HIV Cure et al. 2012; Katlama et al. 2013; Richman et al. 2009; Trono et al. 2010). This review will focus on these two paradigms and discuss IBTs in the context of strategies aiming at HIV eradication and cure.

Cytokine-Based Immunotherapy

Immune Restoration with Cytokine-Based Therapies: The 1990s Paradigm

A primary goal of cytokine-based IBT has been to restore, or maintain, CD4 T-cell counts above the critical threshold of 200 cells/ μ l, a major prognostic factor for clinical progression and opportunistic infections. The major clinical benefits of ARTs are mediated by the sustained quantitative and qualitative restoration of CD4 T-cell numbers and immune function in the context of durable viral suppression (Autran et al. 1997; Guihot et al. 2011). However, some patients, particularly elderly individuals or those with advanced disease, display delays in immune reconstitution despite an appropriate virological response. These patients have been termed “immunological nonresponders” (Massanella et al. 2013). In these situations, it was suggested that cytokines such as IL-2 or IL-7, which have known roles for supporting T lymphocyte development, proliferation, and homeostasis (Ma et al. 2006), might help to accelerate or enhance immune reconstitution during treatment with ART.

Interleukin-2-Based Immune Interventions

Interleukin-2 (IL-2) is a cytokine produced by activated T lymphocytes that induces proliferation of T cells, as well as B and NK cells. IL-2 also promotes cytokine secretion of Th1, Th2, and Th17 cells, promotes NK and CD8 cell cytotoxicity, and modulates programmed cell death (Ma et al. 2006). It is also essential for the development and peripheral expansion of regulatory

T cells involved in immune tolerance. Impairment of IL-2 production by CD4 T-helper cells is one of the first functional defects reported in HIV-positive patients and is predictive of the loss of CD4 T-cell counts and clinical disease progression. Altogether, these features led to the hypothesis that administration of recombinant IL-2 in conjunction with ART would boost the quantitative and/or qualitative immune restoration (Carcelain et al. 2013). Initial phase I and II trials were conducted in chronically infected, ART-treated patients with almost normal CD4 T-cell counts, to whom recombinant IL-2 was administered at a dose of 1.5–7.5 million IU per day by subcutaneous injection for five consecutive days every 6–8 weeks. These trials indicated the dose-dependent ability of IL-2 therapy to increase CD4 T-cell numbers.

In addition, IL-2 combined with ART also restored some qualitative CD4 cell parameters. For instance, there was not only an increase in T-cell proliferation, but there was a functional enhancement of thymopoiesis, suggested by increased proportions of naïve T cells and greater levels of T-cell receptor excision circles (TREC) and a limitation of CD4 T-cell activation with subsequent increase in their survival. It was also hypothesized from *in vitro* studies that IL-2 therapy would trigger active HIV replication from latently infected cells; however, no increases in HIV viremia were reported in the vast majority of IL-2-treated patients that were simultaneously treated with ART, despite transient blips of up to 1,000 copies/mL in some patients. Otherwise, the safety profile of combined treatment with IL-2 and ART was acceptable, despite flu-like symptoms associated with IL-2 infusions. These results raised questions regarding the possible clinical benefit of IL-2 therapy on the course of HIV disease in immunological nonresponders. In an attempt to answer this key question, clinical outcomes rather than CD4 counts had to be used as endpoints in clinical trials.

Two large phase III international clinical trials, SILCAAT (*Subcutaneous, Recombinant, Human IL-2 in HIV-Infected Patients with Low CD4 Counts under Active Antiretroviral Therapy*) and ESPRIT (*Evaluation of Subcutaneous Proleukin*

in a Randomized International Trial), both 7–8 years long, involved hundreds of HIV-infected patients and clearly illustrated that administration of recombinant IL-2 did not lead to long-term clinical improvement. Indeed, IL-2 failed to reduce the rate of opportunistic diseases or deaths, despite sustained increases in CD4⁺ T-cell counts, and was associated with a higher frequency of grade 4 adverse clinical events. Based on these findings, it was concluded that restoring CD4 T-cell counts with this growth factor does not provide clinical benefits, and the adjunct use of IL-2 for enhancing immune restoration was abandoned.

Interleukin-7-Based Immune Interventions

Another cytokine, IL-7, was subsequently proposed to promote or stimulate CD4⁺ T-cell recovery in patients failing to restore appropriate CD4 T-cell counts with ART alone. IL-7 is produced by bone marrow cells, thymus stromal cells, and dendritic cells. Indeed, it is essential for thymopoiesis, for T-cell differentiation and homeostasis, and for enhancing naïve and central-memory T-cell proliferation; moreover, it is a key antiapoptotic factor for lymphocytes (Ma et al. 2006). In addition, high plasma IL-7 levels coincide with CD4 T-cell lymphopenia in untreated HIV infection, while IL-7 levels gradually decline with CD4⁺ T-cell recovery during antiretroviral therapy. IL-7 was therefore suggested to drive CD4⁺ T-cell restoration once HIV replication is controlled.

Several clinical trials demonstrated that administering this cytokine to immunological nonresponders at doses ranging from 10 to 30 µg/kg sustainably increased both CD4 and CD8 T-cell counts over 3–6 months due to its pleiotropic effects on T-cell cycling, survival, and *de novo* generation (Carcelain et al. 2013). IL-7 infusions were associated with major increases in the long-lived naïve and central-memory CD4 T cells. In addition, IL-7 may also have helped to maintain or restore T-cell responses to pathogens. Finally, IL-7 tolerance was much better than that of IL-2. Therefore, IL-7 therapy appeared to have the potential to accelerate and/or enhance immune reconstitution in individuals who failed immune

reconstitution with cART alone. However, effects of IL-7 on clinical endpoints of HIV-1 infection have never been tested in randomized-controlled clinical trials.

Toward an HIV Cure: The New Challenge for Cytokine-Based Immune Interventions

The role of IBTs in the therapeutic arsenal has been completely revised with the emerging concept of HIV remission, exemplified by the “Berlin patient” and reports of small patient populations who were able to control HIV replication after stopping ART. This novel objective raises the possibility of finding strategies to purge the HIV reservoirs which cannot be eradicated with ART alone. Persistence of HIV reflects a composite mechanism of proviral latency in quiescent cells and of a low level of residual virus production. A “shock and kill” strategy has been proposed to reactivate HIV-1 production from latently infected cells, followed by a complementary strategy to kill the cells with pharmacologically induced HIV-1 production (International AIDS Society Scientific Working Group on HIV Cure et al. 2012; Katlama et al. 2013; Richman et al. 2009; Trono et al. 2010). Some IBTs have been proposed for the shock strategy.

Initial attempts using IL-2 showed that infusions of this cytokine increased the reservoir of HIV-infected cells. IL-7 was proposed as an alternative candidate (Richman et al. 2009; Carcelain et al. 2013; Pantaleo and Levy 2013) because of its ability to trigger signaling pathways that induce HIV production and increase and/or reactivate HIV replication in cultures of naturally infected primary CD4 T cells in vitro (Richman et al. 2009; Trono et al. 2010). IL-7 also mediates an increase in transcription and replication of the provirus integrated in Peripheral Blood Mononuclear Cells (PBMCs) of patients, particularly in central-memory CD4 T cells, which are preferentially infected by HIV. Moreover, IL-7 helps to maintain or induce a CTL response against viruses, due to its ability to enhance memory T-cell expansion, providing an additional rationale for proposing IL-7 as a candidate for a “shock and kill” strategy (Katlama et al. 2013).

However, the possible benefits of IL-7 remain controversial because IL-7 may also contribute to increasing the reservoir of HIV-1-infected cells by promoting homeostatic proliferation of latently HIV-infected central-memory CD4 T cells. The first two phase I clinical trials using infusions of exogenous IL-7 in immunological nonresponders treated with conventional ART showed, in addition to the major increase in peripheral blood, some “blips” of HIV replication and transient increases in the blood content of provirus returning to baseline at the end of the study.

In an effort to test whether IL-7 could play a role in the “shock and kill” therapeutic arsenal toward an HIV cure, a randomized proof of concept therapeutic trial recently tested the hypothesis that IL-7 could ultimately decrease the reservoir of HIV-1-infected cells when combined with a synergistic ART intensification to prevent infection of new cells by inhibiting virus entry and integration. Despite an acceptable safety profile, preliminary results indicate that the HIV reservoirs did not decrease 18 months after IL-7 infusions and ART intensification.

Therapeutic Vaccines Against HIV

Antiretroviral therapy induces an exponential decay of anti-HIV effector and effector-memory CD8 T cells that parallels HIV reduction. While this reduction of HIV-specific CD8 T cells occurs when ART is administered in late or chronic stages, there is a restoration of anti-HIV CD4 T cells. The clonal contraction of virus-specific CD8 T cells likely results from the treatment-related reduction of viral antigen below the threshold required to stimulate specific T cells. Immune memory to HIV persists nonetheless, as indicated by transient restoration of T-cell responses after virus relapses during treatment interruptions or by the slow restoration of memory CD4 T-cell responses to HIV after 10 years of fully suppressive ART (Guihot et al. 2011). In contrast to ART administered in late or chronic stages, early treatment of the acute HIV infection preserves the HIV-specific CD4 T-helper cells but delays and

limits the establishment of robust and diverse CD8 T-cell responses to HIV.

Therapeutic Immunization to Restore Immune Control of HIV-1: The 2000s Paradigm

In the early 2000s, “structured-treatment interruptions,” or STIs, were proposed to boost immunity against HIV. This method was proposed to combat the burden associated with daily, lifelong administration of ART as well as the toxicity and high costs associated with antiretroviral agents. An “autovaccination” strategy had been suggested to restimulate the patient’s HIV-specific T cells during STIs with the patient’s own virus in order to restore immune responses that could control HIV during prolonged interruptions of therapy. Although some transient HIV control during treatment interruption coincided with increases in HIV-specific immunity when treatment was initiated in acute infection, such control was not observed when STIs were performed after treatment initiation in chronic HIV infection, although HIV-specific CD4 and CD8 T-cell numbers were restored to some degree. In addition, the relapses of replication-competent virus appeared to be deleterious to the antigen-specific CD4 T cells, which rapidly disappeared after virus production was reestablished.

In order to prolong the control of virus for longer periods of time than with STIs alone, it was proposed to use anti-HIV vaccines to induce a protective immune barrier against HIV when patients were still on ART (Autran et al. 2004; Kinloch-de Loes and Autran 2002). However, several obstacles prevented the development of these strategies.

Firstly, immune parameters that accurately correlated with immune protection against HIV infection were poorly defined (Pantaleo and Koup 2004), although studies in long-term nonprogressors (LTNPs) and elite controllers (ECs) indicated that HIV-specific CTL and T-helper cells can contribute to controlling this retrovirus (Autran et al. 2011). In addition, in several studies, plasma viremia in untreated HIV patients was significantly associated with

the magnitude and HIV-1 *gag* specificity of CD8 T cells producing IFN- γ . Notably, plasma viremia or disease progression seemed to better correlate with the quality of HIV-specific T cells, specifically their multifunctionality, than with their magnitude. Similarly, preserved HIV-1-specific central-memory T cells strongly correlated with levels of both plasma virus and HIV reservoirs in PBMCs of LTNPs and ECs. High functional avidity of both HIV-specific CD8 and CD4 T cells also appeared as appropriate immune correlates of T-cell-mediated control of HIV. The levels of HIV reservoirs, identified by measuring cell-associated proviral DNA copies per PBMC in LTNP studies, were even more strongly correlated with the magnitude of the HIV-*gag*-specific CD8 or CD4 T cells than was the plasma viremia. Therefore, the goal of therapeutic vaccines was to adequately stimulate both central-memory HIV-specific T cells, involved in long-term survival and clonogenic potential, and short-lived effector-memory T cells, with an immediate efficacy to kill. In contrast, anti-HIV neutralizing antibodies – known to appear only during the third month after infection and less prominent in most LTNPs and ECs – did not appear during the early 2000s as decisive players in HIV control. Furthermore, even though passive administration of neutralizing monoclonal antibodies partially controlled HIV during STIs, the high antibody concentrations required in this method prevented further progress in antibody-based strategies.

Secondly, the HIV tropism for CD4⁺ T cells required restimulation of specific CD4 Th cells with noninfectious, nonpathogenic HIV antigens. However, the amplified HIV-specific CD4 Th cells activated by the vaccine would be reexposed to the virus after ART cessation and may then represent a preferential target for new rounds of viral infection.

Thirdly, re-immunizing already infected patients suffering from immune alterations caused by HIV could be futile or even harmful by amplifying these alterations in the face of continuous viral replication (Autran et al. 2004). The

presence of preexisting antigen-exposed T cells – and the anergy and immune exhaustion caused by the continuous exposure to HIV antigens in untreated patients – might limit the ability of a vaccine to stimulate HIV-specific T cells and to amplify new antiviral T-cell clones (Autran et al. 2004). By reducing antigen burden, however, immune restoration clearly had the capacity to reduce, albeit incompletely, such anergy and exhaustion while decreasing the numbers of preexisting differentiated T cells (Guihot et al. 2011). Therefore, it was proposed to wait several months after administration of fully suppressive ART to allow for immune restoration before initiating therapeutic re-immunizations. Fourthly, extensive HIV genomic variability in dominant epitopes could also limit the capacity of therapeutic vaccines to restimulate broad repertoires of specific T cells.

Therefore, therapeutic re-immunization against HIV required a synergistic combination of ART and vaccines: first initiating ART to reverse immunopathological consequences of HIV replication to restore effective immune competence and then boosting the rested immune responses to HIV with a vaccine before halting treatment (Autran et al. 2004; Guihot et al. 2011).

Modest Results of Therapeutic Vaccines Against HIV

The tentative correlates of protection described in the 2000s justified the development of T-cell-based vaccines (Autran et al. 2004; Guihot et al. 2011; Carcelain et al. 2013). Live-attenuated, non-replicative, genetically engineered recombinant viral vectors, such as poxviruses and adenoviruses, were most widely used in T-cell-based vaccines due to their ability to induce endogenous synthesis of antigens in CD8 T cells (McMichael 2006). Another strategy was to avoid vector-specific immunity by using inactivated viruses, pseudoparticles, proteins, peptides, polynucleotides, or RNA-based alphavirus vaccines, though such reagents are less immunogenic for CD8 T cells. These latter antigen preparations can be repetitively

administered and synergistically combined with viral vectors to induce stronger HIV-specific immune responses. Several clinical trials tested these various vaccine candidates in acutely and chronically infected ART-treated patients with a similar design consisting of an immunization added to ART followed by an analytical STI with strict guidelines for ART reintroduction (Carcelain et al. 2013).

Therapeutic Vaccines Using Live Vectors

Two major families of vectors investigated were based on poxviruses and adenoviruses.

Poxvirus Vectors The most widely used vectors were the non-replication-competent, recombinant canarypox vector-based (vCP) vaccines and the vaccinia-derived viruses, such as MVA or NYVAC, which were known to be safe and reasonably immunogenic in HIV-negative volunteers. Because vaccination against smallpox was arrested after the disease was eliminated, populations born after 1980 lacked preexisting immunity against these poxvirus vectors. As such, utilizing these particular vectors may be advantageous. In addition, these large viruses could be designed to express multiple HIV genes, including *env*, *gag*, *reverse transcriptase* (RT), and *nef*. Several generations of vCP-based vaccines, differing in the number of HIV genes inserted, were evaluated as therapeutic vaccines either alone or in combination with other candidate vaccines and both in acutely and chronically infected ART-treated patients. After a first pilot study of the HIV *env-gag-nef-pol* vCP1452 vaccine in conjunction with the gp160 soluble glycoprotein, modest though significant induction of HIV-specific T-cell responses was demonstrated. Subsequently, a large randomized, controlled study (QUEST) was conducted in patients who had initiated a four-drug combination of ARV before completion of seroconversion. Four injections of vCP1452, alone or associated with three injections of inactivated HIV particles (Remune), were efficient at boosting CD4 and CD8 HIV-specific IFN-gamma T cells. The dual vaccine combination illustrated no additional benefit (Goh et al. 2000). Despite vaccine

immunogenicity, the virus was not controlled after halting ART. Another controlled trial conducted in patients started on treatment in acute infection combined four injections of a closely related vCP (vCP1433) with HIV-lipopeptides followed by IL-2 injections. Despite induction of HIV-specific T cells, neither virus control nor clinical benefit was observed during the subsequent ATI, thus confirming the results of the QUEST trial.

Results obtained in chronically infected ART-treated patients were more encouraging. Overall, 800 patients were included in several clinical trials. All patients had undetectable plasma viremia and restoration of approximately normal CD4 T-cell counts. An exploratory study had shown a correlation between the CD4 T-cell responses induced by four vCP1433 injections, containing the same gene inserts as vCP1452, and the duration of time patients were able to stay off treatment during an analytical treatment interruption. In parallel, a controlled trial with the same compounds (vCP1433 plus HIV-lipopeptides and IL-2) and the same design as that of acutely infected patients also boosted HIV-specific T cells. After a series of ATIs, immune responses correlated with a lower viral set point. However, a separate randomized study that administered IL-2 simultaneously with the same vCP1433 was not followed by virus control, and vCP alone induced a modest but significant reduction in plasma viremia during subsequent ATI. To further explore these encouraging findings, another large randomized, controlled trial involved chronically infected patients and utilized regimens including two doses of the vCP1452 vaccine administered with a new schedule of 3 + 1 or 2 + 1 injections followed by ATI a month after the last immunization. Despite a significant booster effect on HIV-specific T cells, the vaccine did not only have no efficacy on virus relapses during the ATI, but the plasma viremia reached significantly higher levels in the immunized arm compared to the placebo arm, independently of the CD4 nadir. Two series of factors might have been responsible for this negative result. Firstly, only HIV-specific CD4 and not CD8 T cells had been significantly boosted by this vCP1452

vaccine. Secondly, the trial design might be responsible for this failure since the ATI was proposed at a time when activation of HIV-specific CD4 T cells might have been maximal, thereby exposing them to the virus in the absence of protective CD8 T cells. However, a similar schedule had been used in the QUEST trial without such negative effects. It was concluded that the HIV-specific CD4 T cells activated by the vaccine may have provided ideal conditions for infection by the virus due to the absence of CD8 T cells, as was previously reported during iterative STIs in the absence of therapeutic vaccine.

Altogether, results of this live-attenuated HIV-recombinant canarypox vector-based candidate vaccine showed a modest immunogenicity and poor efficacy in controlling HIV and preventing disease progression during the analytical treatment interruptions that followed immunizations. Despite some encouraging, though very modest, results obtained with the HIV-recombinant canarypox vector in some treated chronically infected patients, this candidate vaccine appeared to be immunogenic mainly for CD4 T cells. Discrepancies between results obtained in acutely and chronically infected patients might have reflected the differences in preexisting immunity to HIV in those two conditions. In acutely infected ART-treated patients, stronger HIV-specific CD4 T-helper cell responses were associated with lower HIV-specific CD8 T-cell levels compared to the chronically infected individuals, but they did not confer any clinically relevant benefit. These findings are important for developing designs toward an HIV cure.

Among other poxvirus vectors, several vaccinia-derived non-replicative live-attenuated poxvirus candidates were developed, including the MVA vector obtained after serial in vitro passages and the genetically modified NYVAC vector. MVA had been widely used previously in the smallpox eradication campaign and showed, as an HIV-recombinant vector, an acceptable safety profile and an encouraging immunogenicity, although mainly activating CD4 T cells, similar to the canarypox vector. Several HIV-recombinant MVA constructs expressing *nef* alone or multiple HIV

genes, including *gag*, have been tested in preliminary phase I and II clinical trials in chronically infected ART-treated patients. The NYVAC vector, recombined with the *env* and *gag* genes and part of the *RT* and *nef* genes, demonstrated good immunogenicity for CD8 T cells in a small trial of ART-treated chronically infected patients. Therefore, the immunogenicity of the MVA and NYVAC vaccinia derivatives appeared encouraging. However, their capacity to control the virus in the absence of treatment had not been evaluated due to the emerging reluctance against ART interruption after the SMART study demonstrated that even minimal HIV replication was deleterious via its pro-inflammatory effects and was, in fact, worse than most adverse effects of ART.

Adenovirus-Based Vectors and Other Vectors This vector family raised high expectations. The HIV-recombinant, genetically modified, replication-incompetent adenovirus-5 (rAd5)-based vectors appeared to confer a strong immunogenicity for CD8 T cells in both non-human primate models and HIV-negative human volunteers (McMichael 2006). However, major limitations arose – mainly due to the preexisting immunity against adenovirus-5 in almost half of the patients – requiring an increase in the doses to overcome the specific neutralizing antibodies. One HIV-recombinant Ad5 candidate vaccine was evaluated in a phase I therapeutic vaccine trial in Ad5-seronegative chronically infected HIV-infected patients. Despite the robust T-cell immunogenicity, limited benefit was observed in terms of virus control during the subsequent ATI. More recently, two trials were conducted using a prime-boost combination with naked DNA and an even higher immunogenicity in long-term ART-treated chronically infected patients – one of which was performed in the context of HIV cure as detailed below. Because of the consistent negative results of two large clinical trials, i.e., the STEP and the HVTN-505 clinical trials, which evaluated similar Ad5 constructs as preventative vaccines, development of Ad5 candidate vaccines progressively declined. Their appropriate safety profile was, nevertheless, confirmed in ART-treated HIV-infected patients.

Therapeutic Subunit Vaccine Approaches

Recombinant soluble HIV envelope, HIV viral-like particles, inactivated HIV particles, HIV peptides, and naked HIV DNA were evaluated as possible subunit vaccines. Each element was evaluated alone as therapeutic vaccines and then rapidly tested in combination with live vectors in order to synergistically boost immune responses to HIV. In most cases, these subunit candidate vaccines were tested in a prime-boost strategy in combination with vectors. It was thought that “re-priming” with these compounds might help stimulate new T-cell clones with high clonogenic potential, thereby helping to generate durable immunity against HIV in the context of chronic HIV infection. However, such a strategy might be disputed because infected individuals may already have preexisting immunity to HIV.

First, inactivated gp120-depleted HIV particles (Remune) were tested alone, which induced minimal CD4 T-cell responses and no CD8 T-cell responses to HIV. This was associated with some decrease in the risk of virologic failure in a phase II clinical trial. When combined with the canarypox vector, however, it did not augment the vCP immunogenicity or efficacy in the QUEST study and was finally abandoned.

Second, naked DNA vaccines, known to be cheap and to have a good safety profile, were also tested alone or in combination with live vectors. The advantage of DNA vaccines is the lack of vector-specific immunogenicity; however, the weak immunogenicity of naked DNA requires high dosages. Naked DNA plasmids, generally composed of the *gag* gene alone or with *envelope* or *rev*, *tat*, and *nef*/HIV genes, were tested in pilot trials in chronically infected ART-treated patients with encouraging immunogenicity for HIV-specific CD4 T cells. Higher dosages increased immunogenicity for CD8 T cells and resulted in fewer “viral blips” during post-immunization ATIs. The combination of a multiclade *env* DNA plasmid prime followed by the HIV-*gag* recombinant adeno-5 boost induced broad HIV-specific CD4⁺ and CD8⁺ T-cell repertoires, but its efficacy was not evaluated.

Dendritic Cell Approaches

In the absence of an ideal vaccine candidate, approaches using dendritic cells (DCs) from autologous patients loaded *in vitro* with HIV antigens or mRNAs have been evaluated. The rationale was based on the superior ability of DCs in eliciting specific CD8 T cells. A first uncontrolled study of ART-naïve, chronically infected patients had suggested that autologous monocyte-derived dendritic cells (mDDCs) loaded *in vitro* with autologous chemically inactivated HIV may decrease plasma viremia reduction. Different preparations of mDDCs were pulsed either by heat-inactivated HIV particles, peptides, HIV-recombinant canarypox vectors, or autologous HIV mRNAs. Small phase I and II clinical trials generally confirmed their ability to elicit significant HIV-specific CD4 and CD8 T cells. In addition, two controlled studies evaluated high doses of autologous mDDCs pulsed *in vitro* with autologous heat-inactivated HIV in untreated or ART-treated chronically infected patients. A significant transient and partial control of viremia correlated with the boost of HIV-specific CD8 T cells, especially in ART-treated patients with up to a tenfold decrease in pVL. These encouraging proof of concept results confirm that robust and protective HIV-specific CD8 T cells can be generated by a therapeutic vaccine approach even in chronically infected patients. Therefore, further research should be conducted to find good alternatives to these expensive and complex procedures which will not be affordable by the majority of the HIV-infected individuals.

Alternative Strategies to Pulse Dendritic Cells

In Vivo Several innovative strategies aim to load DCs directly *in vivo* with HIV antigens through the skin, which is rich in DCs that are scattered in the epidermis or gathered along the hair follicles. A pilot study in HIV-negative individuals confirmed the superiority of hair-follicle DC targeting, compared with the classical intramuscular route, to induce specific CD8 T cells with an inactivated flu vaccine. Another trial showed some induction of T-cell immunogenicity when DCs were loaded via skin in conjunction with plasmid HIV DNA preparations combined with

mannosylated particles after partial epidermis abrasion in HIV-positive patients. However, clinical efficacy could not be tested in the absence of ATI. Other approaches involving the electroporation of naked DNA directly into skin DCs without skin abrasion will soon undergo clinical trials. These various attempts pave the way toward new modalities of skin or mucosal routes of immunization, such as loading DCs *in vivo* in order to enhance CD8 T-cell immunogenicity.

Overall, these therapeutic vaccine studies performed during the 2000s aimed at alleviating the lifelong burden of antiretroviral therapies. However, these studies were stopped after the SMART results (SMART 2006). In parallel, the continuous progresses in the development of more efficient and less toxic antiretroviral drugs led to a pause in the development of therapeutic vaccines against HIV.

The 2010s Paradigm: Toward a Cure for HIV or Remission

The long-term persistence of latent HIV reservoirs, despite highly effective ART, is the major obstacle toward an HIV cure. These reservoirs predominate in long-lived memory CD4 T cells, mostly in tissues, and can be assessed in the peripheral blood of patients (Guihot et al. 2011). The multifactorial mechanisms responsible for such persistence are due to (1) HIV latency in quiescent CD4⁺ T cells harboring the untranscribed provirus that is invisible to immune defenses and (2) low level residual virus production from activated CD4⁺ T cells that are not efficaciously targeted by ART. To try and purge these reservoirs, it has been proposed to combine a “shock and kill” strategy with agents that can reactivate HIV production from latently infected cells. Therapeutic vaccines can then be utilized to kill the reactivated infected cells producing HIV antigens (International AIDS Society Scientific Working Group on HIV Cure et al. 2012; Katlama et al. 2013; Trono et al. 2010; Autran et al. 2013). The rationale for a therapeutic vaccine is supported by the strong immune control of HIV reservoirs observed in elite controllers (ECs) in

whom a sustained quasi-equilibrium between the virus and its host mimics a functional cure for HIV (Autran et al. 2011). This immune control of HIV reservoirs is particularly obvious in ECs bearing the MHC class I HLA-B*57 gene in whom efficient anti-HIV CD8 T cells help limit the size and imprint the distribution of the HIV reservoirs in long-lived CD4⁺ TCM. The use of therapeutic vaccines was recently supported by in vitro findings which showed that HIV-specific CD8 T cells stimulated with HIV peptides from treated patients could eliminate in vitro autologous CD4 T cells exposed in vitro to an HDAC inhibitor disrupting latency in cells that were transcribing HIV mRNA but could not activate HIV-specific CD8⁺ CTLs. These findings provide a rationale for introducing anti-HIV therapeutic vaccines to HIV cure strategies.

A preliminary trial performed in long-term-treated HIV-infected adolescents born from infected mothers received two poxvirus vectors recombined with the *env*, *gag*, *tat*, *rev*, *nef*, and *reverse transcriptase* genes. Fowl-pox administration, followed by an MVA, illustrated significant but transient reduction in the numbers of infected cells producing replication-competent viruses. This contrasted with previous HIV-recombinant canarypox clinical trials which had failed to reduce the reservoirs. A more recent clinical trial also aimed to decrease the HIV reservoirs of residual virus-producing CD4 T cells using the VRC vaccines in combination with HIV-enveloped naked DNA plus the HIV-gag recombinant rAd5-based vector.

Will a T-cell-based therapeutic vaccine approach still be considered at a time when passive transfers of new generations of broadly neutralizing antibodies (bNABs) can already control SIV in the absence of treatment in SIV-infected macaques? Such passive transfers of bNABs represent another option that needs to be explored in future studies.

Conclusion

The rationale for developing immune-based therapeutic interventions in HIV infection has

recently been supported by the quest for an HIV cure. This new orientation should benefit from lessons drawn from past experiences in IBTs, although none of the multiple strategies and compounds tested offered any significant progress for the clinical management of HIV infection. We learned that cytokine administration or therapeutic immunization is safe, but both methods expose patients to the risk of enhanced virus production, a property of interest in the “shock and kill” strategies. We also learned that IL-2 and IL-7 enhance immune reconstitution, but the clinical benefits of IL-7 are yet to be demonstrated, and IL-2 demonstrated no significant benefit. Therapeutic immunizations have evaluated T-cell-based vaccine candidates almost exclusively, allowing marginal control of HIV; thus, efforts should incorporate broadly neutralizing monoclonal antibodies in the near future. Future cure strategies will benefit from these 15 years of experience in IBT.

HIV Life Cycle: Overview

Frank Kirchhoff

Institute of Molecular Virology, Ulm University Medical Center, Ulm, Germany

Definition

The HIV life cycle defines the steps and changes the virus undergoes from its first contact with a target cell to the production of new infectious viral particles that can initiate the next round of replication. The combination of reverse transcription of viral RNA into DNA and integration of the latter into the host cell genome is a key feature of the retroviral replication cycle.

Introduction

The goal of this chapter is to provide a brief overview on the “life” cycle of HIV, which should perhaps be better referred to as the viral “replication” cycle, since viruses do not have their own metabolism and are thus usually not considered living organisms. Viruses can be considered as intracellular parasites that are strictly dependent on living host cells for reproduction. Understanding how HIV interacts with its target cells in order to replicate is of great interest because it may provide important clues for the generation of improved antiretroviral drugs and the development of novel strategies to control or even eliminate the virus.

The main targets of HIV are CD4+ helper T cells, which are key regulators of the humoral and cellular immune responses. Thus, their destruction and depletion by mechanisms that are not fully understood render the body unable to defend itself against opportunistic pathogens. When HIV infects an activated CD4+ T cell, it hijacks and manipulates its transcriptional and translational machinery to reproduce itself. As briefly outlined below and specified in the following chapters, HIV has to utilize a multitude of

cellular factors and to counteract the antiretroviral activity of others in order to complete its replication cycle. Theoretically, each interaction with cellular factors that are essential for virus replication (termed “virus-dependency” factors) or strengthening of antiretroviral (or “host restriction”) factors provides a potential means to interfere with the HIV life cycle.

Although activated CD4+ helper T cells represent the main target cells for HIV replication, the virus can also infect other cell types, such as macrophages, immature dendritic cells, and more resting T cell subsets. The latter cell types are not important for the bulk of virus replication but most likely play important roles in innate and adaptive antiviral immune responses. Furthermore, they may harbor the virus in a silent integrated proviral form and thus contribute to the establishment and maintenance of viral reservoirs that prevent the eradication of HIV from the human body, even under optimized antiretroviral therapy (ART). Finding ways to activate these latent proviruses to eliminate the infected cells and to cure HIV infection is a main challenge in AIDS research. A better understanding of the steps in the viral life cycle, especially the regulation of proviral transcription, may help to achieve this.

HIV Structure

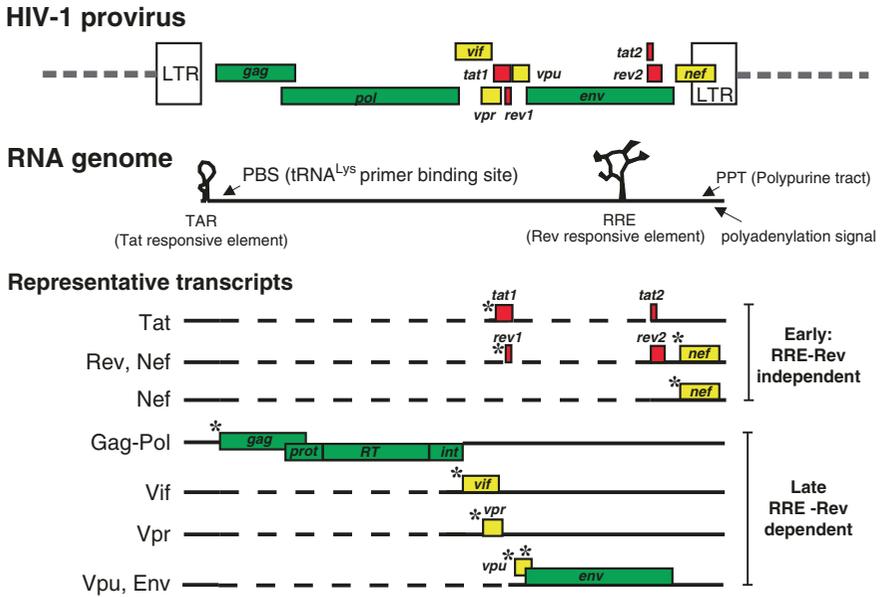

The HIV genome contains the typical retroviral genes *gag*, *pol*, and *env* flanked by long terminal repeats (LTRs), which contain the viral promoter (Fig. 1, upper). *Gag* codes for the structural proteins capsid (CA), matrix (MA), and nucleocapsid (NC); *pol* encodes the enzymes reverse transcriptase (RT), protease (PR), and integrase (IN); and *env* encodes the glycoproteins gp120 and gp41 (Swanson and Malim 2008). In addition, HIV has six regulatory genes (*tat*, *rev*, *nef*, *vif*, *vpr*, and *vpu*) and is thus considered a “complex” retrovirus. Tat enhances proviral transcription, and Rev is essential for the export of incompletely or unspliced viral mRNAs into the cytoplasm. The remaining genes were named “accessory” because they are not absolutely required for replication in

some cell culture systems (Kirchhoff 2010). However, they perform a multitude of activities facilitating viral immune evasion and antagonize a variety of specific antiretroviral cellular (host restriction) factors and are thus essential for viral spread in vivo (Viral Auxiliary Proteins).

HIV-1 belongs to the *Lentivirus* genus (*lentis* = slow) of the *Retroviridae* family. The virion has a spherical shape and a diameter of ~100–130 nm (or 1/10,000 mm) (► [HIV-1 Virion Structure](#)). The viral envelope is composed of a lipid membrane, which is derived from the host cell and contains cellular proteins, as well as about 7–12 trimeric complexes of viral envelope (Env) protein (Fig. 2). Env consists of the external glycoprotein 120 (gp120) that mediates viral attachment and the transmembrane glycoprotein 41 (gp41) that is critical for viral fusion. Gp41 is associated with the viral p17 matrix protein and encompasses a conical capsid that consists of the viral Gag protein, p24. The capsid contains two single strands of viral RNA with positive polarity and a length of close to 10,000 nucleotides. The RNA is associated with the nucleocapsid proteins, as well as the RT and IN. The virions also contain some copies of the viral protease and the accessory Vif, Vpr, and Nef proteins, as well as some cellular factors, such as tRNA^{lys3} which is used as primer for reverse transcription.

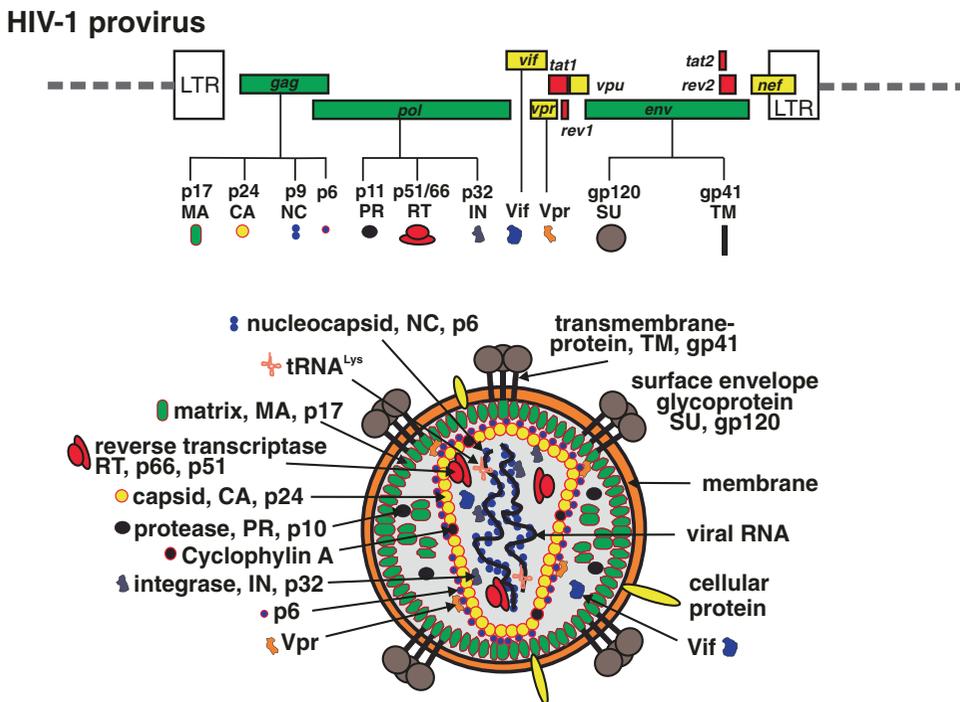

Overview on the HIV Replication Cycle

The HIV-1 life cycle is complex and can roughly be divided in an early and a late phase of replication. The early phase begins with the attachment of the virion at the cell surface and ends with the integration of the proviral DNA into the host genome (Fig. 3). The late phase of replication starts with the initiation of proviral transcription and ends with the release of fully infectious progeny virions. In highly activated CD4+ T cells, the HIV life cycle lasts just one to two days and is associated with the programmed death of both virally infected cells and uninfected bystander cells. The viral life cycle illustrates some of the challenges associated with HIV infection. The viral RT has a very high mutation rate (~1 error

HIV Life Cycle: Overview, Fig. 1 Overview of the organization and expression of the HIV-1 genome. Some *cis*-regulatory elements in the viral RNA genome and

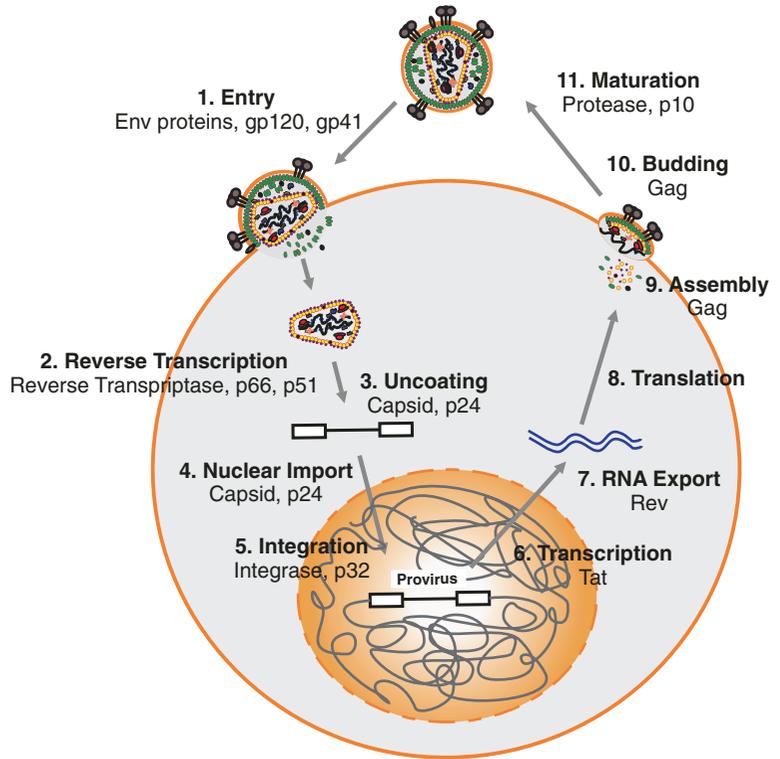

representative early and late RNAs are presented. Stars indicate splice sites

H

per 10,000 nucleotides), and the viral populations in an infected individual are not uniform but rather a collection of the so-called quasispecies. Together with the short generation time and massive virus production (up to 2×10^9 virions per day), this allows HIV to rapidly adapt to its host environment and to develop resistance against antiretroviral drugs or immune responses. To generate a higher barrier for the evolution of resistances, combination therapies are currently used to treat HIV. Furthermore, proviral integration into the host genome allows the virus to hide in long-living cells. Finally, HIV infects and kills CD4+ helper T cells that are crucial for the maintenance of a functional immune system. It is important to consider, however, that other cell types can also be infected and that the time frame of viral replication and the fate of the infected cells vary. Macrophages, for example, may produce HIV over several weeks and store infectious virions intracellularly (► [Macrophage-Specific Aspects of HIV-1 Infection](#)). Although a lot of exciting progress has been made, we are still

just beginning to understand the multitude of interactions of HIV with its host cell.

Viral Attachment

Cell-free HIV virions usually have a half-life of just about 20–30 min in infected individuals. Thus, the virus must find and infect a new target cell within a very short time frame. As described below, CD4 is the primary receptor, and the chemokine receptors CCR5 and CXCR4 are the main co-receptors of HIV entry (► [Fusion](#)). These receptors are sufficient to render cells susceptible to HIV entry and thus determine the viral cell tropism. However, the densities of the Env trimers on the virions and of the CD4 receptor on the target cells are frequently low. Thus, viral attachment is often inefficient and a limiting step for HIV infection. Several receptors, such as polyanions, lectins, and others, can bind HIV virions in a more unspecific manner and may thereby greatly increase viral infection rates

(► [Attachment/Binding](#)). On the one hand, they concentrate virions at the cell surface and facilitate their interaction with CD4 and a co-receptor to allow virion fusion. Furthermore, they may trap viral particles at the cell surface to stabilize them and to mediate trans infection of susceptible T cells. For example, it has been suggested that dendritic cells (DCs) bind HIV virions at the site of genital exposure and transport them to the lymph nodes where they mediate both *trans* infection and stimulation of T cells that results in massive virus production (van Kooyk and Geijtenbeek 2003).

Binding and Fusion

Viral entry is a complex multi-step process that offers multiple possibilities for therapeutic intervention (Didigu and Doms 2012). Either directly or following unspecific binding of HIV to its target cell, the infection process is initiated by the interaction of the external viral glycoprotein gp120 with the cellular CD4 receptor (► [Fusion](#)). CD4 binding induces conformational changes in the Env trimer that allow the interaction of gp120 with either the CXCR4 (X4) or CCR5 (R5) co-receptor. Usually, only R5 viruses are sexually transmitted and found during chronic infection. In comparison, X4 HIV strains emerge late during the course of infection and are associated with rapid progression to AIDS in the absence of antiretroviral therapy. Co-receptor interaction induces additional conformational changes that allow the gp41 transmembrane protein, which is usually hidden by the gp120, to insert its hydrophobic fusion peptide into the cell membrane to make the first direct contact between the virus and its target cell. Thereafter, the trimeric gp41 complex forms a helical bundle structure which pulls the cellular and viral membranes together, thus allowing virion fusion and the release of the contents of the virus particle into the cell. Drugs that block the CCR5 co-receptor or prevent viral fusion are already used to treat HIV infection in the clinic, and other HIV entry inhibitors are in preclinical development.

Reverse Transcription

Once fusion is completed, the genetic information of the virus can enter into the cell. The HIV genome consists of two plus-stranded RNAs that are protected by the nucleocapsid. After fusion, the single-stranded viral RNAs are transcribed into linear double-stranded DNAs by a process called reverse transcription (► [RT](#)). It is called “reverse” transcription because it reverses the order of events that take place during the regular transcription process, i.e., generation of messenger RNA from nuclear DNA followed by export into the cytoplasm and protein synthesis. It is performed by an enzyme called reverse transcriptase that is characteristic – although not unique – to retroviruses and involves a very complex series of events that are outlined in chapter ► [Reverse Transcriptase-Catalyzed HIV-1 DNA Synthesis](#). The very first drugs against HIV inhibited reverse transcription. Currently, there are two different classes: nucleoside and nucleotide analog reverse transcriptase inhibitors (NRTIs), which prevent further elongation of the DNA chain, and non-nucleoside reverse transcriptase inhibitors (NNRTIs) that bind to the enzyme and render it inactive (*cross-link to ART section*).

Uncoating and Nuclear Entry

Uncoating refers to the disassembly of the viral capsid before import of the viral genome into the nucleus. Untimely uncoating due to point mutations in the capsid protein or interactions with the tripartite motif 5-alpha protein (TRIM5a) impairs viral infectivity (► [Uncoating and Nuclear Entry](#)). Early studies suggested that uncoating may occur immediately after viral entry. More recent data, however, suggest that capsids may remain intact for several hours and that this stability is critical for HIV-1 infection. Furthermore, it seems that uncoating is tightly associated with reverse transcription and accompanies the transition of the reverse transcription complex (RTCs) to the pre-integration complex (PIC) that is competent for integration into the host cell genome (Arhel 2010). However, the exact timing of uncoating is

still poorly understood and subject to intense research. Lentiviruses have the unique ability to infect nondividing terminally differentiated cells, such as macrophages; thus, the viral genome must be transported through an intact nuclear membrane. HIV-1 PICs must be actively transported through the nuclear pore since they are too large to cross them by passive diffusion. Originally, the viral matrix protein, Vpr, and integrase have been implicated in nuclear entry. However, recent studies suggest that none of them are essential for infection of nondividing cells and that the HIV-1 capsid protein may play a key role in this process, although the underlying mechanisms remain to be fully elucidated.

Integration

After successful generation of linear ds DNA and its transport across the nuclear membrane, HIV must insert its genome into that of the host cell for gene expression and productive infection (Fig. 3). Once the viral DNA is inserted into the cellular DNA by an enzyme called integrase (► [Integration](#)), the cell is usually infected for the remainder of its life span. As part of the host cell chromosome, the proviral DNA is replicated along with the host DNA. Thus, spread of infection can be achieved either by infection of new cells or by multiplication of cells already containing proviral DNA. Notably, several compounds that inhibit viral integration are now successfully used in the clinic (*cross-link to ART section*). In some long-living cells such as memory T cells, the integrated viral genome, which is referred to as a provirus, may remain silent for many years. This constitutes a main problem for viral eradication because as long as the provirus remains inactive, these cells are not recognized by the immune system and thus not eliminated. Sometimes the proviruses may become activated and produce infectious HIV that damages the immune system if ART is discontinued after many years. Whether or not a cell becomes latently or productively infected depends on the type and state of activation of the infected target cells during infection as well as subsequent

exogenous stimulation (Colin and Van Lint 2009). The viral reservoirs are not fully defined, but quiescent CD4⁺ T cells seem to constitute an important part of them.

Transcription

In productively infected cells, the integrated HIV provirus serves as a template for the transcription of both viral messengers and genomic RNA by the cellular Pol II polymerase (► [Transcription \(Initiation, Regulation, Elongation\)](#)). Proviral transcription is initiated by the viral promoter, which is located in the U3 region of the 5' LTR and active in many cell types. Viral gene expression is strictly dependent on cellular transcription factors, such as NF- κ B and NFAT. Initially, the transcriptional output is low because elongation of viral transcripts is very inefficient and the viral transactivator protein Tat is required for effective viral gene expression (► [Tat Expression and Function](#)). Tat binds to a specific sequence in the R region of the 5' LTR, named the trans-acting response (TAR) element, to increase transcriptional processivity (Fig. 1). This effect is dependent on the cellular factor pTEFb. Tat allows the efficient synthesis of full-length HIV transcripts, and more than 25 different mRNAs in three size classes are generated by alternative splicing: (i) unspliced RNA (9 kb) serving as genomic RNA or to produce the Gag and Gag-Pol precursors; (ii) singly spliced (4 kb) RNA encoding Vif, Vpr, Vpu, and Env; or (iii) fully spliced (2 kb) RNA expressing Tat, Rev, and Nef (Fig. 1). Transport of unspliced and partially spliced mRNAs from the nucleus to the cytoplasm is mediated by the viral Rev protein which interacts with the rev responsive element (RRE) in the viral RNA and the cellular export factor Crm1 to connect these viral RNAs to the export machinery (► [Rev Expression and Function](#)).

Translation and Assembly

As mentioned above, the fully spliced viral RNAs that are initially generated encode for Tat, Rev,

and Nef. Tat boosts viral transcription and RNA elongation, and Rev mediates the transport of unspliced and partially spliced viral RNAs to the cytoplasm. Nef performs a large number of functions and basically seems to make the infected cell less visible to the immune system by down-modulation of several surface receptors, such as CD4 and class I MHC, and manipulates the cells in a way that they become more effective producers of fully infectious viral particles. Synthesis of Tat and Rev allows the generation of full-length unspliced mRNA that expresses the Gag and Gag-Pol precursors which are then processed to major structural and enzymatic proteins. In parallel, the Vif, Vpr, Vpu, and Env proteins are synthesized from single spliced viral RNAs (Fig. 1).

Viral assembly is a complex and highly ordered process (► [Virus Assembly](#)). In brief, the Gag and Gag-Pol precursors multimerize via interactions between Gag proteins. Furthermore, both precursors are N-terminally myristoylated in the matrix domain and thus concentrated in lipid rafts at the inner leaflet of the plasma membrane (Ganser-Pornillos et al. 2008). The viral Env glycoproteins are recruited to these building platforms through interactions with the matrix protein. Finally, two copies of genomic viral RNA are recruited to this complex through interactions of their stem loops packaging signal with the zinc fingers present in the NC domain of Gag (Fig. 3). Furthermore, the viral Vif protein, which antagonizes the restriction factor APOBEC3G, as well as some cellular factors, are also recruited to the sites of virion assembly and incorporated into viral particles. The accumulation of viral proteins and RNA at the plasma membrane induces first its curvature and subsequently the formation of a membrane-coated spherical particle.

Budding

The release of progeny virions from the infected cells is called budding. The late domain of the p6 part of Gag and the cellular Tsg101 protein are involved in this step which allows newly formed HIV to pinch off and enter into the circulation (► [Budding](#)). Notably, also this late step of the

viral replication cycle is targeted by a restriction factor: tetherin (BST-2) tethers mature and infectious viruses to the cell surface and is counteracted by the HIV-1 Vpu and the Nef or Env proteins of other primate lentiviruses (Martin-Serrano and Neil 2011).

Maturation

The HIV particles are released in an immature and noninfectious form that is morphologically characterized by a thick layer of radially arranged Gag and Gag-Pol precursors (► [Maturation](#)). During or shortly after budding, the viral protease becomes activated and cleaves the Gag and Gag-Pol precursors into their mature final components. As a consequence, the configuration of the proteins is reorganized to generate the characteristic electron-dense conical inner core and to render the virus infectious (Briggs and Kräusslich 2011). Drugs that block this last essential step of the viral life cycle by inhibiting the viral protease are a main component of effective ART.

Viral Dependency and Host Restriction Factors

It has long been known that viruses are strictly dependent on live host cells in order to replicate. Only recently, however, it has become clear that these interactions may be far more complex than previously appreciated. Several studies have used genome-wide knockout strategies in order to better assess the cellular factors that may be critical for effective replication of HIV. All of them found that HIV may utilize hundreds of cellular proteins in order to complete its life cycle. Similarly, a recent study performed elegant broad-based screens to clarify how many cellular proteins interact with viral proteins and identified about 500 of them (Jäger et al. 2011). Altogether, these studies provide an exciting first glimpse at the enormous complexity of interactions between HIV and the host cell. However, there are some caveats. For example, the overlap between the potential viral dependency factors in the

genome-wide knockout studies was minimal (Bushman et al. 2009) most likely because of variations in the cell types, viral strains, and experimental conditions used. Furthermore, it is difficult to assess how many other cellular proteins may be affected by each individual knock-down. Similarly, most interaction studies cannot distinguish between direct interactions between viral and host cell proteins or interactions with larger protein complexes. Nonetheless, these studies have provided exciting first insights into the enormous complexity of interactions between the virus and the host cell and may help to identify additional key factors involved in HIV replication.

Although HIV hijacks the host cell and takes advantage of many cellular proteins and pathways, it has become clear that the cell is not a very friendly environment for the virus, because it encodes specific antiviral factors that may inhibit HIV at various steps of its life cycle and are counteracted by the viral accessory proteins (► [Cellular Restriction Factors](#)). In brief, the best characterized antiviral or host restriction factors are APOBEC3G which induces lethal hypermutation of the retroviral genome and affects reverse transcription, TRIM5 α protein that induces untimely uncoating of incoming retroviral capsids, and tetherin that inhibits virion release. Unfortunately, HIV-1 evolved effective strategies to evade or counteract these antiviral host factors (Kirchhoff 2010).

Target Cell Dependency

The main target cells for viral replication *in vivo* are activated CD4⁺ T cells, and the viral life cycle illustrated in Fig. 3 provides a rough overview of the events in this cell type. Similarly, almost all studies on the HIV replication cycle have been performed using immortalized cell lines or fully activated T cells. *In vivo*, however, many T cells are minimally activated. This may not be very important for the bulk of virus replication but most likely highly relevant for the establishment of latent viral reservoirs and for the pathogenesis of AIDS. For example, some long-living memory T cells may return to a quiescent stage upon HIV

infection and not show any gene expression for several years before they finally become activated and start to produce infectious HIV particles. Cells that carry the provirus but do not produce viral proteins cannot be recognized and eliminated by the immune system and constitute a major obstacle to virus elimination. Furthermore, it is important to consider that HIV does not only infect T cells and that the viral replication cycle may be somewhat different in other cell types. Macrophages, for example, are also productively infected by HIV and may contribute to the viral reservoirs and facilitate viral evasion of the blood-brain barrier (► [Macrophage-Specific Aspects of HIV-1 Infection](#)). Furthermore, HIV may also infect immature dendritic cells, microglial cells, and (possibly) stem cells although the relevance of these and other potential target cells of HIV for viral spread and pathogenesis *in vivo* is currently largely unclear.

Conclusions and Perspectives

Although enormous progress has been made in understanding the complex events and interactions that are critical for the life cycle of HIV, a lot remains to be learned. It will be essential to further clarify which host dependency factors are really critical for viral replication in the human host. Currently, only a single cellular factor (CCR5) is targeted for antiviral treatment. Preventing the use of other host cell proteins that are obligatory for viral replication may lead to the development of novel antiretroviral strategies that make it more difficult for HIV to develop resistance. Furthermore, it seems likely that additional restriction factors will be discovered and strengthening them or weakening the viral antagonists may also allow to impair the viral replication cycle at different steps. It will also be important to further clarify why some T cells get stuck after the early stage of infection and become latently infected and how to stimulate them in order to eliminate the viral reservoirs. Furthermore, recent studies suggest that the protection of specific T cell subsets may play a major role in the lack of disease progression in some monkey

species that are naturally infected with simian immunodeficiency viruses. Since the fate and type of the viral target cell determine the damage for the individual, it seems important to further study target cell-dependent differences in the viral replication cycle. Finally, it is important to consider that in vivo HIV is mainly replicating in lymphoid organs that are densely packed with different cell types and may spread through direct cell-cell contact.

HAND Definition

When carefully assessed, human immunodeficiency virus (HIV)-associated neurocognitive disorders (HAND) affect approximately half of persons living with HIV (Heaton et al. 2010). Three subcategories of HAND can be distinguished using a combination of neuropsychological testing, neurological and medical examination, and ancillary testing (Antinori et al. 2007): asymptomatic neurocognitive impairment (ANI), mild neurocognitive disorder (MND), and HIV-associated dementia (HAD). Regardless of the severity of the HAND diagnosis, neuropsychological impairment is often associated with negative daily functioning outcomes such as unemployment and poor medication adherence (e.g., Hinkin et al. 2002). It is important to note, however, that impairment in daily functioning is a key criterion that distinguishes MND and HAD from ANI. One significant challenge in assigning HAND diagnoses is differentiating HAND from other illnesses that can have neurocognitive effects (e.g., substance use, head injury, other chronic medical illnesses). Additional research is needed to clarify the role of risk factors in the development of HAND and to improve treatment of HIV brain disease without causing neurotoxicity. HAND prevention relies on early identification of those at risk to enable mitigation.

It is not yet clear whether the subcategories of HAND (ANI, MND, HAD) represent degrees of cognitive dysfunction on a spectrum or distinct disorders with different mechanisms and treatments. Each of the subtypes of HAND can exist in an active state or enter remission. Thus, unlike some other neurodegenerative disorders such as Alzheimer's disease, HAND-related impairment is not relentlessly progressive. Identification and classification is achieved through neuropsychological (neurocognitive) testing in at least five cognitive domains (attention-information processing, abstraction-execution, complex perceptual motor skills, memory with learning and recall testing, language, simple motor skills or sensory perceptual skills). To allow meaningful comparisons across different tests, results are presented on normalized scale such as a Z score or t score, adjusted for age, education, and other demographic factors as appropriate. Also critical to the current diagnostic schema is an evaluation of daily functioning capabilities, which can be assessed via self-report or other approaches such as performance-based measures of daily functioning.

Research Versus Clinical Diagnostic Approaches

Researchers and clinicians differ in their approach to the diagnosis of neurocognitive disorders in HIV. This fact has caused some confusion. In the research approach, all individuals are assessed with a detailed neuropsychological battery, and then each is classified based on the severity of neuropsychological and daily functioning impairment. By contrast, the clinical approach begins with patient symptoms. Patients (or in some cases family members) reporting difficulties with memory, attention, or concentration are screened for cognitive impairment and depression. In the absence of symptoms, no screening is done. Screening results are then used to decide on subsequent referral for more comprehensive evaluations. Individuals with ANI will of course be missed by such an approach, since by definition they have few if any cognitive symptoms. Additionally, many screening batteries are insufficiently sensitive to detect the predominantly mild neurocognitive impairments that are present

among HIV-infected persons. Thus, there remains a need for instrument that is both sensitive and specific, yet brief, to detect HAND.

ANI

Patients with ANI must be at minimum one standard deviation below the mean in at least two of the aforementioned cognitive domains, and the impairment cannot be explained by non-HIV-related comorbidities such as head trauma with permanent neurological sequelae. An important characteristic of ANI is that there is no evidence that the neurocognitive impairment disrupts the patient's daily functioning.

MND

Mild neurocognitive disorder meets the same neurocognitive testing criteria for ANI but in addition causes mild impairment in performance of activities of daily living. There must be either self-report of reduced mental acuity, difficulty with social functioning, and inefficiency in work or homemaking or first-hand report from a knowledgeable source that the individual has exhibited at least a mild decline in mental acuity that causes difficulty in managing work, homemaking, or social functioning. As with ANI, MND is not due to other conditions.

HAD

The most severe form of HAND is HIV-associated dementia (HAD). Individuals with HAD display marked acquired impairment in cognitive functioning in multiple domains and are at least two standard deviations below the mean. Verbal and nonverbal learning, information processing, and attention are particularly affected. The neurocognitive dysfunction causes significant impairment in daily functioning. HAD is not due to delirium, and there is no alternative diagnosis that would better explain the disorder, such as CNS infection, neoplasm, substance abuse, stroke or cerebrovascular disease, or other neurological disease.

Comprehensive Neuropsychological Testing

Comprehensive neuropsychological testing is the "gold standard" to characterize HAND and is

necessary to differentiate cognitive impairment due to HIV from other dementias and pseudo-dementias. Using valid and reliable assessments chosen and administered by a trained psychologist, a comprehensive neuropsychological testing evaluates at least following seven domains: attention/working memory, verbal fluency, learning and recall, nonverbal memory, abstraction/executive function, motor coordination and praxis, and information processing speed. The raw performance data must be adjusted for demographic and socioeconomic norms before being used for diagnosis. The whole process takes a few hours, thus is not practical for every HIV patient, and is usually reserved for patients who have cognitive deficits that impair their activities of daily living, have progression of HAND, and have an unclear diagnosis or patients with significant risk for HAND due to comorbid conditions.

Epidemiology

The epidemiological findings discussed here apply to individuals with HIV clade B virus, prevalent in North America, Europe, and Australia. Despite early entry of the virus into the central nervous system (CNS), HAND is relatively rare during acute and early infection (the first year after infection), becoming somewhat more common as immunity declines. Thus, incidence increases as the disease progresses. The prevalence of HAND and the demographics of those with HIV/AIDS have undergone a transformation since the introduction of combination antiretroviral therapy (cART). Prior to cART, 15–30% of all HIV-infected individuals developed HAD prior to death. Typically these individuals had advanced immunosuppression (CD4+ T-lymphocyte counts under 200/uL), and their mortality was high. Since cART became widely available in the United States, the incidence of HAD has declined markedly, but the prevalence of HAND, including the less severe forms, remains high, with 52% of patients demonstrating neurocognitive impairment (Heaton et al. 2010). Of those with HAND, most (approximately 60–70%) have ANI, a smaller fraction have MND (30%), and HAD is rare.

Potential explanations for these changes in prevalence and severity of HAND are several. Mortality has declined with cART, but those living longer with HAND do not necessarily return to premorbid cognition. Some cases previously classified as HAD experienced improvement, warranting reclassification to milder forms of HAND. Aging, an inevitable consequence of increased survival due to cART, is itself a risk factor for HAND. This observation will be explored in greater depth below. HIV may continue to cause CNS damage regardless of viral suppression, possibly due to sustained inflammation and immune activation. Finally, antiretrovirals themselves may cause CNS toxicities that contribute to HAND.

The demographics of patients diagnosed with HAND in the United States are reflective of the shifts in the HIV/AIDS epidemic. That is, the current population living with HIV/AIDS has a higher proportion of females and ethnic minority groups while having a lower level of education. Those with HAND in the cART era are more likely to report heterosexual-only contact and injection drug use. In large pre-cART studies, 65% of patients with cognitive impairment were Caucasian, 87% were male, 52% were employed, 70% were men who have sex with men only, and the median duration of HIV infection was 3.4 years. In the cART era, similar large studies have found that of those with neurocognitive impairment, 44% are Caucasian, 81% are male, 29% report being employed, 37% are men who have sex with men, and the median duration of infection is 9.3 years. This increase in duration of infection and the comorbidity linked to intravenous substance use may contribute to the pathophysiology of the disease. Moreover, as persons live longer with HIV infection, it may get increasingly difficult to distinguish HAND from typical age-related cognitive changes or dementias that can develop later in life.

HAND Risk Factors

Risk factors for HAND can be conceptualized in four broad categories: HIV disease severity indicators, nonmodifiable demographic factors, potentially modifiable comorbidities, and other

comorbidities. Whereas in the pre-cART era markers of HIV disease severity such as lower current CD4 counts and higher plasma viral loads conferred an increased risk of dementia and neurocognitive impairment, cART changed this. In the cART era, only nadir CD4 has retained an association with HAND risk. Thus, lower CD4 nadirs are linked to a “legacy” effect of increased HAND likelihood, despite subsequent immune recovery on cART (Ellis et al. 2011). Non-modifiable demographic risk factors include age (older individuals at greater risk than younger) and family history of dementia (patients with positive family history of dementia being more likely to develop HAND). In some studies, women are at greater risk of HAND than men. Additionally, low education, a surrogate for low cognitive reserve, confers greater risk. Among the potentially modifiable risks, recent evidence strongly points toward metabolic syndrome and vascular risk factors. The metabolic syndrome is quite common in HIV (Krishnan et al. 2012), and its underlying pathogenesis is likely to involve visceral adiposity with persistent inflammation (McCutchan et al. 2012). Metabolic syndrome components such as insulin resistance, lipid abnormalities, and hypertension, in conjunction with inflammation and immune activation, may contribute to CNS endothelial dysfunction, leading to neurodegeneration and cognitive impairment. Cerebral small vessel disease is common in patients dying with HIV infection in the cART era (Soontornniyomkij et al. 2014). Whether aggressive management of metabolic syndrome and vascular risk factors reduces HAND risk remains to be tested.

Screening for HAND

Effective screening to identify individuals with neurocognitive impairment is a critical step toward protecting and preserving brain function in individuals with HIV disease. For patients with acute infection, current guidelines recommend neurocognitive screening within 6 months of diagnosis of HIV infection, as HIV invades the CNS early in the disease course and a slow

progression to HAND may commence at this point. For long-term patients, the frequency of screening has not been well defined, and there is still much debate about whether asymptomatic patients should be screened. The current guidelines are that higher-risk patients receive screening more frequently (every 6–12 months), while lower-risk patients can be screened every 12–24 months. In addition, screening should be conducted at the time of antiretroviral changes, when comorbid conditions affecting HAND are identified and if the patient deteriorates. It is also important to differentiate HAND from other neurodegenerative processes such as AD, particularly as HIV-infected individuals age as a result of the HIV epidemic maturation in developed countries.

Since HAND affects a number of different cognitive domains (see above) at different points during the disease course, a useful screening tool should therefore evaluate all potentially affected domains. While there are a number of rapid cognitive assessments available for the clinical setting, each of these has its own limitations, and unfortunately there is no one clinical screening tool that has been found to be appropriately sensitive or specific for HAND yet. The HIV Dementia Scale (HDS) and its variation, the International HIV Dementia Scale, were specifically designed to examine neurocognitive dysfunction due to HIV infection and have been widely used to screen HAND. However, while HDS identifies HAD well, its application in the cART era has been limited due to its insensitivity to the more prevalent milder forms of HAND (Valcour et al. 2011). The Folstein Mini-Mental State Exam (MMSE), a general cognitive function tool that is designed to screen for acute confusional state (delirium) as well as cortical dementias (e.g., AD), might be ineffective to screen HAND as many of its test items are preserved in HAND (Valcour et al. 2011). Montreal Cognitive Assessment (MoCA), a more recently developed tool to assess general cognitive function, might be more useful to screen HAND than MMSE. MoCA examines executive functions, visuospatial abilities, working memory, language, naming, attention, and abstraction, but not psychomotor slowing, a prominent feature of HAND. The

scoring system is similar to that of the MMSE, with which many clinicians are familiar, with a score greater than or equal to 26 treated as normal. Overton and colleagues demonstrated a sensitivity of 59% and specificity of 81% for identifying cognitive impairment in HIV with MoCA using 26 as the cutoff score (Overton et al. 2011). In addition to these three screening tools, there are numerous other screening batteries available, including the Computer Assessment of Mild Cognitive Impairment, Medical Outcomes Study HIV Health Survey, Prospective and Retrospective Memory Questionnaire, and the Rey-Osterrieth Complex Figure Copy and Memory Tests. However, these batteries have been deemed insensitive for diagnosing HAND.

Clinical Features and Differential Diagnosis

HAND affects cognition, behavior, and the motor system. Motor symptoms are typically mild and include slowed repetitive movements and non-specific gait abnormalities. Cognitive deficits may decrease adherence to antiretroviral therapy, and patients may also experience difficulty with employment (Woods et al. 2011).

HAND differs from Alzheimer's disease (AD) in that AD is a cortical, predominantly amnesic syndrome with impaired episodic memory, naming, and visuospatial functions being present early in the disease course. By contrast, HAND is an apathetic-executive syndrome affecting subcortical white matter early in the disease course. HAND should not be confused with frontal-temporal dementia (FTD), in which behavioral disturbances such as disinhibition are common. Patients with cognitive impairment, visual hallucinations, and akinetic-rigid syndrome should be evaluated for dementia with Lewy bodies or idiopathic Parkinson disease depending on the time course and the neurological findings. Vascular cognitive impairment is an important consideration as HIV increases the risk of ischemic cerebrovascular disease. History and radiologic evidence of cerebral infarction assist with diagnosis.

Medical Evaluation

Aside from neurocognitive testing, HIV-infected patients with suspected or confirmed cognitive impairment require additional medical evaluation. The most important part of this evaluation is comprehensive history taking, which includes symptom evolution which may point to another disorder, the presence of confounding comorbid conditions such as depressive mood disorder, head trauma or substance abuse, nadir and current CD4 T-lymphocyte counts, and antiretroviral regimen. In addition, a thorough physical examination including a complete neurological examination should be done to exclude alternate diagnoses. Laboratory evaluation assists the clinician in excluding reversible causes of cognitive impairment including subacute combined degeneration from hypovitaminosis B12, hypothyroidism, and neurosyphilis. Routine laboratory evaluation for reversible causes of dementia includes: complete blood count, metabolic panel, syphilis serology (either rapid plasma reagin or Venereal Disease Research Laboratory test), vitamin B12 and red blood cell folate levels, and thyroid function tests. In addition, CD4 T-lymphocyte count and plasma HIV RNA should be obtained.

Neuroimaging is required to exclude CNS opportunistic disease or other pathologies in cases with focal neurological deficits or low CD4+ T-cell counts. Cranial magnetic resonance imaging (MRI) is preferred over computed tomography (CT), unless the patient is not a candidate for MRI. In this case, contrasted CT should be performed. Intravenous contrast administration is particularly useful in individuals whose CD4 count is less than 200 cells/mm³ to evaluate for CNS malignancies and opportunistic infections. The MRI is an invaluable tool in evaluating for structural lesions from cerebrovascular disease, opportunistic infections, neoplasm, or inflammatory conditions that can affect cognition. Though, unfortunately, pathognomonic MRI findings for HAND have not been defined, abnormal white matter T2 signal prolongation and global or basal ganglia atrophy have been observed in HAND. Magnetic resonance spectroscopy, diffusion tensor imaging, functional MRI, PET, and

SPECT have not demonstrated clinical utility at this time and are therefore reserved for research purposes.

Evaluation of cerebrospinal fluid (CSF) is useful in seeking alternative potentially reversible diagnoses such as infection and neoplasm. CSF cell count, glucose, and cultures are helpful for excluding infection in individuals with CD4 T-lymphocyte counts less than 200 cells/mm³. CSF cytology can be performed as clinically indicated. CSF protein is often elevated in patients with HAND, but this is a nonspecific finding. CSF HIV RNA levels may be useful in patients who have not been treated with cART or who have failed therapy. However, the association between HAND and CSF HIV RNA in patients on cART is less clear. Individuals with detectable CSF HIV RNA in the presence of undetectable plasma HIV RNA may have compartmental drug resistance leading to CSF viral escape. Alternatively this may relate to poor CNS penetration of antiretroviral medications. The clinician should be mindful that CSF HIV RNA does not necessarily reflect parenchymal viral burden.

Biomarkers

The HAND diagnostic process is likely to continue to evolve as additional details are uncovered regarding the pathophysiology of HAND. For instance, recent guidelines in the context of mild cognitive impairment and Alzheimer's disease use a combined approach of neuropsychological testing, biomarkers, and imaging in assigning diagnoses (e.g., McKhann et al. 2011). While neuropsychological impairment and its associated impact on daily functioning are likely to remain the core diagnostic components of HAND, there may be added incremental value to both peripheral (e.g., blood and CSF) biomarkers and imaging for both diagnostic and prognostic purposes.

Plasma and CSF Biomarkers

Given the easy access and low cost of blood sampling, there has been considerable interest in finding blood-based biomarkers that correlate with neurocognitive impairments in HIV.

However, isolating blood biomarkers sensitive to neurocognitive impairments in the cART era has proven to be difficult and is limited by low accuracy. For instance, CD4 cell counts and HIV viral load in peripheral blood do not correlate well with neurocognitive function in patients on cART. In contrast, recent studies have suggested that plasma-soluble biomarkers like CD14 (Lyons et al. 2011) and CD163 (Burdo et al. 2013) might be better predictors of neurocognitive impairment. These plasma-soluble biomarkers can help to monitor monocyte activation, which is related to chronic inflammation.

Compared to plasma biomarkers, CSF-based biomarkers might represent neural injury more closely due to their direct contact with the central nervous system. However, obtaining CSF is generally considered to be more invasive. In some studies CSF, tau levels are elevated in individuals with symptomatic neurocognitive impairment. However, such findings need verification.

Hcorr as a Possible In Vivo Noninvasive MRI Biomarker of Neural Injury in HIV

Advances in neuroimaging techniques like MRI have provided a noninvasive way to examine HIV-related pathological changes. For instance, structural MRI has been used to examine brain lesions and/or volume reductions that can be linked to cognitive impairments in individuals with HIV disease (Ances et al. 2012; Chang et al. 2011; Towgood et al. 2011). However, brain atrophy usually happens at rather late stages of disease with significant and usually irreversible brain damage. Given that HIV infection is hypothesized to lead to changes in neuronal function long before changes in anatomy can be detected (possibly due to early synaptodendritic damages (Ellis et al. 2007)), functional MRI (fMRI), with its ability to "directly" image brain function, has the potential to serve as a biomarker of HIV to identify neural injury at early stages of disease, including those with asymptomatic HAND. However, the effectiveness of recent efforts to use fMRI to study HIV has been limited by the absence of a clear model of how HIV affects the neuronal processing that give rise to behavioral

deficits, and how these changes in neuronal processing could be detected with fMRI at high sensitivity. For instance, recent fMRI studies of HIV have reported “conflicting” findings: both decreased and increased neural activity have been reported in HIV+ patients. These findings might reflect the technical limitations of conventional fMRI techniques: due to the limited spatial resolution, relating fMRI response amplitude to underlying neuronal function is rather ambiguous and difficult (Grill-Spector et al. 2006).

In contrast, a novel fMRI data analysis technique, local regional heterogeneity analysis, or Hcorr, which estimates neuronal sparseness as an indirect measure of neuronal function, has proven to be able to measure neuronal function more directly than conventional techniques (Jiang et al. 2013). This technique was motivated by findings from electrophysiological studies, which suggest the sparseness of neuronal activation pattern correlates with neuronal function and synaptic integrity. Using this technique, a recent study (Liu et al. 2015) provided evidence supporting the existence of neuronal dysfunction in asymptomatic middle-aged HIV+ women, who were on cART with suppressed viral load and normal CD4 cell counts. In contrast, both conventional fMRI techniques and behavioral test failed to detect these early neuronal dysfunctions. While future studies with different and large cohorts are necessary to validate and further improve this novel technique, Hcorr holds a strong promise to serve as a noninvasive biomarker of HAND; compared to more conventional structural and functional MRI techniques, Hcorr offers several distinct advantages: Hcorr is more sensitive to early and subtle neuronal dysfunction. While conventional fMRI techniques are limited to examine neuronal function at the brain regions related to studied cognitive function(s), Hcorr can be calculated for any functionally or anatomically defined brain region using a single data set, making it an ideal tool to examine widespread pathological changes in diseases like HAND. Hcorr can be calculated from resting state data, which avoids the performance-related confounds with the heterogeneous population. Compared to most fMRI techniques that require length scanning time,

Hcorr can reliably assess neuronal function with a few minutes of scan (which is compatible to the time required for a typical structural MRI scan), making it a more feasible tool in typical clinical settings. In addition, we have obtained preliminary data suggesting that Hcorr is significantly more sensitive to detect and evaluate therapeutic effects than traditionally used behavioral assays, suggesting it might be capable of serving as a surrogate measure to assess clinical outcome or to assist developing drugs that target specific brain regions.

Natural History and Treatment

HIV CNS Entry During Acute Infection

HIV enters the nervous system within days after initial infection. Although most cases of acute HIV infection go undiagnosed due to the unspecific nature of symptoms (a flu-like illness, in many cases), rarely acute HIV infection can present with a fulminant encephalopathy. In one case of iatrogenic HIV infection in which the patient died 15 days postinoculation, autopsy already revealed proviral HIV DNA and HIV proteins within the cerebral cortex, even though virus could not be detected in several other organs (Davis et al. 1992). An absence of specific neutralizing immune responses in the hyperacute stage might permit such early and extensive CNS invasion.

Neurocognitive impairment is relatively uncommon during the first year after infection, but brain changes nevertheless may be detected by imaging. One study (Moore et al. 2011) evaluated neurocognitive functioning using a comprehensive battery in individuals with early infection (less than 1 year) using Fiebig criteria and directly compared their performance to that of individuals with chronic HIV infection (median duration of infection 4.9 years) and to a control group of HIV seronegatives (HIV-). The HIV- group showed the best neurocognitive functioning, and although statistically indistinguishable from the acute/early HIV group, the latter showed performance intermediate between that of the HIV- and the chronically HIV-infected subjects.

While clinically evident neurocognitive disorders are uncommon early in infection, brain changes can nevertheless be seen using imaging techniques. For example, proton magnetic resonance imaging spectroscopy (1H-MRS) shows abnormal levels of several cerebral metabolites associated with brain inflammation and neuronal injury – glutamate (Glu), *N*-acetylaspartate (NAA), myoinositol (MI), and choline-containing metabolites (Cho) (Young et al. 2014). Early initiation of combination antiretroviral therapy reduced worsening of these inflammatory cerebral markers, but did not restore them to normal levels as seen in HIV-negative controls.

Impact of cART

Before the introduction of cART in 1996, HIV-associated dementia (HAD) occurred with some regularity and was only temporarily ameliorated by therapy with zidovudine and other antiretroviral medications available at that time. HAD was much more likely to occur in patients with advanced immunosuppression (CD4+ T-lymphocyte counts less than 100 cells/mm³). Untreated, HAD was rapidly progressive, with death occurring often within 6 months of diagnosis. With cART, HAD has become strikingly less common. Nevertheless, ANI and MND frequently persist.

In addition to its benefit on HAD, cART has also lengthened survival, permitting many HIV+ individuals to survive into middle and old age. Indeed, recent UNAIDS data show that the over-age-50 HIV+ subset is growing particularly rapidly in Western Europe and the United States, reaching over 800,000 in 2014 (Mahy et al. 2014). Other parts of the world are not far behind. This is important because older HIV+ individuals disproportionately bear the burden of brain injury and cognitive impairment. This may be partly explained by the high prevalence of abdominal obesity and metabolic syndrome in cART-treated HIV+ individuals, as previously noted.

ANI Progression

While asymptomatic neurocognitive impairment (ANI) – the most common form of HAND nowadays – is mild relative to HAD, it is not a

benign condition. Although not meeting formal criteria for MND, those with ANI on average have more difficulties in activities of daily living, are less likely to be employed, and show deficits on tasks simulating self-management of medications. Furthermore, their risk of symptomatic progression – that is, to MND – is quite high. In one recently published report, over a median follow-up of approximately 4 years, 50% of 121 individuals with ANI at study entry progressed to symptomatic HAND (MND or HAD) during follow-up (Grant et al. 2014). The relative risk for progression of ANI as compared to neuropsychologically normal was 5.8. This relationship held true even for individuals who were virally suppressed on ART at study entry and remained significant after statistically adjusting for important covariates.

Management of HAND

After confirming that HAND is present using neurocognitive testing and the diagnostic scheme described previously, patients should be screened for reversible causes of cognitive impairment such as thyroid deficiency and neurosyphilis. Although major depressive disorder alone rarely explains neurocognitive impairment, when present, depression is disabling in its own right and should be managed with antidepressants and psychotherapy. Additional details of laboratory evaluations and other may be found in a published consensus document (Mind-Exchange-Working-Group 2013).

Antiretroviral Treatment for HAND

All individuals with HAND should be on virally suppressive cART, regardless of CD4 count. In the United States and other developed-world settings, cART comprises combinations of three or more drugs from a least two classes: nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs), non-nucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), early entry/fusion inhibitors, and integrase inhibitors. Individuals with successful virologic suppression on cART have better preserved synaptodendritic complexity and are less likely to be neurocognitively impaired than non-suppressed individuals on cART or those

who have not received cART. The extent and time course of neurocognitive improvement for patients with HAND initiating cART varies widely, but improvement can be detected in 12–24 weeks in 15–30% of individuals and plateaus at 40% after 36 weeks (Cysique et al. 2009). Individuals with HAD and those who are naïve to antiretroviral therapy show the largest benefits (Tozzi et al. 1999; Letendre et al. 2004).

Because antiretrovirals penetrate differentially across the blood-brain barrier into CNS tissues, there has been great interest in the potential to select drugs so as to maximize their effectiveness in treating brain infection. Letendre et al. devised a scheme for ranking individual drugs according to their ability to penetrate the blood-brain barrier and reduce HIV RNA levels in cerebrospinal fluid (Letendre et al. 2009). This scheme has been updated as new medications have been introduced (Letendre et al. 2010). A recently published clinical trial evaluated the potential effectiveness of a CNS-targeted drug selection scheme for HAND (Ellis et al. 2014). The trial failed to fully accrue because of unexpectedly low referrals. It found no evidence of neurocognitive benefit for the CNS-targeted drug selection strategy as compared to a non-CNS-targeted, standard-of-care drug selection approach. Because of incomplete accrual, a benefit for a subgroup or small overall benefits could not be excluded.

Numerous alternative treatment strategies have been tested for HAND. These include memantine, transdermal selegiline, and nimodipine. Unfortunately, as has been the case for neuroprotective strategies in a number of other disorders, benefits have not met prespecified criteria for statistical significance, and these drugs are clinically indicated. Central cholinesterase inhibitors such as donepezil have not been rigorously evaluated in HAND.

Conclusion

HIV-associated neurocognitive disorders (HAND) are defined based on a combination of neuropsychological testing, neurological and medical examination, and ancillary testing into

three subcategories: asymptomatic neurocognitive impairment (ANI) will be missed in typical clinical practice, where individuals are evaluated only if they report cognitive difficulties, since by definition, symptoms in ANI are minimal or absent. Comprehensive neuropsychological testing is the “gold standard” to characterize HAND and is necessary to differentiate cognitive impairment due to HIV from other dementias and pseudodementias. HIV-infected individuals with suspected or confirmed cognitive impairment require additional medical evaluation, since some may have contributing causes other than HIV itself. The risk of symptomatic progression in ANI – that is, worsening to MND – is quite high: 50% over 4 years in one study. Although all individuals with HAND should be on virally suppressive combination antiretroviral therapy (cART), regardless of CD4 count, symptomatic progression may occur even in those with who are virally suppressed on cART.

Definition

African Americans are the largest racial minority in the United States. They comprise approximately 13% of the total US population and are disproportionately affected by HIV/AIDS.

Introduction

HIV affects African Americans at a disproportionately higher rate than other races. Compared to their White counterparts, rates of new HIV infections are over six and a half times higher for African

American men and over fifteen times higher for African American women (CDC 2012). Just under half of the population living with HIV in the United States (US) is African American. While HIV risk for African American men remains highest among MSM, African American women are over twice as likely to be infected with HIV through heterosexual activity. Possibly most alarming is the difference in mortality rates for individuals with HIV. The mortality rate for African Americans with HIV is almost 9 times higher than the mortality rate for White individuals with HIV (CDC 2010). Taken together, these data demonstrate the significant impact of HIV among African Americans and highlight the need to identify factors contributing to these elevated rates to acquire a better understanding of HIV among African Americans and guide prevention and intervention efforts.

In an effort to explain racial disparities in HIV prevalence in the United States, several hundred studies have provided data on the risk factors associated with HIV. However, when these studies are examined individually, the results are often inconsistent. These inconsistencies are likely attributable to factors such as differences in sample size, methodology, and populations. Furthermore, it becomes difficult to separate out individual and environmental risk factors that are solely accountable for higher rates of HIV among African Americans, since they are often interrelated and involve the interplay of several situational and environmental factors. Identified risk factors among African Americans include poverty, risky sexual behaviors, substance use, incarceration, education level, access to health care, discrimination, and HIV/AIDS-related stigma. This entry provides an overview of risk factors related to HIV infection among African Americans and concludes with a discussion of promising interventions for reducing HIV among African Americans.

Factors Contributing to HIV in African Americans

Poverty

Individuals who live below the poverty line or who live in low-income areas are at an increased

risk for HIV such that poverty may be the single most powerful risk factor outside of sex between males and IDU. An analysis in 2010 of over 9,000 heterosexual adults (non-injection drug users) revealed a direct correlation between socioeconomic status (as indicated by income, education, and housing status) and contracting HIV (Denning and DiNenno 2010). The rates for poverty-stricken areas in the United States are similar to countries with widespread AIDS epidemics such as those in Africa. Furthermore, there are no significant differences in the prevalence of HIV by race within poverty areas, which bolster the evidence that economic factors, more than race, may drive the prevalence of this epidemic within the African American community (Denning and DiNenno 2010). Poverty is believed to increase vulnerability to HIV through its association with a myriad of other identified HIV risk factors including substance abuse, homelessness, high rates of sexually transmitted infections (STIs), limited access to health care high incarceration rates, and psychiatric problems.

African Americans face several obstacles which may increase exposure to HIV as well as impede treatment for HIV. Regardless of race, approximately 20% of individuals with HIV are unaware of their status. African Americans have a higher base rate of HIV compared to other races and are more likely to have sex with individuals from their own racial group. A lack of awareness of HIV status combined with a higher base rate of HIV and a tendency to have sex within one's own racial group likely lead to a higher rate of accidental exposure to HIV for African Americans compared to other racial groups. Stigma and discrimination also impede treatment. African Americans already face high levels of stigma. Added stigmas of engaging in high-risk sexual behaviors or injection drug use (IDU) may deter individuals from seeking help or confiding their difficulties in others.

Substance Use

Substance use has long been recognized as a leading risk factor for HIV and is one of several factors driving the HIV epidemic among African

Americans. Drug users are at risk for contracting HIV through two avenues: injection drug use and high-risk sexual behaviors associated with drug use, such as trading sex for drugs or having unprotected sex when under the influence of drugs or alcohol. According to a national survey conducted by the Substance Abuse and Mental Health Services Administration (SAMHSA 2007), past-month illicit drug use was slightly higher among African Americans (9.2%) relative to the Whites (8.1%). However, only half as many African Americans engage in IDU compared to Whites. Overall HIV prevalence as a result of IDU has declined in recent years due to prevention efforts and education; however, IDU continues to be a major risk factor for HIV among African Americans. Compared to Whites, African American injection drug users are at a higher risk for contracting HIV through IDU.

Injection drug users are also at risk for HIV transmission through engaging in high-risk sexual behavior, and this association may be more significant for women than for men (Strathdee et al. 2001). High-risk sexual behaviors have been found to be more predictive of HIV seroconversion among African American women who are injection drug users compared to their male counterparts. Specifically, sex with other injection drug users may be a route through which African American women contract HIV. This relationship is particularly strong for cocaine injection, which has been shown to be more predictive of high-risk sexual behaviors for African American women compared to opiate injection.

Non-injection drug use has also been associated with the sexual transmission of HIV. Drug intoxication often induces hypersexuality, disinhibition, and impaired judgment, all of which can influence risky sexual behaviors. While a number of substances have been associated with high-risk sexual behaviors, crack cocaine in particular has been associated with increased sexual activity, inconsistent condom use, sex with multiple partners, and exchanging sex for drugs or money (Campsmith et al. 2000). Because of its association with risky sexual behaviors, the contribution

of crack cocaine to the HIV transmission has been the focus of the majority of the drug-related research. Furthermore, crack cocaine use is more prevalent among low-income African American communities in which HIV prevalence is already high. This racial disparity in crack cocaine use has been found to be especially strong in HIV-positive individuals, and African Americans have been shown to be more likely to use cocaine both before and after HIV diagnosis in comparison with Whites (Campsmith et al. 2000).

Biological Factors

The prevalence of STIs other than HIV is important when examining factors related to HIV because STIs facilitate the transmission and acquisition of HIV by creating open sores and allowing the virus to enter the bloodstream (Nusbaum et al. 2004). African Americans have higher rates of other STIs than Whites. Gonorrhea rates are especially high among African Americans, though rates have declined from about 30 times higher to 20 times higher than Whites over the past 10 years. Chlamydia and syphilis rates are also higher among African Americans relative to Whites. While STI rates have generally been declining in response to better educational and media campaigns, syphilis rates have been on the rise in young African American men. This increase may be explained by the portion of African American men who have sex with men, as this group represents over half of all new syphilis cases.

Lack of Awareness of HIV Status

One major contributor to the transmission of HIV among African Americans, and certainly other races, is the lack of awareness of one's HIV status (see entry "[► HIV Counseling and Testing, Prevention of HIV](#)"). A meta-analysis found that individuals who are aware of their HIV-positive status are less likely to engage in risky sexual behavior (Marks et al. 2005). Furthermore, more recent evidence has found that individuals who are taking antiretroviral therapy (ART) are less likely to transmit HIV to unaffected sexual partners (Cohen et al. 2011). Increasing HIV testing

and providing treatment among African Americans are both essential components to HIV prevention. However, a number of variables have been identified which may impede African Americans' willingness and ability to be tested, including a lack of knowledge concerning HIV risk factors as well as not perceiving themselves to be at risk. African Americans generally have sought less medical care and may be more apprehensive to seek treatment due to prior bad experiences with the medical system or lack of health insurance. Additionally HIV-/AIDS-related stigma and fear of knowing one's HIV status have both been suggested as potential barriers to treatment.

Sexual Network Patterns

Sexual network patterns (see entry "[► Risk of Sexual HIV-1 Transmission: Coinfections Associated with Risk](#)") appear to be a major contributing factor to the HIV epidemic among African Americans, rather than engaging in unusually high-risk sexual acts (see entry "[► Risk of Sexual HIV-1 Transmission: Coinfections Associated with Risk](#)"). There is no evidence to suggest that African Americans engage in higher-risk sexual behaviors (e.g., anal sex, sex without condoms), yet they remain at higher risk for both HIV and STIs compared to Whites for a number of reasons. African Americans are more likely to engage in concurrent sexual partnerships (sexual partnerships that overlap in time) than other racial groups, which has been identified as a major risk factor for HIV transmission (Morris et al. 2009; Morris and Kretzschmar 1997). Furthermore, concurrent sexual partnerships increase the probability of sexual mixing between high- and low-risk individuals. Since African Americans, similar to other racial/ethnic groups, are more likely to engage in sexual relationships with members of the same race, the risk of HIV remains concentrated among African Americans. Further, the increased rates of the HIV infection in this population increase the likelihood of exposure from having sex with a high-risk partner that gets transmitted to a low-risk partner.

Interventions, Prevention, and Future Directions

Much of what applies to prevention efforts in general also applies to African Americans. Education, media campaigns (see entry “► [Mass Media and HIV Prevention](#)”), and more frequent testing all contribute to reducing HIV. However, tailoring these efforts may better address the specific HIV prevention and treatment needs of the African American community. Tailored interventions and those delivered to African Americans by African Americans have been shown to be more effective. The CDC and several of its collaborators have worked through advertising and funding campaigns to target high-risk groups in efforts to encourage testing in poor neighborhoods, African American women, and African American MSM. They have also put forth an initiative to encourage HIV testing at historically African American universities and colleges and worked to create educational and support groups (i.e., Many Men, Many Voices and Sister to Sister) to destigmatize HIV, provide education, and help groups such as MSM seek support and deal with discrimination. The CDC has also worked to support National Black HIV/AIDS Awareness Day (February 7.) Other organizations such as the Black AIDS Institute and the National Association of People with AIDS have made tremendous strides in publicizing HIV risk in the African American community, increasing testing, and promoting education about HIV testing and prevention. Many of these efforts have come from African American leaders and celebrities and received wide mass media publicity, extending their influence to a nationwide audience.

Conclusions

HIV affects African Americans at a disproportionately higher rate than other races. A number of sociodemographic factors place African Americans at a heightened risk for HIV such as elevated levels of poverty, patterns of substance use, and the stigma associated with the illness. Furthermore, sexual networks greatly exasperate the risk for contracting HIV in the African American

population. Tailored interventions and those delivered to African Americans by African Americans have been shown to be effective. Media campaigns designed to reduce stigma, raise awareness, and increase testing have shown promise as an effective means of intervening at the population level.

HIV Prevention and Asians and Pacific Islanders

Sana Loue

Department of Bioethics, School of Medicine,
Case Western Reserve University, Cleveland, OH,
USA

Definition

The population category of Asians and Pacific Islanders (API) comprises individuals of more than 70 diverse nationalities and more than 100 languages and dialects. The incidence and prevalence of HIV and HIV risk behaviors vary across subgroups of API. Barriers to prevention include linguistic isolation, stigma and discrimination, immigration issues, and cultural norms. Support from social networks and the involvement of religious organizations may be critical to primary, secondary, and tertiary HIV prevention efforts among APIs.

HIV Among Asians and Pacific Islanders in the United States

The Asian and Hawaiian Native/Pacific Islander (API) population of the United States has grown rapidly, comprising 1.5% of the US population in 1980 and growing to 4.4% of the population by 2002 (Reeves and Bennett 2003). According to census data, almost two-thirds (61.4%) of the API population is foreign-born. Although APIs are often thought of as a homogenous group, "Asians and Pacific Islanders" actually encompasses individuals of more than 70 different nationalities, widely differing cultures, and more than 100 languages and dialects. According to the definition

utilized by the US Census Bureau, Asians are persons "having origins in any of the original peoples of the Far East, or the Indian subcontinent including, for example, Cambodia, China, India, Japan, Korea, Malaysia, Pakistan, the Philippine Islands, Thailand, and Vietnam"; Native Hawaiians/Pacific Islanders include persons "having origins in any of the original peoples of Hawaii, Guam, Samoa, or other Pacific Islands" (Humes et al. 2011). Although individuals of all such groups are encompassed under the same umbrella term, it is important to recognize that the incidence and prevalence of both risk behaviors and HIV/AIDS may vary greatly across the numerous subgroups and the development and implementation of effective prevention strategies necessitates consideration of the differences, as well as the similarities, that exist across the many subgroups.

Data from the 33 states that have long-term, confidential name-based HIV reporting indicate that as of 2005, Asians and Native Hawaiians/Pacific Islanders (API) accounted for approximately 1% of all HIV/AIDS cases in the United States. A recent HIV/AIDS surveillance report indicates that between 2006 and 2009, the rate of AIDS diagnosis decreased among Asians and remained stable among Native Hawaiians/Pacific Islanders (Centers for Disease Control and Prevention 2009).

These HIV/AIDS rates appear to be relatively low in comparison with the rates among other US racial subgroups, such as African Americans and Latinos/Hispanics. However, they belie the increasing rate of transmission among some subgroups of Asians and Pacific Islanders in the United States, particularly among men who have sex with men (MSM). The primary mode of HIV transmission among men is unprotected sexual contact between men, which accounts for 67% of all cases, followed by high-risk heterosexual contact, which accounts for an additional 16% of the cases. Several studies conducted in San Francisco indicate that HIV prevalence among some samples of Asian and Pacific Islander MSM may be as high as 3% and that API MSM communities may have a high prevalence of risky sexual behaviors. The use of crystal methamphetamine ("crystal"), methylenedioxymethamphetamine ("ecstasy"),

and inhalant nitrites (“poppers”) in the MSM community has been associated with engaging in high-risk behaviors, which include unprotected anal sex, commercial sex work, and low rates of HIV testing. Because more than one-half of API MSM infected with HIV/AIDS have been born outside the United States, it has been hypothesized that individuals’ experience of stigma and discrimination due to their status as members of a racial minority, as MSMs, and as immigrants may be associated with increased HIV risk. At least one study has found that experiences of anti-immigrant discrimination are associated with increased levels of unprotected anal intercourse with secondary partners (Yoshikawa et al. 2004).

Eighty percent of HIV/AIDS cases among API females are attributable to high-risk heterosexual contact; injection drug use accounts for an additional 16% of these cases (Centers for Disease Control and Prevention 2008). The proportion of young unmarried API women who report having engaged in sexual intercourse is much lower than that among their White, Black, and Hispanic/Latino counterparts; it has been hypothesized that this relative postponement of sexual activity may be related to cultural norms that mandate sexual modesty for women. However, once sexually active, the rates of engaging in unprotected sex appear to be comparable between API women and women of other racial/ethnic groups. Research findings also suggest that API women may be at risk for HIV due to their sexual partners’ risk behaviors, including unprotected sex with secondary partners when traveling overseas (Carrier et al. 1992), a refusal to utilize condoms, even when explicitly asked to do so, and the threat of partner violence (Jemmott et al. 1999).

HIV/AIDS Prevention Efforts

Individual-level prevention efforts may focus on primary prevention (preventing the transmission and acquisition of HIV), secondary prevention (preventing the progression of HIV to symptomatic disease among those who are HIV infected), and tertiary prevention (preventing death among those with symptomatic disease). In the absence

of a vaccine, primary prevention can only be accomplished by reducing risky behaviors. Secondary prevention can be accomplished through early HIV diagnosis and linkage to care, while tertiary prevention is effectuated through the provision of effective HIV treatment.

Primary Prevention Efforts

Individual-Level Prevention Efforts

The single controlled trial of an HIV prevention program for APIs utilized the social cognitive model as the basis for the intervention to reduce incidents of unprotected anal sex and number of sexual partners among API gay men (Choi et al. 1996). Currently, the health belief model appears to be the most frequently suggested framework for the development of effective HIV prevention interventions with API communities. The health belief model suggests that an individual will take preventive action to avoid a disease if (1) the individual believes that he or she is susceptible to the disease (perceived susceptibility); (2) the disease may have a moderately severe impact on a domain in the individual’s life (perceived severity); (3) specified behaviors may help to reduce the susceptibility or severity (perceived benefits); (4) the adoption of these behaviors is not impeded by perceived barriers such as cost, shame, or pain (perceived barriers); and (5) the person believes that he or she is able to perform a specified behavior (Rosenstock 1974; Rosenstock et al. 1988). Research with Taiwanese immigrants to the United States suggests that self-efficacy for maintaining a monogamous relationship and for condom use may be key in primary prevention efforts among some APIs (Lin et al. 2005). Individuals with low self-efficacy for maintaining a monogamous relationship may be more likely to have multiple sexual partners, thereby increasing their HIV risk, and individuals with low self-efficacy for condom use may be less likely to utilize condoms, again resulting in greater HIV risk.

API individuals may experience numerous barriers that not only inhibit their adoption of HIV prevention behaviors but also diminish their willingness to obtain HIV prevention information.

API individuals may be reluctant to discuss HIV risk or prevention or to present for HIV testing due to the relative unavailability of language-appropriate prevention interventions; racism and an accompanying distrust of physicians; cultural norms that shame sexual behavior, sexual orientation, substance use, and/or HIV status; cultural taboos prohibiting the open discussion of sex and sexuality; a belief that discussion of illness or death will lead to bad luck; and fear of potential immigration consequences among those who are not US citizens. API MSM in particular may experience strong feelings of guilt about their sexual behavior due to family expectations that they marry and produce children; the anxiety associated with discussions of sexual behavior may trigger identity conflicts that they wish to avoid (Kanuaa 2000).

Support from social networks may be important in reducing HIV risk behaviors and HIV transmission among API MSM. Research suggests that having conversations with family members and gay friends about experiences of stigma and discrimination is associated with lower levels of unprotected anal intercourse among API MSM (Yoshikawa et al. 2004).

A variety of delivery mechanisms have been identified that could be utilized effectively in Asian Pacific Islander communities. These include newspaper articles published in a variety of languages, mobile vans offering a variety of services including those related to HIV, take-home videos in appropriate languages, home-based prevention programs, and Internet-based strategies (Jemmott et al. 1999).

Community-Level Prevention Efforts

Although community-based initiatives may provide HIV prevention services, their efforts to do so may be hampered by a variety of factors. These include a lack of organizational stability and viability related to human and financial resources, service delivery, and external relations, all of which are critical to engender trust in the community to be served (Sheth et al. 2007). Organizations that lack adequate HIV knowledge or familiarity with and

sensitivity to cultural issues may be unable to develop or implement effective and acceptable HIV prevention services.

The national capacity building assistance (CBA) program established by the Asian & Pacific Islander Wellness Center in the San Francisco and the Asian & Pacific Islander American Health Forum illustrates one model that is available to address many of the barriers that impede prevention efforts (Sheth et al. 2007). The CBA program is premised on three core values: client centeredness, collaboration, and cultural competence. Through the development and provision of individual client-centered trainings, national and regional workshops, and information and technology transfer, the CBA works with community-based organizations, health departments, research scientists, and health and medical service providers to increase the number of health departments that collect and report data related specifically to APIs, increase community investment in HIV-related services for APIs, increase HIV leadership and sustainability in the Pacific Island jurisdictions, and, ultimately, increase the numbers of API individuals who are tested for and learn their HIV status and the acceptance of HIV in API families and communities (Sheth et al. 2007).

Religious organizations are quite important within many Asian immigrant communities (Min 2002) and can potentially aid in HIV prevention efforts (Loue et al. 1999). However, there may be significant divergence of opinion regarding the extent to which involvement of the religious institution in HIV prevention efforts would be considered to be acceptable by attendees at the religious institutions and by the institutions' respective communities (Chin et al. 2005). This may be a particular issue among adherents of Buddhism and Hinduism due to perceived conflicts between religious teachings and the focus of HIV prevention discussions.

Secondary and Tertiary Prevention Efforts

It is clear that many of the barriers that operate to impede primary prevention efforts, such as linguistic isolation, cultural taboos impacting the

willingness and ability to discuss sexuality and sexual behavior openly, and a fear of potential immigration consequences, also impact secondary and tertiary prevention efforts. As an example, researchers have found that HIV-positive APIs are less likely than their White counterparts to be aware of the CD4 count or of services that might be available to them (Wong et al. 2004). Individuals who are unaware of the status of their immune functioning or services that may be available to them for the treatment of their HIV infection will not be able to optimally manage their disease progression.

API individuals who do not disclose their HIV status to friends and/or family members may be deprived of the support that might otherwise be available to them. A desire to shield one's family members from shame, to protect family members from an obligation to provide assistance, and to avoid communication about highly personal matters, such as sexual behavior, has been found to inhibit the ability of HIV-positive API MSMs from disclosing their serostatus to their family members (Yoshioka and Schuztack 2001). API individuals may seek emotional support from gay friends and disclose their HIV seropositivity to family members only when his health deteriorates to a point where disclosure becomes absolutely necessary.

It has been suggested that not only is the provision of HIV/AIDS education to family members important for HIV-positive API individuals but that health-care professionals may need to be actively involved in this process. This can be accomplished through a variety of mechanisms, including addressing the family members with the assistance of an API physician and/or utilizing the services of a trained interpreter in situations in which the family members and health-care provider(s) do not speak the same language.

Conclusion

Asians and Pacific Islanders are highly diverse with respect to culture, religion, and language. Although the numbers of HIV-positive

individuals are low in comparison with other minority groups, specific subgroups are experiencing high rates of HIV transmission.

Significant barriers to both prevention of HIV transmission and treatment for those who are already HIV-positive exist at both the individual and community levels. At the individual level, these include language, fear of immigration consequences, lack of social support, cultural norms related to sexuality, and racism. Community-level barriers include organizational stability, lack of familiarity with Asian and Pacific Islander cultures, inadequate knowledge relating to HIV, and lack of language-appropriate resources. Potential approaches to reduce these barriers and enhance prevention efforts include the provision of support services to individuals and their family members, the development of HIV prevention programs through religious institutions, and increased reliance on home-based delivery mechanisms for the provision of HIV-related information and testing.

HIV Prevention and Hispanics

Yannine Estrada and Guillermo Prado
Department of Public Health Sciences, University of Miami, Miami, FL, USA

Definition

HIV Prevention in Hispanics:

The study of the prevention of HIV among the Hispanic population that includes examination of etiology and intervention strategies at the individual, family, peer, school, community, and macro level.

Epidemiology of HIV/AIDS

Hispanics are disproportionately affected by HIV/AIDS, a public health concern driven by multiple factors including, but not limited to, individual, family, and macro-level variables. For example, while Hispanics accounted for approximately 17% of the total US population, they comprised almost 24% of new HIV infections (CDC 2016a). Young people are also disproportionately affected by HIV, representing 39% of new cases among 13–29-year olds-(CDC 2016b) (Children, epidemiology of HIV/AIDS). Among Hispanics, inequities also exist among young people and men who have sex with men (MSMs). For example, from 2005 to 2014 HIV diagnoses among gay and bisexual men aged 13 to 24 increased 87% (CDC 2016a). Hispanic MSMs accounted for 81% of new HIV infections among Hispanic men (CDC 2015a). Further, 45% of new HIV infections among Hispanic MSM were among people below the age of 30 (MSM, Epidemiology of HIV/AIDS)(risk groups). Since the epidemic disproportionately impacts Hispanic young people and MSMs, this chapter will focus on these subgroups of the Hispanic population.

Hispanics constitute a large and quickly growing segment of the US population with a growth rate faster than all other ethnic/racial groups, including non-Hispanic Whites (U.S. Census

2011). Further, Hispanics are a young population; approximately 34% of Hispanics are under the age of 18 compared to 24% for the rest of the total US population (U.S. Census Bureau 2009). Therefore, given the high percentage of new HIV cases among young people and that the Hispanic population is rapidly expanding, the need for prevention research and intervention is clear.

For HIV prevention to be effective, it is important to understand the social and contextual factors (social contextual factors in HIV prevention) associated with it (Prado et al. 2010). Prevention frameworks underscore the necessity for conceptualizations of problem behaviors among youth, including HIV risk behaviors, as embedded within a system of networks (e.g., Prado et al. 2010; Viruell-Fuentes et al. 2012). Researchers posit that risk and protection do not function independently and that, indeed, conceptualizing risk and protection as separate processes can overstate the impact of each (Prado et al. 2009). Rather, risk and protective factors exert their influence on HIV risk behaviors within the environment in which they are embedded. As such, this chapter will focus on individual, family, and macro-level factors of HIV among young Hispanics and Hispanic MSMs, along with a brief discussion on preventive interventions for Hispanic youth.

Individual Level Factors

Sexually risky behaviors and substance use are two individual-level factors that impact HIV transmission with high rates among Hispanics compared to non-Hispanic whites. Transmission of HIV among youth commonly occurs through risky sexual behaviors including sex without a condom and multiple sexual partners (sexual risk factors for HIV infection, personal). The proportion of Hispanic youth reporting condom use at last sexual intercourse is lower (55.6%) than that of non-Hispanic white (56.8%) and African-American (63.4%) youth (CDC 2015b). Additional individual-level precursors to HIV infection include substance use, which increases the risk for sexually risky behaviors in young people (Prado et al. 2006).

The dangers of drug use are exacerbated among Hispanic youth because they have higher use rates compared to other minorities, making illicit drug use a major risk factor for engagement in unsafe sexual behavior and consequently HIV infection (Prado et al. 2006). According to the CDC's Youth Risk Behavior Surveillance Survey, of those adolescents who reported having sex within 3 months prior to completing the survey, 23.3% reported drinking alcohol or using illicit drugs before their last sexual intercourse. Hispanic adolescents also reported drinking or using illicit drugs before last sexual intercourse (25.6%) more often than both non-Hispanic Whites (25.0%) and African-Americans (14.1%).

The relationship between substance use and unprotected sex is particularly strong among MSMs (Celentano et al. 2006; Dolezal et al. 2000) (sexual factors for HIV infection, personal). A study with mostly young Hispanic MSMs (76% under the age of 35) found higher frequencies of anal intercourse without a condom were correlated with increased alcohol and illicit drug use (Dolezal et al. 2000). Substance use has also been documented among Hispanic MSMs as a means of increasing desire and decreasing inhibition and has been associated with unprotected anal intercourse and multiple sex partners (Fernandez et al. 2007). Age also seems to be a factor in unprotected sex among MSMs. Previous studies have found rates of unprotected anal sex ranging from 40% to 50% among 18–30-year-olds, across studies, suggesting that preventive interventions among young MSM need to include substance use reduction strategies (Celentano et al. 2006).

Family-Level Factors (Family Structure)

Parents and family play a central role in youth development, particularly in Hispanic culture, and are therefore an important point of intervention for HIV prevention. Research demonstrates parents' role in molding youth sexual attitudes and contraceptive behavior and recommends the inclusion of parents in HIV prevention interventions for adolescents (NCLR 2011). Family functioning is a strong predictor of HIV risk behaviors

among Hispanic youth and has been shown to reduce the onset of risky sexual behaviors (Prado et al. 2010).

Communication is an important component of family functioning (communication). Parent-youth communication about sex allows for the transferring of values and beliefs regarding sex in addition to providing a reliable foundation related to sex education for youth (NCLR 2011). Youth who receive information about sex are less likely to participate in sexually risky behaviors, but, unfortunately, Hispanics do not communicate with their parents as much as non-Hispanic whites when it comes to topics related to sex (Baumeister et al. 1995). Lack of communication can lead to decreased familism, a family-level factor which is heavily emphasized in Hispanic families.

Familism refers to an emphasis on family relationships, loyalty, and reciprocity (Sabogal et al. 1987). Familism involves being responsive toward family obligations and placing family interests above self-interests. Higher levels of familism have been associated with better health profiles for Hispanics and with better adaptation to US society (Sabogal et al. 1987). Among MSMs, immediate family support has been identified as a protective factor associated with decreases in unprotected anal intercourse, social isolation, and psychological distress (Diaz and Ayala 2001) (social support). In an examination of protective factors for HIV infection among Mexican-American MSMs, investigators found respect for family as an important motivator and that participants honored their families by safeguarding their health through avoidance of sexually risk behaviors (Meyer and Champion 2010). Researchers have suggested that the value of familism can be used as a tool to prevent HIV infection (NCLR 2011). For example, familism can be called upon as a way of creating family unity in regard to engaging in positive health behaviors that benefit the family as a whole (Guilamo-Ramos et al. 2009).

Macro-Level Factors

Multiple researchers have highlighted the importance of moving away from behavioral strategies of HIV prevention and moving toward models

that account not only for the immediate social environment but that also account for broad social, economic, and cultural environmental factors (e.g., Organista et al. 2012) (social contextual factors in HIV in HIV Prevention). The heavy impact of HIV/AIDS on minorities, such as Hispanics and MSMs, indicate that individual level interventions, while important, are insufficient and that broader, macro-level factors unique to these populations should be considered in HIV prevention efforts (Wyatt et al. 2012). The context of HIV risk must be understood and targeted beyond a behavioral paradigm in order to obtain effective risk reduction (NCLR 2011). Some of the social and cultural drivers of HIV infection among Hispanics include cultural values, acculturation, and discrimination.

Cultural Values (Social Contextual Factors in HIV in HIV Prevention)

Understanding Hispanic cultural constructs are fundamental to the advancement of HIV prevention (NCLR 2011). Cultural beliefs around sex impact how relationships are defined, how and when condoms are used, and what sexual behaviors are considered acceptable (Wyatt et al. 2012). While there has been a focus on how cultural beliefs influence decision-making around sexuality, less is known regarding how cultural beliefs among Hispanics may contradict HIV prevention messages and therefore impact risk for infection and transmission. For example, collectivistic orientations which value interconnectedness and placing the needs of others over self-needs may interfere with consistent condom use (Wyatt et al. 2012). For HIV prevention to work among Hispanics, messages need to be delivered in culturally syntonous ways and must reflect Hispanic cultural values (Marin 2003). The risk for HIV is augmented when populations are not given the necessary skills that are acceptable and congruent with long-held beliefs (Wyatt et al. 2012).

Researchers hypothesize that certain Hispanic cultural values serve as protective and risk factors for HIV. As a group, discussion about sex and sexuality for Hispanics is more private and personal than in white non-Latino cultures (Marin 2003). Due to language and cultural barriers,

accessing information about HIV prevention, HIV testing, and securing timely medical attention can be difficult for individuals born outside the USA (Prosser et al. 2012). Changes associated with the immigration experience like the loss of stable romantic relationships and social networks may contribute to changes in behavior that lead to increased risk of HIV infection (NCLR 2011). Additionally, there are gender norms among the Hispanic population that put males and females at risk for HIV; in particular, gender roles have a significant impact on HIV infection (gender roles).

Hispanic cultural constructs such as machismo and marianismo have been associated with Hispanic sexual behaviors that can lead to or prevent HIV infection. Machismo usually involves beliefs around the meaning of manhood and encompasses hypermasculinity, sexual prowess, and bravado (Raffaelli and Iturbide 2009) which can lead to sexually risky behaviors. The traditional male machismo role supports the acceptability of multiple partners for males and places Hispanic women at risk for HIV and other sexually transmitted diseases (Teitelman et al. 2008). Among Hispanic MSMs, there is a relationship between higher levels of unprotected sex and machismo (among adult men) (Dolezal et al. 2000). In this particular study, machismo was related to unprotected anal intercourse for insertive sex but not receptive. Research also indicates that among Hispanic MSMs, machismo beliefs are associated with a greater number of sexual partners (Jarama et al. 2005). Further, beliefs around machismo uphold the notion that males cannot control their sexual desires and that these desires require release (Jarama et al. 2005). Perceptions of low self-control in regard to sex are frequently used to justify anal sex without a condom in research with Hispanic MSMs (Jarama et al. 2005).

Contrarily, machismo has also been studied in terms of its positive attributes. For example, a “macho” man is a protector of self and family, is monogamous, and sees women as equals (e.g., DeMente 1996). Some researchers have suggested that the construct of machismo among Hispanic youth can be channeled in a manner that highlights males as protectors and used as

motivation for youth to avoid endangerment of their families by taking precautions in their sexual behavior (Meyer and Champion 2010). Overall, while machismo may have positive aspects such as males being seen as the family protector and provider, machismo can disempower both men and women as male masculinity must constantly be proven through multiple sexual partners and demonstrations of fearlessness and lack of sadness (Marin 2003).

Alternatively, the Hispanic traditional value of marianismo suggests that women should be self-sacrificing and subordinate to male authority (Cauce and Domenech-Rodriguez 2002). This cultural value upholds female passivity in sexual relations and places females in a position of disempowerment when addressing sexual needs such as condom use. In many relationships, the suggestion of a condom is enough to call into question its monogamy status and prevent females from insisting on protection. Research with Hispanic females has cited male’s unwillingness to use condoms and inability to employ risk reduction behaviors with partners as barriers to HIV prevention (Amaro 1995). Further, gendered beliefs, such as endorsement of the belief that men should know more about sex than women, promote embarrassment and discomfort with sex and perpetuate sexual silence which results in a lack of access to preventive information (Marin 2003). Although marianismo upholds women’s silence, self-sacrifice, and reluctance to discuss sexual matters, it has also been conceptualized as protective in that it can lead to behaviors such as fewer sexual partners. In summary, HIV prevention and risk reduction strategies need to consider the contextual social factors that shape sexual behaviors and how these are impacted by gender norms (Amaro 1995) and incorporate deeper understandings of how gender roles (gender roles) impact behavior.

Acculturation (Social Contextual Factors in HIV in HIV Prevention)

Acculturation appears to be both a risk and protective factor for HIV infection across multiple studies (Rafaelli and Iturbide 2009). Acculturation involves cultural changes resulting from

interaction between two or more different cultural groups and their members (Berry 2007). Acculturation is important to consider given that some studies indicate 42% of HIV infections among people born outside the USA occurred among Hispanics (Prosser et al. 2012). While most studies regarding Hispanics and sexuality have been conducted with adults, it is likely that many of the findings are applicable to Hispanic youth (Raffaelli and Iturbide 2009). Although lower levels of acculturation have been linked to fewer sex partners in Hispanic women, it has also been linked to lower condom use (Marin 2003). Concomitantly, higher levels of acculturation have been shown to bring along an increase in female power in interpersonal relationships which is associated with more condom use (Raffaelli and Iturbide 2009). Among new immigrants, adolescents living in English-speaking homes were at less risk for sexual activity than their counterparts in Spanish-speaking homes. The opposite was true, however, for US-born Hispanic youth, who were at higher risk for early sexual activity if they were living in English-speaking homes (Guilamo-Ramos et al. 2009).

Among males, higher levels of acculturation have been associated with fewer sexual partners, while other studies have shown the opposite. Lower levels of acculturation have also been associated with coercive sexual practices among Hispanic men (Raffaelli and Iturbide 2009) and indicate that Hispanic males who adhere to traditional sex roles are more likely to endorse or participate in coercive sexual practices, therefore increasing the risk for unprotected sexual contact (Rafaelli and Iturbide 2009). Hence, some findings suggest that higher levels of acculturation lead to more risk behaviors, while others suggest that higher levels of acculturation are associated with less risk behaviors. These mixed findings are also present among youth. The differences in research findings mentioned above are likely related to how acculturation is measured and conceptualized (Schwartz et al. 2010) and to the specific behaviors being measured (Raffaelli and Iturbide 2009). For example, acculturation is usually measured through the use of proxy measures such as language use and amount of time in the

USA instead of directly assessing cultural values (Schwartz et al. 2010). Changes in cultural values resulting from the acculturation process also impact the family system.

Family changes, such as the ones brought on by the effects of acculturation between parents and youth, greatly affect the family system. Acculturation, the process of adapting to a new culture, can have an impact on family processes due to the conflict created by differing cultural values between youth and parent (Prado et al. 2012). As youth become more acculturated than their parents, parents begin to lose parental authority due to a reliance on youth for information, linguistic interpretation, and cultural navigation (Unger et al. 2009). The loss of parental authority can lead to family conflict and inconsistent parental discipline and monitoring, which can result in increased risk for problem behaviors (Unger et al. 2009), including risky sexual behaviors. Parents may become stricter as they attempt to control their youth's behavior, resulting in increased negative behaviors and eventual parental disinvestment (Pantin et al. 2003). Further, parents may continue to hold on to their culture of origin while youth become more Americanized, causing discrepancies in values and beliefs between parent and youth. These discrepancies can lead to family conflict and behavioral difficulties.

Discrimination (Discrimination)

While great strides have been made regarding discrimination and racism in the USA, they continue to be pervasive social problems, particularly in regard to HIV/AIDS and MSMs. Discrimination refers to behaviors from others that cause feelings of being unwanted, stereotyped, or demeaned (Todorova et al. 2010). Discrimination has been shown to have chronic negative health consequences for Hispanics including HIV. There is a growing body of research suggesting that a discriminatory environment is related to lower ratings of self-efficacy and decreased attempts at negotiating safe sex practices or engaging in preventive behaviors such as routine HIV testing (Adimora and Schoenbach 2005). Further, discrimination based on homosexuality has been

found to be related with a higher prevalence of risky anal intercourse (Jarama et al. 2005). Among Hispanics, Latin-American cultures tend to have strong anti-gay views which may prevent gay men from securing information about HIV or be tested for HIV. Further, expectations about male sexuality take place among a backdrop of stigma and discrimination against homosexuality which can decrease exposure to preventive interventions and denial of HIV vulnerability (Jarama et al. 2005)(stigma and stigmatization). Researchers have cited that minorities, including Hispanics, view homosexuality as harmful to core family values and to the continuation of their culture (e.g., Saddul 1996). Indeed, research with lesbian, gay, bisexual, and transgender adolescents indicates that discrimination contributes to HIV disease risk by lowering self-efficacy and reducing the benefits of social and cultural contexts such as peer connectedness and family relationships (Markham et al. 2010). While discrimination and its role in HIV infection is important to examine, researchers suggest investigations that also incorporate explanations for how structural racism affects immigrant health (Viruell-Fuentes et al. 2012). Structural racism such as those present in immigration policy has underlying ideologies which give rise to day-to-day discrimination. Immigration policies have well-documented effects in restricting access to health and social services and have a direct impact on the causes of disease by influencing access (or lack of) to life opportunities such as higher education and well-compensated employment opportunities (Viruell-Fuentes et al. 2012).

Preventive Interventions

Although there is a high need for prevention, few programs are available that target the needs of Hispanic youth and Hispanic MSMs and that incorporate the role of culture into prevention (Unger et al. 2009). The need for interventions is clear, and in order for these interventions to be effective and acceptable to Hispanics, cultural factors should be considered (Prado et al. 2006). Research suggests that culturally specific interventions demonstrate better outcomes than generic interventions. For example, a meta-

analysis across 76 studies found that culturally adapted interventions delivered to specific cultural groups were moderately strong and four times more effective than interventions delivered to clients of diverse backgrounds (Griner and Smith 2006).

Some interventions have been designed for Hispanic youth, including *Familias Unidas* (united families) (family interventions) and *Cuidate!* (take care of yourself!). *Familias Unidas* consists of parent group sessions and participatory dialogue to empower parents in helping adolescents engage in positive behaviors. It addresses the needs of Hispanic families by incorporating cultural components in the prevention of behavior health problems (Pantin et al. 2003). The *Cuidate!* program is a group intervention designed to prevent sexually risky behaviors. *Cuidate!* takes into account the cultural values inherent in Hispanic populations to build HIV knowledge, increase condom use self-efficacy and negotiation of safe sex practices, and identify attitudes and beliefs (NCLR 2011).

Similarly, several macro-level interventions have been developed for youth, but none specifically for Hispanic youth in general. For example, The ACCESS program utilized social marketing to promote HIV testing among adolescents, including Hispanics, in five urban cities across the USA. Findings showed increased HIV testing among youth and an increase in number of phone calls to information hotlines (Futterman et al. 2001). Finally, in 2009 the CDC launched a media campaign, *Act Against AIDS*, to promote HIV and AIDS awareness in the USA. The campaign has a focus on highly impacted groups such as African-Americans, Hispanics, and MSMs (CDC 2009).

Interventions with Hispanic MSM

Though not originally studied with Hispanic MSMs, the following interventions are currently being used to address HIV/AIDS risk among Hispanic MSMs living in the USA: Many Men, Many Voices (3MV), Popular Opinion Leader (POL), and Mpowerment/Mpoderoso (CDC 2011b). The efficacy studies of 3MV, a group-level intervention that addresses social and behavioral

determinants of HIV/STI risk and protective behaviors, were originally conducted exclusively with Black MSMs of varying ethnic backgrounds. POL is a community-level intervention designed to mobilize and empower opinion leaders to promote safer sexual norms within their social networks. It was originally studied for use with white MSM (mean age 29 years old) with low-education attainment and has also been evaluated for use with Black MSM (Kelly et al. 1997; CDC 2011b). Mpowerment/Mpoderoso was adapted for delivery to monolingual Hispanic MSM in at least one setting, among Hispanic migrant worker communities (CDC 2011). To summarize, while there is a need intervention, most interventions have been developed for non-Hispanic populations and later adapted for this population.

Conclusion

HIV continues to be a significant problem with wide health disparities among minority populations, including Hispanics and Hispanic MSMs. Despite great advances in the etiology of HIV/IDS, there are areas of opportunity in HIV prevention:

1. Few interventions have been evaluated for Hispanic subgroups who are most at risk, including Hispanic youth and Hispanic MSMs. Even fewer interventions developed specifically for Hispanics. Cultural factors that impact the acceptability of these interventions including family, gender norms, and discrimination need to be considered in prevention development.
2. Most interventions that have been evaluated for the Hispanic population are small group/behavioral interventions. A focus on targeting macro-level factors in this population, particularly those factors specific to Hispanics, is necessary.

Progress has been made in the HIV epidemic, and although we have seen some gains among Hispanics, there is more to be done. Perhaps it is time that researchers, public health professionals,

and policy makers look in a new direction, one that meets the specific needs of Hispanics and Hispanic MSMs.

HIV Prevention and Labor Migration

Sana Loue

Department of Bioethics, School of Medicine,
Case Western Reserve University, Cleveland, OH,
USA

Definition

Migration refers to the movement of people from one place to another, temporarily or permanently, across borders or from one location to another within a defined territory. Individuals engage in labor migration voluntarily in search of better economic opportunities, or they may become victims of organized trafficking rings. Research has found that labor migrants are frequently at elevated risk of HIV due to individual and structural-environmental factors. Although a number of individual-level intervention strategies for HIV prevention among labor migrants have been evaluated, relatively few prevention interventions have attempted to address the structural-environmental factors that may predispose labor migrants to increased HIV risk.

Labor Migration and HIV Risk

Migration refers to the movement of people from one place to another, temporarily or permanently, across borders or from one location to another within a defined territory. Frequently, migration is driven by social, economic, and political factors; traumatic events such as hurricanes and tsunamis may also cause people to leave their homes in search of another. In some cases, entire families or communities may migrate in search of labor opportunities or as the result of man-made or natural disasters. In the latter case, migration may necessitate a search for labor opportunities even though that may not have been the motivation that prompted the migration. Individuals engaged in labor migration may do so voluntarily or involuntarily; in some instances, individuals

may migrate voluntarily in response to what appears to be a legitimate employment offer, only to find later that they have become, essentially, slaves (labor trafficking). Migration can increase an individual's HIV risk as the result of alterations in his or her risk or prevention behaviors and/or exposure to a differential HIV prevalence between the places of origin and destination.

Researchers have investigated the relationship between HIV risk and voluntary labor migration in numerous contexts. These include the temporary migration of agricultural workers from Mexico to the United States, of construction and bazaar workers from Tajikistan to (Moscow et al. 2008), of construction workers from one province of China to another (Zhuang et al. 2012), of factory workers in Zimbabwe and in Mexico (Magis-Rodriguez et al. 2009), of mine workers in South Africa (Crush et al. 2005), and of labor migrants from one region of Papua New Guinea to another or from one district in India to another (Wardlow 2007). Studies have consistently reported relatively high rates of HIV risk due to unprotected sex with multiple partners, unprotected sex with partners who inject drugs and of unknown HIV serostatus, and relatively low levels of HIV knowledge.

Numerous underlying factors have been implicated in this elevated risk (Soskolne and Shtarkshall 2002). Premigration factors include the prospect of adequately paying employment at the place of origin and the individual's marital or partner status, age, educational level, and attitude toward risk-taking. Emotional and physical trauma during the course of migration or after arrival at the destination may also impact individuals' sexual and substance-using behavior, leading to increased HIV risk. Post-migration factors that have been found to be associated with increased HIV risk among labor migrants include physical and linguistic isolation; loss of social support; limited social capital; anxiety due to migrants' absence from their homes for extended periods of time; poor access to health-related services, including HIV counseling and testing; increased exposure to high risk behaviors due to close living quarters with individuals participating in high risk behaviors; exposure to sexual norms

that are more permissive than those in their home localities; comorbidities such as sexually transmitted infections; and increased financial assets that facilitate the purchase of alcohol, drugs, and/or sexual services. Individuals may also be unwilling to seek out health-related services due to the loss of income associated with time away from their place of employment and/or the threat of loss of employment for failure to appear at a job site. The social and familial controls that may have moderated migrants' risk behaviors at their place of origin may no longer have any effect at their destination, and the migrants' anonymity at their destination may further encourage them to abandon their previous sexual norms.

Gender, Labor Migration, and HIV Risk

Research suggests that the factors that heighten labor migrants' HIV risk may differ between males and females. Among male migrant laborers, loneliness, isolation, increased financial assets, and ready access to sex workers, alcohol, and drugs may lead to a greater likelihood of participation in sexual relations with sex workers or the initiation of short- or longer-term relationships with male and/or female sexual partners (Organista 2007). A lack of transportation, stigma associated with HIV/AIDS, a fear of being discovered and deported, and ineligibility for health services may impede any efforts to obtain HIV testing and treatment. Significantly, researchers have reported that migrants who have resided for longer periods of time at the labor destination are less likely to use sex workers, experience less social isolation, and have increased opportunities to engage in social relations with women other than sex workers, potentially helping to decrease their HIV risk (Saggurti et al. 2009).

The sexual partners, including wives, of male labor migrants may also be at elevated risk of HIV. To some extent, this increase is attributable to the sexual- and drug-associated risk behaviors of their returning male partners and their own lack of HIV-related knowledge and/or inability to negotiate condom use upon his return home.

However, women who are left at home and have limited financial resources to support their families may engage in transactional sex or multiple partnerships to earn additional income.

In contrast to male labor migrants who often migrate in search of better economic opportunities due to the relatively poor employment prospects at their place of origin, the initial motivation for female migrants to search for new opportunities may be the breakdown of a significant relationship (Kendall and Pelcastre 2010). Female labor migrants may be at particularly high risk of HIV infection for several reasons. First, while away from home, female labor migrants may engage in sexual relations with multiple partners as a means of surviving economically. In some cases, they may receive monetary compensation, but in others they may exchange sex for food, safer housing, or other necessities. Second, female labor migrants may become victims of organized prostitution rings and/or physical violence, including rape. Third, women who find employment in entertainment establishments or personal services, such as bars, massage parlors, barber shops, and dancing halls, may be pressured by the establishment owners and/or clients to provide sexual services or face the possibility of losing their employment. Finally, female labor migrants who are engaged in sex work may need to migrate from one country to another in order to reduce the likelihood of being discovered by police and to maintain access to a larger client base in order to meet living expenses. The women's risk of contracting HIV and of transmitting the virus to others is heightened due to movement between higher and lower HIV prevalence areas and the large number of sexual partners (Surratt 2007). Like male labor migrants, female labor migrants may experience reduced access to HIV prevention information, testing, and care due to illegal immigration status (O'Conner 2009).

Prevention Strategies

Despite the large and growing literature indicating an elevated level of HIV risk among labor

migrants, relatively little research has evaluated possible prevention strategies for this population. Significant challenges are associated with the evaluation of HIV prevention strategies for this population, many of which are associated with the population's high level of mobility and their deportation in the case of illegal migration. These challenges include the establishment of trust, the development of a rigorous tracking system, the identification of qualified interviewers, the scheduling of interviews to accommodate the participants' work schedules, and staff safety concerns (de la Rosa et al. 2011).

Intervention studies with migrant laborers have focused on the enhancement of HIV knowledge and promotion of condom use among migrants, the promotion of condom use among female sex workers who were engaged by migrant farmworkers, the identification of problems and potential solutions by migrant farmworkers, and the training of rural health and educational professionals on HIV/AIDS prevention (Magis-Rodriguez et al. 2004). A three-pronged strategy of "Abstinence, Be Faithful, Use a Condom" (ABC) has been advocated as a means of reducing HIV risk among labor migrants. However, reliance on this approach may not be adequate due to fluctuations in the local supply and cost of condoms, economic pressures that reduce women's ability to negotiate male condom use, and the risk of physical violence that may accompany an attempt to negotiate safer sex (Dworkin and Ehrhardt 2007; Kiš 2010).

Intervention studies focusing on migrant laborers have not, in general, attended to the structural or environmental factors that appear to play a role in the increase in risk. In part, this omission may be due to the need to fashion interventions that are context-specific. Nevertheless, intervention strategies that fail to focus on both individual and structural factors may have limited success in reducing HIV risk among labor migrants. Although a number of multilevel and structural approaches have been suggested to reduce HIV risk among labor migrants and individuals to whom they may transmit the infection, such as wives, husbands, and temporary sexual partners, it appears that, to date, none of these

have been subjected to rigorous evaluation. These include:

- Syndromic treatment of sexually transmitted infections in origin and destination areas
- Increased availability of condoms at the sites where labor migrants congregate and live
- Integration of HIV testing, counseling, and treatment services into general health-related services for migrants
- Provision of HIV-related services, such as education, testing, counseling, and treatment, at nontraditional locations such as churches and shopping malls
- Development of mobile system of providing health-related services to migrants
- Increased economic opportunities for women
- Improved housing conditions for migrant laborers
- Integration of migrants' social support networks into HIV prevention services
- Initiatives to reduce the social isolation of migrant laborers
- Provisions for family members to accompany and be housed with migrant laborer
- Coordinated HIV prevention programs between the sending and receiving countries, including HIV testing and treatment
- Family based interventions
- Implementation of interventions through popular opinion leaders

Conclusion

Migrant laborers appear to be at elevated risk of HIV infection due to various individual-level and structural-level factors that may exist before, during, or subsequent to the actual process of migration. Female labor migrants may be at particularly high risk of HIV infection.

Despite the growing literature indicating an increased risk of HIV, relatively little empirical research has been conducted to identify effective HIV prevention programs. Intervention strategies for this population may be most effective if they focus on both individual and structural factors.

Definition

HIV prevention among women involves understanding social risk factors (e.g., relationship power, gender-based violence), cultural risk factors (e.g., gender norms and expectations), and biological risk factors (e.g., anatomy) that are unique to women. It is paramount to also consider contextual issues, such as the social and structural determinants that vary within and across populations and settings and can either support or impede HIV prevention strategies. Biomedical, behavioral, and structural interventions have been developed and implemented to prevent acquisition of HIV infection among women.

Disproportionate Burden of HIV Among Women

An estimated 16 million women aged 15 or older are living with HIV around the world (Joint United

Nations Programme on HIV/AIDS 2014). Globally, women represent approximately half of the global adult population living with HIV. While HIV remains a global epidemic, approximately 80% of the cases among women occur in sub-Saharan Africa, where young women between the ages of 15 and 24 have twice the prevalence (a count or percentage of the number of people with the disease in a given population at a specific point in time) of HIV as young men in this same age group, and they acquire HIV infection 5–7 years earlier than their male counterparts (Joint United Nations Programme on HIV/AIDS 2014). Further, women of childbearing age are disproportionately affected, and heterosexual sex is the primary mode of HIV transmission in this region. In other regions, such as Eastern Europe and Central Asia, injection drug use is a common mode of HIV transmission disproportionately affecting women, and women who inject drugs have higher HIV prevalence compared with their male counterparts (Burns 2009; Pinkham et al. 2012). Because of various social, biological, and cultural factors, women living in low- and middle-income countries, in particular, often have additional contextual issues related to their HIV risk (Joint United Nations Programme on HIV/AIDS 2014). Consequently, it is essential that HIV prevention strategies address individual and interacting environmental factors.

Contextualizing HIV Prevention for Women

HIV infection among women and associated risk behaviors do not occur in a vacuum. HIV risk involves a complex intersection of multiple biological, social, and cultural determinants (El-Bassel et al. 2012; Wechsberg et al. 2015).

Women are biologically more susceptible to HIV infection through heterosexual sex (World Health Organization 2009b), and this vulnerability is compounded by social and cultural factors, particularly for women most at risk for infection. In many societies, gender norms perpetuate stigma and discrimination against women who may engage in risk behaviors such as transactional

sex (the exchange of sex for money or goods) or alcohol and other injection or noninjection drug use (Pinkham et al. 2012). Women at highest risk of HIV infection commonly face gender inequality and experience the resulting disempowerment that often places them in vulnerable circumstances without agency to negotiate safer sex practices and to protect their well-being (Wechsberg et al. 2015). Gendered stigmatization, inequality, and disempowerment can also restrict women from accessing necessary HIV prevention services, which is often compounded for key populations by restrictive legal environments penalizing or criminalizing high-risk behaviors such as injection drug use and sex work (Pinkham et al. 2012).

While these issues are important for HIV prevention, it is also imperative to consider how men are vulnerable as a result of gender norms and other factors, particularly in places where the HIV epidemic is generalized (Higgins et al. 2010). Consequently, effective HIV risk-reduction interventions need to address these multilevel social, cultural, and biological factors.

How HIV Prevention Can Address Women's Vulnerabilities

Biomedical Prevention

Studies have shown that women are biologically more susceptible to HIV infection through heterosexual transmission compared with their male counterparts (World Health Organization 2009b). Factors such as the relatively large surface area of the vagina exposed to semen, high viral load (the amount of HIV) in the semen, and susceptibility of tissue tear during dry vaginal or anal sex contribute to a heightened risk of infection (Canadian AIDS Society). Consequently, biomedical advances in HIV prevention must address the anatomical and biological susceptibility of women to HIV and provide women-controlled methods of protection.

Oral Preexposure Prophylaxis (PrEP)

Preexposure prophylaxis (or PrEP) is when people at very high risk for HIV take HIV medicines daily to lower their chances of acquiring HIV.

Truvada [tenofovir disoproxil fumarate (TDF)/emtricitabine (FTC)] is a combination antiretroviral (ARV) medication for PrEP that was approved for use in adults at high risk for HIV by the US Food and Drug Administration (FDA) in 2012 (Centers for Disease Control and Prevention 2012). Individuals at high risk for HIV, such as women who are HIV negative whose partners are HIV positive, can take PrEP daily to reduce the chances of acquiring HIV infection. Currently, the United States is the only country that has approved TDF/FTC as oral PrEP.

The US Centers for Disease Control and Prevention (CDC) released guidelines for the use of PrEP to prevent HIV infection and recommended it to individuals at high risk of acquiring HIV infection, including women whose partners are HIV positive, women who have had recent bacterial sexually transmitted infections (STIs), and women who engage in high-risk behaviors such as having multiple sex partners and inconsistent condom use (Centers for Disease Control and Prevention 2014). Twenty-two other countries, including the United Kingdom, South Africa, Brazil, and India, are exploring the provision of PrEP through pilot projects (AVAC). Although the United States is the only country to approve the use of PrEP, the World Health Organization (WHO) recommended the use of PrEP for people with substantial risk of HIV infection (World Health Organization 2015). As an intervention that can be woman-initiated and woman-controlled, PrEP can empower women to take control of their sexual health (Kofman and Adashi 2014).

Treatment as Prevention (TasP)

Recently, research has shown that when individuals living with HIV are initiated on antiretroviral therapy (ART) early on and they are adherent to treatment, they are significantly less likely to transmit HIV. This approach, known as treatment as prevention (TasP), has been shown to prevent HIV transmission by up to 96% in the HPTN 052 (Cohen et al. 2011). TasP has essentially bridged the divide between treatment and prevention by demonstrating that treatment “is” prevention. Consequently, promotion of early initiated and sustained ART for people living with HIV, particularly for men when

prevention among women is concerned, has significant potential to curb the number of new HIV infections among women and men.

Additionally, TasP strengthens the earlier termed “test and treat” strategy, which was based initially on the idea of treating people for HIV and then subsequently linking those who test positive to appropriate medical treatment while also engaging them in other interventions to reduce their risk behavior (Kurth et al. 2011). The science now demonstrates that testing and linking persons who are HIV positive to treatment not only reduces risk behavior but also suppresses their virus level, thereby reducing the risk of transmission.

Microbicides

Microbicides are chemical compounds that can be applied inside the vagina or rectum prior to sexual intercourse to protect against STIs, including HIV. Microbicides are most commonly produced in a gel form but can also be creams, films, suppositories, or vaginal rings (Microbicide Trials Network 2012; World Health Organization n.d.). Although microbicides have shown promise in preventing HIV transmission, testing is ongoing and microbicides are not currently on the market for HIV prevention.

Research is currently focused on ARV-based microbicides, specifically tenofovir gel. The initial groundbreaking study, CAPRISA-004, was conducted in South Africa and demonstrated a 39% reduction in new HIV infections when the tenofovir gel was applied vaginally prior to sex (2015; Kofman and Adashi 2014; Mastro et al. 2014). Subsequent studies using tenofovir gel microbicides have not demonstrated the same level of efficacy, although this could be due to inconsistency in use or other factors. Currently, there is an ongoing study, CAPRISA-008, which is reexamining the efficacy of vaginal tenofovir gel (Kofman and Adashi 2014; Mastro et al. 2014).

Behavioral Prevention

The Importance of Male and Female Condoms in Combination with Behavioral Prevention

The promotion of barrier methods, such as the male latex condom and female condom, has been an integral part of behavioral interventions

for women (Centers for Disease Control and Prevention 2015a). A common issue raised about the male condom is that if a woman has a male partner and is trying to get him to use a male condom, it involves negotiation of condom use with the partner, whereas the female condom is a woman-controlled HIV prevention strategy.

The female condom can be inserted vaginally hours before sex, and in certain cases it can be used without the knowledge of a sex partner. The original female condom (FC1), manufactured by the Female Health Company, was introduced in the mid-1990s, but failed to gain the same popularity as the male condom because of issues of high cost and limited acceptability (World Health Organization, Department of Reproductive Health and Research 2007a). A less expensive, second-generation female condom (FC2) was introduced by the Female Health Company in 2005, and it was approved by the US FDA in 2009. Other companies also have developed new designs for the female condom to address issues of cost and acceptability (World Health Organization, Department of Reproductive Health and Research 2007b). To assist with cost and accessibility issues, some health departments provide female condoms free of charge.

HIV prevention behavioral interventions have been developed for women around the world. Rigorous review and evaluation of US-based behavioral interventions have categorized some interventions as “best” or “good” evidence interventions (Centers for Disease Control and Prevention 2015b). Such evidence-based interventions (EBIs) have been efficacious in reducing the incidence (the number of new cases in a given period of time, such as a year) of STIs and/or reducing HIV risk behaviors among women, such as unprotected sex, number of sex partners, and injection drug use (Lyles et al. 2007).

Typically, these behavioral interventions are grounded in a health behavior theory or framework, occur over multiple sessions, and give women the knowledge and skills to take control of their sexual health by reducing risk behavior. While EBIs for women vary in program content and how they are administered, they often use multiple methods and activities for intervention delivery. Common methods and activities include

discussions, role-play, practice, goal setting, and lecture. These components allow for program participants to apply the information to their own lives by building essential skills and strategies for HIV prevention, such as male and female condom use skills and negotiation. Some interventions, known as peer-based interventions, are delivered in group settings and encourage a peer support system. Other interventions use individual sessions to focus on personalized risk-reduction methods.

Behavioral interventions that have reduced HIV-related risk behavior among women are tailored to the cultural and social context of the women being served and take into account the intersection of various HIV risk behaviors, such as alcohol or other drug use, intimate partner violence, age-disparate relationships, inconsistent and incorrect condom use, and concurrent sexual partnerships. Many interventions work to eliminate gender-based inequalities that render women vulnerable to HIV infection. Such interventions may assist women in finding employment, give them skills to maintain healthy relationships, or work to improve their economic status (Centers for Disease Control and Prevention 2015a). Some of these EBIs have been packaged for further testing, dissemination, and sustainability or have been adapted to other key populations of women in the United States and other countries (Saleh-Onoya et al. 2009; Wechsberg et al. 2010).

In addition to the EBIs for women that are administered individually or in single-gender groups (i.e., only with women), some EBIs include women’s sex partners so that HIV prevention can be addressed among couples. Such interventions provide a unique opportunity to address not only sex risk behaviors but also other factors related to HIV risk such as alcohol and other drug use, intimate partner violence, concurrent partnerships, and gender roles (El-Bassel et al. 2012). These interventions are geared toward changing social and cultural norms within a partnership and fostering an equal balance of sexual responsibility in couples. Interventions involving men are also helpful in changing gender norms related to masculinity, fatherhood, and sexual responsibility in a way that is conducive to female empowerment (World Health Organization 2009b).

One general criticism of some behavioral interventions is that outcomes have shown reductions in only proxies for HIV infection, such as acquisition of STIs and/or sex risk behaviors, but not reductions in the incidence of HIV infection. However, when studies measure HIV incidence, it can be difficult to observe significant changes, particularly in areas with low HIV prevalence.

Structural Prevention

Human behaviors, including those that put individuals at risk for acquiring HIV infection, are embedded in a larger context encompassing social, cultural, economic, legal, and political environments (Hardee et al. 2014; Parkhurst 2013). Consequently, structural HIV prevention interventions address these realms in an effort to create enabling environments so that individuals are able to fully benefit from other biological or behavioral HIV prevention efforts. Structural methods of HIV prevention are essential because they provide the basis for long-term change in society.

When considering HIV prevention among women, it is important to address the unique challenges faced globally by many women who are at risk for acquiring HIV infection. Globally, gender inequality and related gender norms, violence against women, and legal norms unfavorable to women have been identified as significantly contributing to the risk of women acquiring HIV infection (Hardee et al. 2014). Increased educational opportunities, decreased violence against women, increased employment and income-generation activities, and the promotion of gender equality have demonstrated a positive impact on decreasing HIV risk (Edwards and Collins 2014; Fieno and Leclerc-Madlala 2014; Hardee et al. 2014).

Many times, cultural expectations prescribe gender roles that encourage male superiority and female subservience. Such gender-based discrimination prevents women from being afforded the same rights as men and can increase their vulnerability to acquiring HIV infection (Hardee et al. 2014). Women in societies with greater gender inequality are more likely to be subject to gender-based violence. This can make it difficult to negotiate safer sex. Also, violence or fear of violence can be an impediment to HIV testing

(Hardee et al. 2014). Inequality in educational attainment and income-generation activities in particular are attributed to higher HIV risk among women. Economic dependence on men can motivate women to engage in alternative risky income-generation activities such as transactional sex or intergenerational sex.

Many countries have laws that criminalize high-risk behaviors such as prostitution or injection drug use. However, such restrictive laws make it difficult for women who are most in need of HIV prevention services to access these services (Hardee et al. 2014; Pinkham et al. 2012). Other laws and policies that limit women's subordinate role can also have a negative impact on prevention efforts. For example, bride and inheritance rules (including those that prohibit women from filing for divorce), laws denying women the right to own property, and policies restricting women from equal access to services (such as opening a bank account) disempower women and can make it difficult to take control of their own health and well-being or to negotiate safer situations (Edwards and Collins 2014; Hardee et al. 2014).

Structural prevention interventions address the abovementioned issues through both broad macro-level and individualized microlevel factors that perpetuate HIV risk among women (Parkhurst 2013). Structural prevention efforts focused on macro-level factors work to tackle national level policies and laws as well as economic and other structures that at the national or subnational level prevent full uptake of HIV prevention efforts (Parkhurst 2013). International institutions such as WHO, World Bank, US Government's Global Health Initiative, and UNAIDS have dedicated much time and effort to HIV issues. Recently, these institutions have dedicated specific support to gender-based or woman-focused HIV prevention. Generally, they view barriers to HIV prevention for women through human rights lens and work to promote gender equality, to decrease gender-based violence, and to increase women's access to medical, social, and legal services (Women Won't Wait Campaign 2010).

For example, WHO has developed a tool to assist the health sector in integrating gender into HIV/AIDS programs. UNAIDS has drafted an

“Agenda for Accelerated Country Action for Women, Girls, and Gender Equality for HIV” that works to empower women at the national level. The US Government’s Global Health Initiative has invested in interventions that respond to gender-based violence. Additionally, the World Bank has supported initiatives to increase women’s employment opportunities and decrease poverty (Women Won’t Wait Campaign 2010; World Health Organization 2009a).

Despite these efforts, specific macro-level structural barriers to HIV prevention for women remain and need to be addressed. Consequently, countries are now including women in their national HIV strategies. For instance, of 170 countries reporting in 2012, 81% included women in their HIV strategies. However, only 41% of these 170 countries budgeted specifically for woman-focused HIV programs (UNAIDS 2012).

Structural prevention addressing microlevel factors affecting women, such as limited education or economic dependence, also has potential for influencing reductions in HIV risk behaviors and incidence (Fieno and Leclerc-Madlala 2014; Parkhurst 2013). Two prevalent types of structural prevention interventions addressing microlevel factors are microcredit financing programs and conditional or unconditional cash transfer programs. Microfinancing interventions that provide loans for women to establish businesses have demonstrated potential to economically empower women, making them less likely to engage in risky alternatives to generate income (Edwards and Collins 2014; Hardee et al. 2014).

Several countries have implemented pilot conditional and unconditional cash transfer interventions in efforts to reduce HIV vulnerability, particularly among girls and young women (Fieno and Leclerc-Madlala 2014). Unconditional cash transfer interventions are aimed at decreasing financial burden and improving women’s economic independence, thereby mitigating structural barriers to care and treatment, such as food insecurity or inability to attain education. Pilot interventions have demonstrated the potential of unconditional cash transfers in reducing sex risk behaviors that are perpetuated by economic dependence, such as transactional and

intergenerational sex (Fieno and Leclerc-Madlala 2014). Conditional cash transfers are financial incentives provided to young women and their families for fulfilling certain behaviors, such as young women staying in school (Doetinchem et al. 2008). For example, by providing incentives for school attendance, these interventions aim to increase educational attainment, thereby empowering women to make positive decisions about their health and life, such as decreasing the likelihood of early marriage, sexual activity, and pregnancy (Baird et al. 2010).

Although there have been some successes, issues of scalability for broad impact and cost for value – for example, are there other interventions that involve the same cost but have greater impact – need to be assessed further.

Conclusion

Research on women’s increased social, cultural, and biological susceptibility to HIV has identified gender-based violence, limited social mobility, economic inequality, intersecting risk behaviors such as alcohol or other drug abuse, and limited education as contributors to HIV risk. Despite the fact that strong research findings have moved HIV prevention for women onto the agendas of some nongovernmental organizations, health departments, national governments, and international health organizations, greater action is needed to incorporate a gender focus into all HIV risk-reduction policy and practice to effectively reduce HIV infection in women globally.

To capitalize on the strengths of biomedical, behavioral, and structural HIV prevention efforts, recent interventions are integrating these approaches in what is termed “combination HIV prevention” (Parkhurst 2013). In order for HIV prevention efforts to have lasting impact, it is crucial that they are multipronged and address the individual, social, and structural barriers to HIV prevention. Additionally, such efforts should take into account women across the HIV care continuum – from early prevention with key populations to treatment for women living with HIV. Taking the biomedical, behavioral, and

structural aspects into consideration can help to facilitate effective HIV prevention among vulnerable women.

HIV Prevention Efforts Within Substance Use Disorder Treatment Settings

Definition

Substance use disorders treatment agencies serve individuals known to be at high risk for engaging

in HIV risk behaviors. To target this group, these facilities are ideal settings in which to administer HIV prevention interventions.

Substance use disorder (SUD) treatment facilities represent a promising venue in which to implement behavioral HIV prevention interventions. Gathered within these clinics is an appropriate target audience for HIV prevention given that individuals struggling with substance use disorders often engage in risky drug use and sexual behaviors. Their status as treatment clients theoretically implies that they are working on substance use issues (Substance Use) and ideally making substantial life changes. Reflection on current behaviors can be an important part of recovery and therefore an appropriate time to introduce HIV prevention interventions. The following discussion will further flesh out the reasons why substance use disorder treatment agencies are an ideal setting for HIV prevention, review existing evidence-based HIV prevention interventions targeting substance use disorder treatment clients, and discuss the HIV prevention services typically offered in such settings.

Treatment Settings as a Platform for HIV Prevention Interventions

Substance use disorder treatment facilities by their nature capture a particular group of individuals at higher risk for engaging in behaviors that put them at increased risk for HIV. Out-of-treatment injection drug users (IDUs) have been shown to engage in high levels of risky drug use behavior (e.g., using contaminated injection paraphernalia; Strathdee et al. 2001) (► [Harm Reduction for Injection Drug Users](#)). Individuals struggling with addiction have been shown to engage in risky sexual behavior (Raj et al. 2007). In particular, the stimulant users in this sample had substantial rates of reporting multiple partners in the past 6 months, inconsistent or no condom use; this group also reported high rates of exchanging sex for drugs or money. While trading sex for drugs or money may not be inherently risky, coupling this behavior with other sexual risk factors raises the risk profile (Sex Work and Sex Workers). Once

Donald A. Calsyn: deceased.

admitted to treatment, risk behavior may subside for a proportion of clients (Drug Treatment as HIV Prevention). That said, the most compelling changes made in the context of treatment are typically in substance use behavior and injection practices, whereas sexual risk behavior may or may not decrease as a result of drug treatment (Sorensen and Copeland 2000). In a focus group of SUD counselors, continuation of risky sexual behavior in the context of recovery was understood as an impediment to successful recovery; the perspective of these counselors was treatment seekers are at high risk for engaging in sexual risk behavior and that these behaviors are most assuredly a relevant treatment issue. Research studies show that treatment-seeking samples exhibit widespread sexual risk behavior in men (Calsyn et al. 2010) and women (► [HIV Prevention and Women](#)) (Engstrom et al. 2011; Tross et al. 2008). These studies, all of which use SUD treatment-seeking samples, take place in an array of settings (i.e., opioid treatment programs, outpatient, and residential) and demonstrate the need for HIV prevention efforts across a variety of treatment modalities.

SUD treatment facilities may be a place where people seek help specifically for alcohol and drug issues; however, the format is such that clients can easily be provided with or exposed to HIV prevention material. Clients typically meet regularly with counselors, who are in an ideal position to provide HIV prevention intervention, since they can do so in an ongoing way and there is already a clinical relationship established between counselor and client. Counselors may be in an ideal position to understand a client's current HIV risk behaviors and help their clients contemplate and facilitate change in HIV risk behaviors in the context of the client's history and current circumstances and ongoing patterns (Brown 2000).

SUD treatment seekers not only represent a captive audience to which HIV prevention interventions can be targeted, they are also active participants in the treatment process, many of whom are already reflecting on problematic behaviors in multiple domains of their lives. Engaging people as they enter treatment may be the ideal time to motivate individuals to adopt

safer sex practices. As SUD treatment clients begin recovery, they may begin to consider changing aspects of their lives that put their recovery at risk, including unsafe sexual behavior. Evidence indicates that HIV sexual risk behavior is something women in particular may want to change (Brown et al. 2005). Specifically, researchers found that readiness to change sexual risk behavior was significantly related to initial readiness to seek help for substance use problems among women in a community-based outreach program focused on preparing women for entry into substance use disorder treatment. Findings suggest that a woman's readiness to seek treatment may provide an opportunity to capitalize on readiness to change sexual risk behavior as well. It should be noted that the same conclusions cannot be made about men since the above mentioned study was conducted with women. Nonetheless, both treatment-involved men and women appear to be open to HIV prevention interventions based on changes in sexual risk behavior exemplified within these settings (Metzger and Navaline 2003a, b). Given that treatment settings capture an at-risk population that may exemplify readiness to change HIV risk behaviors, it makes sense to leverage existing SUD treatment agencies to increase the reach of HIV prevention interventions.

Evidence-Based HIV Prevention Interventions Targeting SUD Treatment Clients

Embedding HIV risk prevention interventions within existing SUD treatment programs has garnered attention by researchers and clinicians leading to development of a growing and robust evidence base. Three meta-analyses examining behavioral HIV prevention interventions among drug users have indicated that such interventions are effective at reducing injection and drug use behaviors, and to a lesser extent sexual risk behaviors (Prendergast et al. 2001; Semaan et al. 2002; Copenhaver et al. 2006). The interventions cited are often based on one of several behavioral change theories applied to HIV prevention interventions (Behavior Change). Prendergast

et al. (2001) included 18 studies of HIV prevention interventions conducted within SUD treatment settings; they found such interventions are effective in overall risk reduction and for sexual behavior risk reduction. Intervention effectiveness was associated with intervention intensity, number of therapeutic techniques utilized, and, to a lesser extent, total number of hours. Sexual risk behavior reduction was associated with having separate sessions for men and women, including coping skills training and peer group discussions. The Semaan et al. (2002) meta-analysis focused on effectiveness of HIV preventions targeting drug users at reducing sexual risk behavior (decrease in number of unprotected sexual events or increase in condom use). They included 33 studies with most targeting injection drug users (94%) or crack users (21%). Only 15% of the studies reported conducting the intervention within a SUD treatment setting. These researchers also determined that interventions can lead to reductions in sexual risk behavior among drug users. The meta-analysis conducted by Copenhaver et al. (2006) included 37 randomized controlled trials examining 49 interventions and focused on injection drug users. Participants were recruited from SUD treatment settings in 53% of the studies. Most interventions included the following components: HIV/AIDS education (90% of interventions), condom use skills (69%), self-management skills (e.g., coping with drug cravings; 57%), and both drug-related and sex-related risk reduction (70%). They found that compared to controls, intervention participants reduced injection drug use (IDU) and non-IDU, increased drug treatment entry, increased condom use, and decreased trading sex for drugs. Interventions were more successful at reducing IDU when participants were non-Caucasians, when content focused equivalently on drug-related and sex-related risks, and when content included interpersonal skills training specific for safer needle use. Overall, these meta-analyses validate the appropriate use of HIV prevention interventions with treatment-seeking individuals with substance use disorders.

Subsequent to the three meta-analyses the National Institutes on Drug Abuse (NIDA)

Clinical Trials Network (CTN) conducted two randomized clinical trials of HIV prevention within SUD treatment settings building on the knowledge gained from the prior work cited in these meta-analyses. The Real Men Are Safe (Calsyn et al. 2009) and the Safe Sex Skill Building for Women (Tross et al. 2008) were five-session gender-specific interventions targeting sexual risk behaviors. The interventions employed multiple techniques, didactic lectures, peer group brainstorming, male and female condom skill practice (► [Female Condoms](#) and ► [Male Condoms](#)), communication/negotiation skills role plays, and motivational exercises. The interventions were conducted by two counselors employed at the treatment programs as cofacilitators. Both “Real Men Are Safe” and “Safer Sex Skills Building for Women” were shown to be effective in reducing the number of unprotected sexual occasions (USO; vaginal or anal intercourse without a male or female condom) compared to a standardized HIV prevention educational intervention for both women and men, although the pattern of risk reduction differed by gender (Calsyn et al. 2009; Tross et al. 2008). Women randomized to the “Safer Sex Skill Building” intervention and women in the control HIV intervention had a similar significant decrease in the number of USO at the 3-month follow-up compared to baseline. For men, however, only those randomized to the “Real Men are Safe” intervention significantly decreased their USO at the 3-month follow-up. Both women and men who were randomized to “Real Men are Safe” or “Safer Sex Skill Building,” respectively, reported significantly greater reductions in the number of USO at 6-month follow-up compared to participants in the control HIV educational interventions.

Although the interventions for “Real Men Are Safe” and “Safer Sex Skills Building for Women” have many similarities, such as providing basic information about HIV and behaviors to prevent transmission as well as development of communication skills related to sexual situations, they are gender-specific HIV prevention interventions. In “Real Men Are Safe” there is a focus on the interplay between sex and drugs, a focus on

recognizing partner needs and the role played by society's "gender roles," the importance of accepting responsibility for one's own behavior is stressed, and the use of assertive communication skills and "I" statements in safe sex negotiations. In "Safer Sex Skills Building for Women," there is a focus on increasing self-efficacy, decision-making skills, negotiation and refusal skills, and skills for recognizing risk of partner abuse and preemptive safety planning in the context of sexual relationships with substance-using men. Consistent with the emphasis on reducing sex under the influence, men assigned to the Real Men Are Safe intervention were less likely to have engaged in sex under the influence of drugs or alcohol during their most recent sexual event prior to the 3-month follow-up assessment than men assigned to the control intervention (Calsyn et al. 2010). "Real Men Are Safe" and "Safer Sex Skills Building for Women" have been placed on the Centers for Disease Control and Prevention (CDC) HIV/AIDS Prevention Research Synthesis (PRS) Project website as evidence-based practices (CDC 2012). Initiated by the CDC in 1996, the purpose of PRS is to systematically review and summarize HIV behavioral prevention research literature with the goal of translating scientific evidence into practical information that can be used by prevention providers, state and local health departments throughout the United States, and HIV prevention researchers. To gain acceptance within the compendium, interventions must be formulated from established psychological and sociological theories and tested in rigorous, randomized controlled trials. It is clear that clinical researchers appreciate SUD treatment settings as an ideal platform for HIV intervention delivery, and they have generated a multitude of interventions, some of which have demonstrated a strong evidence base.

HIV Prevention in SUD Treatment Settings: Standard Practice

State and federal agencies recognize the value in promoting HIV prevention in SUD treatment settings. As one of its principles of effective

treatment, the National Institutes on Drug Abuse (NIDA) suggests that SUD treatment programs should assess clients for the presence of HIV/AIDS, as well as "provide targeted risk-reduction counseling to help patients modify or change behaviors that place them at risk of contracting or spreading infectious diseases" (NIDA 2009, p. 5). Guidelines regarding the implementation of HIV prevention in SUD treatment agencies appear to be – for the most part – observed, according to administrators and directors of relevant agencies. Brown et al. (2007) surveyed 269 agencies across the United States examining available services and related state policies and funding associated with HIV and other infections in SUD treatment settings. They found that most agencies (88–90%) offer HIV/AIDS education and risk assessment, even those without state guidelines, policies, regulations, or reimbursement.

While agencies report offering HIV prevention services, it is less clear what these services actually look like. One specific area emphasized within the literature is on HIV counseling and testing (C&T) (► [HIV Testing and Counseling](#)) in outpatient SUD treatment (Pollack et al. 2010). These investigators have found that the rate of agencies conducting HIV C&T increased significantly in the 1990s and more modestly in recent years to a total of 28.8% of agencies in a national sample. Other researchers have attempted to gauge the kinds of HIV prevention services occurring in SUD treatment settings more generally. Researchers in the NIDA Clinical Trials Network (CTN) conducted a "snapshot" survey of 65 agencies participating in the CTN to determine more details about the HIV services provided (Shoptaw 2001). Most agencies (73.8%) reported that formal HIV/AIDS assessment was conducted upon admittance to the agency, ranging from HIV counseling and testing to referral to outside community testing sites for these services. A much smaller percentage of programs (28.3%) reported conducting outreach to drug-using groups at high risk for HIV transmission. Finally, the snapshot indicates that 82.8% of agencies reported that AIDS education is provided to clients on site and upon admission. For most programs (85.4%) the

amount of education provided ranged from 30 to 90 min delivered in a single group or individual session. The bulk of the education delivered was limited to providing basic information about HIV and risk behaviors associated with its transmission. Skill training interventions, using tools such as role-plays and practice of putting condoms on models, were infrequent. Overall, the results from the “snapshot study” go against the findings from the three meta-analyses cited above that indicated that more effective HIV prevention interventions with individuals struggling with substance use disorders consist of multiple sessions, employ a wide variety of techniques, and have separate sessions for men and women. Instead, agencies involved in the snapshot study provide only a single session and use information-focused interventions. Furthermore, the HIV/AIDS educational and prevention programs provided are not standardized, resulting in an array of session format, content, and timing. This lack of standardization in services offered, along with other evidence demonstrating that treatment programs do not always offer the specialized services they claim to (Cochran et al. 2007), suggests the need to examine barriers to implementing HIV prevention services in SUD treatment settings.

Implementation of HIV Prevention Interventions in SUD Treatment Settings

SUD treatment clinics have been slow to adopt evidenced-based HIV prevention interventions despite empirical support, and implementation appears to be hindered both at the organizational and individual clinician levels. Campbell et al. (2011) and Calsyn et al. (2012, CTP representative survey – REMAS-CA, Unpublished) demonstrated a clear disconnect between the availability of evidence-based HIV prevention interventions and adoption of these interventions by SUD treatment facilities in their surveys of clinics participating in the CTN. Specifically, these researchers examined the extent to which these evidence-based interventions were adopted by clinics in the “Real Men Are Safe” and “Safer Sex

Skills Building for Women” original studies, as well as clinics involved in the CTN, but did not participate in the original studies. Both surveys found that only one program had fully adopted “Real Men Are Safe,” while three continued to use materials from the trial, mostly the information/educational materials rather than the motivational or skill-building materials. The main reasons given for not adopting “Real Men Are Safe,” were: lack of staff time (54%), competing treatment priorities (52%), need for additional funding (44%), or a mechanism for reimbursement (42%) (Calsyn DA, Hatch-Maillette MA, Burlew AK, 2012, CTP representative survey – REMAS-CA, Unpublished). Similarly, Bini et al. (2011) surveyed SUD treatment program administrators and counselors to determine barriers in providing HIV and STI health services (including prevention efforts). In addition to funding issues, the authors identified client acceptance and staff training as being important barriers to delivering these services.

At the individual level, counselor discomfort with the material may prohibit adoption of HIV prevention interventions. For example, Tracy et al. (2009) surveyed SUD treatment clinicians regarding opinions and the delivery of services for STIs and found that clinicians were more likely to provide more of these services if they were more comfortable discussing sexual and intimate relationship issues. SUD treatment patients may respond better to HIV prevention interventions administered by counselors more comfortable with the material, in particular if counselors take a nonjudgmental stance (Brems and Dewane 2007).

Conclusions

SUD treatment facilities are an ideal venue in which to administer HIV prevention interventions, not only because the people served in such settings exemplify high risk behavior but also because they receive ongoing care and interface regularly with counselors. Clinical researchers have responded to this need by generating and testing interventions, which are in accordance with well-known models of behavior change.

The wealth of research in this area has resulted in the identification of several evidence-based behavioral interventions. Of those examined in the context of existing SUD treatment programs, “Real Men Are Safe” and “Safer Sex Skill Building for Women” are among those that enjoy the strongest degree of empirical support. While these have been shown to be effective, implementation of evidence-based HIV prevention interventions has been hindered by a number of barriers, including cost to clinics, motivation, counselor desire, and skill. To ameliorate some of these barriers more resources should be allocated to clinics attempting to implement these interventions. Furthermore, interventions could be shortened, and counselors may be encouraged to talk with their patients in an ongoing way about risk reduction, instead of having intervention be a circumscribed event. Integrating HIV prevention interventions into SUD treatment should be a priority in order to create a safe and accepting environment in which clients can engage in conversations about sex and sexual risk reduction in the context of recovery.

HIV Prevention for MSM

Keletso Makofane¹ and Theo Sandfort²

Columbia University, New York, NY, USA

Definition

While globally the number of newly HIV-positive people continues to fall, this is not the case for men who have sex with men (MSM) (Beyrer et al. 2012; UNAIDS 2012), who continue to be severely affected. HIV prevalence estimates among MSM range from 3% in the Middle East to over 30% in the Caribbean (UNAIDS Caribbean Regional Support Team 2010). In nearly

every country for which information is available, the odds of contracting HIV are higher among MSM than among men in general, sometimes by more than 30 times. This is the case even in most countries in sub-Saharan Africa – a region that was long believed to have an exclusively heterosexual epidemic. Studies suggest that HIV prevalence continues to rise among MSM for specific subgroups or in some geographical areas. In the USA, for instance, it is estimated that new HIV infections in this population have increased by 8% per year since 2001. This dire situation can be understood as a consequence of a variety of factors, including the high HIV transmission rate per sex act for anal intercourse – estimated to be about 18 times higher than for vaginal intercourse. In addition, the global response to the epidemic among MSM thus far has been insufficient, largely as a result of antigay stigma and, in some countries, the criminalization of homosexuality.

MSM: Diverse Category

The use of the label “MSM” to identify this population has become common practice since the late 1980s. The label was introduced in the context of public health to acknowledge that not all men who had sex with men are identified as “gay.” The label categorizes a very diverse group of persons who, as a single feature, have in common that they were identified at birth as biological male and have sex with other male-bodied persons. MSM is in itself a label that men do not usually identify with. It also leaves open how men understand and organize their sexual lives and whether they sexually identify in a specific way and, if so, how they identify. The label encompasses gay-identified men, Moffies in South Africa, Hijras in India, Kuchus in Eastern Africa, but also straight-identified men who sell sex to other men, men who have sex with men “on the down low,” men who have sex with men in prison, men who exclusively have sex with other men, and men who have sex with both men and women. Also included in this category are biologically born males who no longer identify as such, male-to-female transgender persons. The MSM

label has been criticized because it ignores cultural differences between the various groups, deflecting attention away from the “social dimensions of sexuality that are critical in understanding sexual health. . . [and obscuring] elements of sexual behavior that are important for public health research and intervention” (Young and Meyer 2005, p. 1144). Nonetheless, the term continues to be used by major stakeholders in the global response to HIV. In order to be effective, HIV prevention efforts should, however, acknowledge the diversity of men captured by the label.

Various Kinds of Risk

Not all MSM are at the same risk of acquiring HIV. This is clearly illustrated by the dramatic disparity between Black MSM and MSM of other ethnicities in the USA, where Black MSM are three times more likely to be HIV positive (Millett et al. 2012). Research aimed at understanding risk has focused mainly on engagement in unprotected anal intercourse (UAI) – the primary mode of transmission among MSM. Factors for risk of HIV infection can be distinguished on various levels, such as individual and structural, and do not necessarily have universal relevance. It is also important to note, for the purpose of developing prevention strategies, that some of these factors are more amenable to change than others.

At the individual level, knowledge, attitudes, beliefs, skills, and self-efficacy – factors derived from health behavior models – have been shown to be related to sexual risk as well as to protective behavior (e.g., condom use for anal sex). Other individual-level factors associated with HIV risk behavior include mood states, personal history, and various personality characteristics. For example, depression has been found to be related to sexual risk practices, although findings are inconsistent. In terms of personal history, risk factors include traumatic experiences such as sexual abuse and intimate partner violence. Personality characteristics related to sexual risk include internalized homophobia (which can also be understood as a structural factor which is as a

consequence of antigay stigma in one’s society) and sexual compulsivity.

Individual connectedness to a gay community has been thought to be a protective factor, because it increases exposure to HIV prevention messages and services and offers social support. The evidence for this is, however, inconclusive. This might be because being connected to a community also increases access to sexual partners and exposure to factors that might increase HIV risk, such as permissive norms around drug use.

Other microlevel factors associated with HIV risk behavior include peer influence, romantic relationships, family acceptance, and support. Identifying a sexual partner as primary (as opposed to casual) has consistently been found to predict higher rates of UAI, suggesting that trust and love as primary qualities of intimate relationships impede condom use.

Other risk factors are related to sexual interactions themselves, with alcohol and drug use most consistently shown to be associated with UAI. While the exact nature of the association still needs to be clarified, evidence suggests that it is moderated by other situational variables such as partner type (the association between drug use and UAI is stronger with casual partners versus primary partners) and sexual role (some drugs are more strongly associated with receptive UAI than insertive UAI and vice versa). The context of sexual interactions also structures HIV risk among MSM: public sex venues such as sex clubs or bathhouses are strongly associated with risky behaviors.

HIV risk is also dependent upon with whom MSM have sex. For instance, the ethnic disparity in HIV infection in the USA is not explained by higher levels of risky practices in Black MSM. Rather, it is explained by the higher prevalence of HIV among Black MSM and the fact that Black MSM are more likely to have sexual partners that are Black (Millett et al. 2012). More generally, the importance of the role of social and sexual networks in risk behavior and the spread of HIV is being increasingly acknowledged and understood.

The most crucial among various structural factors associated with HIV risk include societal

rejection and criminalization of homosexuality. Other structural factors are low education, unemployment, and poverty. These factors are thought to work in a variety of ways, though their effects are difficult to measure. That structural factors play a role in the risk of HIV infection is, for instance, suggested by the higher HIV prevalence among MSM in Guyana and Jamaica, where homosexuality is criminalized, compared to the Dominican Republic and Suriname, where no such laws exist (UNAIDS Caribbean Regional Support Team 2010). Stigma and discrimination also affect ways that sexuality is expressed, e.g., they promote adoption of heterosexual marriage to hide oneself, increase the risk of blackmail, and promote transactional sex. As such, stigma and discrimination might contribute to risk or create barriers to access prevention and care.

The various risk factors do not necessarily work independently but could reinforce each other, as formulated in syndemic theory (Stall et al. 2008). Syndemic theory is concerned with culturally produced epidemics that reinforce one another in a particular population. It has been used to explain the high rates of concurrent psychosocial problems among MSM including substance use, sexual abuse, violence, and mental health conditions, which together increase HIV risk.

Responses to Risk Among MSM

Since the beginning of the epidemic, MSM have adapted their behavior by using condoms and reducing number of partners. Without this response, the epidemic would likely have had an even more disastrous impact. Informed by medical evidence, MSM further invented alternative strategies to reduce their risk of contracting HIV. The introduction of HIV testing facilitated serosorting: a practice by which MSM only have unprotected sex with partners with the same HIV status in order to avoid contracting HIV or transmitting HIV to a negative partner. Because serosorting is not always based on accurate information about one's own HIV status or that of sexual partners, the term "seroguessing" has been coined to illustrate the pitfalls of strategy

(Zablotska et al. 2009). Other strategies include withdrawal before ejaculation and strategic positioning, in which the HIV-positive partner takes the receptive position and the HIV-negative partner takes the insertive position, based on the understanding that insertive partners are less likely to contract HIV than receptive partners (Parsons et al. 2005). Although these strategies plausibly reduce HIV risk, they do not always eliminate it and might lead to exposure to other risks, such as HIV superinfection or infection with other STIs (Vallabhaneni et al. 2012).

Another risk reduction strategy employed by MSM is negotiated safety (Kippax 2002). This strategy, adopted in intimate relationships, involves abandoning condoms after both partners have tested HIV negative and an agreement to avoid UAI with partners outside the relationship (and maintaining that agreement). While theoretically protective, in practice, the strategy does not always work, with some men simultaneously making negotiated safety agreements and engaging in UAI with outside sexual partners.

Prevention Approaches and Strategies

There is a wide diversity of HIV prevention interventions, informed by various theoretical approaches (Glanz et al. 2008). These interventions can be broadly divided into two categories: individual-level and structural-level interventions (Cohen and Scribner 2000). Individual-level interventions primarily have effects on the individual level. They include behavioral interventions such as education and social influence strategies and biomedical interventions such as condom use, postexposure prophylaxis (PEP), and preexposure prophylaxis (PrEP). Individual-level interventions can be implemented on an individual as well as a group level, but are expected to have their effect primarily on the individual; these interventions can have a population-level impact if individual changes lead to decreased HIV incidence and a reduced viral load in the community.

Structural-level interventions target conditions outside the control of individuals. Such

interventions primarily have an impact on the population level but may also affect individual persons. For MSM, structural interventions include ensuring that condoms and lubricants are adequately available, influencing social norms via mass media, implementing formal or informal policies that require provision of condoms in sex establishments, and decriminalizing same-sex sexuality.

Numerous studies have demonstrated that HIV prevention programs effectively contribute to the promotion of safer sex behavior among MSM (Herbst et al. 2007; Johnson et al. 2008; Lorimera et al. 2013). A review of systematic reviews of behavioral interventions among MSM (Lorimera et al. 2013) has shown that the effectiveness of interventions varies. There is strong and consistent evidence that group- and community-level interventions are associated with substantial reductions in UAI and increases in condom use. The evidence regarding interventions addressing individuals is, however, less consistent. In general, interventions based on theory have been shown to be more effective than those that are not, specifically interventions that are based on diffusion of innovation theory or the model of relapse prevention. Group-level interventions that incorporate skills-building activities have also been shown to be particularly effective. Interventions can be strengthened by addressing co-occurring psychosocial risk factors. Interventions that ignore structural barriers to safer sex, such as homosexual stigma, are likely to be less effective.

Most interventions have been tested with samples predominantly composed of white MSM from high-income countries. If other MSM groups were involved, the measured effect of interventions has been found to be stronger among white MSM. It is not clear whether and how these interventions can be adapted to understudied subgroups, such as MSM of color, MSM who do not identify as gay, and MSM who use drugs, nor is it clear how they can be adapted to MSM diverse cultural contexts and in lower-income countries.

While many interventions have been designed and implemented for MSM, program coverage

continues to be low. Although governments increasingly recognize the needs of MSM and funding for HIV programs for MSM is increasing (in low- and middle-income countries primarily from international donors), programs that target MSM have not enjoyed high priority, and epidemiological surveillance among MSM has been inadequate (amfAR and Johns Hopkins Bloomberg School of Public Health 2012). Community organizations, supported by international agencies, bear the burden of implementing HIV programs for MSM, jeopardizing sustainability.

Conclusion

Promotion of safer sex practices will continue to be a major aim of future HIV prevention among MSM. The prevention landscape however changes continuously. First, the sexual behavior of MSM will continue to change. This happened, for instance, in response to the availability of antiretroviral treatment (ART), when MSM who believed that ART reduced HIV transmission became more likely to engage in unprotected sexual behavior. In addition, the Internet has increased opportunities for MSM to find sexual partners and is changing the ways in which men connect. The worldwide development of gay communities, partly stimulated by HIV prevention efforts, will have consequences for how MSM in low- and middle-income countries express their same-sex sexuality.

Also affecting the prevention landscape is the increasing number of strategies that become available to address the epidemic. PrEP, daily oral antiretroviral preexposure prophylaxis, approved in the USA by the FDA, is widely seen as most promising. There is evidence that PrEP is safe and has potential for substantial efficacy. However, with its strong reliance on adherence and need for medical follow ups, PrEP will be challenging to implement on a large scale. Also, several unanswered questions still remain, including the effect of pill taking on risk behavior, long-term safety of ongoing use, and how to best make PrEP available. Furthermore, PrEP, as most other biomedical approaches, includes a behavioral component that

needs preventive attention. When the effectiveness of less challenging PrEP regimens is established and other modes of delivery (e.g., by injection) prove to be effective, PrEP likely will be a major ingredient in future HIV prevention. Ethical issues, resulting from the fact that there is no universal access to HIV medication for those who are HIV positive, will need to be resolved.

The Internet and the growing popularity of social media have not only changed MSMs dating patterns but also greatly expanded opportunities to deliver evidence-based HIV prevention (Chiasson et al. 2010). While gay consumers seem to be among the earliest adaptors of new technology, the “digital divide” continues to shrink. Major advantages of the Internet and other digital media, such as cell phones, include the ability to tailor prevention efforts to the needs of individual men and the relatively low costs. One of the major barriers of these new strategies is attracting users.

In addition to the promotion of safer sex, early treatment of HIV has become a major way to prevent further spread of HIV. There is increasing evidence that early treatment improves health outcomes for the individual and also curbs the epidemic by reducing infectiousness. This strategy requires that MSM test regularly for HIV, are linked to care if HIV positive, and stay in care, resulting in suppressed viral load. Interventions are needed to promote frequent HIV testing and to ensure that barriers to accessing HIV care are reduced for MSM. A negative effect of such campaigns could be that HIV testing replaces safer sex behavior, a negative test result lowering perceptions of HIV risk.

There is a growing awareness that there is not one intervention strategy that will end the epidemic among MSM (Coates et al. 2008). A combination of approaches is needed not just to change MSM sexual practices but also to sustain accomplished changes. Combination approaches work best when employed synergistically. For instance, the protective effect of PrEP can be enhanced by combining it with interventions to promote adherence and prevent risk compensation. Approaches that integrate behavioral strategies with biomedical and structural

approaches are likely to be most effective. Current efforts to address the epidemic among MSM remain insufficient. Innovative science and political commitment are needed to effectively address the HIV epidemic among MSM.

HIV Prevention for Serodiscordant Couples

Nabila El-Bassel, Louisa Gilbert and
Stacey A. Shaw
Social Intervention Group, Columbia University
School of Social Work, NY, USA

Definition

Introduction

HIV transmission in serodiscordant couples continues to fuel the spread of HIV worldwide, particularly in Africa, which has the largest share of HIV cases (UNAIDS 2010). Globally, 80% of new HIV cases among women occur through heterosexual transmission, most often from steady partners (UNAIDS 2010). Moreover, men who have sex with men (MSM) bear a disproportionately heavy burden of the HIV pandemic in low- and middle-income countries, and the majority of

sexually transmitted HIV cases among MSM also stem from primary partners (UNAIDS 2010).

Despite high rates of HIV transmission in heterosexual and MSM couples worldwide, research suggests that both sexual and drug use risks occur largely within a dyadic context between intimate partners, and few couple-based HIV prevention interventions have been tested and disseminated. In this entry, the authors define couple-based HIV prevention and describe couple-based HIV prevention approaches for serodiscordant couples including couple HIV counseling and testing (CHCT), HIV/STI risk reduction beyond CHCT, and adherence to ART and biomedical prevention strategies (ART, PrEP).

Defining Prevention for Serodiscordant Couples

HIV prevention for serodiscordant couples includes a combination of both behavioral and biomedical strategies. An HIV-serodiscordant couple is defined as a couple having an ongoing sexual and/or intimate relationship where one partner is HIV-positive and the other is HIV-negative. HIV prevention studies define who constitutes a “couple” in different ways. The majority of couple-based studies outside the United States (USA) define a couple as two individuals who are married or cohabiting; however, most studies in the United States define a couple by the length of time that the individuals have been together (usually at least 3–6 months). Couple-based behavioral HIV prevention strategies for serodiscordant couples include three major types: (1) couple HIV counseling and testing (CHCT), (2) couple-based HIV sexual and drug risk reduction beyond CHCT, and (3) couple-based adherence to antiretroviral therapy (ART).

Couple-based behavioral HIV prevention strategies may be delivered simultaneously to each member of the couple individually, to the couple together, or to a group of couples together (El-Bassel et al. 2010a, b). Couple-based behavioral HIV interventions are often guided by social cognitive theories and focus on providing information, motivation to reduce or eliminate risk behaviors, and technical, personal, or interpersonal skill building to reduce both sexual and drug-related risk

behaviors between partners (El-Bassel et al. 2010a). These interventions go beyond individual determinants of sexual and drug risk behaviors to include interpersonal dynamics and interactional forces (El-Bassel et al. 2010a). Biomedical couple-based HIV prevention approaches include two major types: (1) use of ART for HIV-positive partners and (2) pre-exposure prophylaxis (PrEP) for HIV-negative partners. These biomedical advances have been classified as “treatment as prevention” because early access to ART and PrEP has been found to significantly reduce the likelihood of HIV transmission among serodiscordant couples.

Couple-Based Behavioral HIV Prevention

Couple HIV Counseling and Testing (CHCT)

CHCT has been widely utilized in Africa and, more recently, in the United States. HIV testing is an important first step in identifying serodiscordant couples. CHCT involves providing informed consent for voluntary HIV testing to individual partners, testing a couple for HIV together, informing them of their test results, and providing a forum to ensure that both partners are aware of their HIV status and able to discuss ways to protect the HIV-negative partner, as well as to access HIV treatment and care for the HIV-positive partner and to identify and provide appropriate referrals to address psychosocial needs of HIV-affected couples. Using CHCT’s pre- and posttest counseling techniques, a trained counselor facilitates the disclosure of HIV (Curran et al. 2012). Serodiscordant couples are also given information about how to correctly and consistently use condoms to reduce chances of HIV transmission to the HIV-negative partner (Padian et al. 1993). Some CHCT approaches also address abstinence, avoiding anal sex, and negotiating risk reduction plans (Padian et al. 1993). The World Health Organization (WHO) recommends that HIV-negative individuals with a known HIV-positive partner retest in 4 weeks to assess for recent HIV transmission and semiannually afterward, if they continue to be

sexually active (WHO 2012). Recent WHO recommendations suggest HIV testing should be conducted every 6 months and informed by the couples “risk assessment,” fertility intentions, as well as by symptoms for acute HIV (see entry “► [HIV Testing and Counseling](#)”). In addition, WHO also recommends educating both partners in strategies to reduce the risk of HIV transmission, such as male circumcision and PrEP, if available. WHO recommendations underscore the importance of clinical follow-up for the HIV-positive partner that should include (1) a CD4 cell count to assess his or her eligibility for ART, (2) technical skills to ensure correct condom use and recommendations to use condoms consistently (see entries “► [Male Condoms](#)” and “► [Female Condoms](#)”), (3) discussions on family planning, safe conception, and pregnancy, and (4) prevention of mother to child transmission (PMTCT) for HIV-positive pregnant women (WHO 2012) (see entry “► [Behavioral Aspects of HIV Mother-to-Child Transmission](#)”).

Benefits: CHCT promotes mutual disclosure of HIV status and can assist partners in providing support for each other, if one or both are HIV positive (Curran et al. 2012). CHCT also increases uptake and adherence to ART, promotes condom use, and, by encouraging behavior change, leads to a reduction in the risks of HIV transmission (Curran et al. 2012). Promotion of disclosure of HIV status in a serodiscordant relationship within a stable partnership has been found to foster family support, improve engagement in HIV care for the HIV-positive partner, and result in high adherence to ART (Curran et al. 2012). Recently, the US Food and Drug Administration (FDA) approved an HIV home test (HT) manufactured by Orasure for over-the-counter sale. The Orasure HT has the potential to promote testing among couples that do not know their HIV status. Home testing can serve as a tool to help couples learn their HIV status discreetly. Moreover, HT may avoid the stigma and barriers associated with going to a clinic for HIV testing and may promote privacy. Despite these advantages, couples in serodiscordant relationships that learn their HIV status through HT would still benefit from CHCT to ensure that they receive concrete referrals and

gain access to ART, are encouraged to use condoms regularly, and address negative reactions that may be associated with disclosure of HIV. This is particularly relevant because some studies have found that disclosure of HIV among serodiscordant couples has been associated with increased risk of divorce, separation, and intimate partner violence. For example, the Partners in Prevention HSV/HIV Transmission Study and Partners PrEP Study found that counselors observed disbelief and misconceptions about HIV results among couples, including skepticism about the accuracy of the test, desire for retesting and hopes for a different outcome, sadness, blame toward the partner for infidelity, and concern about children's HIV status, where couples needed support and counseling (Curran et al. 2012). These findings underscore the need for couple-based HIV prevention that moves beyond CHCT in order to promote risk reduction within stable relationships as well as with other partners and creates prevention approaches that help the couple feel safe to talk about sensitive issues that increase risks (e.g., extra-dyadic affairs and HIV risk behaviors such as bisexuality, sharing drugs and equipment, and sexual violence).

HIV/STI Behavioral Prevention Beyond CHCT

Couple-based HIV interventions that moved beyond CHCT were introduced in the early 1990s, and the first such intervention study was published in the United States in 2001 (El-Bassel et al. 2010a). Couple-based HIV prevention was initiated when the HIV field recognized that serodiscordant couples who learned about their HIV status and participated in CHCT needed additional opportunities to learn how to use strategies together to maintain safer sex practices, reduce drug risk behaviors, and address HIV, STI, and reproductive health issues. The core elements of couple-based HIV prevention include skill building to increase male and female condom use and promote behaviors that reduce sexual and drug risk behaviors (e.g., reduction of sexual concurrency, sex trading [see entry “► [Female, Male and](#)

[Transgender Sex Workers, Epidemiology of HIV/AIDS](#)”], bisexuality, sharing needles); identify and learn ways to confront interpersonal and structural barriers to fight HIV (see entry “► [Multilevel Interventions/Structural Approaches to HIV Prevention](#)”), gender roles and expectations as contributors to unprotected sex, injection, and drug risk behaviors (see entry “► [Harm Reduction for Injection Drug Users](#)”); integrate STI, HIV, and reproductive health services; build healthy relationships; and address goal setting to allow couples to practice risk reduction strategies in real-world settings (El-Bassel et al. 2010a, b). Risk reduction group approaches with serodiscordant couples have been found to be highly acceptable, feasible, and efficacious in reducing sexual and drug risk behaviors in multiple countries (El-Bassel et al. 2010a). Multiple studies have been conducted with serodiscordant couples. For example, a cognitive behavioral group-based intervention for HIV-positive women and their partners in Zambia found higher rates of increased condom use when male partners had a higher level of intervention participation (Jones et al. 2005). A multisite study on HIV prevention in the United States among serodiscordant African American couples found higher rates of consistent condom use as a result of a couple-focused risk reduction approach when compared to an individually focused health promotion intervention (El-Bassel et al. 2010b). A couple-based study with 282 HIV-negative drug-using couples from New York City found, at 12 months follow-up, that there was a 41% reduction in the incidence rate of the number of unprotected sex acts with intimate partners and 39% reduction in unprotected sex acts with other partners when the couple received the seven-session intervention together when compared to one person receiving the intervention alone (El-Bassel et al. 2011).

Benefits: Bringing couples together sends a message that the responsibility for HIV risk reduction falls on both members of the dyad and underscores that both men and women can put each other at risk for HIV. Second, this type of intervention provides a supportive environment that may enable a couple to more safely disclose to each other extra-dyadic sex partners, a history of

STIs, a history of injection drug use, or past experiences in abusive relationships (El-Bassel et al. 2012). Third, it provides an environment in which a couple can learn communication skills and practice them and discuss gender differences (e.g., how men and women discuss sex, the meaning of requesting and/or refusing the use of condoms), gender power imbalances associated with sexual coercion and the inability to negotiate condom use, gender inequalities in risk practices, and sexual expectations (El-Bassel et al. 2010a). Couple-based behavioral prevention is particularly useful for women who are fearful of negotiating condom use, uncomfortable in suggesting safer sex practices, or afraid to refuse unsafe sex because of a partner's reaction and abuse (El-Bassel et al. 2010a, b). Research has shown that when women attempt to negotiate safer sex practices with their partner, they may experience an increased risk of intimate partner violence (El-Bassel et al. 2010a).

Biomedical HIV-Serodiscordant Couple-Based Prevention

A number of recent biomedical advances for serodiscordant couples have made significant contributions to HIV prevention science and provide a dramatic difference in reducing the incidence of HIV. For example, in an HIV Prevention Trials Network study (HPTN 052) of 1,763 serodiscordant relationships where the HIV-positive partner (CD4 count of 350–550 cells per cubic millimeter) received early initiation of ART, there was a 96% reduction in the number of linked HIV-1 transmissions, when compared to those receiving delayed therapy (CD4 count of 200–250 cells). The mechanism by which prevention occurs is likely the suppression of HIV-1 in genital secretions, resulting from ART (Cohen et al. 2011). Another study, which considered the use of suppressive therapy (acyclovir) for serodiscordant couples, found that daily acyclovir therapy did not lead to a reduced risk of HIV transmission, although treatment did reduce plasma HIV-1 RNA levels and the occurrence of genital ulcers (Celum et al. 2010).

Additionally, the Partners PrEP Study with serodiscordant couples (Baeten and Celum 2011) showed that daily oral tenofovir (TDF) and emtricitabine/tenofovir (FTC/TDF) PrEP for the HIV-negative partner reduced risk of HIV acquisition, by 62% and 73%, respectively, in African men and women. Similar efficacy between TDF and FTC/TDF HIV protection effect was robust in both women and men (Baeten and Celum 2011). PrEP has been recommended for the HIV-negative partner in a serodiscordant relationship, or for a partner whose HIV status is unknown or who engages in HIV risk behavior (see entry “► [Pre-exposure Prophylaxis \(PrEP\)](#)”). Moreover, PrEP has been recommended for the HIV-negative partner when the couple decides to conceive.

Benefits: Access to early ART reduces HIV incidence among serodiscordant couples, improves the health and survival of HIV-positive individuals, and significantly reduces infectiousness and the likelihood of transmission to HIV-negative partners. Mathematical modeling predicted that treating HIV-serodiscordant couples, in countries such as Malawi and Lesotho with a high HIV prevalence rate (7.1–19.5%), where a large percentage of couples are serodiscordant (9.8 and 13%), could result in significant reductions in population-level HIV incidence (Dunkle et al. 2008).

These biomedical advances highlight that treatment is prevention and promoting HIV testing and ART (test and treat), as well as linkages to care, is critical in reducing new HIV infections. Treatment as prevention among serodiscordant couples would increase the number of people who are aware of their HIV status, with the subsequent benefit of causing a decline in new infections among serodiscordant couples and reducing community viral load. However, treatment as prevention needs to be complemented with education and behavioral changes to reduce HIV risks and couple-based behavioral prevention approaches.

Adherence to Treatment

As access to antiretroviral therapy (ART) may be insufficient to ensure full adherence to treatment

regimens, behavioral interventions that address barriers, educate, and promote adherence help to ensure that the benefits of ART are fully realized within serodiscordant couple relationships (see entry “► [Behavioral Aspects of HIV Treatment as Prevention](#)”).

Couple-based ART adherence interventions are designed to bring the couple together to learn strategies to ensure that the medication is taken regularly. The responsibility for adherence is placed on both members of the couple. The HIV-negative partner becomes involved in a number of activities with a third party (e.g., counselor, nurse, doctor) to promote adherence to prescribed medication regimens. Currently, there is only one evidence-based adherence study for serodiscordant couples. The Sharing Medical Adherence Responsibilities Together (SMART) Couples Study is the first and only couple-based ART adherence intervention (Remien et al. 2005). The intervention was designed to improve medication adherence among HIV-positive patients by fostering active support from their HIV-negative partner and addressing sexual transmission concerns within the dyad.

Benefits: Adherence to antiretroviral therapy among HIV-positive individuals reduces sexual HIV transmission (Reynolds et al. 2011). There are also a number of advantages to bringing couples together in terms of improved adherence to HIV care and treatment. Intervening with both members of the dyad, rather than with the individual patient alone, can produce increased (1) motivation to maintain good health, (2) understanding of how medications work to control HIV viral load and of the necessity for high levels of adherence to the treatment regimen, (3) commitment to obtain and maintain a steady supply of medications and to provide daily reminders for medication taking, (4) ability to identify and resolve ongoing barriers to optimal adherence, (5) encouragement to confront HIV-related stigma and feelings of isolation which can contribute to treatment avoidance, and (6) ability to communicate and provide mutual care-taking behaviors within the dyad. Furthermore, in the context of HIV infection, it

is important to integrate HIV prevention into HIV care whether couples are HIV serodiscordant or concordant because, as noted above, there is a clear association between viral load control and transmission risk.

Conclusion

Couple-based behavioral and biomedical HIV prevention strategies for serodiscordant couples can play a pivotal role in the fight against HIV/AIDS and have the potential to significantly reduce new incidence of HIV. Given that sexual and drug use behaviors occur in a dyadic context, involving both members of a couple jointly in an intervention to reduce transmission risk and support each other in adhering to ART and other biomedical treatment (PrEP) is paramount to fighting the HIV epidemic where no vaccine is available. A couple-based approach underscores the joint responsibility of both members of the dyad and, in particular, increases men’s awareness of their responsibilities. CHCT combined with behavioral risk reduction strategies and the promotion of condom use remains a strategic prevention priority in the United States and other countries. Even with the FDA approval of over-the-counter sales of home HIV testing, CHCT remains important for couples to deal with negative reactions associated with discovering one’s HIV status. Behavioral prevention that moves beyond CHCT and includes skill building (technical skills, communication skills, and healthy relationship skills) and integration of prevention of STIs, HIV, and reproductive health is needed to address couple’s needs and promote behavioral change. Recent biomedical advances for HIV-serodiscordant couples have made a significant contribution to HIV prevention science and provide new avenues for reducing the incidence of HIV, demonstrating that ART treatment is prevention. A combination of behavioral and biomedical strategies to address risks between serodiscordant couples holds more promise for reducing HIV transmission than either strategy alone.

Definition

HIV and stimulant use are interconnected epidemics among men who have sex with men (MSM) in the USA. Among MSM, stimulant use and its behavioral sequelae are critical targets for interventions across the spectrum of HIV prevention, treatment, and care.

Epidemiologic Profile

HIV Risk Among MSM in the USA

More than 54,000 Americans acquire HIV each year, and men who have sex with men (MSM) represent over half of these new diagnoses.

Representing approximately 2.0–5.0% of the male population in the USA, MSM comprised 68.0% of adult and adolescent men living with HIV in 2013. In the same year, male-to-male sexual contact was attributable to 65.8% of new HIV diagnoses in males (CDC 2015). Furthermore, new infections among MSM have remained steady over the past 5 years (2009 = 21,811; 2013 = 21,498; CDC 2015).

Stimulant Use and Sexual Risk-Taking Among MSM in the USA

In the past decade, stimulants, including cocaine/crack, crystal methamphetamine (meth), amphetamines, and methylenedioxy-methamphetamine (MDMA/ecstasy), and alkyl nitrites (poppers), have become increasingly popular among MSM worldwide (Bourne 2012). In high income nations, such as USA, the prevalence of recent (past 12 months) amphetamine use among MSM is reported to be between 7.2% and 18.8% (Koblin et al. 2007), crystal meth use between 2.8% and 18.0% (Forrest et al. 2010; Spindler et al. 2007), and ecstasy use from 18.5% to 36.7% (Greenwood et al. 2001; Mansergh et al. 2001).

Existing literature highlights the intertwined relationship between stimulant use and sex for MSM. Stimulants are thought to amplify sexual desire and pleasure, decrease sexual inhibition, and enhance sexual endurance. Research demonstrates that for many MSM, sex either “always” or “often” accompanies stimulants. Stimulant use may also involve protracted periods of sexual activity and group sex. MSM who use stimulants are known to engage in high-risk sexual practices, including unprotected anal sex. The physical and psychological effects of the drugs can result in an impaired ability or desire to use condoms, high numbers of sex partners, as well as instances of condom breakage and slippage due to incorrect use and prolonged sexual encounters. Consuming certain stimulants has been shown to double or triple the probability of engaging in high-risk sexual behaviors among MSM (Colfax and Shoptaw 2005; Vu et al. 2015; Mayer et al. 2006).

HIV Infection Among MSM Who Use Stimulants in the USA

Stimulants are highly associated with the acquisition and transmission of HIV and other sexually transmitted infections (STI) among MSM. For instance, a 2015 meta-analysis found that MSM who use amphetamine and/or crystal meth were 1.70 times more likely to be infected with HIV than non-using MSM (Vu et al. 2015). The prevalence of HIV among MSM who use stimulants in the USA has been reported to be as high as 60.0% across epidemiologic studies (Strathdee and Stockman 2010). While overall HIV survival rates have significantly improved over the last two decades, studies have shown that MSM living with HIV who use stimulants experience difficulties with antiretroviral therapy (ART) access and adherence. Stimulants have also been shown to accelerate HIV disease progression independently of adherence to ART. Additionally, immunological failure, increased plasma viral load, and a heightened risk of mortality are associated with stimulant use among MSM living with HIV. The additive effect of increased plasma viral load, the direct physiological effect of stimulants, and increased sexual and drug use risk behaviors significantly potentiates the risk for HIV transmission to sex partners.

Stimulant Treatment Interventions

Treating MSM who use stimulants, especially in the context of sexual risk behaviors, is recognized as a powerful means of preventing both HIV spread and promoting favorable HIV treatment outcomes. The field of stimulant use treatment has made strides in the past decade due to the development and testing of behavioral and pharmacological interventions. However, existing treatment options have proven to be, at best, only moderately effective and there is an insufficient number of randomized controlled trials (RCTs) to support one intervention over another. Below is a summary of the current literature on the development and testing of some of the most promising treatment approaches.

Behavioral Approaches to Stimulant Treatment

At present, behavioral and cognitive interventions are the mainstay of stimulant treatment. Prominent among these approaches is contingency management (CM), a therapeutic technique that is based on the principles of operant condition to encourage specific behavioral goals. In the case of stimulant use, CM involves the delivery of vouchers that are exchangeable for money or commodities. Vouchers are contingent on negative toxicology screens that indicate abstinence from stimulant use. A 2014 meta-analysis of several CM trials to reduce stimulant use found an overall effect size of 0.46. This suggests that CM has a moderately meaningful impact on stimulant use (Benishek et al. 2014). Unfortunately, the treatment gains garnered by CM have not proved sustainable in the long term. The same meta-analysis documented a decrease in effect size from the completion of treatment to the 6-month follow-up. Furthermore, meta-analyses such as these provide limited insight into the efficaciousness of CM with MSM and other key populations for HIV infection due to the small number trials conducted among these groups.

Cognitive behavioral therapy (CBT) is a therapeutic technique that addresses cognitive distortions through a problem-solving based process involving cycles of clinician and patient interaction. CBT provides skills that are valuable in assisting people to stop using drugs and prevent relapse. CBT has been moderately successful at reducing the use of crack-cocaine, crystal meth, and amphetamines (Vocci and Montoya 2009). Among MSM who use crystal meth, CBT interventions have been shown to reduce incidence of receptive unprotected anal intercourse (Shoptaw et al. 2005). While there is a growing body of evidence supporting CM as the more effective treatment option, CBT has been shown to be equally as effective at sustaining treatment effects in the post-discharge period. Studies combining CBT and CM in the treatment of crack-cocaine and crystal meth among MSM and other populations have yielded strong effect sizes as a whole but there is a lack of evidence to support abstinence and maintained sexual risk reduction

gains in the post-treatment period. On the positive side, adding CM to CBT protocols has been shown to improve rates of attrition, suggesting that the integration of these approaches may enhance over all treatment efficiency (Vocci and Montoya 2009).

Behavioral activation (BA) is a front-line, evidence-based treatment for depression and anxiety. BA is intended to provide people who use stimulants with the necessary tools to reengage in positive reinforcement behaviors allowing for gradual increases in potentially rewarding and pleasurable activities that do not involve drug use. While BA interventions to reduce stimulant use among MSM have yet to be tested in a RCT, results from small open pilot trials are encouraging. For instance, Mimiaga and colleagues piloted an intervention for crystal meth use among high-risk sex in MSM in the USA. The intervention included 10 weekly sessions of BA with integrated HIV risk reduction counseling. The mean unprotected anal intercourse episodes decreased significantly from baseline to end of treatment and from baseline to 6 months post-baseline. On average, there was a significant decrease over time in the number of self-reported crystal meth episodes in the prior 3 months and the number of days that crystal meth was used in the prior month. Statistically significant reductions in depressive symptoms and poly-substance use were also maintained (Mimiaga et al. 2012a).

The rationale for using BA in conjunction with CM is supported by formative research which found that MSM continue to engage in crystal meth use as a means to seek out pleasurable experiences because without the drug activities that used to be pleasurable were no longer fulfilling (Mimiaga et al. 2008). In 2012, an open pilot of a BA/CM intervention was conducted among MSM and heterosexual men and women living with HIV who used crystal meth and/or crack-cocaine in the USA. The intervention combined 12 weeks of CM and 10–16 sessions of BA. Reductions in stimulant use (as indicated by negative saliva toxicology screens) and improvements in self-reported ART adherence and engagement with HIV care were observed from baseline to 6 months post-baseline (Mimiaga et al. 2012b). Due to the

small sample sizes and open study designs, further efficacy testing of both the BA and BA/CM interventions is required.

Pharmacologic Options for Stimulant Treatment

An increased focus on the neurobiology of substance use over the past 20 years has contributed to a growth in research on pharmacotherapies to increase stimulant abstinence. There is a solid evidence base suggesting that pharmacotherapies can be developed by altering the pharmacokinetics and pharmacodynamics of stimulants or its effects on the brain. Yet, determining optimal pharmacological targets has been difficult. As with behavioral interventions, no single pharmacotherapy has been found to be broadly effective in clinical trials. Novel methodological approaches will make the process of drug discovery more predictable and efficient (Brensilver et al. 2013; Kampman 2005).

Numerous classes of medication have been studied, mainly in small clinical trials. Medications presumed to have potential for stimulant treatment target dopaminergic, serotonergic, glutamatergic, and opioidergic brain pathways. In addition, medications that enhance cognitive process such as modafinil have gained attention in light of the known cognitive deficits associated with long-term stimulant use (Brensilver et al. 2013; Kampman 2005). In the treatment of crystal meth and amphetamines, promising research has been reported for methylphenidate, naltrexone, bupropion, and mirtazapine. RCTs of these pharmacotherapies have documented higher percentages of stimulant-free urine samples and rates of continuous abstinence as compared to the placebo in subgroups of patients (Brensilver et al. 2013). For crack-cocaine use, disulfiram (also known as antabuse), an established medication for treating alcohol dependence, is one of the most promising treatment candidates to emerge (Kampman 2005). There are now more than 10 published trials showing that disulfiram reduces cocaine use in cocaine-dependent patients.

In recognizing the need for novel treatment and delivery approaches, recent research has focused on the development of “anti-addiction” vaccines

that block the pharmacological effects of cocaine (Kosten et al. 2014a). A trial of a vaccine being developed for the treatment of cocaine use in the USA showed that cocaine-dependent adults who received a high dose of the vaccine produced the most cocaine-free urine samples and had better retention rates than those in the control and low dose study arms. However, differences between the three study arms were found to be insignificant (Kosten et al. 2014b). Further investigations of innovative pharmacological options such as vaccines are necessary, as these approaches may be particularly useful for individuals who engage in activities (e.g., stimulant use) that are barriers to medication adherence and engagement in care.

Settings for Stimulant Use Treatment and HIV Prevention Counseling

Given the interconnections between stimulant use and HIV risk among MSM in the USA, there is a need for further integration of substance use treatment with HIV prevention in places where MSM seek care, including substance use treatment facilities, clinics, and tertiary care centers. The reduction or cessation of substance use is the principal concern of most inpatient programs; however, individuals receiving inpatient treatment may experience co-occurring problems (e.g., depression) that remain unaddressed and may increase HIV risk. Such risk behaviors not only complicate their recovery process but also have broad public health significance with respect to rates of infectious disease transmission. Moreover, at specialized settings serving MSM, a lack of effective treatments for stimulant use and difficulties implementing traditional HIV prevention modalities within the context of stimulant use are a significant barrier to addressing these concomitant health concerns.

Conclusion

By reducing stimulant use, impacts can be made on individual risk behaviors and HIV-related outcomes, subsequently reducing HIV transmission rates vulnerable subpopulations such as MSM. For

MSM who use stimulants in the context of sex, treatment for stimulant abuse and dependence is an essential part of primary and secondary HIV prevention. For MSM accessing HIV care and prevention services, behavioral interventions that address stimulant use in the context of sex will support service engagement, treatment adherence, and safe sex. If recent successes in the treatment of opiate addiction into HIV care clinics are any indication, the integration of pharmacologic options for stimulant use into these settings will likely be beneficial – in terms of promoting retention, reducing sexual risk, and improving health outcomes among MSM.

During the last decade researchers have made strides in identifying and testing pharmacotherapies to treat stimulant use. However, as behavioral treatments are currently the corner stone of stimulant use treatment, pharmacological options should be considered an adjunct rather than a replacement for behavioral approaches. If medications can decrease the cravings and neuropsychiatric effects of stimulant withdrawal, individuals will be better able to engage in behavioral interventions. Over time, these combined modalities may help to sustain treatment gains.

The future of HIV-related behavioral interventions for MSM who use stimulants should include comprehensive programs that provide treatment for mental health problems – with and without pharmacotherapy – along with the use of other evidence-based biomedical and behavioral techniques to decrease HIV risk behaviors. To this end, further research is needed to pilot, test, and refine novel behavioral approaches and pharmacological treatments to establish the best methods for addressing stimulant use in the context of HIV prevention among MSM.

HIV Prevention in Persons 50 and Older

Tonya N. Taylor¹ and Stephen Karpiak²

¹College of Medicine/Special Treatment and Research (STAR) Program, SUNY Downstate Medical Center, Brooklyn, NY, USA

²ACRIA Center on HIV and Aging, AIDS Community Research Initiative of America (ACRIA) and New York University College of Nursing, New York, NY, USA

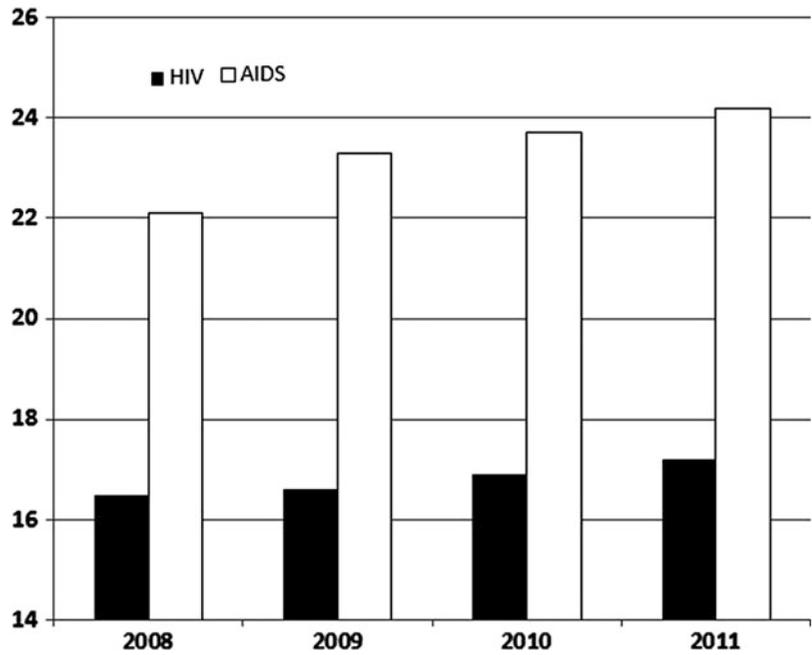

Definition

Primary and secondary HIV prevention efforts targeted to HIV-positive and HIV-negative persons 50 years and older.

The CDC estimates that in the United States, 50% of all people living with HIV (PLWH) will be 50 years and older by 2015 (CDC 2008). Part of this phenomenon, often called the “graying of the epidemic” is primarily driven by the effectiveness of HIV antiretroviral therapy (ART), as well as new HIV infections among older adults (defined as persons 50 and older) (see Fig. 1). For 2010, the CDC reports that 17% of all new HIV diagnoses occurred in people aged 50 and older and 24% of all AIDS diagnoses occurred in this older adult population (CDC 2013; see Fig. 2).

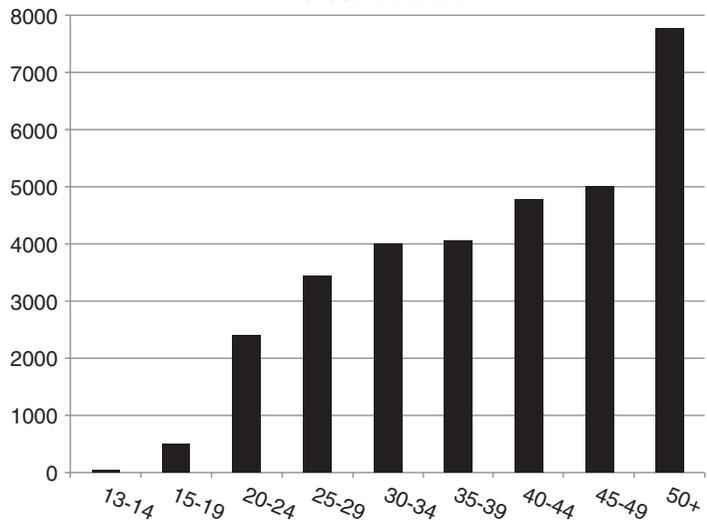

In the beginning of the US epidemic, persons 50 years and older acquired HIV primarily through blood transfusion and most died before the advent of ART. Today, the modes of HIV transmission among older adults, similar to their younger counterparts, occur mostly through sexual contact and injecting drug use (IDU). The groups of older adults most at risk and affected by HIV are men who have sex with men (MSM), women, and injecting drug users. In 2011, 60% of new HIV diagnoses were among MSM, 23% were due to heterosexual contact, 27% were women, and 14% were due to IDU (CDC 2013).

HIV Prevention in Persons 50 and Older, Fig. 1 % of total US new HIV infections for adults aged 50 and older (CDC Surveillance Report 2013)

HIV Prevention in Persons 50 and Older, Fig. 2 US AIDS diagnoses by age for 2010 (CDC 2012)

Number of Newly Diagnosed AIDS Cases by Age in the US 2011
CDC Surveillance Data

Older MSM, more than any other group, who have aged with constant exposure to myriads of HIV prevention messages, represent the majority of new HIV infections over the age of 50 (CDC 2013). In the second decade of the US epidemic, the rate of HIV infection among women ages 50–59 rose by 56%, doubled among women aged 60–65, and tripled among

women over 65 (Collier 2012). These groups are comprised of racial and ethnic minorities. Between 2007 and 2010, older Blacks and Latinos, respectively, had 13 times and 5 times higher rates of HIV infection than older Whites (Linley et al. 2012). In 2010, 46% of the men and women aged 50 years and older were Black, 36% were White, and 16% were Latino (CDC

2013). Racial disparities are particularly pronounced among women: 63% of all women aged 50 years and older living with HIV were Black compared to 18% Latina and 16% White (CDC 2013).

The sexual behaviors of older adults most at risk for HIV infection as well as those living with HIV have not been adequately researched. Few valid HIV prevention interventions have been developed (Negin et al. 2014). This neglect is premised in part on assumptions that older people do not engage in sexual activity and/or HIV risk behaviors. Yet some studies consistently show that older adults with HIV, like their HIV-negative peers, are sexually active and engage in unprotected sex and substance use (illicit drugs, alcohol, and tobacco) (Golub et al. 2010; Lovejoy et al. 2008; Cooperman et al. 2007). Although older adults share similar risk factors with younger groups, there are differences that emerge. As part of the baby boomer generation, older adults at risk for HIV and older PLWH share different norms and values regarding sexual behavior and substance use. Compared to their younger counterparts, older adults get tested for HIV less frequently, have lower knowledge about HIV transmission, and are often less aware of how to protect themselves against HIV. They are also experiencing age-related physiological changes, declining sexual function, as well as long-term relationship changes that may increase vulnerability for HIV infection. There is a clear need for data-driven sexual risk reduction interventions or evidence-based social media prevention campaigns that target older adults. The following summary identifies the different prevention needs of older adults at risk of HIV and older PLWH.

Older Adults at Risk of HIV Infection

In the last 10 years, the rates of sexually transmitted infections (STIs) among 45- to 65-year-olds have nearly doubled and tripled (CDC 2004, 2010). Many attribute the rise of STIs among older adults to generational norms regarding condom use and age-related physiological and sexual

function changes. In one national study of sexuality and health among heterosexual older adults, 93% of those who were sexually active reported inconsistent condom use (Leigh et al. 1993). Another national survey of men and women over 50 years of age found that 14–17% reported penile-vaginal intercourse (PVI) and only 20–25% used condoms during their most recent PVI episode (Schick et al. 2010). Many older women and their partners may be less consistent with condom use because pregnancy is no longer a concern. Additionally, menopausal and postmenopausal women may be at increased risk for STIs and HIV because of physiological changes in the vaginal lining as it becomes thinner and dryer, making them more vulnerable to infection (CDC 2008). The use of erectile dysfunction medications by men has increased sexual activity and sexual risk taking, resulting in increased rates of STIs among the over-50 age group (Jean et al. 2010).

Certain psychological and interpersonal changes exacerbate many of these risk behaviors and reinforce vulnerability to HIV infection. These include changes in relationship status from being married to being separated, divorced, or widowed. Changing relationship factors among older adults, including deaths, children or family members moving away, and friends relocating as they retire, can result in diminished social support and increased mental health issues due to grief, isolation, and concomitant loneliness. To compensate for these “losses,” older adults may use alcohol, tobacco, and/or drugs, further compromising their health and ability to sustain safer sex practices. Interpersonal changes may lead to new intimate relationships, which can lead to increased sexual risk, especially when coupled with psychosocial challenges. One study found that for older women, the acquisition of new partners is accompanied by decreases in safer sex practices due to many older male partners’ difficulty using condoms (Rich 2001).

A barrier to HIV prevention for older adults at high risk for HIV infection is the well-documented observation that many health-care providers underestimate their risk for HIV and STIs (Lindau et al. 2007). HIV symptoms, or

AIDS-related opportunistic infections, are often overlooked among older adults because such symptoms may overlap with other age-related conditions. For example, HIV-related cognitive dysfunction is often misdiagnosed as Alzheimer's. Extreme weight loss and fatigue may be viewed as part of the typical aging process. Few providers encourage older adults to test for HIV and STIs. Consequently older adults are more likely to be diagnosed late in the course of HIV infection with many having progressed to AIDS. When HIV infections are detected late, many older adults develop AIDS within 12 months of their diagnosis, placing them at higher risk for morbidity and mortality (Linley et al. 2012).

Older Adults Living with HIV

Among sexually active older adults with HIV, studies find that between 33% and 42% report unprotected insertive intercourse (Golub et al. 2010; Illa et al. 2008; Aidala et al. 2006). Risk factors for unprotected sex among older adults with HIV include misconceptions about viral load and risk of HIV transmission, recent substance use, and poor psychological well-being (Golub et al. 2010; Karpiak et al. 2006). Evidence has shown that over time PLWH might abandon safer sex practices due to the belief that adherence to ART together with low or undetectable viral loads reduces the risk of transmitting HIV to zero (Sullivan et al. 2007). In the ROAH (Research on Older Adults with HIV) study, a cross-sectional survey of 1,000 older adults with HIV in New York City, 50% of older adults reported sexual activity and a third of sexually active individuals reported unprotected sex in the last 3 months, which was significantly associated with loneliness and recent substance use (Karpiak et al. 2006; Golub et al. 2010).

Depressive feelings and neediness are factors underlying risky sexual behavior. Studies consistently report associations between unprotected sex and negative affect such as depression and anxiety. These elevated levels of depression that are typically accompanied by loneliness, anxiety, and

chronic stress occur across gender, race/ethnicity, and sexual orientation in studies of older adults with HIV. Such data supports the contention that stress and mental health problems are often identified as significant determinants of risk behavior among HIV-positive older adults (Groves et al. 2010; Heckman et al. 2000; Kalichman et al. 2000a, b). In the older adult with HIV, high rates of depressive symptoms persist (Heckman et al. 2000; Asch et al. 2003; Berger-Greenstein et al. 2007; Junqueira et al. 2008; Hoerger et al. 2012; Saito et al. 2012; Bhat et al. 2013; Traeger et al. 2013; Vance 2013) with clinical depression being the most commonly observed mental health disorder in that population (Goodkin et al. 1996, 2003; Heckman et al. 2011; Relf et al. 2013). These rates are almost five times higher than the general New York City population (Havlik et al. 2011; Golub et al. 2010; Groves et al. 2010). Depression has been highly correlated with lack of engagement in care and poor adherence to ART medications, which causes HIV viral levels to rise, thereby increasing infectivity (Gonzalez et al. 2011).

Loneliness and recent substance use among ROAH participants were significantly associated with unprotected sex among sexually active older adults with HIV (Golub et al. 2010; Brennan et al. 2011). Substances most often used with sex were alcohol (32%), marijuana (20%), crack (17%), cocaine (15%), and poppers (11%). Those who report current use of alcohol or drugs were more sexually active (58%) compared to those who did not use substances (42%). Almost half (47%) of sexually active HIV older adults reported using alcohol or drugs during sex. Unprotected insertive sex occurred more frequently (40%) when alcohol or illicit drugs were used with sex (Karpiak et al. 2006; Brennan et al. 2009; Golub et al. 2010).

Prevention Challenges

Very few HIV prevention efforts are aimed at people over 50, and most social media and health promotion campaigns primarily use images of young adults, creating the false perception that

HIV Prevention in Persons 50 and Older, Fig. 3 Examples of HIV and older adults social media campaign in New York City developed by the AIDS Community Research Initiative of America (ACRIA)

older adults are not at risk (Negin et al. 2014). Age-appropriate social messaging campaigns are uncommon. One campaign: “Age is Not a Condom” has been developed and deployed in New York City bus shelters by the AIDS Community Research Initiative of America (ACRIA) in New York City for that past 4 years (2011–2014) (see Fig. 3). The *Older Adults and HIV Toolkit* developed by the government’s AoA (Administration on Aging) and the website of the National HIV/AIDS and Aging Awareness (NHAAA) day are other sustained prevention campaigns for older adults.

Programs are needed to increase HIV testing among older adults at risk for HIV infection. To increase older adults being tested for HIV, the CDC recently recommended that routine HIV testing in adults be extended up to 64 years of age (Branson et al. 2006). Making testing routine for older persons may initiate discussions about risk behavior between health-care providers and older patients. Few older adults report that they discuss their sexual health with their health-care provider (Abrass et al. 2012; Hughes 2011; Working Group for HIV and Aging Consensus Project 2012). Providers must be better trained to recognize and act (e.g., recommend testing) when an

older patient evidences clinical symptoms that are indicative of HIV infection and encourage those who are at elevated risk to have regular HIV tests.

There is growing evidence that among PLWHA, there exists prevention fatigue or complacency (Valdiserri 2004; Spire et al. 2008). This is manifested by a return to unsafe sexual behaviors based on the rationale that HIV is easily treated and akin to managing a chronic illness (Sullivan et al. 2007). The need to implement the recent CDC initiative (HIP – High Impact Prevention) must be extended to the older adults with HIV. The recent approval of the daily use of an antiretroviral (Truvada) for HIV prevention strategy is historic (CDC 2014), with some suggesting that there are parallels to the introduction of “the pill.” Providers and their older adult patients must familiarize themselves with this newest approved prevention option. The impact on the sexual health of older adults with and without HIV infection may be momentous. When combined with sustained connection to care and adherence to ARVs, we may begin to witness the beginning of the end of AIDS (CDC 2014). Older adults must be included in the HIP effort.

Primary and secondary HIV prevention for older PLWH and older adults at risk of HIV

should have as a goal reduced transmission risk. HIV prevention efforts have largely adopted a pathogenic perspective, identifying psychological factors that increase HIV risk behavior. There is a need to implement salutogenic models that engage health-promoting factors that are positive. Placing emphasis on positive psychological health factors may result in more sustained safer sex practices. This approach necessitates that health-care providers acknowledge the psychological resources of their clients, many of whom are long-term HIV survivors exhibiting a high level of resiliency (Halkitis et al. 2012). Prevention efforts should include addressing psychosocial and interpersonal factors that may undermine health and well-being as individuals get old. Psychological distress and poor mental health, weak social networks, and loneliness are especially frequent among older PLWH and are common determinants of sexual risk taking (Groves et al. 2010). For example, in secondary HIV prevention for PLWH, also known as *Prevention for Positives*, support should be provided to assist older PLWH in how best to disclose their HIV status to new sexual partners. Disclosure issues are one of the challenges created by pervasive and detrimental effects of AIDS-related stigma (Emlet 2006; Hult et al. 2012).

Ageism, HIV-related discrimination, and stigma create barriers to HIV prevention efforts. Older adults at risk of HIV infection may not be comfortable disclosing their sexual behaviors or substance use to others, thereby making it difficult for them to access prevention information and support. These barriers result in delayed testing, diagnosis, and treatment. HIV/AIDS-related stigma may be more severe among older persons, leading them to hide their diagnoses from family and friends and new sexual partners (CDC 2008). Failure to disclose HIV infection limits access to potential emotional and practical support and can result in self-imposed defensive social isolation that may also manifest itself in depression.

To address the aging needs of older PLWH and older adults at risk for HIV, some have suggested integrating the *Healthy Aging* model into HIV prevention. *Healthy Aging* programs focus on helping older adults develop and maintain optimal

physical, mental, spiritual, and social well-being so that they can remain active, connected, and engaged (CDC 2014; Hansen-Kyle 2005; Vance and Robinson 2004). Such integration may strip away the stigma of ageism and help older PLWH and older adults at risk for HIV to reduce risk, effectively by using available health services and by encouraging and supporting relationships.

Conclusion

The aging of the HIV epidemic has generated awareness that HIV risk behaviors are not exclusive to the young. Already over 20% of all new AIDS diagnoses occur in the 45 and older group, and 1 in every 6 new HIV diagnoses is in the over-50 population (see Fig. 2; CDC 2013).

Educating older adults, especially those in high incidence groups (MSM, women, IDU), about the risk of HIV and other STIs is necessary for HIV prevention. Additionally, it is critical to educate physicians and health-care providers to interact with their older adult populations, engage them in conversation about their sexual health, and encourage regular HIV and STI testing. Educating older adults and their care providers regarding HIV risk is a needed structural prevention intervention that will assuredly reduce new HIV infections as well as late detection of HIV and AIDS.

HIV Prevention in the Correctional System

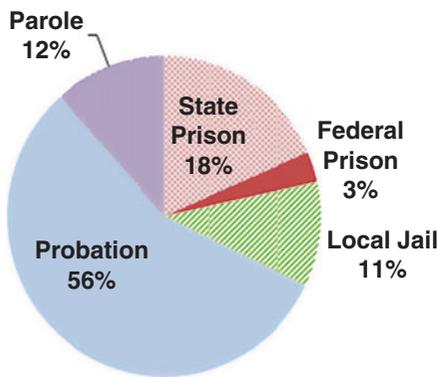

Shawnta L. Lloyd, Lauren C. Messina and Anne C. Spaulding
Department of Epidemiology, Rollins School of Public Health, Emory University, Atlanta, GA, USA

Definition

The Correctional System: Prisons Versus Jails

The criminal justice system has many components, and HIV prevention takes on different forms according to venue. All countries under the rule of law have a system for confining those who break laws. In the USA, the nation with the highest incarceration rate in the world, there are

divisions by status (convicted or awaiting trial, confined in a locked facility, or followed in the community) and age (adult versus juvenile). Prisons incarcerate adults convicted of felony offenses, which result in sentences for at least a year up to life. Those serving time for breaking federal laws go to a prison run by the Federal Bureau of Prisons; most felony convictions are for state offenses, punished by serving in a state-run prison. Jail systems, operated by counties or cities, hold individuals who are awaiting trial or have been convicted of a misdemeanor. The median length of stay in a jail is 2–5 days; the mean is a couple of weeks. It is rare that a person stays in jail for more than a year, but legal preparation for a complicated trial may prolong pretrial detention. The number of persons confined inside a locked facility is dwarfed by those under community supervision, by either the probation or parole systems. For the relative proportions of the various components of the adult US criminal justice system, see Fig. 1; the number of juveniles held in confinement on a given day is considerably smaller than the number of adults. In other countries, the relative size of the various components can differ. For example, if a court system processes people slowly, a higher proportion of persons will be detained awaiting trial. Also, not all countries separate the awaiting trial from the sentenced.

HIV Prevention in the Correctional System, Fig. 1 US Correctional populations, 2011 (Source: Bureau of Justice Statistics, Publication NCJ239972)

Fundamentals of HIV in the Correctional System

The USA has both the highest incarceration rate in the world and the greatest number of persons confined (International Centre for Prisons Studies 2012), accounting for approximately 2.2 million Americans serving time behind bars in jails and prisons on any given day (Glaze and Parks 2012). In 2006, one in six persons (16.9%) in the USA infected with HIV was incarcerated at some point over the course of the year (Spaulding et al. 2009). Incarcerated individuals are three times more likely to be living with HIV disease at all stages, including AIDS, compared to the general adult population (Maruschak 2012). This concentration of the HIV epidemic in jails and prisons has at least two explanations. By disproportionately incarcerating men over women and Blacks over non-Blacks, the criminal justice system draws from portions of the population with the highest rates of HIV (see Table 1). Social factors epidemiologically associated with high HIV risk include poverty and homelessness (Braithwaite and Arriola 2003); these demographic factors are also overrepresented in the correctional system. Additionally, some of the risk behavior that puts an individual at higher risk of HIV (e.g., intravenous drug use, commercial sex work) is illegal, thus putting persons engaging in these activities at higher risk of confinement.

Most incarcerated men and women who are infected with HIV acquire their infection while in the community, before entering a correctional facility (Centers for Disease Control and Prevention 2009, Braithwaite and Arriola 2003). High-

HIV Prevention in the Correctional System, Table 1 Disproportionate share of men and minorities confined in the USA, 2009

Characteristic	US general population (%)	Prison/jail population (%)	Americans living with HIV (%)
Male sex	50%	91	75
Black race	14%	39	46
Hispanic ethnicity	16%	21	17

Sources: West (2010), Centers for Disease Control and Prevention (2012)

risk behaviors such as unprotected sexual encounters are not infrequent among persons who subsequently enter a correctional facility. Among newly diagnosed HIV-positive jail detainees, 29% admitted to participating in unprotected anal sex in the 30 days prior to incarceration (de Voux et al. 2012). Furthermore, a high prevalence of sexually transmitted diseases (STDs) has been found among inmates, placing them at an increased risk for HIV transmission and acquisition (US Department of Health and Human Services 2011).

Drug and alcohol use is common among persons who enter correctional facilities (Braithwaite and Arriola 2003). Injection drug use can directly lead to both HIV infection and incarceration; injection drug users represented 11% of new HIV-positive cases among a group of jail detainees (de Voux et al. 2012). Substance abuse besides injection drug use can lead to behavior disinhibition which promotes high-risk activity, making users of cocaine and methamphetamine through other routes than intravenous, as well as abusers of alcohol also vulnerable to HIV infection.

Special Considerations for Jails

While not commonly conducted, HIV testing and linkage to medical care and treatment is feasible in the fast-paced environment of jails. In 2003, the states of Florida, Louisiana, New York, and Wisconsin received funding from the CDC to conduct HIV testing in jails. These four programs successfully performed 33,211 tests and identified 269 new HIV cases. With the use of rapid HIV testing, 99.9% inmates received their test results before discharge from jail. Among those with reactive rapid HIV tests, many reported no risk behavior that was considered high risk, such as including injection drug use, male-to-male sex, transactional sex, sexual assault, STDs, or sex with an at-risk partner. Therefore, new cases may be missed if inmates were only offered testing based on risk behaviors; these testing programs demonstrated that jail-based testing should be offered as universal opt-out testing.

A total of 440 known and newly diagnosed HIV-positive inmates with a reactive rapid HIV test were referred to medical care, treatment, and prevention services (Macgowan et al. 2009), demonstrating that jails provide a setting to offer HIV testing and treatment, if necessary, to thousands of persons daily.

The median length of stay in many jails is 48 h or less (Spaulding et al. 2012). In a jail setting, inmates may be released soon after being diagnosed as HIV positive; therefore, inmates may not have the opportunity to receive a pretreatment evaluation and begin antiretroviral treatment in jail. Considering the short length of stay for most jail inmates, few persons newly diagnosed in this setting would begin costly treatment before release (de Voux et al. 2012).

For newly diagnosed cases with a longer length of stay, pretreatment evaluation can be completed. Community-based medical care can be offered to those with a short length of stay to ensure treatment begins. Occasionally, the stay is long enough to commence highly active antiretroviral treatment (HAART). Linkage to HIV medical care and treatment in the community is critical to ensure that these HIV-positive individuals begin or continue to adhere to treatment after release (see “[Linkage to Medical Care after Release](#)”).

For those individuals who have been involved in medical care and treatment prior to entering jail, the detainment may be long enough to break appointments and interrupt therapy. Jails need a protocol to continue treating patients who report taking a reasonable HAART regimen prior to confirmation with outside providers.

Special Considerations for Prisons

HIV-positive persons incarcerated in prisons have sentences longer than a year, providing adequate time to conduct testing, deliver results, and start HAART. Incarceration can be an opportunity for prisoners to receive quality healthcare from medical staff and to adhere to medical treatment in a controlled environment. Sustaining HIV treatment allows HIV-infected individuals to achieve undetectable viral loads, which can greatly

decrease the risk of HIV transmission to sexual or drug injection partners. An increased CD4+ count in a HIV-infected person allows preservation of the immune system to help the infected person avoid life-threatening medical conditions. When inmates are provided with adequate care, health outcomes can be comparable to those in the community setting. The Bureau of Justice Statistics found that between AIDS-related deaths in state prisons decreased from 24 deaths per 100,000 inmates in 2001 to 5 per 100,000 in 2010 (Maruschak 2012). This massive decrease in correctional AIDS-related deaths parallels the decrease in HIV-/AIDS-related deaths nationwide.

Due to the variation of healthcare services currently offered in correctional facilities, health outcomes vary from facility to facility. A study completed in Texas found that approximately half of HIV-infected inmates receive HAART during imprisonment (Baillargeon et al. 2009). Inmates have the right to refuse treatment and may do so for reasons such as stigma associated with HIV, adverse side effects, or poor prognosis.

Prevention of HIV by Testing

Why is Screening Warranted?

Since nearly 16.9% of Americans infected with HIV pass through correctional facilities annually (Spaulding et al. 2009), jails and prisons are logical venues for testing. In the general US population nationwide, approximately 18% of HIV-positive persons are unaware of their infection (Centers for Disease Control and Prevention 2012). There is no evidence that the ratio of diagnosed to undiagnosed infection is any better in the correctional setting. Thus, HIV testing of asymptomatic persons in a correctional setting has the ability to identify cases that may otherwise go undiagnosed and untreated.

Just as HIV testing is an HIV prevention strategy in the outside community, HIV diagnosis may help prevent further HIV transmission in jails and prisons. After learning their status, HIV-positive persons tend to decrease risk behavior such as unsafe sex; the prevalence of unprotected anal

and vaginal intercourse can drop by more than fifty percent after HIV diagnosis (Marks et al. 2005). The same phenomenon has been observed among inmates who tested HIV positive during incarceration; receipt of an HIV diagnosis is associated with lower rates of anal intercourse among male inmates (Jafa et al. 2009). Furthermore, HIV diagnosis improves the health of the inmate, by allowing the inmate to access necessary medications. Early access to HAART prolongs the lives of those diagnosed with HIV infection and reduces the likelihood of transmission. Additionally, HIV testing in correctional facilities, either during or after entry, not only benefits those incarcerated but also those in the community as well. Partner services conducted by the local health department (Altice et al. 2010) may be able to locate former sexual and injecting drug partners of incarcerated HIV-positive individuals, allowing those in the community to seek testing; if positive, these individuals can obtain clinical care and HIV/AIDS education. For serodiscordant couples, vigilance with HAART on the part of the infected person can lower the risk of transmission to the uninfected one. Thus, testing is an opportunity to decrease the transmission of HIV/AIDS and to increase HIV/AIDS knowledge in the community, extending the potential benefits of HIV testing in the correctional system.

Without routine testing, undiagnosed HIV-positive individuals will continue to remain untreated and engage in riskier behaviors, increasing the risk of transmitting the virus. Routine opt-out testing has the ability to normalize HIV management in correctional facilities and communities, reducing the stigma and fear associated with HIV testing and treatment if testing reveals a positive result.

Testing Procedures in the Correctional System

The Centers for Disease Control and Prevention (CDC) published the *HIV Testing Implementation Guidance for Correctional Settings* in 2009. The CDC recommends the adoption of a universal, routine, opt-out testing approach to improve HIV detection among the incarcerated population. This approach includes incorporating consent for HIV screening into the general consent form for

medical services within the institution and HIV testing all inmates unless an inmate refuses. Inmates should be given information about HIV/AIDS before testing occurs, and the decision to test must be noncoercive (Centers for Disease Control and Prevention 2009). Although HIV/AIDS diagnosis in the correctional system has its benefits, some inmates may delay or refuse HIV/AIDS related services in correctional facilities for reasons such as mistrust of staff and/or fear of discrimination from peers.

Despite CDC recommendations, in many prisons and most jails, HIV testing is provided only upon request. In a harsh environment such as a correctional facility, inmates may not feel comfortable stepping forward and requesting an HIV test during an opt-in entrance screening program. Inmates may feel less threatened about submitting to testing when collecting specimens is a routine practice (Centers for Disease Control and Prevention 2009).

Universal opt-out testing at entry may not be perceived as an option in some facilities when budgets are tight or where custody staff are unable to provide security services for a prolonged medical encounter in the intake area. Alternatives to the optimal approach of universal testing by nursing at entry include screening during subsequent medical encounters or risk-based screening. Risk-based screening constitutes targeting HIV testing to inmates who have the highest-risk characteristics (injection drug use, men who have sex with men, sex with an at-risk partner, transactional sex, multiple sex/drug partners, and STDs) within the last 12 months. These approaches allow correctional facilities to test those individuals that may be at the highest risk of HIV infections; however, these methods may preclude the testing of most infected individuals. Studies of jail detainees newly diagnosed with HIV reveal that the plurality had no risk for HIV acquisition other than heterosexual sexual relations (Macgowan et al. 2009). Thus, limiting HIV screening to those who report injection drug use or men who have sex with men is less effective in identifying HIV cases compared to universal testing. Partnerships with local health departments and/or community-based organizations can aid in carrying out HIV

testing and counseling in correctional facilities where further resources are needed.

As of late 2012, most long-term correctional facilities use HIV enzyme immunoassay (EIA) in HIV screening; any positive HIV screening test is followed by a second, confirmatory test using a Western blot assay (Centers for Disease Control and Prevention 2009), though the algorithm for confirming positive tests may be changing in the near future. This traditional HIV testing requires venipuncture, so a fear of needles may be a barrier to testing. Additionally, this testing also requires that the specimen is processed in an external laboratory; results can take several days to be returned to the staff of the correctional facility. Inmates who are detained for only a short stay might not receive their test results. However, this screening strategy may be a practical, low-cost option for inmates with a longer length of stay such as those found in prisons (see *Prisons*).

In correctional facilities with rapid population turnover such as jails, newer rapid HIV tests, although more expensive than traditional tests, can offer the advantages of quicker turnaround compared to screening with EIA and Western blot (see *Jails*). Rapid testing is performed either by swabbing the oral mucosa or sticking the finger; results of these tests are available in as little as 10–30 minutes, a period of time that fits with the hectic pace of a jail (Altice et al. 2010). The medical staff can quickly inform inmates of a preliminary result shortly after the testing, rather than bringing the person back to the healthcare setting at a later time, in a situation where every movement of persons uses the resources of correctional officers. Preliminary positive results from rapid testing require confirmatory testing with conventional assays.

Treatment in Correctional Facilities

Principles of treatment for a person newly diagnosed with HIV in correctional setting should mirror those in the general community. For example, the first step to treatment is HIV education to ensure that the inmate is aware of necessary lifestyle changes and the importance of adherence to

treatment (US Department of Health and Human Services 2011). Before initiating antiviral medications, untreated infected persons need genotype testing to assess for viral resistance; some jail physicians have mistakenly started persons on medications prior to genotype testing in a rush to initiate medications before discharge. HIV-infected persons may need to be referred to an HIV specialist depending on the complexity of the inmate's medical issues and the primary care physician's familiarity with HIV management. Many inmates suffer from comorbidities such as mental illness, viral hepatitis, tuberculosis, and STDs. Medical staff in some correctional facilities may lack HIV specialists or persons with adequate HIV experience and education; these facilities can develop links to HIV specialists in the community and contract with providers to provide the necessary consultative care (Centers for Disease Control and Prevention 2009). Medical staff in the correctional facility who learn that an inmate has HIV and has been prescribed antiretroviral medication prior to incarceration should continue or resume treatments with assistance from the previous provider and medical records.

The two methods of administering HIV medications in facilities include directly observed therapy (DOT) and keep-on-person (KOP) therapy. The DOT system involves nurses administering medications in pill lines or by visiting cells; patients are known to have better adherence using this system, but an inmate may fear the loss of confidentiality. Conversely, KOP therapy requires an inmate to be responsible for taking his/her own medication on schedule. This method can aid in the adherence of HIV treatment after release, though as the infected person is not monitored by the medical staff, adherence to medical treatment while incarcerated will be unknown.

There are many aspects of HIV treatment in correctional facilities that can lead to breaches in confidentiality. For example, other inmates may learn of a positive HIV status if the number of pills fellow inmates receive is observed or if only HIV-infected inmates are receiving a medication with special handling, such as refrigeration. Most correctional facilities have abandoned the prior and unnecessary practice of segregating those

with HIV, but when selected inmates are called to the infirmary on the days the HIV specialist visit, an HIV diagnosis may be disclosed. It is important for facilities to create methods to guarantee inmates' medical privacy during HIV treatment delivery. In a setting where HIV may be stigmatized and the risks of violent acts are high, inmates may not feel safe while disclosing and receiving medical care from the medical staff. Trust between the staff and inmates is vital to encourage the treatment of HIV and to persuade HIV-positive inmates to initiate and adhere to the recommended treatments during their sentence and when released back into the community (Centers for Disease Control and Prevention 2009). Ultimately, the medical staff and the custody staff must work as a team to keep safe inmates being tested and treated for HIV.

Primary HIV Prevention in the Correctional System

More risk behaviors for HIV transmission such as substance abuse and unprotected sex takes place in the community than during incarceration (Braithwaite and Arriola 2003); however, the potential to transmit HIV and other infectious agents to others during incarceration exists. High-risk behaviors associated with HIV are present in correctional facilities, even though sexual activity and drug use are banned. A study completed in Georgia found 67 new cases of HIV during incarceration among inmates who tested negative at prison-entry HIV testing (Jafa et al. 2009). Precise data on HIV incidence and methods of transmission are not known. The incidence of HIV likely varies by facility.

Prevention programs for HIV in correctional facilities have met with controversy in some jurisdictions. Even providing education about HIV can face resistance among jail and prison staff. To decrease the concern that some curricula may contradict the rules and policies of the correctional system, such as using condoms for sex, educational messages to reduce HIV transmission may be presented in a way as it applies to hypothetical situations "once released from a correctional

facility.” In this way, correctional staff would not have to deviate from the rules in their facilities, and inmates would still have the opportunity to learn how to protect themselves and sexual and/or drug injection partners from HIV transmission (Braithwaite and Arriola 2003). Demonstration programs have shown that inmates and staff of jails and prisons can be reached with HIV education programs successfully. Education received in correctional facilities can benefit inmates during incarceration and in the community, upon release.

In 2006, the World Health Organization and the Joint United Nations Programme on HIV/AIDS published *HIV/AIDS Prevention, Care Treatment and Support in Prison Settings*, which strongly recommends the use of harm reduction strategies such as the distribution of clean needles and syringes or diluted bleach, along with instructions for cleaning injection equipment to reduce HIV transmission during drug injection, tattooing, or skin piercing, and condoms in correctional facilities (The World Health Organization and The Joint United Nations Programme on HIV/AIDS 2006). These prevention programs are not been politically feasible in the USA, despite the potential benefits to the population. Permitting condoms and syringes acknowledges that banned risk behaviors continue to take place despite official proscription. Condoms are available in state prisons in only Vermont and Mississippi and in jails in five cities (New York City, Philadelphia, San Francisco, Los Angeles, and Washington DC). Implementing strategies to reduce harm associated with injection drug use behind bars has largely occurred only outside of the USA.

Linkage to Medical Care After Release

Over nine million individuals are released from confinement to the community each year. Over 150,000 of these releasees have HIV. Medical services offered during incarceration may be the individual’s first link to primary and mental healthcare, as well as HIV/AIDS care. However, former inmates may encounter a host of social and medical challenges upon release. In a population

with an exceedingly high number of substance abusers, relapse to drug use is common upon release; homelessness and poverty often burden releasees as well. It is common for incarcerated persons to return to poor communities with inadequate access to HIV medical care. Upon release, inmates must find a doctor, make and keep an appointment, and fill prescriptions. These tasks require money, transportation, and motivation. As there are a considerable number of obstacles immediately after release, adherence to HIV treatments may not be a high priority for many releasees while trying to gain stability in the community. Any improvements in an inmate’s health observed during incarceration may quickly diminish if adequate care and treatment is not continued. Poor adherence to HAART can lead to disease progression and emergence of drug-resistant viral HIV strains (US Department of Health and Human Services 2011).

Prerelease discharge planning allows inmates to develop a plan to access medical care and treatment upon reentry into the community. A study in the Texas prison system showed that assistance with completing an AIDS Drug Assistance Program application increased the percentage of releasees who filled a HAART prescription before running out of 10 days of medications given at release from 2.5% to 7.9% (Baillargeon et al. 2009). HIV case managers assist with discharge planning to link recent releasees to healthcare and resources to alleviate social burdens in the community. Comprehensive discharge planning involves making an appointment with a community care provider, education about the importance of adherence to medications, transfer of medical records, assistance with insurance applications, and linkage to community HIV case management services. Upon release, former inmates should be provided with an adequate supply of medication to avoid interruption in treatment until an initial appointment in the community (Centers for Disease Control and Prevention 2009).

Starting in 2006, the Rollins School of Public Health at Emory University and Abt Associates, Inc., coordinated the evaluation of the Enhancing Linkages to HIV Primary Care and Services in Jail

Settings Initiative (EnhanceLink). This initiative successfully provided HIV testing in 20 US jails, resulting in 822 new diagnoses among 212,464 inmates (0.4%) who agreed to HIV testing. Services were provided to not only address linkage to medical care but also to address social needs upon release such as mental health and substance abuse treatment and linkage to housing. Transitional services were accepted by 82% of the HIV-positive persons in the program offered services (Spaulding et al. 2012). A substantial portion of these releasees linked to care were retained in care and were virally suppressed 6 months later; the study design permitted a cost analysis to demonstrate cost-effectiveness.

Conclusion

With a large proportion of HIV-positive individuals passing through jails and prisons in the USA, correctional health services have the opportunity to play an instrumental role in the diagnosis, clinical care, and linkage to services of HIV/AIDS patients. Improved HIV educational programs, HIV testing, and linkage to community care are needed to ensure that better health outcomes are observed in this population while incarcerated and after release to the community. The length of stay in a correctional facility determines what services can feasibly be delivered in correctional settings. Although several challenges are associated with HIV treatment and prevention in correctional facilities, demonstration projects have shown that public health involvement in jail and prison healthcare provides an opportunity to improve the lives of those who pass through the criminal justice system.

HIV Prevention in Transgender Persons

Jae Sevelius¹ and Mallory O. Johnson²

¹Department of Medicine, Center for AIDS Prevention Studies, Center of Excellence for Transgender Health, University of California, San Francisco, CA, USA

²Department of Medicine, Center for AIDS Prevention Studies, University of California, San Francisco, CA, USA

Definition

The term “transgender” applies to a range of diverse individuals whose sex, gender identity, and/or gender expression are not concordant with the sex they were assigned at birth. The term “transgender women” will be used here to refer to individuals who were assigned male at birth and identify as female (sometimes described as “male-to-female” or “MTF”), and the term “transgender men” will be used to refer to individuals who were assigned female at birth and identify as male (sometimes described as “female-to-male” or “FTM”). Some transgender people do not identify as male or female but have identities

that fall outside of the binary; they may identify as “genderqueer” or as a nontraditional gender.

Although HIV is a concern for transgender communities in general, extremely high rates of HIV have been documented among transgender women of color in particular. However, research demonstrating efficacious HIV prevention strategies for transgender populations has lagged, due in part to the complexities of research with this population. Transgender identity can be difficult to assess due to variations in terminology, defining and reaching this hidden population, and varying preferences among transgender people regarding the disclosure of their transgender status.

Data about transgender people are currently not collected on a national level in the United States; therefore, there is currently no accurate way to estimate the number of transgender people living in the United States. Due to limitations on how data are collected in public health settings, transgender people are usually either deleted from datasets or misclassified. For example, transgender women are routinely included in the risk group “men who have sex with men” (MSM). While the MSM data then include HIV rates among transgender women, the programs that are then funded based on these data are not inclusive of transgender women’s needs and concerns. HIV prevention research with this population has also faced barriers related to “syndemic dynamics” or numerous co-occurring and interrelated epidemics that influence HIV risk among transgender people, such as mental health issues, substance abuse, and victimization (Brennan et al. 2012; Operario and Nemoto 2010).

HIV Prevalence Among Transgender People

Although national-level data are not available, many regional studies have been conducted around the United States to estimate rates of HIV among transgender people, to document risk factors, and to determine HIV prevention needs and strategies. Most research has been conducted with transgender women as opposed to transgender

men, due to the disproportionately high risk for HIV among transgender women. A meta-analysis of 29 studies found that in the four studies that included HIV testing, 28% of transgender women tested positive for HIV (Herbst et al. 2008), with higher rates (56%) found among African-American transgender women. In the 18 studies that relied on self-report only, 12% of transgender women reported living with HIV. Less is known about rates of HIV among transgender men due to the paucity of studies focused on this population; rates that have been reported thus far range from 0% to 3% (Herbst et al. 2008).

Despite high rates of HIV among transgender women, multiple barriers to HIV testing exist for transgender populations, including low levels of knowledge, comfort, and skills among health and social service providers, lack of transgender-friendly testing sites, and a lack of transgender-specific HIV prevention programs providing education about risk and the importance of HIV testing (Sevelius et al. 2011).

Factors that Contribute to High Rates of HIV Among Transgender Women

Social and Structural Issues

Transphobia

The negativity that transgender people face in society is referred to as “transphobia” and is defined as the discrimination against or devaluation of someone due to their gender presentation and/or transgender identity. Many transgender people endure transphobia from a very young age, often emerging as conflict with their families and at school (Brennan et al. 2012). Young transgender women are especially vulnerable to harsh treatment in our society where effeminate men are often targets of ridicule and abuse. Subsequently, many young transgender people, especially young transgender women, drop out of school and live on the streets, leaving them with few job skills and the prioritization of basic survival (Sugano et al. 2006). Data suggest that young transgender women who experience more transphobia are also more likely to engage in behavior that put

them at high risk for HIV infection (Sugano et al. 2006).

Internalized Transphobia and Mental Health

Experiences of discrimination and victimization negatively impact mental health by increasing anxiety, depression, and suicidality (Clements-Nolle et al. 2001; De Santis 2009). Internalized transphobia occurs when transgender people incorporate society’s negative beliefs about being transgender into their own self-concept. Internalized transphobia may lead to low self-esteem and high levels of depression and anxiety (Melendez and Pinto 2007), which in turn can lead to (higher rates of) unprotected sex (De Santis 2009). Internalized transphobia may also contribute to transgender people seeking gender affirmation from sexual partners in ways that jeopardize their health (Melendez and Pinto 2007; Sevelius 2012). Transgender women have reported having unsafe sex to affirm their female gender identities, thereby decreasing sexual negotiation and communication (Nuttbrock et al. 2009). A new model that conceptualizes how the need for gender affirmation contributes to risk behavior may inform future research and interventions to address sexual risk due to the need for gender affirmation among transgender women and girls (Sevelius 2012).

Incarceration

Rejection from families of origin, being homeless or marginally housed, and experiencing unemployment are some primary reasons why transgender women may engage in survival activities, such as sex work. Sex work may lead to incarceration (Garofalo et al. 2006), which partially accounts for the overrepresentation of transgender women in prisons and jails. When released from custody, transgender women face continued employment and housing discrimination and often become caught in cycles of sex work, drug use, and incarceration (Operario and Nemoto 2010).

Like shelters, most prisons and jails in the United States sex-segregate prisoners according to genitalia, and many transgender women do not have access to genital surgery (even if they would choose it) due to the high costs of these

procedures. For this reason transgender women are usually housed with male inmates, which can lead to violence, sexual assault, and harassment while incarcerated, directly increasing their HIV risk (Grant et al. 2011). Transgender women often do not receive trans competent health care while incarcerated, and transgender inmates are often denied medically necessary hormone replacement therapy (Grant et al. 2011).

Behavioral Risk Factors

The severe stigma, discrimination, and violence that transgender women face underlie many of the HIV-related risk behaviors frequently reported in this population. Risk behaviors for transgender women include multiple sex partners, unprotected receptive anal intercourse, sex work, sex under the influence of alcohol and drugs, and unsafe needle use for injecting drugs and gender-related hormones or silicone (Brennan et al. 2012; Operario and Nemoto 2010). HIV risk behaviors among transgender women appear to be disparately distributed along racial and ethnic lines. In several studies, African-American and Hispanic transgender women reported greater risk behaviors compared with white and Asian and Pacific Islander transgender women (Herbst et al. 2008; Nuttbrock et al. 2009).

Despite high HIV prevalence rates, transgender women frequently underestimate their risk of acquiring or transmitting HIV (Herbst et al. 2008). The previously mentioned meta-analysis found that almost half (44%) of transgender women reported unprotected receptive anal intercourse, with the highest rates being reported with sex work clients (39%) and primary partners (37%) (Herbst et al. 2008). Sex under the influence of drugs and/or alcohol is one of the most commonly cited sexual risk factors among transgender women as it is often unprotected (Wilson et al. 2009).

While current rates of HIV among transgender men are lower compared with rates among transgender women, initial evidence suggests that some transgender men who have sex with non-transgender men may be at higher risk (Sevelius 2009). In addition, some transgender men engage in sex work and substance use,

although these rates are also significantly lower than those among transgender women (Clements-Nolle et al. 2001).

Sex Work

Experiences of employment and housing discrimination are common among transgender women and lead directly to the need to engage in survival sex work for many who are denied opportunities for education, job training, and basic social services due to their transgender identity and/or gender presentation (Brennan et al. 2012; Grant et al. 2011; Nuttbrock et al. 2009).

Sex work is common among transgender women, with reported rates of involvement ranging from 26 to 80% (Operario et al. 2008). Sex work may be perceived as the only means of survival, due to lack of other forms of social support, pervasive employment discrimination, and issues with legal documentation of gender identity. There may also be a generational effect in which older transgender women sometimes introduce younger women into sex work practices (Wilson et al. 2009). Young transgender women are often quickly introduced to the financial rewards of sex work as a means of survival, receiving much needed support from older transgender people and being validated in their chosen gender identity by both their colleagues and their clients (Brennan et al. 2012; Wilson et al. 2009). Young transgender women of color are particularly vulnerable.

The financial incentive to engage in sex work is especially high for transgender women who pursue gender confirmation procedures, such as taking hormones and undergoing surgeries (i.e., facial feminization, breast augmentation, and genital reconstruction), which are expensive and usually not covered by health insurance. The financial need created by expensive gender confirmation procedures may lead some transgender women to engage in particularly risky behaviors because sex work clients will sometimes pay more for barrier-free sex or to have women inject drugs with them.

Transgender women often report using substances to cope with sex work and other stressors associated with the stigma of being transgender,

thereby decreasing their desire for and self-efficacy to negotiate safer behaviors. In particular, sex work has been consistently linked with use of methamphetamines as a means of coping with the stress of sex work and maintaining stamina. Drug use can in turn increase sex workers' risk of acquiring HIV through needle sharing and sex under the influence of drugs. Indeed, it has been demonstrated that transgender female sex workers have higher rates of HIV than non-transgender male or female sex workers; a recent meta-analysis of studies examining HIV status of transgender female sex workers found that 28% were HIV-infected (Operario et al. 2008).

Substance Use

Substance abuse has been consistently linked to HIV risk among transgender people (Herbst et al. 2008). Among transgender women, unprotected sex under the influence of substances seems to be especially prevalent with primary partners, but is also reported with paying and casual partners (Melendez and Pinto 2007). In San Francisco, transgender people who reported injection drug use were almost three times more likely to be HIV positive than those who did not report injection drug use (Clements-Nolle et al. 2001).

Despite high rates of reported substance use and associated negative health outcomes, there are few recovery or detoxification programs that are perceived as safe for transgender women to access and designed to address trans-specific treatment needs. Few training programs prepare substance abuse treatment professionals by providing the necessary knowledge and skills to support transgender people in treatment. Often, when transgender people seek substance use treatment, they are forced to choose between expression of their gender identity or staying in treatment, disclosing or forgoing the use of hormones, and tolerating or combating gender-based harassment from staff and/or other residents. If transgender people find a treatment program willing to serve them, they are often housed according to birth sex and not according to their gender identity and expression. As a result of these negative experiences, many transgender people avoid treatment settings altogether. Anti-discrimination policies in

drug treatment settings, arranging appropriate accommodations, increasing the sensitivity of providers, and honoring the experiences, preferences, and self-expression of transgender people in treatment are all important ways to begin creating trans-inclusive substance abuse treatment programs.

Best Practices for HIV Prevention with Transgender Populations

It is vital that any HIV prevention efforts with transgender populations are grounded in the transgender community through partnerships, advisory boards, and opportunities for transgender people to contribute. By involving transgender people in shaping and promoting HIV prevention efforts, the acceptability and relevance of the programs is enhanced dramatically. Programs should acknowledge that transgender people of color are affected differentially by HIV, and prevention programs should address issues that are relevant to their local communities of color, when appropriate. Multicomponent interventions that address multiple co-occurring issues that influence HIV risk among transgender people are likely to be most effective (Operario and Nemoto 2010). Another important aspect of HIV prevention with transgender people is advocacy to identify and mitigate structural barriers, such as lack of access to safe housing, employment, addiction recovery services, and health care.

Based on the high proportion of undiagnosed HIV infection among those tested, transgender people represent an important community for enhanced HIV testing and prevention efforts. Yet, HIV prevention programs often do not adequately represent and reflect the lives and experience of transgender people. In addition, most HIV prevention programs that do prioritize transgender people tend to exclude transgender men. Many HIV prevention providers assume that transgender men only have sex with non-transgender women and are therefore at low risk for contracting HIV. Efforts should continue to develop novel strategies to overcome barriers and provide HIV testing and prevention services

to transgender people. Based upon current clinical findings and evidence pertaining to the frequency of HIV risk-related behaviors, transgender people should be encouraged to have an HIV test at least annually, or more often if indicated.

Conclusion

Public health intervention research has produced few culturally specific, evidence-based HIV prevention interventions for transgender people. Of the published interventions that have been implemented with transgender women, none have yet been controlled trials or were rigorously evaluated for efficacy or effectiveness. The Centers for Disease Control and Prevention has funded programs to adapt evidence-based interventions for transgender women, but these interventions were developed for other target populations and do not account for the unique cultural context of risk behaviors among transgender women. Given the complex sexual risk factors present among transgender populations, HIV prevention programs developed for other populations that are simply adapted to include new language will not ultimately address the cultural context in which risk behaviors occur and in which protective factors develop. HIV prevention interventions need to be based on the culture and context that most influence the lives of transgender people (Sevelius et al. 2011).

HIV Prevention in Youth

Felisa A. Gonzales, Ana María del Río González and María Cecilia Zea

Department of Psychology, The George Washington University, Washington, DC, USA

Definition

HIV prevention in youth refers to programmatic efforts that aim to prevent new HIV cases among individuals younger than 25 years of age. Youth between the ages of 15 and 24 account for a disproportionate amount of worldwide HIV incidence (United Nations Children's Fund (UNICEF) 2011). In order to halt the HIV epidemic, numerous interventions have been designed to prevent the transmission of HIV among youth. Evaluations of these interventions indicate that they are especially effective in changing young people's HIV-related knowledge, attitudes, and skills but less effective in generating behavioral change. A continuum of prevention that targets not only youth but also their sociocultural context (► [Multilevel Interventions/Structural Approaches to HIV Prevention](#)) throughout adolescence and early adulthood is necessary for the reduction of HIV incidence among this population.

Epidemiology of HIV Among Young People

In 2009, youth aged 15–24 accounted for 16% of the people living with HIV and 42% of new infections among all people aged 15 and older (Joint United Nations Programme on HIV/AIDS (UNAIDS) 2010). The characteristics of the HIV epidemic among youth vary greatly by country and area of the world. In developing and least-developed countries, HIV prevalence is over twice as high among young women as it is among young men. By contrast, in industrialized countries, prevalence is generally higher among young men (UNICEF 2011).

Modes of transmission also differ by region. In sub-Saharan Africa, heterosexual activity is the primary driver of the epidemic among young people. In Central and Eastern Europe, injecting drug users (IDUs) account for about 80% of all new infections (Interagency Youth Working Group 2008). In the Americas and western-European Countries, young men who have sex with men (YMSM) (► [HIV Prevention for MSM](#)) are particularly affected by the epidemic (UNICEF 2011). In the United States, for instance, nine of every ten HIV-positive young men become infected through male-to-male sexual contact (CDC 2012).

Developmental Considerations and HIV Risk

Adolescence refers to the transitional period between childhood and adulthood. Although the specific age ranges are not well established, it is generally agreed that adolescence starts with puberty and ends when the person becomes an independent adult. UNICEF divides the developmental period corresponding to adolescence into young adolescence (between ages 10 and 14), older adolescence (ages 15–19), and young adulthood (ages 20–24).

Because morbidity and mortality rates are generally lower during this period than during other life stages, adolescence has traditionally been seen as a healthy period of life. However, the physical, psychological, and social changes that occur at this age can place young people at increased risk for HIV. Prevention of HIV infection among youth requires an understanding of how the characteristics unique to this developmental stage may increase young people's risk for HIV infection. These include individual characteristics, such as physical and psychological changes; characteristics of the relationships with close others, like peers, parents, and partners; and characteristics of the broader social context, such as the legal system.

Individual characteristics. Early in adolescence, individuals undergo pubertal changes that result in the maturation of the sex organs. The

ability to produce sperm (spermarche) and ova (menarche) signals the young individual's potential for sexual reproduction. As these biological changes take place, the adolescent begins establishing his or her own identity or sense of self (Arnett 2010). Adolescence is a time of exploration that allows shifting identities across contexts and experimentation with new behaviors that may increase one's HIV risk.

Sexual activity and drug use usually occur for the first time during adolescence. However, both physiological as well as cognitive characteristics may increase the likelihood of experiencing negative outcomes from these experiences. For example, neuroscience research has provided evidence that the prefrontal cortex, which is associated with higher-level processing, self-regulation, and decision-making, is not fully developed until young adulthood (Arnett 2010). As a result, many youth start using drugs or become sexually active before their ability to evaluate the long-term consequences of their behavior is fully developed.

In terms of cognitive development, adolescence is characterized by egocentric thinking or the belief that one is unique and thus not susceptible to the negative outcomes that befall others (Arnett 2010; Pedlow and Carey 2004). This form of optimistic bias results in lowered risk perceptions regarding one's chances of acquiring HIV. Furthermore, the availability of highly active antiretroviral therapy (HAART) (► [cART and Supportive Care for HIV-Associated Malignancies](#)) may minimize the perceived severity of HIV (The Foundation for AIDS Research (amfAR) 2010).

Relationships with close others. Although parental figures are generally very important for adolescents, peers and sexual partners become increasingly relevant in this stage. Much research has shown that perceiving that one's peers are engaged in sexual activity and drug use can increase one's own likelihood of engaging in similar risky behaviors. It is important to recognize that, although peers may influence the adoption of unhealthy behaviors (such as drug use), they may also encourage healthy behaviors (like condom use).

The characteristics of the relationships with sexual partners are also relevant for HIV risk among youth. Adolescents tend to engage in serial monogamy or several short-term monogamous relationships. This can lead to several sexual partners in a short period of time, which increases the risk of HIV acquisition. Furthermore, adolescents may have older sexual partners, making it harder for them to refuse sex and negotiate condom use. This is particularly a concern for young women, especially when males are accorded more social and political power and gender-based violence is prevalent (UNAIDS 2010; UNICEF 2011).

Broader social context. Poverty, limited access to education, and lack of employment opportunities are structural characteristics that can also increase the likelihood of HIV infection among adolescents. Young people in impoverished conditions are less likely to have accurate knowledge about HIV and how to prevent it. Additionally, homeless youth and out-of-school youth have increased likelihood of engaging in high-risk behaviors, like drug use and sex work, often as a means of survival.

Laws and policies are important contributors to adolescents' engagement in safe or risky practices. In several countries, parental consent is legally required for youth seeking access to health services such as HIV testing, contraceptive counseling, and harm reduction programs. However, young people are often unwilling to discuss their risk behaviors with their parents and thus are forced to forgo these services. The stigma associated with HIV-risk behaviors, such as male-to-male contact (► [HIV prevention for MSM](#)), sex work, and drug use, may further hamper youth's access to services (Access to Care) and programs, even in countries that have provisions allowing minors to access services without parental consent.

HIV Prevention Interventions for Youth

Awareness of the threat to adolescent health posed by HIV has resulted in the development and implementation of several risk reduction interventions targeting preadolescents, adolescents, and young adults. Because the majority of HIV

infections among youth are acquired through unprotected sexual intercourse, most of these interventions provide information and skills to enable youth to delay sexual onset and/or decrease sexual risk behaviors. Schools across the world provide a convenient location for such interventions because they have the infrastructure to serve large proportions of youth before and, in many cases, after sexual debut (Gallant and Maticka-Tyndale 2004). Nonschool-based programs are also fundamental in meeting the needs of at-risk subpopulations like IDUs or YMSM (► [HIV Prevention for MSM](#)).

School-based interventions. To achieve the greatest reduction in HIV incidence, school-based sex education programs that promote knowledge about HIV and positive health beliefs, skills, and behaviors should be implemented early, as they are particularly effective among youth who have not yet become sexually active (UNICEF 2011). Much research has shown that youth are not likely to return to abstinence after sexual debut. Thus, school-based interventions must target both sexually active and nonsexually active adolescents with prevention messages. Comprehensive risk reduction programs that encourage abstinence but provide information about medically accurate risk reduction strategies are likely to reach more students than abstinence-only programs. Research has shown comprehensive sex education programs to result in increased condom use (► [Male Condoms](#); ► [Female Condoms](#)) as well as reduced current sexual activity, frequency of sexual activity, number of sex partners, frequency of unprotected sex, and reduced pregnancy and STI rates. Abstinence education programs may reduce current sexual activity but fail to show significant effects on any other behavioral outcomes (Chin et al. 2012).

HIV education in primary and secondary schools is quite common: 64% of primary schools and 88% of secondary schools in 137 reporting countries included HIV in their curricula in 2007 (UNICEF 2011; United Nations). It is important to note that content and provision of sex education is often dictated by policies at multiple levels of government. Furthermore, school-based interventions are often delivered by teachers or health

educators who may alter important content or refuse to deliver components to students (Gallant and Maticka-Tyndale 2004; Poobalan et al. 2009).

Although schools provide an ideal setting to reach large numbers of youth throughout the process of sexual and social maturation, it can be difficult to engage youth from diverse backgrounds with various levels of experience in programming activities. School-based programs may not be well suited to reaching youth that are most at risk of HIV, such as YMSM (► [HIV Prevention for MSM](#)) and IDUs. By nature, tailored interventions targeting such high-risk populations are not relevant for all youth and thus are more likely to be implemented in community settings familiar to the targeted population than to be implemented in school settings. The impact of school-based interventions is further limited when schools are unable or unwilling to provide condoms and HIV tests.

Nonschool-based interventions. School-based interventions are an important component of the prevention continuum. However, given the aforementioned limitations of school-based programs, it is fundamental to implement preventive activities in other settings such as health care systems, youth-serving organizations, and the broader community.

Provision of health care services, including condom distribution and HIV testing (► [HIV Testing and Counseling](#)), is central for HIV prevention among youth. Making these services “youth friendly” and providing outreach or out-of-facility services for those youth who are unwilling or unable to attend health care settings have been found to be effective (Denno et al. 2012). Youth-serving organizations that understand the needs of high-risk youth are well suited to offer tailored harm reduction interventions. For example, it may be difficult to identify lesbian, gay, bisexual, and transgender (LGBT) youth in school settings, but organizations serving LGBT youth provide a safe place to talk about sensitive issues such as sexual behavior.

Community-wide interventions can be useful in providing education, changing social norms regarding sexual activity, and decreasing the stigma of HIV among the public. There is some

evidence to suggest that theory-based mass communication (► [Mass Media and HIV Prevention](#)) campaigns that target specific audiences with health-promoting messages can increase condom use and HIV testing intentions and behavior (Noar et al. 2009). Multicomponent (► [Multilevel Interventions/Structural Approaches to HIV Prevention](#)) campaigns that include efforts to change individual behavior as well as promote awareness are likely to be most effective.

Characteristics of Successful Interventions

HIV prevention programs aimed at youth measure success in terms of behavioral outcomes such as delayed sexual onset (► [Delayed Sexual Debut](#)), decreases in frequency of sexual activity, increases in condom use (► [Male Condoms](#); ► [Female Condoms](#)), and decreases in number of sexual partners. Cognitive antecedents of behavior change, such as attitudes and knowledge, are also frequently used as indicators of program success. Several reviews of HIV risk reduction interventions have found that they are more likely to have a positive impact on sexual knowledge and attitudes than on sexual behavior in general (Poobalan et al. 2009). When interventions do influence behavior, they are more likely to change sexual risk behaviors than level of sexual activity (Pedlow and Carey 2003). A systematic review of HIV prevention interventions found large effect sizes for sexual risk communication skills (.50), condom use skills (.30), and quantity of sexual risk communications (.27), but only small effect sizes for condom use (► [Male Condoms](#); ► [Female Condoms](#)) (.07) and reduced sexual frequency (.05) (Johnson et al. 2003).

The approaches taken to achieve these outcomes vary considerably. However, there is some consensus regarding the characteristics necessary to effect positive change. Reviews of successful HIV prevention programs targeting youth in developed and developing countries suggest at least four key components: (1) a focus on HIV, (2) structured learning activities based on a

theoretical framework, (3) developmentally appropriate information, and (4) consideration of the needs of the target audience (Gallant and Maticka-Tyndale 2004; Kirby et al. 2006; Poobalan et al. 2009).

HIV focus. The prevailing recommendation for HIV risk reduction interventions is to narrowly focus on behaviors that can reduce the likelihood of HIV acquisition, such as condom use (► [Male Condoms](#); ► [Female Condoms](#)), and communicate clear messages in progressive stages to encourage increases in the desired health behaviors and reductions in the undesired risk behaviors (Kirby et al. 2006; Poobalan et al. 2009). An alternative approach is offered by positive youth development programs that do not focus on a single health risk behavior but rather target the well-being of adolescents by promoting the development of confidence (including optimism about the future), caring, connection, character, and competence (Lerner et al. 2003).

Theoretical framework and structured learning activities. Successful interventions include learning activities that are guided by theory. Because health behavior theories specify determinants of behavior and behavior change, they are useful in identifying targets for intervention. The most common theoretical basis for HIV risk reductions targeting adolescents is social cognitive theory. This theory posits that behavior is the result of learning that is acquired through interactions between the individual and his or her environment. Additionally, the theory notes that belief in one's ability to execute the recommended behavior (e.g., condom use) is critical to enactment of the behavior. Programs based on social cognitive theory frequently employ skill-building activities that are appropriate for the developmental stage of the participants (DiClemente et al. 2008). For example, intervention programs often include role-playing activities that allow youth to develop their communication, negotiation, decision making, and condom application skills (Pedlow and Carey 2004). These types of active learning activities are more effective than passive learning activities such as watching films (Poobalan et al. 2009).

Developmentally appropriate. Programs should focus on delaying sexual initiation (► [Delayed Sexual Debut](#)) of nonsexually active youth and aim to increase safe sex practices among sexually active youth (Malow et al. 2007), especially as research has shown abstinence among sexually active youth to be unlikely (Pedlow and Carey 2004). Interventions targeting preadolescents and those who are not yet sexually active have been found to be most effective in decreasing sexual risk (Poobalan et al. 2009), perhaps because they can aid in the development of safe sexual behaviors before patterns of sexual risk behaviors are established (Pedlow and Carey 2004). However, programs targeting sexually active adolescents are also important, as adolescents tend to have several short-term monogamous relationships in close succession (resulting in multiple partners) and are not likely to consistently use condoms (Pedlow and Carey 2004; amfAR 2010). Furthermore, given the importance of peers during adolescence, interventions that target youth within their social networks may be particularly effective. Group interventions, such as those that occur in school settings, are poised to leverage social influences such as reinforcement, norm change, and interpersonal learning (Pedlow and Carey 2003). Additionally, booster sessions after the formal conclusion of interventions have been identified as an effective means of providing youth with meaningful information at various stages of sexual experience (Pedlow and Carey 2004).

Tailoring. Successful interventions are tailored to meet the needs of the adolescent population of interest (Malow et al. 2007). In addition to age, programs should be sensitive to the differential influence of gender roles and sexual orientation (Sexual Orientation). It has been found, for example, that interventions targeting condom use (► [Male Condoms](#); ► [Female Condoms](#)) are more effective among young men than among young women, arguably because it is harder for young women to negotiate condom use and to refuse sexual intercourse (Michielsen et al. 2010).

Interventions targeting most-at-risk subgroups should clearly be tailored to address the specific

needs and risk patterns of such groups. In the United States, for example, despite the fact that YMSM (► [HIV Prevention for MSM](#)) are disproportionately affected by HIV, only about 5% of HIV interventions among youth addressed same-sex sexual activity or gay/bisexual sexual orientation (Harper and Riplinger 2013). IDUs are another group at high risk for HIV infection. Prevention among this group should not only include harm reduction (► [Harm Reduction for Injection Drug Users \(IDUs\)](#)) strategies (like access to needle-exchange programs) but should also aim to reduce high-risk sexual practices (such as inconsistent condom use) frequently linked to substance use (UNICEF 2011).

Approximately 7.5 million children and youth under the age of 25 were living with HIV in 2009 (UNICEF 2011; United Nations). Interventions for HIV-positive youth should focus on testing (► [HIV Testing and Counseling](#)) and treatment as most infected youth are not aware of their status. For example, it is estimated that 20% of infected youth in the United States do not know their status. Of those that do know their status, only 30% have access to adolescent health services (Access to Care) (amfAR 2010). Promoting adherence to treatment as well as safe sexual practices has the potential to decrease transmission of HIV among youth. “Treatment as prevention” (► [Prevention for People Living with HIV](#)) efforts should be accompanied by community-wide programs that aim to decrease stigma and discrimination (Stigma and Stigmatization) towards HIV-positive youth (UNICEF 2011).

Future Directions

Researchers have called for better measures of behavioral outcomes such as condom use (► [Male Condoms](#); ► [Female Condoms](#)) (which has been measured in terms of frequency at first sexual encounter, at last sexual encounter, and numerous other ways) as well as biological markers to confirm the presence or absence of STIs and HIV (DiClemente et al. 2008; Michielsen et al. 2010; Pedlow and Carey 2003). More research on, and programs for, vulnerable

populations such as YMSM (► [HIV Prevention for MSM](#)) are needed (amfAR 2010). There is also a need for better understanding regarding the impact of contextual factors on youth's beliefs and behaviors. Viewing HIV as a health outcome that is influenced by relational, familial (► [Family Interventions](#)), community, and societal contexts (DiClemente et al. 2008) may encourage the development of multilevel interventions (► [Multilevel Interventions/Structural Approaches to HIV Prevention](#)) that allow for a more comprehensive explanation of behavior and lead to lasting behavioral change.

Conclusion

A world without AIDS requires prevention of HIV among today's youth. Although adolescence is widely considered a period of good health characterized by relatively low disease burden, the health risk behaviors of adolescents merit special attention given their contribution to current and future health. Comprehensive sex education programs that provide medically accurate information regarding condoms and contraception hold particular promise for reaching youth with HIV educational messages and skill-building activities before and after sexual debut. However, these types of programs may not be welcomed by politicians, school administrators, and parents. Efforts to reach particularly vulnerable populations such as YMSM (► [HIV Prevention for MSM](#)) and IDUs will require tailored interventions that address their social and cultural context. Progress has been made in the global fight against AIDS and continued HIV prevention efforts targeting youth can contribute to a world with zero HIV infections, zero discrimination, and zero AIDS-related deaths (UNAIDS 2010).

Definition: The Lymphatic Reservoir

The lymphatic reservoir is constituted by subsets of the CD4+ T lymphocytes, dendritic cells, and cells of monocyte–macrophage lineage which become infected by HIV. After infection, these cells harbor transcriptionally silent but replication-competent HIV DNA, beyond the reach of host immune responses and antiretroviral therapy (ART) (Shan and Siliciano 2013). These cells are generally long-lived and maintain the capacity for viral replication throughout their life spans.

Introduction

After entry into the body, HIV rapidly spreads to regional lymph nodes and other lymphoid tissues. This early exploitation of the lymphatic system is mediated by specific host cells and defines the long-term course of HIV infection (Brenchley et al. 2004; Kramer-Hammerle et al. 2005; Moir et al. 2015). CD4+ T lymphocytes, dendritic cells, and cells from the monocyte–macrophage lineage are principal players in these events, and subsets of these cells become latent reservoirs of the virus within the lymphatic system (Blankson et al. 2002; Vicenzi et al. 2007).

The Lymphatic System

The lymphatic system consists of a complex network of vessels connecting primary lymphoid organs (bone marrow and thymus) to secondary lymphoid organs such as spleen, tonsils, lymph nodes, and gut-associated lymphoid tissue (GALT). Among other roles, the lymphatic system serves essential functions in immune system regulation and as the channel of transport for leukocytes, T lymphocytes, macrophages, and dendritic cells throughout the body (Angeli and Randolph 2006; Platt and Randolph 2013a, b). Lymphatic capillaries (also known as initial lymphatics) are lined with a permeable endothelium of a single cell layer and permit the migration of leukocytes between the lymphatic system, interstitial tissues, and bloodstream. Lymphatic capillaries unite at larger-caliber lymphatic vessels, which may contain muscle cell layers and unidirectional valves to facilitate lymph transport (Baluk et al. 2007). Lymph arrives via afferent lymphatic vessels to lymph nodes and other lymphoid organs and tissues.

Lymphatic vessels are closely coupled to blood vessels throughout the body, with the exception of the brain. Due to strict volume and pressure environment of the brain's enclosed space as well as the selective permeability of the blood–brain barrier, the brain lacks its own lymphatic network. Nevertheless, lymphatic vessels at the cribriform plate play an integral role in cerebrospinal fluid

drainage, with cervical lymph nodes serving as important sites for immunologic responses of CSF-derived leukocytes (Koh et al. 2005; Weller et al. 2006; Wagshul and Johnston 2013).

Lymph enters the subcapsular sinus of lymph nodes and flows through the sinusoidal spaces, where antigens from the periphery, carried mainly by the antigen-presenting dendritic cells, elicit a cascade of immune responses. Follicles within the lymph node cortex are sites of antigenic stimulation and are comprised mainly of B lymphocytes. T lymphocytes mostly comprise the deeper paracortex, while the even deeper medulla is the site of plasma cell maturation (Miranda et al. 2013).

The migration of leukocytes through the lymphatic system is a highly selective process requiring regulated interactions between leukocyte surface proteins and endothelial cell receptors (Cyster and Schwab 2012). The majority of leukocytes transported by afferent lymphatic vessels are lymphocytes, while up to 20% are dendritic cells, mostly derived from mononuclear phagocytes but distinct from macrophages (Smith et al. 1970). Other types of leukocytes, including plasma cells, neutrophils, eosinophils, and basophils, make up a minority of the afferent lymph leukocytes (Smith et al. 1970). Of the T lymphocytes in the afferent lymph, CD4⁺ T lymphocytes are overwhelmingly more abundant than CD8⁺ T lymphocytes, with a ratio several times higher than their ratios in the bloodstream (Mackay et al. 1990). Efferent lymph cellularity is mostly comprised of lymphocytes (as dendritic cells generally remain in lymph nodes until cell death) which are dispersed back into the bloodstream (Kamath et al. 2002; Braun et al. 2011).

Lymph Nodes as an Epicenter of HIV Pathogenesis

Viral dissemination occurs via infected lymphocytes and dendritic cells circulating throughout lymph nodes and lymphoid tissue (Moll 2003). Subsequent production of various pro-inflammatory cytokines (IL-1 α / β , IL-2, IL-6, IL-7, IL-12, IL-15, TNF- α) stimulates lymph

node cell proliferation; this is the fundamental etiology of the diffuse lymphadenopathy of acute and asymptomatic HIV infection (Levy 2007; Vicenzi et al. 2007). Lymph nodes at this stage are characterized by robust follicular hyperplasia with prominent germinal centers. The expansion of B lymphocytes within the lymph node sinuses also contributes to lymphadenopathy (Miranda et al. 2013). Accumulation of lymphocytes within lymph nodes disrupts germinal centers, resulting in follicular lysis and hemorrhage. The intense inflammatory responses secondary to cellular migration and pro-inflammatory cytokine production lead to an alteration of the lymph node structure, with additional cellular recruitment, angiogenesis within the lymph node, and irregular collagen deposition (Miranda et al. 2013). In advanced HIV infection, follicles undergo atrophy and are dominated by follicular dendritic cells, with scant presence of lymphocytes as they are gradually depleted (Miranda et al. 2013). As such, lymph nodes in advanced HIV are fibrotic and exhibit a distorted architecture.

Throughout the course of HIV infection, CD4⁺ cell counts decline as infected lymphocytes are destroyed by cytopathic effects of HIV, cytotoxic lymphocytes, and apoptosis. Furthermore, infection and destruction of thymocytes impairs repletion of the lymphocyte pool (Vicenzi et al. 2007). Eventually, the dendritic cell network deteriorates as well (Burton et al. 2002).

Resting Memory CD4⁺ T Lymphocytes as Reservoirs

CD4⁺ T lymphocytes, containing integrated HIV DNA and circulating between peripheral lymph nodes, are a stable reservoir, which has been extensively studied and represents a major barrier to HIV cure (Chun et al. 1997; Moir et al. 2015). In addition to lymph nodes and the spleen, GALT tissue harbors this reservoir. The reservoir burden varies between different tissues with GALT CD4⁺ T lymphocytes harboring HIV DNA at levels several times higher compared to peripheral blood, even in the setting of effective ART (Moir et al. 2015). Of the different CD4⁺ T cell subsets,

resting or unactivated, memory CD4⁺ T lymphocytes are the main reservoir due in part to their long life spans. The role of infected naïve CD4⁺ T lymphocytes is less clear though there is evidence to suggest that they may also serve as a reservoir (Wightman et al. 2010). Integrated viral genome (provirus) in CD4⁺ T lymphocytes remains in an archived state and does not contribute to viral replication unless the cell is activated.

It is not well understood how resting T lymphocytes become reservoirs of HIV. One possibility is that HIV simply infects resting T lymphocytes; however, this mechanism would be inefficient because cellular activation is generally required for HIV genome integration (Moir et al. 2015). Unactivated, resting CD4⁺ T lymphocytes have intrinsic barriers to HIV infection, including low CCR5 expression and inefficient capabilities for reverse transcription and integration (Shan and Siliciano 2013). Alternatively, HIV may infect activated T lymphocytes to initiate the reservoir. Activated T lymphocytes possess a cytoplasmic and nuclear environment conducive to efficient reverse transcription and integration and are primary drivers of viral replication. Unlike resting T lymphocytes, however, activated T lymphocytes are generally short-lived; if not destroyed by cytopathic effects of HIV or by cytotoxic T lymphocytes, they are destined for apoptosis. Activated T lymphocytes infected by HIV occasionally escape the pathways that lead to cell death and instead revert back to a resting memory state through poorly understood mechanisms (Shan and Siliciano 2013). Regardless of the mechanism, establishment of T-lymphocyte reservoirs likely occurs most abundantly during the viremia peaks of acute infection, but viremia in chronic infection may replenish or expand the reservoir.

Only a small fraction of resting T lymphocytes become reservoirs of HIV. Indeed, infected resting T lymphocytes are relatively scarce during effective ART, measuring only about one per million resting T lymphocytes. Nonetheless, this means there may be 1×10^7 resting T-lymphocyte reservoirs in an individual (Chun et al. 1997). Recently, it was suggested that the size of the latent reservoir may be up to 60-fold higher than

previous estimates (Ho et al. 2013). CD4⁺ T lymphocytes thus provide an expansive, stable reservoir, which can persist for a significant period of time. The half-life of resting memory T lymphocytes has been estimated to be 44 months, theoretically requiring approximately 70 years for this reservoir to fully decay naturally, provided 100% effective ART and limited reservoir clonal expansion (Siliciano et al. 2003; Moir et al. 2015).

Follicular Dendritic Cells as Reservoirs

Dendritic cells are crucial to adaptive immunity. They trap and process foreign antigens on their dendritic processes and migrate to secondary lymphoid sites, where they induce strong T-lymphocyte activation and proliferation in an antigen-specific manner (Soumelis et al. 2007). Multiple lineages of dendritic cells exist, with plasmacytoid dendritic cells (derived from lymphoid precursors) and myeloid dendritic cells (derived from myeloid precursors) being the major peripheral dendritic cells (Soumelis et al. 2007). Both express CD4, CCR5, and CXCR4 to varying degrees and can become infected by HIV, but display limited capacity for viral replication (Schmidt et al. 2007). Immature myeloid dendritic cells are likely the first lymphoid cells to come into contact with HIV during sexual transmission, given their presence at sites necessary to bind antigens in the anal, vaginal, and foreskin epithelium. They bind HIV viral protein gp120 to a unique surface protein, dendritic cell-specific ICAM-3-grabbing nonintegrin 1 (DC-SIGN), and then disseminate the virus via migration to lymph nodes (Cunningham et al. 2007; Del Cornò et al. 2007). Follicular dendritic cells (FDCs) reside within lymph node follicles and are particularly important participants in the establishment of the HIV reservoir. As with any other antigen, they trap intact, circulating HIV, usually in the form of antigen-antibody complexes. The trapped viruses may remain infectious for several months despite the production of neutralizing antibodies, suggesting that FDCs conformationally change

the antigen–antibody interaction (Smith et al. 2001; Burton et al. 2002).

Early in infection, lymph node FDCs become extensively coated with HIV virions trapped on their surfaces, which accounts for the majority of the virus particles in an acutely infected person (Tenner-Racz and Racz 1995). Unlike myeloid and plasmacytoid dendritic cells, FDCs are not known to become infected with HIV; viral DNA has not been isolated from FDCs (Keele et al. 2008), perhaps because the virus cannot enter FDCs or undergo reverse transcription within this cell type. Rather, FDCs preserve infectious HIV particles on their surfaces during and following periods of viremia in the vicinity of trafficking T lymphocytes. FDCs intimately interact with T lymphocytes, an important immunologic relationship which HIV exploits. FDCs present the virus to T lymphocytes, haplessly infecting them (Keele et al. 2008). Though infectious virus can remain tied to FDC surfaces for several months, it is likely that any period of viremia (even very low-level viremia) in chronic infection can replenish this infectious potential of FDCs.

Despite effective ART, HIV RNA can be found in the subcortical regions of lymph nodes, which has been attributed in part to the activity of FDCs (Moir et al. 2015). Unlike other HIV reservoirs, where each infected cell harbors on average one virus, a single FDC may trap and retain multiple, genetically diverse, replication-competent virus particles (Keele et al. 2008).

Cells of the Monocyte–Macrophage Lineage as Reservoirs

Tissue macrophages are derived from circulating monocytes and constitute another important latent reservoir for HIV within the lymphatic system. Although they mainly reside in specific tissues and organs, macrophages do constitute a small minority of lymph cellularity (Platt and Randolph 2013b). Like T lymphocytes, they express CD4 and chemokine receptors necessary for HIV entry (Szabo et al. 1990). While most

T lymphocytes become activated upon infection and are then destined for apoptosis, macrophages are more resistant to the cytopathic effect of HIV and can persist for longer periods (Le Douce et al. 2010). Generally, very low levels of lymph node macrophages (0.05%) are latently infected with HIV in chronic infection (Redel et al. 2010). Nonetheless, macrophages possess the characteristics of a latent reservoir; they are quite long-lived and achieve viral replication upon activation. Activation of these macrophages may be driven by pro-inflammatory cytokines or other infections, such as herpesviruses (Caselli et al. 2005; Kumar et al. 2014). Macrophage HIV reservoirs are not limited to the lymphatic system; central nervous system and gastrointestinal tract macrophages, for example, also serve as important HIV reservoirs (Kumar et al. 2014).

Lymphatic Reservoirs as a Barrier to Cure

The rebound of viremia after ART interruption confirms inability of ART to eradicate the latent viral reservoir (Levy 2007). Even during ART, very low viremia persists chronically, often far below the detection limits of commercial assays. Intermittent viral release (from reservoirs) without complete rounds of replication is a source of such low-level viremia (Sahu 2015), although cryptic viral replication in long-lived reservoirs cannot be excluded (Shan and Siliciano 2013). “Sterilizing” HIV cure thus requires eradication of all latent reservoirs, but no scalable strategies have been identified to date.

Conclusion

The lymphatic system is one of the main theaters of HIV pathogenesis. Circulating and tissue-based reservoirs are established very early in infection within this system, predominantly in resting memory CD4⁺ T lymphocytes, FDCs, and macrophages. The lymphatic system

reservoir is a part of the formidable barrier against HIV cure.

HIV Reservoirs in the Central Nervous System

Lauren Tompkins, Elena Dukhovlinova and Ronald Swanstrom
The University of North Carolina, Lineberger Cancer Center, Chapel Hill, NC, USA

Definition

The central nervous system (CNS) is a unique anatomical compartment that is shielded from the rest of the body by the blood-brain barrier (BBB). Exchange of substances between the CNS and the blood is controlled and limited by the BBB. Human immunodeficiency virus (HIV) enters the CNS early after viral transmission and, in some cases, replicates independently of that in the blood. Viral replication in the CNS could be supported in multiple cell types including CD4⁺ T cells, macrophages, microglia, and potentially astrocytes or other cells lacking CD4 receptor expression. Following productive infection of permissive cells, it is plausible that viral species persist in the CNS in the form of a reservoir, or dormant state of infection that is capable of reactivation and production of new viral particles. Analyzing such a reservoir in the context of the CNS is challenging, given the fact that brain tissue can only be sampled at death. Yet, studies using cerebrospinal fluid (CSF) as a surrogate for analyzing HIV infection of the CNS have described four states of infection, which will be discussed in this section. Importantly, physiological and viral factors influence the outcome of HIV replication in the CNS, which affects the composition of a persistent viral reservoir within an individual. Future work aimed at a total cure to HIV infection will need to address all potential viral reservoirs, including those that reside within the CNS.

Introduction

Human immunodeficiency virus type 1 (HIV-1) is the cause of acquired immunodeficiency

syndrome (AIDS), where uncontrolled infection in the blood and lymphoid organs depletes CD4⁺ T cells and diminishes immune competence over time. Although antiretroviral therapy (ART) controls viral replication and disease progression, these drugs must be taken throughout life to suppress infection. A major focus of current research is to eradicate HIV-1 and cure infected patients. HIV-1 persistence in cellular and anatomical reservoirs precludes a cure; thus, efforts to characterize these reservoirs are an important part of developing a strategy for eradicating all forms of HIV-1.

In order to discuss reservoirs of HIV-1, it is important to understand how the virus utilizes different cell surface receptors for productive infection. HIV-1 infects cells that express CD4 (the viral receptor) and CCR5 or CXCR4 (viral coreceptors). Preferential infection of a specific cell type by HIV-1 (cell tropism) is defined by receptor usage. Most transmitted/founder virus strains are CCR5-utilizing and infect CD4⁺ T cells (R5 T cell-tropic), but over time, HIV-1 can evolve to utilize CXCR4 expressed on CD4⁺ T cells (X4 T cell-tropic) due to the depletion of CCR5⁺ CD4⁺ T cells from untreated infection. Additionally, HIV-1 can evolve to infect macrophages, which express CD4 and CCR5 (R5 macrophage-tropic). R5 macrophage-tropic viruses are predominantly found in the central nervous system (CNS) as an evolutionary adaptation to the paucity of T cells in the CNS. The composition of the latent reservoir could differ between individuals depending on nadir CD4, although probably all permissive cell types are infected at all times, at least at low level (reviewed in Joseph 2014b).

The central nervous system (CNS) is an anatomic compartment that harbors potentially multiple cellular reservoirs of HIV-1. The CNS is a unique anatomical site as it is relatively “immune privileged” due to the physiology of the blood–brain barrier (BBB), a selectively permeable barrier that controls communication between the CNS and the periphery. It is difficult to investigate CNS infection, as brain tissue is only available at autopsy. The cerebrospinal fluid (CSF), which bathes the CNS, is a surrogate for studying

CNS infection, but these studies are limited in their ability to characterize CNS tissue reservoirs of HIV-1. To understand potential CNS reservoirs of HIV-1, it is important to discuss the following: the dynamics of viral and permissive cell entry into the CNS; the conditions that favor viral replication and contribute to reservoir stability; and the potential for viral egress from cells constituting the CNS reservoir.

Defining a Viral Reservoir

Two essential criteria exist to define a viral reservoir of HIV-1 (reviewed in Blankson et al. 2002). First, a reservoir must preserve replication-competent virus in some form (i.e., viral particles or viral genomes) so that the virus can reestablish productive infection in the future. Second, a reservoir must have mechanisms of longevity. For example, reservoirs composed of virions would require escape from biochemical decay, as seen with virion particles that become trapped extracellularly in dendritic cell processes. Cell-associated viral reservoirs, however, require cell survival and escape from immune control including cytotoxic T cell (CTL) activity. Latent infection, a state with no active replication, is the best characterized cellular reservoir of HIV-1, but another type of reservoir could be composed of productively infected cells with slow turnover. The concept of a reservoir is further complicated by the detection of cells that clonally expand in vivo through transactivation of cellular growth-promoting genes by integrated viral DNA (Maldarelli et al. 2014).

A reservoir will most likely occur in cells that are normally infected with HIV-1. This virus infects cells that express the viral receptor CD4 and coreceptor (CCR5 or CXCR4). Activated CD4⁺ T cells are the most permissive cell type for HIV-1. Latently infected resting memory CD4⁺ T cells are the hallmark reservoir of HIV-1 infection and are thought to predominantly arise from productive infection of activated CD4⁺ T cells as they are transitioning back into a resting state (reviewed in Siliciano and Greene 2011). Latently infected T cells contain replication-

competent HIV-1 genomic DNA (provirus) integrated within the human genome in the absence of ongoing viral replication. Although dormant, latently infected resting T cells can be induced to become activated and thereby transcribe integrated DNA to generate new progeny virions capable of productive infection. It is important to note that integrated DNA can be either intact or defective; thus, many infected T cells contain HIV-1 DNA that is incapable of producing functional virions (Ho et al. 2013). Latently infected cells are established early after a person becomes infected, and these cells persist even in the presence of ART-mediated viral suppression. Persistence of the latent reservoir is due in part to the virus escaping immune surveillance, as integrated viral DNA in latently infected cells is likely transcriptionally silent and does not produce antigens that signal immune attack (reviewed in Archin et al. 2014).

A second type of HIV-1 reservoir could be a productively infected cell with slow turnover. After the onset of suppressive ART, which prevents new infections without affecting previously infected cells, the blood viral load decreases rapidly (1–2 weeks) due to rapid turnover of short-lived infected T cells. For most people, the same pattern of rapid viral decay is observed in the CSF. However, occasionally the viral load decays much more slowly in the CSF than in the blood, which suggests that cells with a longer half-life than T cells can support HIV-1 replication in the CNS (reviewed in Joseph 2014b). Potential CNS cell types infected with HIV-1, including T cells as well as longer-lived cells, will be discussed later in this chapter.

The BBB and BCSFB: Barriers to HIV Infection of the CNS

The CNS, consisting of the brain and spinal cord, is an anatomical compartment isolated from the rest of the body by the blood–brain barrier (BBB) and blood-cerebrospinal fluid barrier (BCSFB). The BBB and BCSFB are semipermeable barriers that limit exchange of substances between the CNS and peripheral blood. These physiologically

distinct barriers influence the composition of CNS fluid, including the CSF and CNS interstitial fluid, which differs greatly from the blood. For example, concentrations of white blood cells, albumin, and immunoglobulin G (IgG) in the CSF are all <1% of that in the blood in spite of the fact that the water portion of the CSF is derived from the blood plasma. Key to barrier function of the BBB and BCSFB are intercellular tight junctions, which connect cerebrovascular endothelial cells (BBB) or choroid plexus epithelial cells (BCSFB). Otherwise, the BBB and BCSFB differ in physical composition and function (reviewed in Ransohoff and Engelhardt 2012).

The BBB is present along CNS blood vessels throughout the brain. Tight junction-connected BBB endothelial cells are separated from the brain parenchyma (the brain tissue proper) by two basement membranes: the endothelial and parenchymal. At the capillary level, these membranes are fused, but at all other vascular levels, these membranes separate to delineate the CSF-filled perivascular space (reviewed in Engelhardt and Ransohoff 2012). The BBB exhibits specialized function based on its position within the overall CNS vasculature: Nutrient transport occurs primarily at capillaries that lie in close proximity to neurons, whereas immune modulation occurs at the postcapillary venule (a small vessel that blood flows through after leaving the capillaries) where the perivascular space can accommodate the presence and movement of cells (reviewed in Obermeier et al. 2013).

The BCSFB resides in the choroid plexus located in each of the four brain ventricles. The choroid plexus is composed of fenestrated, permeable blood vessels (vessels containing endothelial pores) surrounded by tight junction-connected epithelial cells that are directly exposed to the CSF. Ependymal cells of the choroid plexus produce CSF from arterial blood. Newly produced CSF fills the brain ventricles, circulates around the exterior surfaces and perivascular spaces of the brain, and ultimately is reabsorbed into venous blood at the meninges. CSF flow is mediated by pulsation of the choroid plexus and action of ependymal cell cilia. Interstitial fluid of the brain parenchyma is also drained into the CSF,

a fluid that acts as a surrogate for lymph by mediating immune surveillance throughout the CNS (reviewed in Spector et al. 2015).

The CSF is considered to be an immunologically active fluid as it houses T cells, B cells, and monocytes, cells which have limited access to the CNS. During physiologic conditions, T cells are primarily restricted to the CSF. However, monocytes can exit blood vessels, enter the brain, and differentiate into macrophages that primarily concentrate around CNS vasculature (perivascular macrophages) but can also be found in the meninges (meningeal macrophages) and choroid plexus (choroid plexus macrophages). CNS myeloid cells, as well as microglia (resident macrophages of the brain), have antigen-presenting capability and are considered important for immune surveillance and interaction with circulating central memory T cells (reviewed in Ransohoff and Engelhardt 2012).

Viral Entry and Cell Migration into the CNS

HIV-1 is found in the CNS very early after transmission, although the associated mechanisms of entry are not well understood (Sturdevant et al. 2015). One theory, which is the most favored, proposes trafficking of HIV-infected CD4⁺ T cells into the CNS as part of routine immune surveillance or in the context of neuroinflammation. Alternatively, HIV-1 virions could cross the BBB/BCSFB, likely in the setting of high blood viral load. Consistent with this hypothesis, some studies suggest that HIV-1 can specifically interfere with the production of proteins involved in the maintenance of tight junctions thereby disrupting the integrity of the BBB (reviewed in Zayyad and Spudich 2015). In contrast, the work of Price and colleagues has shown that, in the absence of neurocognitive symptoms, the CSF viral load decreases late in infection, while the viral load in the blood is on average increasing. This disparity in viral load occurs as CD4⁺ T cells are being depleted in the blood and white blood cell (WBC) count drops in the CSF, the latter of which suggests that T cells in the CSF

are also reducing in number. These data suggest that the reduction in CSF viral load is due to a loss of CD4⁺ T cells that come from the blood, and thus virus enters the CNS in the form of trafficking T cells (reviewed in Price et al. 2014). Regardless of how HIV-1 enters the CNS, persistent infection in the brain requires a population of permissive cells that reside in or are trafficked to the CNS.

Peripheral immune cells, including T cells and monocytes, leave the blood and enter the CNS through a sequential mechanism of cell binding to the vascular endothelium, rolling along the endothelial lining, and extravasation into the CSF and/or CNS. First, circulating immune cells transiently bind blood vessel endothelial cells through receptor-ligand interaction involving either the selectin family of adhesion molecules or α 4-integrins (reviewed in Ransohoff and Engelhardt 2012). Through these interactions, immune cells roll along the endothelium until they come into contact with chemokines that bind to their G-protein-coupled receptors on the immune cell surface. Chemokine binding induces signals that lead to increased affinity and avidity of cell surface integrins for their ligands and arrest of rolling cells. Immune cells then crawl along the endothelium by exposing protrusions that search for sites to cross, a process mediated by additional adhesion molecule interactions. Finally, the cell traverses the endothelium, either between endothelial cells or through endothelial pore-like structures, into the CSF-filled spaces of the brain. The cell then crosses the parenchymal basement membrane and underlying glia limitans, a membrane composed of astrocyte cell foot projections, to enter the parenchyma (reviewed in Engelhardt and Ransohoff 2012).

Brain pathology affects barrier function of the BBB/BCSFB, and as an associated immune response is mounted, this increases the number of CNS-infiltrating immune cells. During inflammation, CNS inflammatory cells secrete leukocyte-attracting chemokines and endothelial cells upregulate expression of adhesion molecule receptors, thereby aiding immune cell recruitment and extravasation into the CNS. Neuroinflammation can be a protective immune response to CNS tissue damage or infection, but immune pathology

can also compromise the BBB/BCSFB, which alters CNS homeostasis and the proportions of immune cells in the brain (reviewed in Obermeier et al. 2013).

HIV-1 infection is associated with increased inflammation and immune activation both systemically and in the CNS. Neuroinflammation and BBB/BCSFB integrity both appear to affect the population of HIV-1 present in an infected CNS in a multifaceted, dynamic manner. Theories behind some of this complexity have been proposed based on studies comparing viral populations in the CSF, a surrogate for examining the CNS in living people, with those in the peripheral blood of the same individuals. First, in people who have very low or undetectable CSF viral load, it is likely that virus is not replicating, at least not appreciably, in the CSF or CNS but perhaps gains transient entry to the CNS. CSF virus likely comes from infected CD4⁺ T cells in the blood that cross the BBB/BCSFB and release viral progeny in the CNS. Second, in people who have elevated levels of HIV-1 in the CSF that is genetically similar to virus in the peripheral blood, it is likely that CSF virus also comes from migrating infected T cells but now in higher levels as part of an immune response associated with increased white blood cell count in the CSF (pleocytosis). Low-level, focal replication in the CSF or CNS could also account for increased viral load with or without pleocytosis, although without establishment of a persistent CNS infection. Third, in people who have detectable CSF virus that is genetically distinct from that in the peripheral blood, CSF virus could come from transient, clonal amplification of certain viral species in the CSF or CNS that may or may not establish persistent infection over time. The term “compartmentalized” viral replication is used to describe independent replication of HIV-1 within a given bodily compartment and is illustrated by genetic differences in the viral population between compartments, such as the CSF/CNS and blood. “Equilibrated” viral replication defines a state where HIV-1 populations are genetically similar between two compartments due to ongoing or recent intercompartmental movement of viruses (Sturdevant et al. 2015).

Roughly 30% of acutely HIV-1 infected people have pleocytosis, which generally correlates with higher viral load in the CSF. Thus, increased viral burden in the CSF could result from an influx of infected cells in response to neuroinflammation. Consistent with this hypothesis, BBB dysfunction, indicated by an increased CSF/blood albumin ratio, often accompanies pleocytosis. A loss of barrier integrity in the context of enhanced immune cell trafficking to the CNS could allow more infected cells and/or cell-free virus to enter the CNS. Viral replication in the CSF/CNS also increases viral load in the CSF, irrespective of pleocytosis. Yet, pleocytosis occurs in a fraction of people with compartmentalized CNS replication and in an even greater proportion of people with equilibrated replication. How pleocytosis affects viral replication in the CNS is unclear, and it is plausible that pleocytosis occurs as a consequence of CNS HIV-1 infection. On the other hand, an influx of permissive cell types for infection could also promote viral replication in the CNS (Sturdevant et al. 2015; Spudich et al. 2005).

CNS Cell Types as Potential Reservoirs

CD4⁺ T cells

The primary target of HIV-1 infection is the CD4⁺ T cell; however, there are relatively few T cells in the healthy CNS. The concentration of T cells found in the CSF is less than 1% of that found in blood and even fewer, if any, are seen in the brain parenchyma. Despite the low absolute number of T cells present, the CSF has a relatively large proportion of permissive T cells; the CSF cellular composition includes primarily T cells (90% of total CSF cells), which are mostly of memory phenotype (central and effector) and recently activated (CD69⁺) (reviewed in Ransohoff and Engelhardt 2012). As noted above, pro-inflammatory conditions promote immune cell influx into the CSF/CNS, thus increasing the number of potential target cells for HIV-1 replication.

The traditionally described cellular reservoir of HIV-1 is the latently infected T cell. For such a cell to contribute to a CNS reservoir of HIV-1, the cell must reside over time in the CNS. CD8⁺ T cells

have been shown to persist in the CNS of mice infected with vesicular stomatitis virus (VSV). These cells are CD103+, which is an integrin found on tissue-resident CD8+ T cells, and expression of CD103 follows antigen recognition in the brain. Furthermore, CD103 appears to be important for retention of CD8+ T cells in the CNS, as knockdown of this molecule resulted in reduced accumulation of CNS T cells. Interestingly, CNS-resident CD8+ T cells in the brain parenchyma were shown to form clusters, some of which contained CD4+ T cells (Wakim et al. 2010). Although CNS CD4+ T cells were not analyzed thoroughly in this study, another study showed that tissue-resident CD4+ T cells in the skin are antigen-experienced and express CD103 (Watanabe et al. 2015). Taken together, these data suggest that a population of CNS-resident CD4 + CD103+ T cells could exist in the CNS and harbor HIV-1.

Some evidence exists in support of HIV-1 replication in CNS T cells. In some cases there is elevated viral load in the CSF sufficient to indicate HIV-1 replication in the CSF/CNS and rapid viral decay in the CSF upon ART initiation, suggesting that this virus was replicating in a short-lived cell, such as a T cell. Some people with rapid CSF viral decay have compartmentalized replication of HIV-1 in the CSF, and CSF virus is T cell-tropic, meaning that the virus replicates best in T cells compared to other cell types. Such individuals likely have a CNS-derived population of HIV-1 arising from infected T cells, a population that differs from T cell-tropic virus in the blood (Joseph 2014a). Alternatively, people with relatively high CSF viral load, equilibrated viral population, and evidence of pleocytosis may also have HIV-1 replicating in CNS T cells due to an increase in CSF/CNS T cell concentration but in a manner that does not result in a distinct population of virus in the CSF compared to the blood (Sturdevant et al. 2015).

Macrophages

Slow decay of CSF virus with ART suggests that, in this case, HIV-1 is being produced from a longer-lived cell type than a T cell. HIV-1 cell tropism depends at least in part on CD4 receptor

expression density on the surface of a cell. R5 T cell-tropic virus replicates robustly in cells that express high levels of CD4 (T cells) but poorly in cells that express low levels of CD4, including macrophages, which have a similar number of cell surface CD4 molecules to T cells, but the molecules are less densely packed due to the larger surface area of macrophages (Joseph 2014a).

The ability to use low levels of CD4 for cell entry is an evolved feature of the viral envelope gene that cannot be attributed to a single mutation (Arrildt 2015). Rather, macrophage tropism likely evolves as an adaptation to the lack of CD4-rich target cells in the CNS, and the evolution of macrophage tropism appears to involve multiple genetic changes that differ between people. Pleocytosis further complicates macrophage-tropic evolution as it may alter the relative proportion of permissive cell types in the CNS thereby supporting viral replication from either T cell- or macrophage-tropic lineages. Indeed, a rhesus macaque animal model of HIV-1 infection showed that infection causes activation of bone marrow-derived monocytes and increased traffic of activated monocytes to the CNS with subsequent differentiation into CNS macrophages (Burdo et al. 2010).

The CNS is rich in macrophages that could serve as a reservoir for HIV-1. Perivascular macrophages, choroid plexus macrophages, and meningeal macrophages are all bone marrow-derived and are named for anatomical regions in which they reside. These cells could be infected by macrophage-tropic virus or with much lower efficiency by an R5 T cell-tropic virus. Perivascular macrophages are likely exposed to cell-free or cell-associated virus that crosses the BBB. Such virus could come from either the blood or CSF, depending on barrier physiology at the point of entry. Indeed, immunohistochemical staining of autopsied brain shows the presence of HIV-1 nucleic acid and protein in perivascular macrophages. Similarly, meningeal macrophages, located at the superficial brain meninges, are likely also exposed to blood or CSF virus that crosses the leptomeningeal BBB. Choroid plexus macrophages, on the other hand, are likely exposed to predominantly blood virus, as these

macrophages are located in the choroid plexus stroma, which harbors fenestrated capillaries that provide blood for the production of CSF (reviewed in Joseph 2014b).

A rhesus macaque animal model of HIV-1 infection suggested that the virus could migrate between the CNS meningeal and parenchymal regions or replicate autonomously in each of them. The rapid migration of genetically homogeneous virus throughout the brain was associated with faster disease progression and widespread encephalitis. Furthermore, compartmentalized replication in the meninges versus parenchyma was associated with localized detrimental inflammation within these respective brain regions. One macaque with compartmentalized replication in the meninges versus parenchyma was suggested to have macrophage-tropic virus present in both regions, an observation that exemplifies how regional macrophages may contribute to CNS infection and disease. Collectively, these data suggest that the uncontrolled replication of HIV-1 in different brain regions, and potentially in regional macrophages, may be detrimental for local physiology through induction of pathological inflammation (Matsuda et al. 2013).

Microglia

Microglia are resident macrophages of the CNS and the predominant immune cell type in the brain parenchyma. Unlike macrophages, microglia are not bone marrow-derived, rather they arise during embryonic development and are maintained throughout adulthood via local proliferation. Microglia have immune functions including phagocytic ability, inflammatory cytokine secretion, and weak antigen presentation. Studies using HIV-infected human brain tissue at autopsy show that microglia can contain HIV-1 nucleic acid and protein. Furthermore, as with monocyte-derived macrophages, HIV-1 can infect microglia in vitro, suggesting that this cell type is permissive to HIV-1 infection. Like macrophages, microglia have low surface densities of CD4, so virus capable of successfully infecting these cells is likely macrophage-tropic (reviewed in Joseph 2014b). Microglia are thought to have very long life spans, even longer than CNS bone marrow-derived

macrophages, thus persistent infection of these cells could constitute a CNS reservoir of HIV-1. Alternatively, persistent replication in this cell compartment deep in the brain parenchyma could maintain an active reservoir even in the face of poorly penetrating anti-HIV-1 therapy.

Astrocytes

Astrocytes provide mechanical and metabolic support for neurons and are the most abundant cell type in the brain. Viral DNA has been detected in astrocytes of HIV-infected people, and astrocytes can be infected at low levels in vitro (reviewed in Joseph 2014b). However, it is unclear whether astrocytes are productively infected in vivo, as they express no CD4, the viral receptor. Indeed, an analysis of macrophage-tropic HIV-1 *env* genes from individuals with HIV-associated dementia failed to detect CD4-independent infection (Joseph 2014a). Yet, CD4-independent infection was characterized in another study where rhesus macaques were infected with chimeric human/simian immunodeficiency virus (SHIV) that contains an R5 T cell-tropic HIV-1 *env* in the context of an SIV backbone. Still, only one HIV-1 *env* clone isolated from the CNS of a single infected macaque was able to infect CD4⁺ cells in vitro, so it is difficult to draw definitive conclusions from a single observation (Zhuang et al. 2014). An alternative explanation for the presence of HIV-1 nucleic acid in astrocytes is that these cells have phagocytic ability and could ingest infected T cells (reviewed in Joseph 2014b). The extent to which HIV-1 can enter cells in the absence of receptor and/or coreceptor is a poorly studied issue that deserves more attention given the number of cells without viral receptors present in a person and the concern that these alternative cell types could contribute to the reservoir.

Assessing the Contribution of CNS Reservoirs to Viremia

The defining criterion of a reservoir is that the virus is preserved in some form that allows for reestablishment of productive infection. In the

case of the blood reservoir, latently infected CD4 + T cells can be isolated from the blood and used in a viral outgrowth assay to directly assess the prototypical latent reservoir (reviewed in Archin et al. 2014). Such methods are essentially moot for analyzing the CNS reservoir due to the logistics of collecting viable CNS cells postmortem in a timely manner. An alternative method of determining whether HIV-1 in the CNS can reestablish infection is to characterize virus in the CSF that emerges following ART treatment interruption (rebound virus).

HIV-1 rebound virus appears in the CSF roughly 2 weeks after the detection of virus in the blood (de Almeida 2005). Phylogenetic analysis of rebound viral populations in the CSF versus blood could be used to determine if populations in these two compartments differ, indicating that “compartmentalized” CSF rebound virus comes from the CNS and thus illustrates the presence of a CNS reservoir of HIV-1. Furthermore, if viral species previously confined to the CSF arise in the blood during rebound, then reestablishment of systemic infection would be influenced by the CNS reservoir. Although it would be difficult to prove what cell type recrudesced CNS virus originates from, the use of *in vitro* infectivity assays would illustrate cell tropism of rebound virus. The phenotype of CSF rebound virus likely depends on the state of viral replication in the CNS prior to initiation of ART; therefore, studies are required to characterize viral populations throughout the brain of ART-naïve as well as experienced individuals.

Although evidence greatly supports the concept of HIV-1 persistence being attributable to latency, the immune privileged CNS may represent a unique anatomical reservoir, as crosstalk with the periphery is limited due to the BBB, and many ART drugs are relatively poor at penetrating the CSF/CNS. Treatment intensification using ART drugs with optimal CNS penetrance (relative to others) does not reduce levels of HIV-1 RNA in the CSF (Yilmaz et al. 2010). These data suggest that low-level viral replication does not account for the presence of residual CSF virus. However, treatment intensification studies are limited in informing our understanding of latency in the

CNS. Examination of CSF rebound virus could help fill this gap in knowledge. CNS viral persistence is further complicated by the fact that the cellular composition of the CNS is macrophage-rich with limited exposure to T cells, which reside primarily within the CSF. Thus it is possible that mechanisms of HIV-1 persistence differ between the CSF/meninges and the CNS/parenchyma and these mechanisms are affected by the presence of neuroinflammation, which alters the interaction between these bodily compartments. Finally, we do not understand the extent to which viral replication in the parenchyma is “reported” as virus in the CSF.

Recently the concept of “immune privilege” of the CNS has been confounded with the discovery of meningeal lymphatic vessels in the brain. These vessels appear to drain fluid and immune cells from the CSF and connect with deep cervical lymph nodes, which are part of the peripheral lymphatic system (Louveau 2015). The discovery of meningeal lymphatic vessels complicates our understanding of how the cerebrospinal, blood, and lymph fluids are linked. The classical mechanism of fluidic drainage from the CSF to the blood occurs across meningeal arachnoid villi, which are microscopic projections of the arachnoid mater, the middle of the three CNS membranes that enclose the parenchymal tissues and CSF (meninges). Furthermore, CSF fluid is thought to cross the cribriform plate, a paper-thin, perforated bone in the nasal cavity, to drain to the deep cervical lymph nodes (reviewed in Ransohoff and Engelhardt 2012). Meningeal lymphatic vessels comprise a potential bypass of the known CSF draining mechanisms and could contribute to HIV-1 dissemination from the CNS to the rest of the body.

Conclusion

Many aspects of HIV-1 infection within the CNS are poorly understood, but several key features of CNS infection can be gleaned from studies to date. It is evident that virus enters the CNS early by one or more mechanisms and that permissive or semipermissive cell types are present to support

productive infection. Furthermore, the CNS is rich in long-lived macrophages and microglia, which could house virus in a similar manner to resting memory CD4⁺ T cells, although studies have not shown that infection of macrophages can have a persistent, dormant state. Studies using CSF rebound virus could inform our understanding of CNS viral persistence. Likewise, animal models are a valuable platform for addressing mechanistic questions of CNS infection. Defining the CNS reservoir is an important aspect of HIV-1 cure strategies and current research is aimed at clarifying our understanding of HIV-1 persistence in the CNS.

HIV Reservoirs Within the Lungs

Cecilia T. Costiniuk¹ and Mohammad-Ali Jenabian²

Definition

Over recent years, efforts aimed at understanding HIV persistence have intensified, with the hopes that this understanding will provide the platform for developing strategies to eliminate HIV reservoirs. Traditionally, efforts have focused on the gut-associated lymphoid tissue, which is the largest HIV reservoir within the body, and the genitourinary tract due to implications for HIV transmission. The central nervous system has also been a focus of study due to interest in the ability of the blood-brain barrier to protect the brain from various pathogens, clinical observations surrounding HIV-associated neurocognitive disorders, and questions regarding antiretroviral penetration into the cerebrospinal fluid and brain parenchyma. The lungs as HIV reservoirs received greater attention in the pre-highly active antiretroviral therapy (HAART), whereby patients had indications for bronchoscopy due to active lung symptoms, compared to the HAART era whereby opportunistic infections are less frequent. However, with increasing rates of chronic lung disease and a significant burden of bacterial pneumonia in HIV-infected individuals on suppressive HAART, further consideration for the lungs as sanctuaries for HIV is merited.

HIV as an Independent Risk Factor for Chronic Lung Disease

Despite the efficacy of HAART, HIV-infected individuals continue to suffer from a disproportionate

burden of chronic lung disease and non-opportunistic infection (Feikin et al. 2004; Gingo et al. 2014). Bacterial pneumonias were found to be up to 25 times greater in HIV-infected individuals with suppressed peripheral viral loads on HAART compared to HIV-uninfected counterparts (Feikin et al. 2004). Furthermore, although smoking has traditionally been blamed as the primary cause for chronic diseases such as chronic obstructive pulmonary disease (COPD), the important contribution of other factors is becoming increasingly recognized. HIV appears to be an independent risk factor for COPD, pulmonary hypertension, and lung cancer (Gingo and Morris 2013). Uncontrolled HIV has been associated with worse results on spirometry and diffusing capacity measurements and has been shown to hasten decline in lung function by 55–75 ml/year (Drummond et al. 2013). Interestingly, a study conducted in perinatally acquired HIV-infected children found that perinatally acquired HIV was associated with increased airways resistance and frequent abnormal results on spirometry testing and that the severity of airway resistance related more to duration of HIV infection rather than history of respiratory complications (de Martino et al. 1997). Although HIV may not infect pulmonary vascular endothelial cells, lung endothelial cells appear to be a target for HIV's gp120, a protein which has been implicated in apoptosis and inducing release of endothelin-1, a vasoconstrictor (Barnett and Hsue 2013). HIV nef and tat are also thought to play deleterious roles in pulmonary artery endothelial cells, supporting a direct role for HIV damage to the blood vessels of the lungs (Barnett and Hsue 2013).

Perturbations in Pulmonary Immunology

During acute infection, HIV typically gains entry into cells via interactions with CD4 receptors and CCR5 chemokine receptors, and in later stages of disease, HIV tends to gain entry via interactions with the CD4 receptor and the CXCR4 chemokine receptor. Following primary infection, HIV traffics from peripherally infected lymphocytes and

monocytes to the lungs through its vascular blood supply (Clarke et al. 1998). Within the lungs, infected monocytes differentiate into alveolar macrophages (AM) which proliferate (Clarke et al. 1998). Intrapulmonary HIV also infects CD4 and CD8 T cells in addition to fibroblasts as well as cell-free bronchoalveolar lavage (BAL) fluid (Beck 2013; Costiniuk and Jenabian 2014).

The presence of HIV within the lungs results in various immune aberrancies. In addition to distorting the numbers of various cells in BAL (with increased AMs, neutrophils, and eosinophils and reduced CD4/CD8 ratios observed in the BAL fluid of HIV-infected individuals), there are also functional abnormalities observed (Beck 2013; Costiniuk and Jenabian 2014). These have been most extensively characterized in AMs, which have impaired accessory cell function required to initiate cellular responses toward T cells (Koziel et al. 1993). Increased AM production of several pro-inflammatory cytokines, such as interleukin (IL)-1, IL-6, IL-8, tumor necrosis factor (TNF)- α , granulocyte-macrophage colony-stimulating factor (GM-CSF), in addition to others, has been described (Beck 2013; Costiniuk and Jenabian 2014). AMs also display impaired oxidative burden and reduced ability to bind and internalize organisms due to mannose receptor impairment (Koziel et al. 1993). Polyclonal B-cell activation results in nonspecific polyclonal gammopathy and reduced pathogen-specific antibodies and may contribute to disrupted Th1/Th2 balance (Beck 2013; Costiniuk and Jenabian 2014). Ratios of Tregs (CD4 + CD25^{high}FoxP3^{high} cells) from BAL fluid of HIV-infected individuals are increased compared to HIV-uninfected individuals (Jambo et al. 2011). Given that these cells play a key role in limiting immune activation and T-cell function in cancer and chronic viral infections, disruption of Treg homeostasis may render the lungs vulnerable to disease processes. In HIV-uninfected individuals, abnormal Treg function has been observed in COPD, and murine studies suggest that Tregs protected against hypoxia induced pulmonary hypertension (Tan et al. 2014; Chu et al. 2015).

Peripheral immune cells which have become increasingly recognized as important players in

bridging innate and adaptive immune responses are mucosal-associated invariant T (MAIT) cells. These are mostly CD8 cells which express CD161 + and the invariant V α 7.2 T-cell receptor segment, and their responses are activated through antigen presented by MHC-related protein 1 (MR1) (Eberhard et al. 2014). In peripheral blood of HIV-infected individuals, MAIT cells are reduced in number, including in elite controllers and long-term non-progressors (Eberhard et al. 2014). In the context of HIV, peripheral MAIT cells have been observed to be activated and functionally exhausted, with reduced levels independently predictive of disease progression (Leeansyah et al. 2013; Eberhard et al. 2014). Furthermore, it has been shown that intrapulmonary MAIT cells are increased in the lungs during pulmonary tuberculosis in both HIV-infected and HIV-uninfected individuals and thus may redistribute to the lungs, suggesting an important role for these cells in pulmonary immunity (Wong et al. 2014).

Recent advancements in molecular biology have provided the platform for exploring the effect of the microbiota on health and disease. In HIV-uninfected individuals, changes in pulmonary microbiota have been described in the context of cystic fibrosis and COPD (Lynch 2014). Pulmonary pathogens induce inflammatory responses within the lungs, and commensal organisms play a role in regulating these responses and protecting the lungs against inflammatory and oxidative stress (Lynch 2014). Although studies are currently ongoing, relatively little is known about the composition of the microbiome in HIV-infected individuals. Thus far, it appears that colonization with *Pneumocystis jirovecii* is associated with more severe airflow limitation and obstructive lung disease in HIV-infected individuals (Morris et al. 2009).

Pulmonary Reservoirs of HIV

HIV's propensity to infect AMs, with their resistance to apoptosis, enables HIV to persist for prolonged periods within the lungs (Perno et al. 1998). The virus' propensity to infect CD4 cells, some of which later transition to a resting

memory state, also facilitates its ability to persist for prolonged time periods. A portion of this integrated provirus is replication competent, and interactions between appropriate HIV regulatory proteins and cellular transcription factors result in reversal of latency following exposure to antigens and stimulatory cytokines. Like the gut, the lungs are exposed to pathogens and a wide array of exogenous materials which may induce inflammatory responses and provide antigenic stimulation, reactivating HIV from latently infected cells. Nicotine has been shown to induce HIV replication within AMs and in peripheral blood, while coinfection can also contribute to the maintenance of the HIV reservoir (Clarke and Israel-Biet 1996; Costiniuk and Jenabian 2014). Lipoarabinomannan from *Mycobacterium tuberculosis* activates the long-terminal repeat promoter and induces TNF- α and IL-6 production, contributing to HIV replication (Collins et al. 2002). Coinfection may also upregulate CD4 expression on cells, rendering them more susceptible to HIV infection and weaken host immune responses (Ablashi et al. 1995; Beck 2013). Although never formally examined, rise in disinhibited cell growth and pro-inflammatory cytokines observed in neoplasia plausibly contribute to HIV pulmonary replication in the setting of lung cancer. Similarly, it is plausible that inflammation associated with other chronic lung diseases influences HIV persistence.

Although the lungs are highly vascular and do not have a specific barrier preventing entry of certain agents, they nonetheless are a unique anatomical compartment. Notably, the millions of closely packed cells promote cell-to-cell spread of virus which enables for escape from host immune defenses and exposure to antiretrovirals (Sigal et al. 2011). Evidence from both simian and human studies shows that HIV burdens in lungs often, but not always, exceed than in peripheral blood. In a simian study whereby primates had suppressed peripheral viral loads, the lungs and gut had approximately equal amounts of HIV (Horiike et al. 2012), and various human studies, involving heterogeneous groups of HIV patients, showed marked differences in quantities of HIV in lungs versus peripheral blood (Costiniuk and Jenabian 2014). In one of the largest early studies

examining 78 HIV-infected patients undergoing bronchoscopy for respiratory symptoms or abnormal chest X-rays, Clarke et al. documented a mean DNA copy number in BAL of 2791/10⁶ cells, mean HIV proviral DNA copy number in non-adherent BAL of 1746/10⁶ cells, and mean HIV proviral DNA copy number in adherent BAL of 1478/10⁶ cells (Clarke et al. 1994). In contrast, mean DNA copy number in adherent peripheral blood leukocytes was 391/10⁶ leukocytes, HIV proviral DNA copy number in peripheral blood lymphocytes was 303 copies/10⁶ lymphocytes, and mean HIV proviral DNA number in monocytes/peripheral blood-derived macrophages was 606 copies/10⁶ cells (Clarke et al. 1994).

Some studies have also found genotypic variability between HIV in the lungs and peripheral blood. Using DNA sequence analyses of HIV gp120 V3–V5, Nakata et al. demonstrated full separation of HIV lineages from lungs and blood in four out of five patients (Nakata et al. 1995). HIV within AMs has also been shown to evolve to a greater degree than HIV in peripheral monocytes (Itescu et al. 1994). Coinfection may also influence HIV evolution in anatomical compartments. Using phylogenetic and phonetic analysis of the C2–C3 coding regions of HIVenv, Collins et al. found compartmentalization of HIV quasi-species between blood and the pleural space in four out of eight patients, with migration between the blood and pleura (Collins et al. 2002). They found a trend toward more genetic heterogeneity within the pleural space, which they suggest could be due to increased HIV replication due to coinfection or local selection pressure (Collins et al. 2002). Finally, HIV co-receptor usage within the lungs is CCR5 tropic, while HIV in peripheral blood may be both CCR5 and CXCR4 tropic, although secondary co-receptor usage does not differ between HIV from blood versus lungs (Singh et al. 1999).

Effect of HAART on HIV Reservoirs and Pulmonary Immunity

The majority of studies which have examined HIV burden between lungs and peripheral blood

were performed in the pre-HAART era, whereby many individuals either were not on therapy or were on zidovudine or didanosine monotherapy and many individuals had indication for bronchoscopy such as pulmonary symptoms or abnormal chest imaging (Costiniuk and Jenabian 2014). Many of the studies were confounded by smoking (Costiniuk and Jenabian 2014). In the HAART era, Twigg III et al. examined the effect of HAART after 1 month and 6 months of treatment. They observed a decline in BAL fluid HIV in addition to a decline in CD8 T cells, although intrapulmonary HIV still remained detectable, especially in DNA in BAL CD4 T cells (Twigg III et al. 2008). Interestingly, the rate of HIV decay within the lungs was more rapid than that observed in peripheral blood (Twigg III et al. 2008). In another study by Knox et al., they found that BAL CD4 lymphocytes were not depleted in gross quantities in chronic HIV infection that CD4 BAL lymphocytes begin to reconstitute 1 month after HAART initiation and reconstitute to an even greater extent after 1 year of HAART (Knox et al. 2010). They suggest that the mechanism of reconstitution is due to proliferation of local CD4 T cells rather than redistribution (Knox et al. 2010). They also found that pulmonary CD4 T cells are more polyfunctional than peripheral blood CD4 T cells (Knox et al. 2010). With regard to peripheral CD161+ MAIT cells, Eberhard et al. found that peripheral MAIT cells did not recover to levels observed in HIV-uninfected controls despite HAART (Eberhard et al. 2014). In terms of antiretroviral penetration into the lungs, to date, little research has been conducted. In one study involving 24 HIV-infected individuals, assays for a variety of antiretrovirals were performed following 4 and 24 weeks of therapy initiation (Twigg III et al. 2010). Efavirenz, the only non-nucleoside reverse transcriptase inhibitor (NNRTI) examined, was detectable in 63% of BAL fluid measurements, while nucleoside reverse transcriptase inhibitors (NRTIs) were detectable in 44% and protease inhibitors (PI) in 46% of BAL fluid measurements (Twigg III et al. 2010). Furthermore, BAL fluid concentrations of NRTIs, the NNRTI

efavirenz, and PIs were 60–73%, 31%, and 66–200% of those observed in plasma, respectively (Twigg III et al. 2010). Of note, efavirenz had the longest half-life and was the most lipid soluble of all the antiretrovirals examined (Twigg III et al. 2010).

Future Areas of Study for the Lungs as HIV Reservoirs

An important first step for the study of the lungs as HIV reservoirs will be to better quantify the burden of pulmonary disease among HIV-infected individuals via heightened screening for individuals with clinical symptoms or risk factors for lung disease. It will also be important to screen individuals at risk of developing future lung disease, in an attempt to detect subclinical disease and attempt to halt disease progression. This may take the form of screening programs involving spirometric and diffusion capacity assessment. In smoking HIV patients, there may be a need for screening CTs to help identify early signs of cancer and continued emphasis on smoking cessation. Identification of the role of different pulmonary immune cells involved in the control of pulmonary HIV will also be important. Although they have not yet been examined in the lungs of HIV-infected patients to date, tissue resident memory T cells (Trm) will likely gain attention in upcoming years. These cells initiate cytokine release following infection and induce antimicrobial response through pattern recognition receptors (PRR). It will also be important to refine our understanding of the role of AMs as in maintaining the pulmonary HIV reservoir given their relative resistance to apoptosis and expression of drug efflux transporters, limiting entry of HIV into these cells (Perno et al. 1998). Similarly, it will be important to better understand the role of HAART-induced reduction in pulmonary inflammation in BAL fluid and its effects on pulmonary immune cell function and the intrapulmonary HIV reservoir. In order to understand the HIV reservoir, mucosal lung biopsies in order to quantify the level of HIV, compared with other

compartments, may be informative. However, bronchoscopy itself is invasive. Although noninvasive techniques are available to study pulmonary inflammation, such as sputum induction and exhaled breath condensate, they are not always reliable. Furthermore, exhaled breath condensate does not allow for the collection of cells in order to quantify the pulmonary cellular reservoir.

Characterization of the pulmonary microbiome may also shed insight into HIV-associated chronic lung disease and maintenance of the pulmonary HIV reservoir. This will likely change in different geographic situations and will be influenced by coinfection with pathogens such as *Mycobacterium tuberculosis*. Furthermore, understanding the implications of the pulmonary reservoir on defined clinical outcomes will be of paramount importance. Finally, although most work on the lungs as reservoirs of HIV have been conducted in North America, where clade B virus predominates, understanding different viral clades, and especially clade C which is endemic in the sub-Saharan Africa, would broaden our understanding of the HIV reservoir on a global scale.

Conclusion

With increasing longevity, HIV-infected individuals are developing more chronic lung diseases. Epidemiological studies have revealed that HIV itself is a risk factor for chronic lung disease. Pulmonary HIV is associated with various immune perturbations, not all of which normalize with HAART. Evidence for the lungs as HIV reservoirs comes from studies demonstrating different HIV burdens and distinct HIV variants in lungs versus peripheral blood. HIV persistence is also supported by its propensity to infect AMs, long-lived cells relatively resistant to apoptosis, and the high density and close proximity of millions of cells within the lungs which enable cell-to-cell spread of HIV. Understanding the role of the lungs as HIV reservoirs is important as we continue to invest efforts toward HIV eradication strategies.

Definition

HIV testing and counseling (HTC) has been a mainstay of HIV prevention since the late 1980s

in the USA and worldwide. Since its inception, HTC has provided the opportunity for individuals to learn their status, develop a plan to reduce their risk of contracting or transmitting HIV, and, if necessary, link to HIV services. Expanding coverage of HIV testing continues to be an urgent national and global priority (Joint United Nations Programme on HIV/AIDS 2014; White House Office of National AIDS Policy 2015; Office of Disease Prevention and Health Promotion 2016). There has been a growing recognition both in the United States (USA) and internationally that there are a sizeable number of persons living with HIV who are not aware of their HIV status. In the USA, it is estimated that one in eight HIV-positive individuals are unaware of their status (Centers for Disease Control and Prevention 2016a), and globally, it is estimated that the majority of adults are unaware of their HIV status. In 2015, only 44.1% of adults in the USA had tested for HIV at some point in their lifetime (Kaiser Family Foundation 2016). This represents a modest increase since 1997, when 31.8% of adults had ever tested for HIV (Centers for Disease Control and Prevention 2011). Young people (defined as aged 13–24) are at particular risk, accounting for 22% of all new HIV diagnoses in 2014 (Centers for Disease Control and Prevention 2016b). Yet, this age group exhibits low rates of testing, and young people currently have the highest rates of undiagnosed HIV as well as the lowest rates of linkage to care and viral suppression, in the USA. For example, in 2012, it was estimated that 57,200 young people aged 18–24 were HIV positive in the USA, of which 25,300 (44.2%) were not diagnosed (Centers for Disease Control and Prevention 2016b). According to data from the US Centers for Disease Control Youth Risk Behavior Surveillance System, only 22% of sexually active high school students have ever received an HIV test (Coeytaux et al. 2014).

In addition, the 2006–2010 National Survey of Family Growth found that less than 30% of men aged 15–44 who reported high-risk behaviors had not been HIV tested in the prior year (Handel et al. 2015). In sub-Saharan Africa, the geographic region most heavily burdened by HIV/AIDS, some countries have implemented national campaigns that have helped expand testing (AVERT

2016); for example, the number of individuals tested in Kenya increased from less than one million in 2008 to over six million in 2013 (National AIDS Control Council of Kenya 2014). Yet, in other sub-Saharan regions like Ghana, Guinea, Niger, and Liberia, the prevalence of individuals ever tested is less than 10% (Staveteig et al. 2013). Increased HIV testing coverage is therefore needed in order to implement appropriate interventions that may link HIV-positive individuals to antiretroviral treatment, reduce HIV transmission, expand access to HIV care for persons living with HIV/AIDS, and access to preventive interventions such as pre-exposure prophylaxis (PrEP).

History of Testing and Counseling

In 1985, the enzyme-linked immunosorbent assay (ELISA), or enzyme immunoassay (EIA), became the first licensed HIV antibody test and was widely used in clinical-care settings, blood banks, plasma-collection centers, and health departments. The United States Public Health Service (USPHS) also sponsored 874 alternative test sites, where individuals at high-risk could learn their status, by the end of 1985 (Centers for Disease Control and Prevention 2006). In 1986, the Centers for Disease Control (CDC) issued the first official guidelines on testing and counseling, which emphasized the importance of voluntary testing and counseling for individuals at high risk for HIV/AIDS, and stressed the inclusion of risk-reduction strategies and clear explanations of positive and negative results. These guidelines also highlighted the urgent need for confidentiality in order to increase rates of testing and counseling at a time when discrimination against HIV-positive individuals was increasingly widespread. One year later, CDC guidelines were revised in order to expand testing further. The 1987 guidelines aimed to reach individuals engaging in high-risk behaviors by recommending HIV testing for all individuals seeking treatment or testing for sexually transmitted infections (STIs) and/or individuals seeking treatment for injection drug use. These guidelines cited concerns about confidentiality as a major barrier to testing and

emphasized the importance of maintaining confidentiality.

In 1993 and 1994, the CDC issued new guidelines for HTC, outlining the need for a client-centered approach to counseling, which included an interactive risk assessment and a personalized risk-reduction plan during pretest counseling. In client-centered counseling, the provider aims to interact with the individual in an objective, non-judgmental manner, in order to communicate messages of risk reduction that are relevant and meaningful to the individual. The ultimate prevention goal of client-centered counseling is to develop a plan to reduce behaviors that put clients at risk for contracting or transmitting HIV. During this time, HIV antibody testing typically involved two visits: one visit to draw blood and one visit to receive test results. Because of the sensitivity of the ELISA test, tests were confirmed with the Western blot blood test, which lead to a wait time of up to 2 weeks until the second visit to receive test results. Pretest counseling occurred during the first visit and typically included a client-centered risk assessment, the development of a personalized risk-reduction plan, and preparing the client for understanding their test result. The second visit included the delivery of the test result along with posttest counseling, which generally consisted of helping the client to interpret their test result, integrating that knowledge into their personalized risk-reduction plan, and referral of support services (Centers for Disease Control and Prevention 1994). This second visit presented a significant barrier to the receipt of test results – up to 50% of individuals testing at clinics failed to return to receive their results (Branson 2003).

Rapid HIV tests have the advantage of potentially delivering test results at the point of care, which guarantees increased receipt of test results. Therefore, the implementation of rapid HIV point-of-care (POC) testing was a critical development to HIV prevention efforts. In 1992, the first rapid HIV-1 test called single-use diagnostic system for HIV-1, or SUDS, was developed and approved by the Food and Drug Administration (FDA). However, it was found to be unsuitable for point of care because it requires centrifugation

which must be performed in a laboratory. In 2002, a new rapid HIV-1 test, OraQuick Rapid HIV-1 Antibody Test, was approved by the FDA and granted a 2003 waiver under the Clinical Laboratory Improvement Amendments (CLIA), allowing OraQuick to be used as a point-of-care testing strategy using a blood stick. The CLIA waiver allowed the OraQuick test to be used in non-laboratory settings, an important element in the expansion of HIV testing. While CDC protocols mandated confirmatory testing for all rapid HIV testing with a Western blot or immunofluorescence assay (IFA), rapid testing offered a drastic reduction in wait times for results, and OraQuick could deliver results in 20–45 min. In 2004, the first rapid oral fluid test was approved by the FDA and granted a CLIA waiver. This OraQuick Advance HIV-1/2 test was approved for use with oral fluid and plasma specimens (Branson 2003). Again, the OraQuick Advance HIV-1/2 test was to be confirmed by a Western blot or IFA. The development of blood stick and oral fluid rapid HIV testing allowed the implementation of HIV in nontraditional settings, expanding HIV testing even further.

In 2006, the CDC released new guidelines that recommended the expansion of HIV screening as a routine part of healthcare for all adults (Centers for Disease Control and Prevention 2006). By recommending an opt-out routine screening system, the CDC hoped to reduce HIV transmission by identifying and counseling individuals with HIV, linking persons with HIV to care, reduce perinatal transmission, promote early detection of HIV, and normalize HIV testing (Centers for Disease Control and Prevention 2006). The 2006 CDC-recommended model included information provision as an element of screening and encouraged counseling for individuals at high risk, at the discretion of the provider (Holtgrave 2007; Bartlett et al. 2008). This shift was fostered by the lack of scientific consensus at the time regarding the benefits of HIV counseling for HIV-negative individuals and the high levels of general HIV knowledge in the US population (Janssen 2007).

The recommendation to integrate HIV testing into routine healthcare was met with strong

approval. However, critics noted the potential ramifications of testing without respect to risk, issues of consent including patient consent and conflicting state regulations regarding consent, problems with third-party reimbursement of HIV screening, cost-effectiveness of opt-out testing versus targeted HTC, and a possible lack of adequate counseling (Holtgrave 2007; Lyons et al. 2007; Bartlett et al. 2008; Mahajan et al. 2009). Additionally, previous studies have raised concerns over the feasibility of integrating HIV screening into primary care settings, such as lack of time, perceptions of patient nonacceptance and discomfort, lack of training for providers, and low awareness of or agreement with screening guidelines (Koester et al. 2007; White et al. 2014; Zheng et al. 2014). Recent research has demonstrated that in spite of these potential barriers, integrating HIV screening into primary care increases patients' feelings of empowerment and reduces stigma associated with HIV and HIV testing (Simmons et al. 2011). Physicians who have been trained to deliver HIV screening have demonstrated increased levels of self-efficacy, comfort, and willingness to discuss prevention issues with patients (Dreisbach et al. 2014; Thrun et al. 2009). Furthermore, trained physicians reported perceiving HIV screening to be within their mission as primary care providers (Myers et al. 2012).

The 2006 CDC recommendations provided a foundation to alter the traditional model of client-centered HTC and facilitate expanded HIV testing to other nontraditional healthcare facilities, such as the dental setting (Pollack et al. 2014; Durall et al. 2015), substance use disorder treatment programs (Pollack and D'Aunno 2010; Metsch et al. 2012), and emergency departments (Brown et al. 2007). The CDC's Expanded Testing Initiative has supported these recommendations by funding programs to increase testing in new clinical, non-healthcare settings in US jurisdictions that are disproportionately impacted by HIV/AIDS (Centers for Disease Control and Prevention 2015). Finally, the Affordable Care Act (ACA), enacted in March 2010, mandated that non-grandfathered health insurance plans cover,

without additional cost-sharing, preventive services that are given an A rating by the United States Preventive Services Task Force (USPSTF), which includes HIV testing for individuals aged 15–65 years as well as younger and older individuals who are at heightened risk (U.S. Preventive Services Task Force 2016). By minimizing patient financial burden, the ACA helped enhance access to healthcare and recommended preventive and treatment services, including HIV testing (Viall et al. 2016). While the impact of the ACA on HIV testing uptake has not yet been systematically assessed, projections estimate that by 2017, the ACA will account for an additional 466,153 individuals receiving testing and almost 2,600 new HIV diagnoses (Wagner et al. 2014).

Effect of HIV Testing and Counseling

Studies of HTC provide a complicated portrait of its effectiveness. Researchers have found it difficult to measure the effects of HTC together, as opposed to the simple effect of knowing one's status. Reductions in risk behaviors in the 1990s may have been attributable to a general increase in knowledge and awareness of HIV/AIDS prevention among high-risk populations. Several studies have demonstrated substantial risk reduction among HIV discordant couples or couples in which one partner is HIV positive, and one partner is HIV negative. For other populations, studies demonstrating the effectiveness of HTC have been mixed.

In the 1990s, several studies were released that demonstrated the limited effects of counseling on various populations. In 1991, a prominent meta-analysis found that counseling had greater effects on reducing risk behaviors in HIV-positive individuals than HIV-negative individuals (Higgins et al. 1991). In a 1999 meta-analysis, a different group of researchers argued that HIV counseling was not an effective primary prevention strategy or method of reducing HIV transmission among HIV-negative individuals, asserting instead that counseling could be perceived as a *secondary*

prevention strategy or a method to reduce risk behavior among individuals who had tested positive for HIV (Weinhardt et al. 1999). Their main finding supported the conclusion that HIV-negative individuals who participated in counseling did not modify their sexual risk behavior any more than individuals who had not participated in counseling, while HIV-positive participants and HIV discordant couples (e.g., counseled together) reduced unprotected sex and increased condom use relative to HIV-negative and untested participants. However, CDC researchers subsequently argued that the majority of the studies included in the 1999 meta-analysis had taken place prior to the adoption of the 1993 client-centered counseling approach, and therefore did not provide an accurate evaluation of its effects (Holtgrave and McGuire 2007). CDC researchers asserted that Project RESPECT, an ongoing multicenter randomized control trial (RCT), demonstrated the effectiveness of their client-centered counseling approach (Kamb et al. 2000).

Project RESPECT was the first RCT to report findings that demonstrated the reduced incidence of STIs (including HIV) among participants who had engaged in HTC since the 1993 CDC-recommended client-centered approach had been implemented. It is important to note, however, that Project RESPECT enrolled only persons at risk for heterosexual transmission and did not account for men who have sex with men (MSM). Findings from Project RESPECT indicated that interactive, client-centered HIV and STI counseling led to a reduced STI incidence among HIV-negative participants, both men and women (Kamb et al. 1998). Additionally, Project RESPECT was conducted among busy, public, inner-city clinics, demonstrating that client-centered counseling was not only feasible among publicly funded clinics but also successful and effective. Further reports from Project RESPECT found client-centered HTC to be effective among high-risk groups, such as teenagers, individuals with STIs at enrollment, and drug users (Bolu et al. 2004; Semaan et al. 2010). However, a 2008 systematic review of behavioral counseling HIV/STI prevention interventions found that of 15 RCTs, Project RESPECT was the only study

of moderate-intensity counseling to document an impact on subsequent STI acquisition (Lin et al. 2008).

The 2009 HIV Rapid Testing and Counseling Study, which assessed the use of on-site HIV testing at 12 US community-based drug treatment programs, showed that the addition of counseling to on-site HIV testing offered no significant effect on testing or sexual risk behaviors (Metsch et al. 2012). In addition, a cost analysis of the study demonstrated that risk-reduction counseling provided no added benefit to the patient, accounting for projected life expectancy, lifetime costs, and quality-adjusted life years; researchers concluded that on-site rapid testing with information provision only was the most cost-effective approach (Schackman et al. 2013). In 2010, Project AWARE evaluated the effectiveness of HIV testing in STI clinics, comparing brief patient-centered risk-reduction counseling with information provision only; researchers found no significant difference in cumulative STI incidence after 6 months, demonstrating that counseling at the time of testing provides no additional benefit to the patient (Metsch et al. 2013). Given the additional resources and financial costs associated with counseling at the time of testing, these findings indicate a need to reevaluate the role of risk-reduction counseling offered at the time of HIV testing (Haukoos and Thrun 2013).

Other innovative testing and counseling interventions have been developed for focused high-risk populations, such as men who have MSM and drug users. For MSM, studies have demonstrated the effectiveness of personalized cognitive counseling (PCC) in producing significant behavior changes (Dilley et al. 2007). PCC includes targeting “self-justifications” that individuals utilize in their decisions regarding high-risk behavior. These self-justifying thoughts, attitudes, and beliefs are identified and discussed with a counselor, with the primary goal of developing alternative ways of thinking in order to affect behavior change. Couples-based voluntary HIV counseling and testing (CVCT) has also been developed for MSM partnerships and evaluated the association between relationship characteristics, such as

relationship satisfaction and monogamy and positive testing behaviors (Mitchell 2014).

Global Developments in HIV Testing and Counseling

Global HIV testing uptake has increased dramatically in the past decade. In 2007, the WHO and UNAIDS recommended the adoption of provider-initiated testing and counseling (PITC) as a standard of care in an effort to expand global HIV testing coverage and encouraged the routine offering of PITC in clinical settings such as antenatal care services, tuberculosis (TB) clinics, and STI clinics in high-burden areas (World Health Organization 2007). Along with the expansion of PITC, the implementation of other testing strategies, such as community- and home-based testing and the use of rapid testing to deliver same-day test results, contributed to a substantial increase in HIV testing coverage between 2005 and 2015, as the percentage of people living with HIV worldwide who knew their status increased from 12% to 60% (World Health Organization 2015a, 2016). While these numbers represent significant progress in global HIV testing coverage, 40% of people living with HIV globally remain unaware of their status, and the WHO has called for the expansion and improvement of HIV testing services in order to reach people living with HIV who are unaware of their status and link them to HIV care and treatment programs (World Health Organization 2015b).

In 2014, UNAIDS released new global targets for HIV diagnosis and treatment, known as the “90-90-90” plan, proposing that by 2020, 90% of all people living with HIV will know their status, 90% of all people living with HIV will receive sustained antiretroviral therapy (ART), and 90% of all people receiving ART will achieve viral suppression (Joint United Nations Programme on HIV/AIDS (UNAIDS) 2014). In response to these ambitious goals, the WHO updated and expanded their guidelines on HIV testing and counseling in 2015, releasing “Consolidated Guidelines on HIV Testing Services 5Cs: Consent, Confidentiality, Counseling, Correct Results

and Connection.” These new guidelines replace the term “HIV testing and counseling” with “HIV testing services (HTS),” in order to embody the full range of services that accompany HIV testing: pretest information; posttest counseling; linkage to prevention, care, and support; and laboratory quality assurance to ensure correct results (World Health Organization 2015c). Guidelines also affirm the need for expanded HTS, noting that additional approaches to HTS are needed to increase testing uptake among men in high prevalence settings, adolescents (10–19 years of age), infants and children, and couples and partners, including serodiscordant couples. Additionally, WHO guidelines call for increased efforts to expand HTS for key populations such as men who have sex with men, people in prisons, people who inject drugs, sex workers, and transgender individuals and for vulnerable populations in high prevalence settings such as migrant workers, refugees, and other displaced populations (World Health Organization 2015c).

While 2015 WHO guidelines maintain the importance of counseling as an integral part of HTS, counseling recommendations have been updated to adapt to resource limitations and new HIV testing strategies, such as rapid diagnostic tests (RDT), which deliver same-day test results. Guidelines recommend the provision of pretest information and discourage the use of individualized risk assessment and individualized counseling during the pretest period. After testing, guidelines recommend that individuals who test HIV-negative receive brief health information about their HIV status, future HIV prevention, and how to link to HIV prevention services as appropriate; individuals who are diagnosed as HIV-positive or who are part of a couple where one or both individuals are diagnosed HIV-positive should still receive post-test counseling and linkage to care and treatment (World Health Organization 2015c).

Innovative approaches to HTS are needed to increase HIV testing coverage globally. The WHO calls for expansion of PITC, particularly in family and pediatric healthcare settings to increase early infant diagnosis, and recommends the adoption of new testing tools and strategies,

including self-testing (with confirmatory clinic testing), the use of lay health providers to administer rapid diagnostic tests (RDTs), and a new model of community-based testing called “test for triage,” in which individuals are tested via RDT and then linked to clinical care for confirmatory testing and treatment (World Health Organization 2015c). Recent studies of HIV testing uptake interventions have demonstrated promise with various strategies such as community-, home-, mobile-, and work-based testing (Bateganya et al. 2010; Chamie et al. 2016; Corbett et al. 2006; Labhardt et al. 2014; Sabapathy et al. 2012; Suthar et al. 2013), index patient testing approaches (offering testing to household members of high-risk individuals) (Shapiro et al. 2012; Velen et al. 2016; Were et al. 2006), partner testing (offering testing to partners of high-risk or HIV-positive individuals) (Onyango Osofi et al. 2014; Plotkin et al. 2016), and self-testing (Figueroa et al. 2015; Pant Pai et al. 2013).

Moving Forward

Efforts to expand HIV screening have utilized new technologies in order to increase the uptake and effectiveness of screening. Researchers have found rapid testing to be highly acceptable as a screening tool and more effective than standard HIV testing at communicating results, due to the reduced need for a return visit (Pottie et al. 2014); individuals are 1.5–2.2 times more likely to receive their results by using rapid testing than standard HTC (Hutchinson et al. 2006). Other innovative approaches have included integrating HIV screening and services into substance use disorders treatment programs, which was found to be highly feasible and effective, and implementing routine HIV screening in hospital emergency departments, which was found to be feasible and cost-effective and was well-received by patients (Brown et al. 2007; Gunn et al. 2005). Incorporating rapid HIV testing into dental visits has been suggested as an opportunity to reach patients that may not have contact with other clinical providers (Pollack et al. 2010, 2014). In June 2012, the CDC announced their 2-year plan

to train pharmacists and staff at 24 community pharmacies and retail clinics with high HIV prevalence or significant testing needs, in order to deliver confidential rapid HIV testing (Centers for Disease Control and Prevention 2012b). Studies have since demonstrated the feasibility and acceptability of rapid HIV testing in the pharmacy setting in both rural and urban communities in the USA (Darin et al. 2015; Weidle et al. 2014). Strategies such as these represent new resourceful approaches that work to expand HIV screening by reaching untapped populations and environments.

In 2012, the US Food and Drug Administration (FDA) approved the first over-the-counter at-home rapid HIV test kit, the OraQuick In-Home HIV Test, capable of testing for both HIV-1 and HIV-2. The OraQuick In-Home HIV Test is an oral fluid test that captures results in 20–40 min, and does not require a laboratory analysis. The FDA has approved the kit for use by adults over 17 years of age and has asserted the need for confirmatory testing. The creator of the test kit, OraSure, has set up a 24-h toll-free telephone-based consumer support center that will offer information for referrals to care and any questions about the test. The approval of this at-home rapid test kit may normalize HIV testing; however critics have voiced concerns regarding the lack of provider guidance and in-person counseling.

Finally, HIV testing technologies are advancing quickly. Immunoassays that detect antibodies earlier are now approved for HIV diagnosis by the FDA, which will allow for earlier diagnosis and linkage to care (Branson 2012). Given the limited sensitivity of the Western blot, alternative confirmatory strategies have been suggested, such as the combination of rapid tests and/or the use of nucleic acid amplification tests (NAATs), which detect HIV RNA (Daskalakis 2011). In 2013, the FDA approved rapid diagnostic tests that are able to detect the HIV-1 antigen in addition to HIV antibodies and distinguish between acute versus chronic HIV infection, leading to faster results and facilitating early HIV diagnosis (U.S. Food & Drug Administration 2013). Emerging technologies include multiplex tests to identify multiple pathogens (e.g., HIV and hepatitis) simultaneously and POC nucleic acid tests, which utilize

targeted RNA/DNA amplification to facilitate early identification of acute infections (Wesolowski et al. 2017). Alternative confirmatory strategies in rapid HIV testing could facilitate significant increases in HIV testing and early diagnosis, receipt of results, and HIV prevention and linkage to care.

Conclusion

New technologies, approaches, and policies to HIV testing and counseling are rapidly being developed and implemented in order to expand HIV screening, both in the USA and globally. More research is needed on unconventional strategies and locations for HIV testing and counseling and/or screening, in order to develop feasible and effective interventions. It is important to remain vigilant regarding the possible ramifications of expanding HIV screening, by continuing to research the role of counseling in HIV prevention. By expanding coverage and increasing access to HIV screening, more individuals will be able to learn their status, reduce risk of transmission, and seek care.

HIV Transmission in Female Commercial Sex Workers and Host Protective Factors

Kristina Broliden¹, Andrea Introvini¹ and Adam Burgener²

¹Department of Medicine Solna, Karolinska Institute, Center for Molecular Medicine, Karolinska University Hospital, Stockholm, Sweden

²Department of Medical Microbiology, University of Manitoba, Winnipeg, MB, Canada

Introduction

HIV currently infects over 33 million people globally and the major route of transmission remains heterosexual intercourse. Already at the beginning of the epidemic, it was noted that a minority

of highly HIV-exposed seronegative (HESN) individuals seemed to resist the infection and remain uninfected despite continuous contacts with the virus over years. These individuals include sex workers, HIV-serodiscordant couples, children born to HIV-infected mothers, and other individuals that are at risk of acquiring HIV. For more than 25 years, the scientific community has tried to define correlates of protective immunity to HIV studying these cohorts. One of the strategies was to assess blood and mucosal fluids from men and women with high-risk behavior living in endemic communities. These samples have been compared to those of individuals who are at low risk of infection as well as to samples of HIV-infected individuals. Although a number of markers have been found to differ between these three groups, there is only one, a deletion in the CCR5 co-receptor for HIV (CCR5 Δ 32), that has been demonstrated to mechanistically account for resistance against infection (Liu et al. 1996). This mutation is however rare in the global population and almost absent in Africa, where most HIV infections occur; therefore, it cannot account for the approximately 5% of high-risk individuals that seem to be relatively resistant to infection. Despite intensive research efforts that have been spent, very little has been known about the specific immune mechanisms and/or genetic background responsible for decreased susceptibility to HIV infection. It is most likely that a combination of factors are necessary to confer protection and no single explanation can be found, with the exception of the CCR5 Δ 32 mutation, that strongly accounts for HIV resistance by itself. By studying a specific risk group, female commercial sex workers (CSW), several correlates of resistance have been suggested and more unified patterns of protection have finally been starting to emerge.

Defining Study Groups for Assessing Correlates of HIV Resistance

If the search for correlates of resistance to HIV infection is narrowed down to the situation of heterosexual transmission during vaginal intercourse, the most common transmission route

globally, female CSW can be used as a study group. These women may have a different genital microenvironment than non-CSW due to frequent unprotected sexual encounters with multiple clients. In general they also have a higher risk of acquiring other sexually transmitted infections, and their immune responses may be chronically activated by the continuous exposure to components and pathogens present in seminal fluid as well as frequent vaginal hygienic practices. The sex work as such may thus influence the immune parameters in addition to the exposure to HIV and must be taken into account when selecting appropriate control groups. The control groups available are usually non-sex-working low-risk subjects from the same geographical area. To control for the influence of sex work, it is common to include sex-working HIV-seronegative women who do not have sufficient infection pressure to be considered HIV resistant. Although a few of these may actually belong to the resistant phenotype, it is likely that at least 90% of them are susceptible to HIV infection. Nevertheless, in order to find true correlates of HIV resistance, the HESN CSW groups must have a very high rate of exposure to HIV since only an estimated 1:200–1:2,000 sexual encounters between HIV-serodiscordant men and women result in HIV infection (Powers et al. 2008). With an increasing condom use among CSW and a higher number of clients being on antiretroviral treatment, the exposure to HIV will likely be too low to allow the identification of truly HIV-resistant individuals and define appropriate study cohorts in the future.

HIV Entrance into the Female Genital Tract

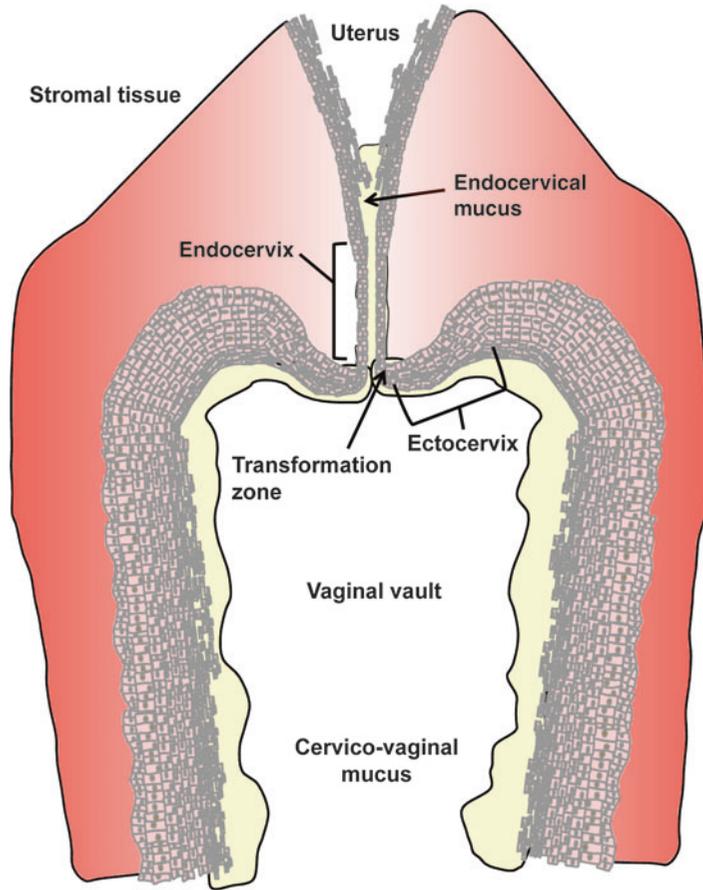

To identify host protective factors against HIV infection in female CSW, it is important to understand the early events in viral transmission to the female genital mucosa. The female genital tract is endowed with anatomical and biological defensive mechanisms, such as a robust epithelium covered by mucus (Fig. 1), several types of immune cells, and soluble immune factors

(Fig. 2). Together this barrier is normally effective in preventing infection from invading microorganisms including HIV. The virus can be present in both blood and seminal fluid of HIV-infected men and can be transmitted to the female genital mucosa during sexual intercourse (Southern 2013). The risk of transmission is increased in the presence of inflammation of the female genital mucosa which may be caused by preexisting infections, altered microflora, and particular hormonal conditions, associated with different stages of the menstrual cycle or the use of hormonal contraceptives. Genital inflammation results in the local recruitment of immune cells and may also impair the epithelial barrier, favoring viral penetration into the subepithelial layer of the mucosa. Although an increased number of immune cells within the mucosa may enhance the defenses against HIV, activated CD4+ T cells are among the preferential target of the virus and can thus promote local amplification and spread of the infection. HIV can also directly bind and pass through epithelial cells and be captured by macrophages, Langerhans cells, or dendritic cells to subsequently be transferred to CD4+ T cells. Once the founder pool of infected CD4+ T cells in the mucosa starts to expand, it is hard to hinder further spread of the virus to regional lymph nodes followed by systemic infection and establishment of reservoirs of latently infected cells (Fig. 2).

The physical barriers and the anatomical structure of the female genital tract, including the thickness of the epithelium and quality of epithelial junction proteins, have not been specifically evaluated in HESN CSW, although they could be an important defense factor against HIV transmission through sexual intercourse. To date most of the studies on this cohort aimed to identify correlates of protection within the immunological responses and genetic background of the host, which will be reviewed in the following sections.

Genital Immune Responses Against Primary HIV Infection

In general, whether it is an allergic reaction or a response to an invading pathogen, the outcome of

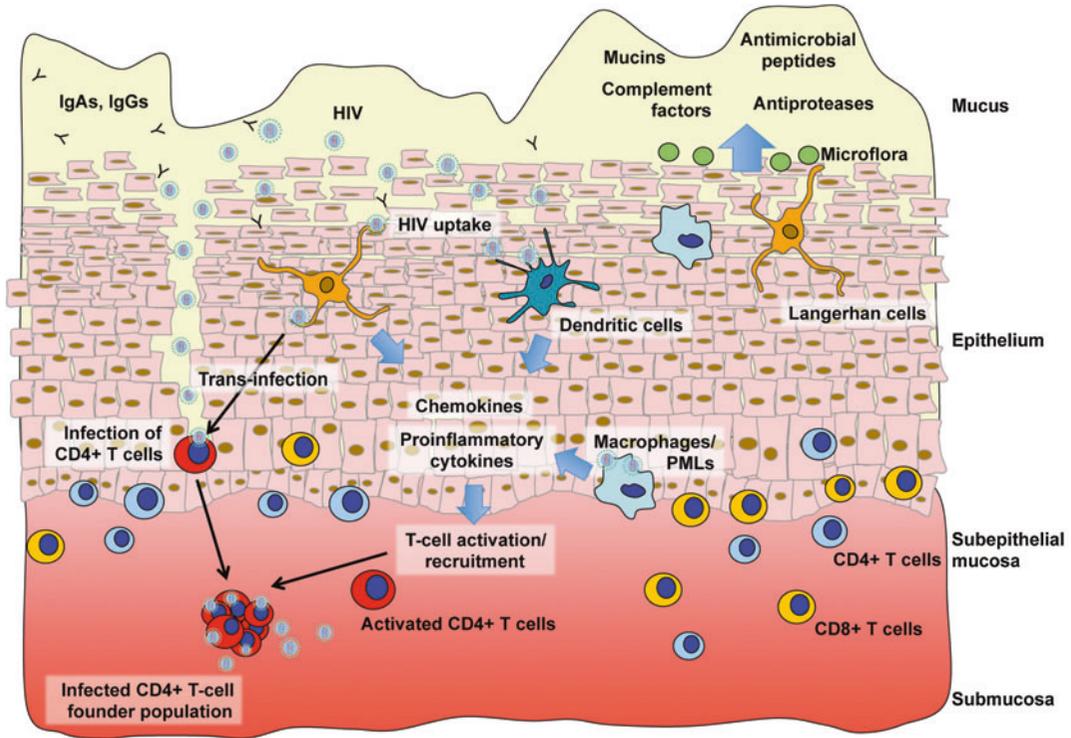

HIV Transmission in Female Commercial Sex Workers and Host Protective Factors, Fig. 1 Anatomy of the lower female genital tract. The cervix represents the lower part of the uterus. The endocervix lines the lumen of the canal that provides communication between the cavity of the body of the uterus and that of the vagina. The protruding portion of the cervix projects into the vagina through the upper anterior vaginal wall and is referred to as ectocervix. The epithelium of the cervix is varied. The ectocervix is covered by stratified squamous nonkeratinized epithelium, which is a continuation of the vaginal epithelium. Usually, this type of epithelium extends from a very short distance into the cervical canal, where it forms a rather abrupt junction with the simple

columnar epithelium lining the rest of the endocervical canal, called transformation zone. Unlike the mucosa of the body of the uterus, the endocervical mucosa does not slough off at menstruation. It does, however, respond to cyclic changes in the levels of the ovarian hormones. It secretes up to 60 mg of mucus a day throughout much of the cycle, but near the time of ovulation, the secretion rate increases tenfold and the abundant clear mucus fills the cervical canal. The mucus that covers the ectocervix and the vagina is a mix of locally produced secretions and endocervical mucus. The stroma beneath the epithelium consists primarily of dense collagenous connective tissue and only about 15% of its substance is smooth muscle

an immune reaction is strongly dependent on the balance between the pro-inflammatory (active) and the anti-inflammatory (dampening) response. A number of different immune cells and soluble molecules can have either one or both of these properties depending on timing, localization, and concentration in tissue, blood, or mucosal

secretions. In the case of HIV, it is even more complex since the same cellular subset (e.g., CD4⁺ T cell) and molecule (e.g., CCR5-binding chemokines) can act as friend and foe of the host, by enhancing the anti-HIV defense and the recruitment and activation of HIV target cells at the same time, as mentioned above. Studies on

HIV Transmission in Female Commercial Sex Workers and Host Protective Factors, Fig. 2 HIV infection and defenses of the female genital mucosa.

The pluristratified epithelium represented in the figure is characteristic of the ectocervical-vaginal mucosa. The mucosa comprises the epithelium and the stroma immediately beneath the epithelium. The deeper layers of stromal tissue represent the submucosa. HIV can infect the mucosa of the vagina as well as that of the uterine cervix, either the ectocervical or endocervical mucosa, although differences, if any, in the contribution of these three sites to the global transmission rate via vaginal intercourse remain unknown. The layer of mucus covering the epithelium mechanically hinders the invasion of HIV virions, which can also be neutralized by the soluble components present therein. The composition in immunological soluble factors of mucus varies. For instance, changes in the local microflora and invading microorganisms can be sensed by epithelial, polymorphonuclear leukocytes (PMLs) and antigen-presenting cells, in particular Langerhans cells, through

an array of receptors able to discriminate between pathogens and commensals, which represent an important link between innate and adaptive immunity. Local inflammation can weaken and damage the epithelium, promoting the penetration of HIV into the subepithelial layer of the mucosa, where most CD4+ T cells reside. Micro-abrasions of the epithelium also normally occur during sexual intercourse. Production of pro-inflammatory cytokines and chemokines, associated with preexisting inflammation or induced by recognition of HIV and co-transmitted pathogens, facilitates the establishment of an expanding pool of HIV-infected CD4+ T cells in the mucosa by recruiting and activating target cells of the virus at the site of infection. In the absence of inflammation, CD4+ T cells rarely reside within the epithelium, in contrast to dendritic cells and Langerhans cells. HIV can be uptaken by these cells in the upper layers of the epithelium and transported to the subepithelial mucosa or up to the draining lymph nodes, where CD4+ T cells are abundant and infection can be easily established

CSW women have revealed that adaptive as well as innate cellular and secretory responses are associated with resistance to HIV infection. Whether these correlates are a true hallmark of protection, or merely bystanders, needs further investigation in experimental systems or in prospectively followed clinical cohorts. Nevertheless, it has

been suggested that a silent immune response (immune quiescence) in the female genital mucosa is more beneficial for resistance to infection than a pro-inflammatory profile (Songok et al. 2012). To better understand the balance between pro- and anti-inflammatory responses to HIV, a detailed overview will be presented as

regards the immunological correlates of protection identified in HESN female CSW.

Innate Immunity

The first line of defense of the female genital tract is represented by a layer of mucus that covers the epithelium. The cervicovaginal mucus comprises many soluble components present in the secretions from various glands within the endometrium and oviducts, from epithelial and immune cells, as well as plasma transudate, which together constitute an extraordinary physical and immunological barrier against invading pathogens. Among these soluble components is indeed a plethora of molecules of different natures belonging to the innate arm of the immune system (Fig. 2). They possess a broad-spectrum antimicrobial activity, capable of targeting bacteria, fungi, and viruses by disrupting critical microbial structures, binding essential nutrients and rendering them unavailable to pathogens, and blocking cellular molecules targeted by pathogens. Gathering evidence supports an important role of these soluble factors in HIV infection, as they have been shown to inhibit HIV replication *in vitro*. Among these molecules are mucins, antiproteases, complement components, and antimicrobial peptides, such as defensins and cathelicidins. Serine and cysteine protease inhibitors, such as serpins, trappin-2 (also known as elafin), and cystatins, have been found in increased concentrations in cervicovaginal secretions from HESN CSW as compared with HIV-uninfected and HIV-infected control groups (Burgener et al. 2011). As antiproteases have anti-inflammatory properties, it is believed that they are an important component or driver of the reduced immune activation response that has been associated with resistance to HIV infection. On the other hand, increased levels of some soluble antimicrobial factors in cervicovaginal secretions have been correlated with genital infection and inflammation (e.g., SLPI and lactoferrin) as well as enhanced risk of HIV acquisition (e.g., LL-37 and alpha-defensins) (Levinson et al. 2009). These data indicate that the

mucosal immune defense against HIV is complex and likely an interplay of multiple mechanisms.

For this reason, as an important link between innate and adaptive immunity, the contribution of Toll-like receptors (TLR) and cytokines to the resistant phenotype displayed by female CSW has been investigated. Elevated levels of the chemokines RANTES and MIP-1alpha have been detected in the genital mucosa of these individuals, although the role of CCR5-binding chemokines in the transmission of HIV remains controversial. Recently, it was found that reduced expression of TLR7 and TLR8, which recognize HIV ssRNA genome, in the cervical mucosa of HESN CSW correlated with a reduction in the local expression of pro-inflammatory cytokines (Yao et al. 2014). Similarly, reduced concentrations of pro-inflammatory cytokines, such as TNF-alpha, IL-1alpha, and IFN-gamma, and the chemokines MIG and IP-10, which are involved in the recruitment of leukocytes to the mucosa, were detected in cervicovaginal secretions of HESN CSW compared to HIV-infected women (Lajoie et al. 2012).

Natural killer (NK) cells have been the most investigated innate cell subset in the resistance to HIV infection. Enhanced activity measured as increased expression of activation and degranulation markers on NK cells isolated from blood was shown to be associated with the HESN phenotype in a number of cohorts. However, no study has ever characterized the phenotype and function of these cells in the genital tract of HESN female CSW.

Adaptive Immunity

HIV-specific CD4+ helper and CD8+ cytotoxic T lymphocytes (CTLs) have been encountered in both the blood and genital tract of HESN female CSW. Late seroconversion of HIV-resistant CSW with preexisting HIV-specific CTL responses, possibly following a break from sex work, indicates that ongoing exposure to the virus may be required to maintain the resistant status (Kaul et al. 2001). This seroconversion happened in

the absence of detectable CTL escape mutations and was related to the waning of HIV-specific CTL responses, most likely as a result of the sex break. CD4⁺ T cells in HIV-resistant CSW from the same cohort were shown to have a lower activation profile but a much greater ability to proliferate in response to HIV antigens than HIV-infected women. Reduced activation of T helper cells and CTLs was found to be associated with increased frequency of circulating regulatory T cells in HESN (Card et al. 2009), indicating that regulatory T cells can contribute to a lower immune activation profile, although they may inhibit important anti-HIV responses as well. The detection of HIV-specific cytotoxic responses raised the question whether productive viral infection is required to elicit such a response. However, a different, eventually more efficient, ability of some antigen-presenting cells to “cross-present” exogenous antigens on HLA class I molecules, compared to individuals susceptible to HIV infection, may account for the presence of HIV-specific CTLs in resistant individuals.

Immune protection from HIV transmission has also been linked to the presence of HIV-specific mucosal IgA antibodies in a number of cohorts of HESN subjects exposed to HIV through sexual intercourse. Among these studies, it was reported that HIV-neutralizing IgA isolated from cervicovaginal secretions of CSW can block infection of peripheral blood cells *in vitro* as well as inhibit transcytosis of viral particles across a mucosal membrane (Devito et al. 2000). Because secretory IgA molecules in mucosal fluids do not activate complement factors, they may contribute to a favorable noninflammatory environment. These antibodies can protect from HIV transmission to the female genital mucosa by aggregating the virus before it reaches the epithelial layer, by blocking its passage across the epithelium, and by inhibiting virus spread between target cells in the subepithelial mucosa. On the other hand, the relevance of HIV-specific mucosal IgA as mechanism of protection has been questioned by reports on their absence or low levels of detection compared to those of IgG antibodies in cervicovaginal secretions of HESN

CSW and women in a serodiscordant relationship (Mestecky et al. 2011). According to this hypothesis, the presence of HIV-specific antibodies in mucosal secretions of HESN individuals would be a mere marker of exposure to the virus, as may be true for other mucosal HIV-specific as well as innate immune responses.

Genetic Influences of Mucosal Protection Against HIV Infection

Already in the beginning of the epidemic, it was noted that relatives of HIV-resistant female CSW (mothers, sisters) had a higher chance of being resistant than women in general (Fowke et al. 1996). A genetic component was therefore suspected, and it was hypothesized that production and maintenance of HIV-specific protective immune responses in the mucosa and low-level immune activation may depend on genetically determined factors. Likewise, single nucleotide polymorphism in noncoding regions of the interferon regulatory factor (IRF)-1 was found to correlate with reduced expression of IRF-1 and reduced responsiveness to IFN- γ in a cohort of HESN female CSW. Recent studies have shown that HIV-resistant women have a sharper, but transient, expression of this gene when induced by IFN- γ compared to prolonged activation in control groups (Sivro et al. 2013). Although the downstream effects of this response are currently unknown, these data may suggest that an immediate and potent innate immune response, without sustained immune activation, is beneficial for developing resistance to HIV infection.

A number of other haplotypes and genetic variants have been described to contribute to favorable immune responses to HIV and eventually account for resistance to infection in several cohorts of HESN, including killing inhibitory receptors on NK cells, human leukocyte antigens, intracellular restriction factors (e.g., APOBEC3G, TRIM5 α , etc.), chemokines, and their receptors. Nevertheless the role of the genetic background in shaping the local immunological

milieu in the genital mucosa of either HIV-resistant or HIV-infected women has been poorly addressed. Interestingly, a recent genome-wide analysis of approximately eight million genetic variants in 1,350 individuals of European ancestry among HIV-infected and HIV-uninfected found no association with the risk of HIV acquisition, with the exception of the CCR5 Δ 32 homozygosity, suggesting that the host genetic background by itself plays little role in determining the efficiency of transmission (McLaren et al. 2013).

Conclusion

Altogether current knowledge suggests that multiple factors can contribute to reduced susceptibility of HESN female CSW to HIV transmission via vaginal intercourse. This phenotype may be associated with the full prevention or an early block of the spread of HIV infection in the female genital mucosa due to a finely controlled inflammatory response and a low number of activated HIV target cells, a strong early innate response able to contain viral replication, and the development of HIV-specific responses effective against future infections. In this regard, a continuous exposure to the virus, which nature is yet to be defined, could be pivotal for the maintenance of some of these immune responses. Understanding how the immune system of HESN female CSW can prevent HIV transmission to the genital mucosa, which represents the main portal of entry of the virus globally, has important implications for the design of prophylactic strategies aimed at dampening the rate of acquisition by targeting the early immune response at the site of infection.

HIV-1 Assembly Cofactors

Lillian S. Kuo¹ and Eric O. Freed²

¹Virus-Cell Interaction Section, HIV Drug Resistance Program, National Cancer Institute, Frederick, MD, USA

²HIV Drug Resistance Program, Frederick National Laboratory, Frederick, MD, USA

Definition

Despite the highly evolved and complex nature of HIV-1, it is still merely an obligate parasite. Thus, the HIV-1 replication cycle is completely dependent on host cellular proteins, lipids, and nucleic acids, herein defined as “cofactors.” HIV-1 advantageously usurps host cellular cofactors to facilitate a number of steps throughout the viral replication cycle. For example, HIV-1 fusion and entry are mediated by the major receptor, CD4, and coreceptors, CCR5 or CXCR4 (► [Fusion](#)). Upon entry into the cell, HIV-1 reverse transcription is primed by cellular tRNA^{Lys3}. Integration of the newly synthesized double-stranded viral DNA into the target cell genome is promoted by a cellular integrase-binding protein known as lens epithelium-derived growth factor (► [LEDGF/p75](#)). The focus of this chapter will be to describe host cellular cofactors required late in the HIV-1 replication cycle, specifically, during viral assembly, budding, and release.

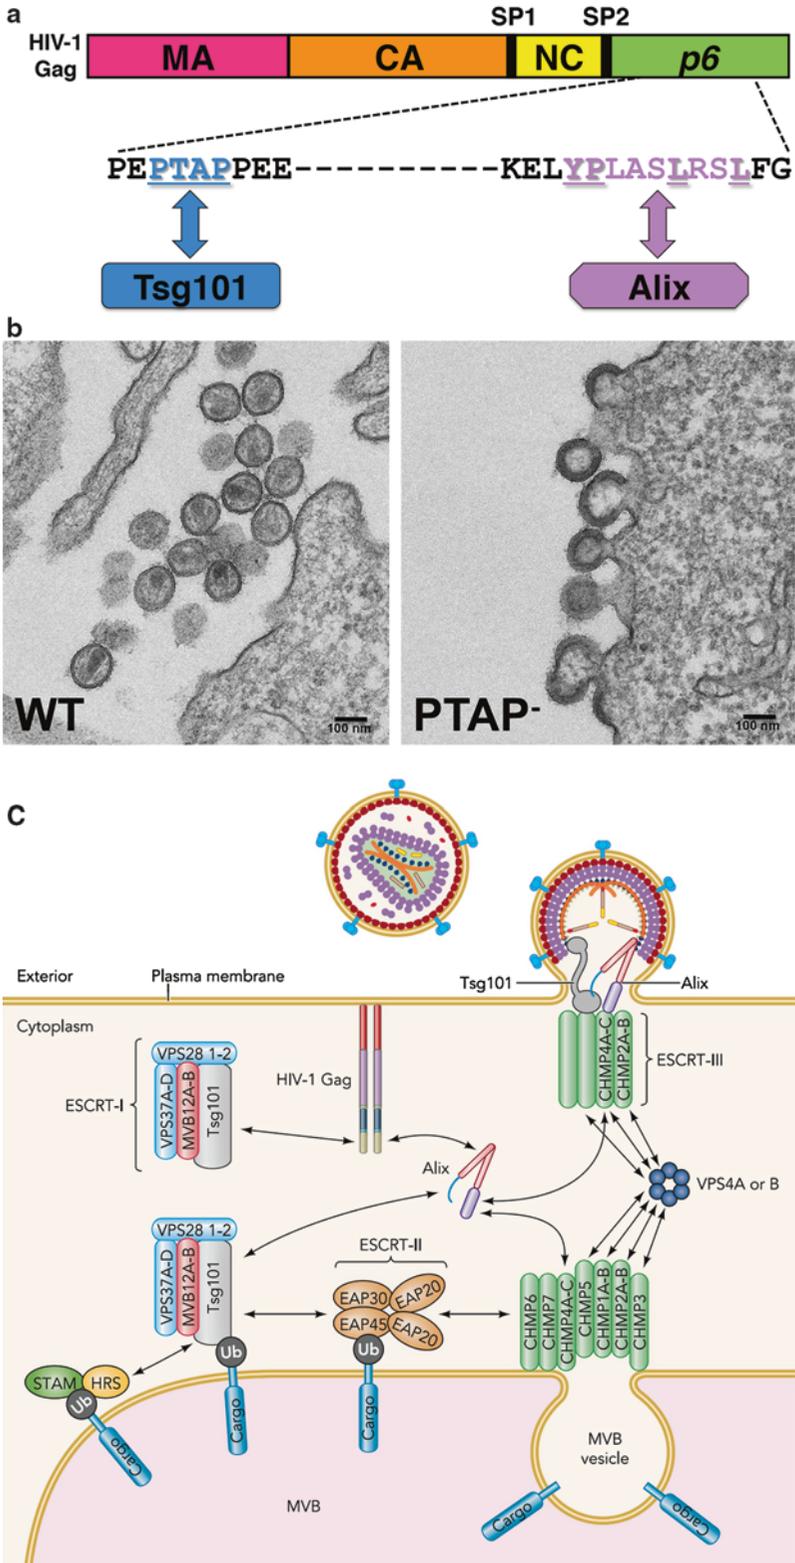

HIV-1 Gag Proteins Constitute the Virus Assembly Machine

The HIV-1 Gag polyprotein precursor, known as Pr55^{Gag}, is the primary viral determinant of particle assembly. Pr55^{Gag} itself is necessary and

sufficient to generate noninfectious viruslike particles (► [Assembly](#)). However, the complete process of virus assembly, budding, and maturation requires a highly regulated proteolytic processing cascade mediated by HIV-1 protease to generate mature Gag proteins and intervening spacer peptides (SPs), specifically matrix (MA), capsid (CA), spacer peptide 1 (SP1), nucleocapsid (NC), spacer peptide 2 (SP2), and p6 (Fig. 1a; ► [Maturation](#)). MA is responsible for Gag protein trafficking, membrane binding, and the incorporation of the viral envelope (Env) glycoproteins into virions. The N-terminus of MA is co-translationally modified by covalent attachment of a myristic acid moiety; this myristylation of MA is required for the binding of Gag to membrane. CA plays an important role in Gag multimerization and in the formation of the mature capsid core. NC, which contains two zinc fingerlike motifs flanked by highly basic sequences, is required for the encapsidation of viral genomic RNA into assembling particles. The p6 domain contains highly conserved peptide motifs, known as late domains, which are required for virus budding (Adamson and Freed 2007).

The Basic Steps in Virus Assembly and Release

The late stages of the HIV-1 replication cycle are characterized by mRNA export from the nucleus to the cytoplasm, a process dependent on the viral Rev protein. The Gag and Gag–Pol polyprotein precursors are subsequently translated in the cytosol and traffic to the sites of virus assembly on the inner leaflet of the plasma membrane. Once Gag and Gag–Pol associate with the membrane, Gag multimerization occurs, driven by CA–CA interactions as well as interactions between RNA and NC. The Env glycoproteins are incorporated into nascent virions during the assembly process. The final steps of particle budding and release are driven by p6 interactions with host cellular cofactors (Adamson and Freed 2007; Balasubramaniam and Freed 2011; ► [Budding](#)).

HIV-1 Assembly Cofactors, Fig. 1 Cofactors in HIV-1 assembly. (a) The HIV-1 Gag polyprotein consists of matrix (*MA*), capsid (*CA*), and p6 with intervening spacer peptides SP1 and SP2. The N-terminal p6 domain contains

HIV-1 Gag Targeting to the Plasma Membrane Requires Interactions with Cellular Lipid and Protein Cofactors

As indicated above, proper Gag trafficking and targeting to the sites of virus assembly are key steps in the HIV-1 replication cycle. Gag targeting to the plasma membrane is mediated by a highly basic patch of amino acid residues in the MA domain. This basic patch interacts with a specific plasma membrane lipid, phosphatidylinositol-(4,5)-bis-phosphate [PI(4,5)P₂]. Initial biochemical studies demonstrated that depletion of cellular PI(4,5)P₂ resulted in the mistargeting of Gag to intracellular compartments. Subsequent structural studies led to the proposal that binding of MA to PI(4,5)P₂ induces a conformational change at the N-terminus of MA that triggers exposure of the myristate group. This so-called myristyl switch occurs concomitantly with Gag multimerization, which together are required for efficient membrane binding (Ghanam et al.). Thus, PI(4,5)P₂ regulates Gag targeting to the plasma membrane, establishing this lipid as a key cellular cofactor for HIV-1 assembly (Ono 2009).

Membrane microdomains that are enriched in cholesterol and highly saturated lipids (often referred to as “lipid rafts”) play important roles both early and late in the HIV-1 replication cycle. In particular, lipid rafts serve as sites for virus assembly at the plasma membrane. Depletion of cholesterol from virus-producing cells impairs HIV-1 assembly by disrupting Gag–membrane association, and, as discussed below, cotargeting of Gag and Env to lipid rafts may increase the efficiency of Env incorporation into virions (Waheed and Freed 2009).

Apart from the abovementioned role for PI(4,5)P₂ and lipid rafts in Gag trafficking, the

pathway by which Gag reaches the plasma membrane is not well understood. It is widely accepted that Gag is synthesized in the cytosol and that the plasma membrane is the primary site for virus assembly (► [Assembly](#)). It has also been demonstrated by pulse–chase analyses that Gag becomes membrane associated within minutes of its synthesis. However, it is not clear whether Gag reaches the inner leaflet of the plasma membrane through passive diffusion or whether an active process involving the host cell cytoskeleton and/or vesicular trafficking machinery is used to promote Gag trafficking. Although it has been demonstrated that specific domains of Gag (e.g., NC) associate with cytoskeletal elements, divergent data can be found in the literature regarding the role for the cytoskeleton in Gag transport. Several recent studies have implicated host cell factors that function in vesicular trafficking in Gag–membrane association. These include the ADP ribosylation factors (Arfs) that associate with clathrin adaptor protein (AP) complexes to regulate protein and membrane trafficking in the cell and the SNARE [for SNAP (soluble NSF attachment protein) receptor] machinery that is required for movement and fusion of transport vesicles between membrane compartments in the cell. The AP complexes themselves have also been reported to modulate HIV-1 particle assembly. Kinesins (e.g., Kif3 and 4), P-body components (e.g., MOV10), Staufin, the ATPase ABCE1, and other host cell factors, as well as intracellular calcium levels, have also been implicated in various aspects of Gag transport. In some cases, a role for these factors could be linked to movement of the viral RNA, which, via association with the NC domain of Gag, regulates virus

assembly (Balasubramaniam and Freed 2011). Clearly, more studies will be needed to dissect the pathway and mechanism by which Gag traffics to the inner leaflet of the plasma membrane.

HIV-1 Env Glycoprotein Trafficking and Incorporation

The HIV-1 Env glycoproteins are synthesized in the rough endoplasmic reticulum as a 160-kDa precursor protein known as gp160. gp160 oligomerizes in the ER and is transported to the Golgi apparatus. In the Golgi, furin or a furin-like protease cleaves gp160 into the surface glycoprotein subunit gp120 and transmembrane subunit gp41. Non-covalently associated gp120/gp41 complexes are transported to the plasma membrane where they form the functional Env complex, which consists of a heterotrimer of gp120 and gp41. The Env glycoproteins are heavily decorated with high-mannose oligosaccharide side chains in the ER; many of these side chains acquire complex modifications during transit through the secretory pathway. Indeed, >50% of the mass of gp120 is comprised of oligosaccharides. The cytoplasmic tail of gp41 contains recognition motifs for clathrin AP complexes. As a result, Env is rapidly internalized after it reaches the plasma membrane. Levels of Env at the plasma membrane are thus relatively low, limiting Env-mediated cell–cell fusion (syncytium formation) and detection by the host immune system.

Although the pathway by which Env reaches the plasma membrane is well understood (in contrast to the situation with Gag), many questions remain concerning the mechanism by which Env glycoprotein complexes are incorporated into virions. Data in the literature support four non-mutually exclusive models for Env incorporation. (1) The simplest “passive incorporation” model proposes that there is no interaction between HIV-1 Gag and Env; Env complexes are randomly incorporated into virions as a consequence of their presence at the plasma membrane. (2) Evidence that the gp41 cytoplasmic tail can interact with the MA domain of Gag favors a “direct Gag–Env interaction” model whereby MA

binding to the gp41 cytoplasmic tail allows for Env incorporation. (3) As mentioned above, lipid rafts are sites of virus assembly at the plasma membrane, suggesting a “Gag–Env cotargeting” model whereby colocalization of Gag and Env to lipid rafts or other plasma membrane microdomains enhances the efficiency of Env incorporation. (4) Finally, a variety of host cell proteins have been implicated as potential linkers that might bridge or otherwise promote Gag–Env interaction, leading to the “indirect Gag–Env interaction” model. Furthermore, the requirement for the gp41 cytoplasmic tail in Env incorporation has been shown to be markedly cell type dependent, consistent with a role for host cell machinery in Env recruitment into virions. Thus far, however, no host cell protein has been definitively established as a direct mediator of Env incorporation (Checkley et al. 2011).

Host Factors Incorporated Into HIV-1 Virions

As described above, various steps in the HIV-1 replication cycle require host cellular cofactors. For example, the process of reverse transcription, by which the single-stranded RNA genome that is packaged into virions is converted to double-stranded DNA, is primed by tRNA^{Lys3}. This tRNA is incorporated into virions during the assembly process via interactions with the primer binding site of the viral RNA and the NC domain of Gag. Lysyl-tRNA synthetase may also promote packaging of tRNA^{Lys3} into particles and placement onto the primer binding site. A number of membrane proteins are associated with the virion lipid bilayer, where they serve incompletely defined roles. Other host factors, such as cyclophilin A and cytoskeletal elements, can also be detected to varying levels in HIV-1 particles (Ott 2008). Cyclophilin A, which interacts directly with the CA domain of Gag, may function in viral counteraction of the innate host restriction factor TRIM5a (cross-reference with cyclophilin A). In other cases, incorporated proteins either play no discernible role in virus replication or perform functions that remain to be characterized.

HIV-1 Late Domains Mediate Virus Budding

All retroviral Gag proteins contain so-called “late” domains that play key roles in virus budding (► [Assembly](#) and ► [Budding](#)). These retroviral late domains are highly conserved peptide motifs that come in three varieties: proline–serine/threonine–alanine–proline (PS/TAP), tyrosine–proline–variable–leucine (YPXnL), and proline–proline–proline–tyrosine (PPPY). These peptide motifs are referred to as late domains because they function in the late stages of virus budding from an infected host cell. Equine infectious anemia virus (EIAV) contains a single YPXnL motif. A number of retroviruses, e.g., murine leukemia virus (MLV) and Rous sarcoma virus (RSV), contain PPPY motifs. In many cases, retroviruses encode multiple late domains. For examples, Mason–Pfeizer monkey virus (M-PMV) and human T-cell leukemia virus 1 (HTLV-1) contain two functionally redundant motifs, PPPY and PS/TAP. It is currently unclear why retroviruses often contain multiple late domains, but this feature presumably provides a functional redundancy that allows efficient budding under varying circumstances and in different cell types.

The HIV-1 p6 domain contains two highly conserved peptide motifs that promote the release of virions from host cells upon direct binding to host cell cofactors. Early studies observed that deletion of the p6 domain prevented release of assembled virus particles from the cell surface. Mutational analysis of the p6 domain mapped the defect in virus particle production to a highly conserved PTAP near the N-terminus of p6. Disruption of the PTAP motif yielded a striking phenotype when visualized by electron microscopy (Fig. 1b); cells expressing wild-type (WT) HIV-1 displayed numerous mature virions that had been released from the cell surface. In contrast, cells expressing a PTAP-mutated (PTAP-) HIV-1 displayed an accumulation of immature particles that failed to detach from the cell surface.

HIV-1 p6 also contains a secondary late domain – YPXnL – located downstream of PS/TAP. Although mutations in the YPXnL motif do not impair virus release as profoundly

as do mutations in PS/TAP, they do delay the kinetics of release and impose defects in Gag processing and virus replication. Altogether, the prevalence of these three retroviral late domains (PTAP, YPXnL, and PPPY) across divergent retroviruses demonstrates the fundamental role of these canonical peptide motifs in virus budding (Freed 2002; Fujii et al. 2007).

Retroviral Late Domains Directly Interact with Host Cell Cofactors: The ESCRT Proteins

A large number of studies have demonstrated that retroviral late domains promote virus budding and release by recruiting a cellular apparatus known as the endosomal sorting complex required for transport (ESCRT) machinery. Four ESCRT complexes (ESCRT-0, ESCRT-I, ESCRT-II, and ESCRT-III) were initially described in yeast and then shown to be highly conserved across eukaryotes (Hurley et al. 2010). The ESCRT machinery plays a key role in the sorting of ubiquitinated cargo proteins to the lysosome (the vacuole in yeast) by delivering them into vesicles that bud into late endosomes to generate multivesicular bodies (MVBs). In addition to MVB sorting, a subset of ESCRT machinery is also required for abscission, the pinching off of the intercellular membranous bridge at the end of cytokinesis. The underlying parallels between these three biological functions – MVB sorting, cytokinesis, and virus budding – are their topological similarity, i.e., budding oriented away from the cytoplasm (Martin-Serrano and Neil 2011).

As depicted in Fig. 1c (bottom), ubiquitinated cargo proteins destined for the MVB pathway are recognized sequentially by the four ESCRTs. First, ESCRT-0 initiates the cascade upon STAM (signal-transducing adaptor molecule) binding to Hrs (hepatocyte growth factor-regulated substrate). This STAM/h complex recognizes and binds ubiquitinated cargo. Hrs contains a PSAP motif that binds the ESCRT-I subunit Tsg101. ESCRT-I is a heterotetramer comprised of Tsg101, Vps28, Vps37, and Mvb12. The

C-terminal domain of Vps28 subsequently interacts with the ESCRT-II complex. The mammalian ESCRT-II complex consists of two copies of EAP20 that bind asymmetrically to EAP30 and EAP45. Importantly, EAP45 binds ubiquitin via the GLUE (GRAM-like ubiquitin-binding in EAP45) domain. EAP20 recognizes the N-terminal domain of CHMP6, thereby recruiting ESCRT-III. The final membrane scission step is catalyzed by ESCRT-III, which assembles a ring-like constriction around the neck of the budding vesicle or virion. The energetics of membrane scission may also be favored by the catalytic activity of the ATPase Vps4, which, after pinching off is completed, is required for the release of the ESCRT components from the membrane (Hurley et al. 2010).

Tsg101 Is a Cellular Cofactor Required for HIV-1 Budding

As described above, multiple lines of evidence suggested that the highly conserved PS/TAP motif in HIV-1 p6 is required for efficient virus budding. Key studies from multiple groups in 2001 and 2002 determined that the PS/TAP motif of HIV-1 p6 binds Tsg101, essentially mimicking the interaction between Tsg101 and the PSAP motif of Hrs. siRNA-mediated depletion of Tsg101 from virus-producing cells resulted in profound defects in HIV-1 budding, recapitulating the previously observed effects of PS/TAP mutation (Fig. 1b). Support for the role of Tsg101 in HIV-1 budding also came from experiments showing that fusion of Tsg101 to Gag could rescue the budding defects induced by p6 mutation. Furthermore, expression of a dominant-negative Tsg101 fragment (TSG-5') potently inhibited HIV-1 release in a PTAP-dependent manner (Morita and Sundquist 2004).

Alix Serves a Secondary Role in HIV-1 Budding

Alix (apoptosis-linked gene 2 (ALG-2)-interacting protein X or AIP1) is another

ESCRT-related protein that serves as a cofactor in HIV-1 budding. The domain structure of Alix consists of an N-terminal Bro1 domain, a central V domain, and a C-terminal Pro-rich domain. The central domain of Alix is composed of two extended three-helix bundles that form elongated arms to fold back into a V-like conformation, hence the V-domain designation. Alix interacts with the YPXnL motif in p6 (Fig. 1a) via a highly conserved Phe in the V domain. Functional studies revealed that the Alix V domain itself could inhibit HIV-1 budding in a dominant-negative fashion (Fujii et al. 2007); this inhibitory activity was eliminated by mutation of the abovementioned Phe, demonstrating that V-domain-mediated inhibition required a direct p6–Alix interaction. Alix has been shown to interact with Gag not only via the YPXnL motif in p6 but also through the NC domain, an interaction that maps to the Bro1 domain of Alix and the NC zinc fingers. Mutation of the Alix binding site in p6 causes delayed virus release kinetics and impaired virus replication. A role for Alix in virus budding is also supported by the observation that the budding defect imposed by mutation of the PTAP motif can be rescued by overexpression of Alix.

Although ESCRT-II is required for the sorting of many cargo proteins into MVBs, it does not appear to be required for HIV-1 budding. How budding bypasses ESCRT-II remains an unresolved question. Interaction of Alix with Gag could provide a bridge between ESCRT-I and ESCRT-III since Alix harbors binding sites for both complexes (Fig. 1c). However, the small effect on budding of Alix depletion relative to that observed with Tsg101 knockdown suggests that Alix is not the primary host factor that allows HIV-1 to bridge between ESCRT-I and ESCRT-III. Further studies will be required to clarify this issue.

Discovery of Host Dependency Factors

As described above, a number of host factors – including proteins, nucleic acids, and lipids – have been demonstrated to play positive

roles in HIV-1 assembly and release. Several recent studies have used genome-wide siRNA screens to identify genes required for HIV-1 replication. While most of these analyses used viral infection as the readout and thus were not designed to identify factors required late in the virus replication cycle, one study (Brass et al. 2008) did incorporate an experimental arm aimed at identifying late-acting factors. Most of the factors identified in this study as being required for late steps in virus replication have not been validated or characterized; however, the genome-wide RNAi approach will no doubt be useful in the future for identifying host factors that play essential roles throughout the virus replication cycle.

BST-2/Tetherin Restricts Retrovirus Release

Although this chapter focuses on cellular machinery that plays a positive role in HIV-1 replication, it should be noted that mammalian cells have evolved a variety of mechanisms to restrict retroviral infection (Harris et al. 2012). These factors, which in some cases are interferon inducible, constitute a component of the innate cellular immune response to viral infection. An example of such a cellular restriction factor is BST-2/tetherin, a protein with an unusual topology comprised of an N-terminal cytoplasmic domain followed by a transmembrane anchor, an extracellular coiled-coil domain, and a C-terminal glycosylphosphatidylinositol (GPI) anchor. Expression of tetherin in the HIV-1 producer cell results in the retention of mature, released particles at the plasma membrane, apparently as a result of dimerization between the coiled-coil domains of tetherin molecules present on the plasma membrane and in the lipid bilayer of the viral envelope. The retention of particles at the plasma membrane greatly diminishes the number of cell-free virions that are produced from an infected cell. Since its discovery as an HIV-1 restriction factor, tetherin has been shown to impair the release of a number of enveloped viruses. In many cases, viruses have evolved strategies to counteract tetherin; in the

case of HIV-1, the viral accessory protein Vpu induces the internalization and degradation of tetherin, thereby neutralizing its activity. The antiviral activity of tetherin helps to illustrate the concept that mammalian cells are not passive vessels for retroviral infection but rather have developed an active, dynamic, and rapidly evolving set of cellular defense mechanisms that limit the assault by these viruses.

Conclusion

It is clear that HIV-1 and other retroviruses utilize host cellular cofactors to facilitate virus assembly and budding. To date, the best-described host cofactors for retrovirus assembly and release are members of the cellular ESCRT machinery. However, a myriad of additional, putative host cell cofactors have been implicated in the late stages of HIV-1 replication. These candidate protein cofactors may play functionally redundant roles across different retroviruses. Characterization of these cellular cofactors remains an exciting area of investigation. In particular, outstanding questions to be addressed include the following: (1) Do host cofactor(s) serve as an adaptor or scaffolding protein to facilitate Gag and Env interaction during Env incorporation? (2) What host cellular cofactors could provide a functional link between the ESCRT-I and ESCRT-III complexes during HIV-1 budding? (3) What are the differences in cell type and/or replication strategy that account for late domain redundancies among retroviruses? (4) And, ultimately, how can understanding of these key interactions between the virus and the cell be translated into the development of therapeutically effective inhibitors?

HIV-1 Maturation

Barbara Müller and Hans-Georg Kräusslich
Department for Infectious Diseases, Virology,
University Hospital Heidelberg, Heidelberg,
Germany

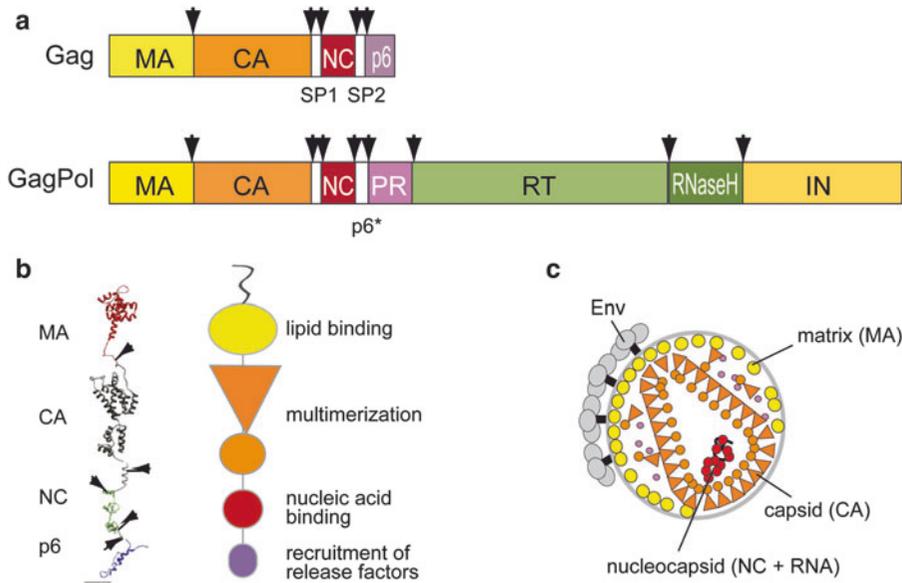

Definition

The term “virus maturation” in general refers to alterations of the architecture of a virus that occur after the particle with all its constituents has been formed. In the case of HIV-1 and other retroviruses, maturation involves cleavage of the main structural polyprotein, Gag, by the virus-encoded protease once the immature virion is released from

the cell. Gag proteolysis results in dramatic changes of the virus morphology that are essential for HIV-1 infectivity. Inhibitors of proteolytic maturation are commonly used as antiviral drugs in current regimens for treatment of HIV-infected patients.

HIV-1 Particle Maturation: What Is It and What Is It Good for?

Viruses may be regarded as “miniaturized” forms of life, reduced to the bare necessities required to ensure efficient replication. They employ various strategies of “genetic economy” to increase the amount of information encoded in a minimal length genome. An important genetic economy strategy is the production of polyproteins consisting of multiple functional domains. The polyprotein precursors can play a particular role in the replication cycle, whereas individual subunits produced by regulated proteolysis of the precursor may serve different purposes. This strategy is also used by HIV-1 and all other retroviruses. The HIV-1 genome is less than 10,000 nucleotides long and encodes only 15 proteins (Frankel and Young 1998). The inner structural proteins of the virus (Gag products) and the viral enzymes protease (PR), reverse transcriptase (RT), and integrase (IN) are produced as parts of the Gag and Gag-Pol polyproteins, respectively (Fig. 1a). Newly produced viruses are assembled from these precursors. As outlined below, the Gag polyprotein is a central organizer of productive HIV-1 assembly, and the presence of multiple functional domains within the molecule is crucial for the assembly process (Sundquist and Krausslich 2012) (► [Virus Assembly](#)). Released progeny virus particles containing Gag and Gag-Pol polyproteins as well as other essential virion components are still noninfectious and are designated “immature.” Cleavage of Gag and Gag-Pol into their individual functional subdomains by the virus-encoded PR leads to extensive rearrangements of the Gag subunits within the particle, activates the viral enzymes, and increases entry efficiency. This process is called “maturation,” and it is essential for HIV-1 infectivity.

Krausslich (2011)) and functional domains of the poly-protein (*left*). (c) Gag subunits MA, CA, and NC as structural elements of the mature HIV-1 virion. Arrowheads in (a) and (b) indicate cleavage sites of HIV-1 PR

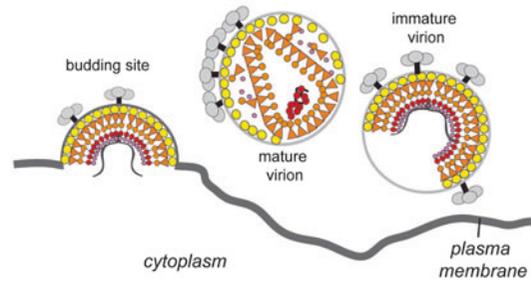

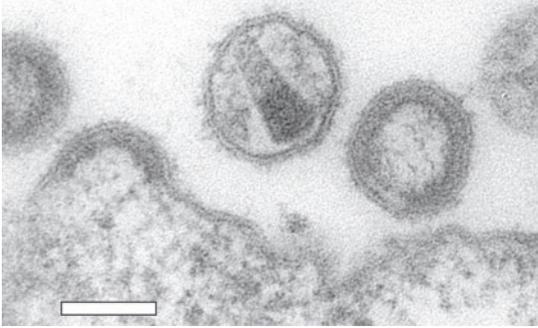

The Polyprotein Gag: A Multitasking Protein

HIV-1 particle morphogenesis is the final step of HIV-1 replication. Newly synthesized virion components assemble at the inner face of the plasma membrane of infected cells into spherical buds that are released by abscission of the surrounding lipid envelope from the host cell membrane (Sundquist and Krausslich 2012). The viral structural polyprotein Gag is the central orchestrator of these processes. Gag forms the inner protein shell of HIV-1; approximately 2,500 molecules represent ~50% of total virion mass. Gag traffics to the plasma membrane where it assembles into spherical particles that can be formed even in the absence of other HIV-1 proteins. In HIV-1-infected cells, Gag brings further components of the infectious virus, e.g., the viral Env glycoproteins, the Gag-Pol polyprotein, and the viral RNA genome, to the budding site (► [Budding](#)). It is also responsible for recruitment of the cellular ESCRT (endosomal sorting complex required for transport) machinery that catalyzes membrane fission

(Sundquist and Krausslich 2012). For a detailed description of these events, please see the entries on “► [Virus Assembly](#)” and “► [Budding](#).”

To organize this complex sequence of events, Gag needs to interact with various proteins, as well as with lipids and nucleic acids, in a temporally and spatially controlled manner. This is supported by the modular design of the polyprotein (Fig. 1b). Gag comprises a myristoylated lipid membrane binding domain (matrix, MA), a multimerization domain (capsid, CA), a nucleic acid binding domain (nucleocapsid, NC), and an adapter domain for the recruitment of other proteins (p6). In the polyprotein, these domains are linked by flexible hinge regions; two small spacer peptides, SP1 and SP2, separate the CA, NC, and p6 domains and provide additional flexibility (Fig. 1b). The interplay between these different domains regulates HIV-1 particle assembly (Sundquist and Krausslich 2012; Ganser-Pornillos et al. 2012).

Although particles formed in this manner contain all essential components of the virion, they are noninfectious. The generation of infectious

HIV-1 Maturation, Fig. 2 Stages of HIV-1 particle morphogenesis. The thin-section electron micrograph (*left*) and cartoon (*right*) show an HIV-1 budding site at the plasma membrane of a virus-producing human T-cell,

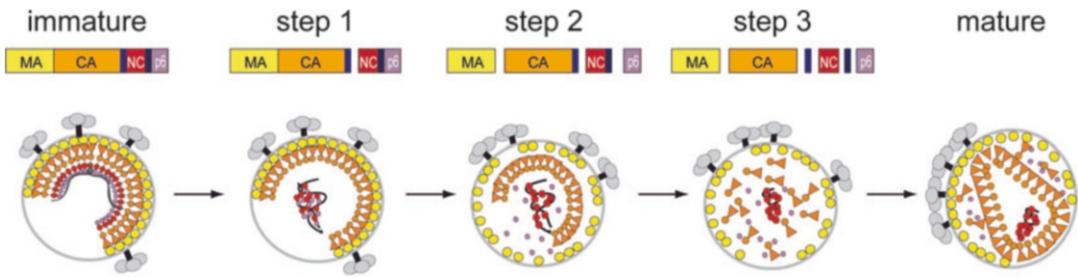

as well as an immature and a mature HIV-1 virion (electron micrograph: Sonja Welsch, Virology Heidelberg. Scale bar: 100 nm)

HIV-1 requires a further step, termed virus maturation, occurring concomitant with or after the release. During maturation, the viral PR incorporated in the particles as part of Gag-Pol cleaves Gag and Gag-Pol polyproteins into their mature subunits, accompanied by a dramatic alteration of virion morphology (Briggs and Krausslich 2011; Ganser-Pornillos et al. 2012). While immature particles display a truncated sphere consisting of a lattice of Gag polyproteins underneath their envelope, mature, infectious particles can be recognized in electron micrographs by a distinctive conical capsid encasing the viral genome (Fig. 2). In the mature particle, an MA layer lines the lipid envelope, and CA forms the characteristic conical capsid within which NC complexes and condenses the genomic RNA (Fig. 1c). It is evident that proteolysis needs to be tightly controlled: not only delayed but also premature processing is deleterious to HIV-1 infectivity. Surprisingly, it is still not clearly understood how maturation is triggered, however. Since each Gag-Pol molecule contains only a monomer of the dimeric enzyme PR, protein dimerization is clearly essential. However, other yet unknown factors may contribute to the initiation of the maturation process as well. Likewise, while it can be estimated that assembly and release of an HIV-1 particle occur within a period of 15–30 min, the duration of maturation has not been determined. The fact that mature particles are readily detected in the vicinity of the membrane of virus-producing cells, whereas

intermediates of morphological maturation are not observed by electron microscopy, suggests that the process is fairly rapid, but the determination of its kinetics has so far not been possible.

Mechanism and Regulation of HIV-1 Particle Maturation

Electron microscopy analyses of the mature and immature virion yielded detailed insights into the formation and architecture of HIV-1 particles and provided information about the mechanism of morphological maturation (Virus Structure). The basic element of both the immature Gag shell and the mature capsid is a CA hexamer. However, the structures of the “immature” and “mature” CA hexamer are not identical (Briggs and Krausslich 2011; Ganser-Pornillos et al. 2012). In the nascent virus bud and in the immature particle, Gag molecules are organized in parallel perpendicular to the membrane in a hexameric lattice with a spacing of 8 nm. A regular arrangement of hexamers would be flat, but small irregular defects in the Gag lattice permit the outward curvature of the nascent HIV-1 bud. While Gag-derived proteins can assemble into spherical particles *in vitro*, cryo-EM analysis of immature HIV-1 particles revealed that the Gag shell is not a closed sphere but covers only $\sim 2/3$ of the lipid envelope and that the degree of shell closure varies between individual virus particles. This finding suggested

HIV-1 Maturation, Fig. 3 Model of the HIV-1 maturation process. Stepwise cleavage of the Gag polyprotein (*top*) regulates the process of morphological rearrangements within the particle (*bottom*). See main text for details

that the membrane closure mediating virus abscission occurs in parallel to Gag assembly and not after completion of the Gag shell. Membrane fission is mediated by the cellular ESCRT machinery (► [Budding](#)), and the degree of completion of the Gag shell of an individual particle may thus depend on the relative kinetics of the polymerization of Gag and ESCRT. Structural analyses of the mature capsid indicated a buckminsterfullerene-like architecture consisting of CA hexamers, with a small number of CA pentamers (Briggs and Krausslich 2011; Ganser-Pornillos et al. 2012). With a spacing of 9.6 nm, CA hexamers in the mature lattice are more loosely packed compared to the immature lattice. Furthermore, only about half of all CA molecules contained in the virion are used for assembly of the mature capsid. Both findings suggest that capsid maturation does not occur through condensation of the immature shell into a cone shape but rather involves disassembly of the immature structure followed by reassociation of CA molecules to form the mature lattice. Since this complex transition occurs within the confined and tightly packed space of the released virion at millimolar CA concentration, it requires precise regulation.

Numerous biochemical and structural analyses contributed to the current model describing the sequence of events in the HIV-1 maturation process (Virus Structure) (Briggs and Krausslich 2011; Sundquist and Krausslich 2012; Ganser-Pornillos et al. 2012). The necessary regulation of the complex morphological transitions is accomplished by an ordered sequence of cleavage events within Gag and Gag-Pol by the viral protease that releases the mature subunits in an

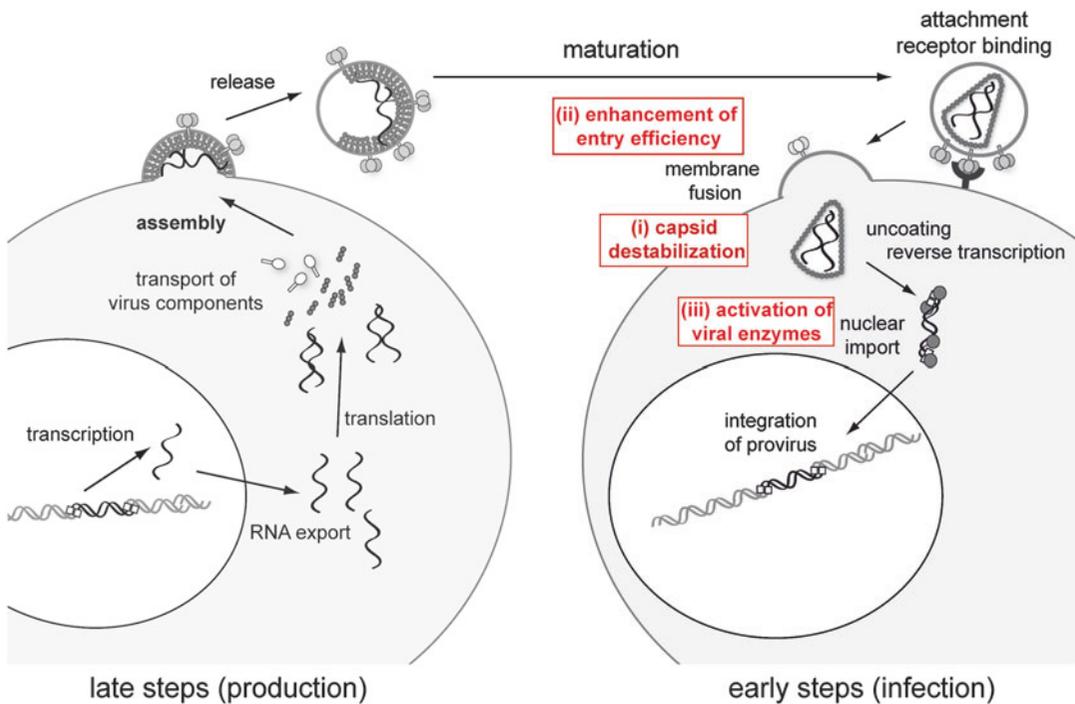

organized manner (Fig. 3). Different amino acid sequences at the individual processing sites and differential accessibility of the cleavage regions result in different rates of cleavage by PR. As a first step, proteolysis at the N-terminus of NC releases the viral genome-protein complex from the membrane-attached N-terminal portion of Gag. This allows initial condensation of the nucleoprotein complex, while the immature CA lattice remains unaltered (Fig. 3, step 1). Next, processing between MA and CA separates the CA lattice from the surrounding lipid membrane (Fig. 3, step 2). This separation is a prerequisite for dissociation of the immature CA lattice. If it is blocked by mutagenesis while all other cleavage events are allowed to proceed, CA retains the immature lattice structure. However, MA-CA separation is not sufficient for immature lattice dissociation, but cleavage at both ends of CA is required. An important regulatory function governing mature core formation is apparently provided by the spacer peptides SP1 and SP2 which are removed from the C-termini of CA and NC, respectively, during the final stages of maturation. The release of SP1 from CA allows CA multimer dissociation, thereby providing the building blocks for the mature core (Fig. 3, step 3). The role of SP2 is currently less well understood. Mutations that prevent the proteolytic cleavages within the C-terminal portion of Gag (NC-SP2-p6) severely diminish infectivity and disturb mature capsid formation, although mature CA protein is released. Based on available virological, biochemical, and structural data, it appears likely that a function of multiple ordered cleavages within the NC-SP2-p6 region may be to

ensure controlled condensation of the nucleoprotein complex in order to coordinate it with progression of the assembly of the surrounding conical capsid.

HIV-1 Maturation: The End or the Beginning?

HIV-1 maturation is required for the generation of functional viral enzymes PR, RT, and IN, contained in the immature virus in an inactive (or partially active) form as parts of the Gag-Pol precursor polyprotein. It is therefore usually displayed as the final step in graphic representations of the viral replication cycle (► [Overview Life Cycle](#)). Alternatively, maturation can be considered as an initial step, preparing the virus for cell entry. Mediated by proteolysis of the inner structural proteins, the particle switches from an “assembly mode” into an “infection mode” (Fig. 4). This solves a general problem

encountered by viruses, which has been described by A. Helenius as the “assembly-disassembly paradox.” Viral shells have to be assembled as stable structures in order to encase and protect the viral genome in an extracellular environment. However, in the newly infected host cell, this particulate structure needs to disassemble in order to release the infecting virus genome (“uncoating”) (► [Uncoating and Nuclear Import](#)). Since the producing cell and the newly infected cell are often of the same cell type and may be immediately adjacent, rapid alterations within the virion structure are necessary to mediate differential stability in these similar cellular environments. In the case of HIV-1, virus maturation leads to at least three functional changes important for infection: (i) destabilization of the inner protein structure, (ii) increased fusogenicity of the viral envelope, and (iii) activation of viral replication enzymes. Gag proteolysis transforms the protein shell of the particle from a mechanically stable into a metastable state ready for disassembly (Sundquist and

HIV-1 Maturation, Fig. 4 Maturation prepares HIV-1 for early replication events. Scheme of the late and early steps of the HIV-1 replication cycle. Red boxes indicate

functional consequences of maturation that affect the entry and postentry replication steps. See main text for details

Krausslich 2012). Biochemical studies revealed that the immature Gag shell remains stable upon removal of the surrounding lipid envelope by detergent treatment, while the mature capsid dissociates rapidly under these conditions. Moreover, physical measurements suggested that immature particles are more rigid than mature HIV-1 virions. Mutations in the viral CA protein that alter capsid stability in the test tube have been shown to affect HIV-1 infectivity. Interference with genome uncoating seems to block replication steps occurring after cell entry, in particular the reverse transcription of the viral genome. Both stabilization and destabilization of the capsid is detrimental for infectivity (► [Reverse Transcription](#)). Temporally controlled dissociation of the mature capsid thus apparently regulates events in the early postentry phase of HIV-1 replication. Vice versa, the progress of reverse transcription seems to be coupled to capsid uncoating: inhibition of reverse transcription has been reported to enhance the stability of entering capsids. The regulation of the uncoating process thus represents a main function of HIV-1 proteolytic maturation.

Interestingly, the inner structural maturation of the particle is also correlated to the entry competence of the virion. HIV-1 cell entry occurs by fusion of the viral lipid envelope with the membrane of the host cell (► [Fusion](#)), mediated by the viral Env glycoproteins on the virus surface. Immature HIV-1 particles generated by mutation of processing sites in Gag or by inhibition of PR display significantly reduced fusion efficiency, although these treatments do not affect Env incorporation or processing (Checkley et al. 2011). Recently, visualization of subviral details by super-resolution fluorescence microscopy provided evidence for a mechanism linking changes within the virion to its surface. In contrast to many other enveloped viruses, HIV-1 carries only a sparse number of Env molecules on its surface, which may be important for immune escape. Super-resolution microscopy revealed that in immature or partially mature virions, these molecules are distributed in several patches on the viral surface, while they cluster more closely together on the envelope of mature virions. Clusters of Env molecules contact patches of receptor molecules

on the cell surface, and Gag maturation-dependent Env clustering may thereby enhance the entry efficiency of the virus. This “inside-out signaling” strategy might ensure that only virus particles whose interior has sufficiently matured to allow efficient progression of early postentry steps are able to enter a new target cell.

Furthermore, proteolytic maturation is also essential for activation of viral enzymes RT and IN that mediate essential postentry replication steps. RT transforms the ssRNA virus genome into a double-stranded DNA copy (Catalyzed HIV-1 DNA Synthesis), whose covalent integration into the host cell genome is catalyzed by IN (► [Integration](#)). A monomer of each RT and IN is encoded as part of the Gag-Pol precursor protein. The active form of HIV-1 RT, however, is a heterodimer from the encoded RT monomer (p66) and p51, which is generated by PR-mediated cleavage of the p66 C-terminus. The active form of IN is a structured “intasome” complex, in which a dimer of IN dimers is bound to the ends of the viral genome (Engelman and Cherepanov 2012). Proteolytic release of the respective monomers from the precursor is required for proper formation of these active enzyme complexes.

HIV-1 Maturation as Target for Antiretroviral Therapy

HIV-1 maturation is crucial for viral infectivity, thereby representing a target for antiviral intervention. Since the maturation process required precise coordination, maturation inhibitors may either impair proteolysis at one specific site or inhibit viral proteolysis in general by targeting HIV-1 PR. Together with inhibitors of the viral reverse transcriptase, HIV-1 PR inhibitors (PIs) are the keystones of modern antiretroviral therapy (highly active antiretroviral therapy, HAART) (Anderson et al. 2009; Adamson 2012). PIs bind to the active site of HIV-1 PR and prevent the enzyme from cleaving Gag and Gag-Pol, thereby blocking morphological virus maturation. The infected cell releases virus particles with normal efficiency, but these particles remain immature

and are unable to infect a new target cell. The powerful antiviral effect of PIs illustrates the delicate balance of HIV-1 morphological maturation. In tissue culture inhibition experiments, even modest effects on Gag processing are correlated to a significant reduction of virus infectivity. A small proportion of uncleaved or partially cleaved Gag apparently suffices to disturb the ordered process of morphological maturation, thereby enhancing the inhibitory effect of PIs.

Mutagenesis studies revealed that even inhibition of cleavage at one of the five processing sites within Gag is sufficient to reduce or abolish virus infectivity. This is exploited by the maturation inhibitors bevirimat and PF-46396 (Salzwedel et al. 2007; Waheed and Freed 2012; Adamson 2012). These compounds do not affect the enzymatic activity of HIV-1 PR but rather act on its substrate. By binding to Gag in the vicinity of the processing site that separates CA and SP1, they specifically impair proteolysis at this position and prevent formation of the mature CA lattice. Although cleavage inhibition at the CA-SP1 site by bevirimat is incomplete and processing at the remaining sites in Gag and Gag-Pol is not impaired, HIV-1 infectivity is efficiently inhibited in tissue culture. The compound also proved to be effective in early clinical trials in HIV-1-infected patients. However, mutations in Gag that conferred bevirimat resistance *in vitro* could be selected under drug pressure. Unfortunately, these mutations were also detected in a significant proportion of viruses isolated from patients that had not been treated with bevirimat, indicating that these resistant isolates represent naturally occurring virus variants. The clinical development of the drug is halted, but compounds with a similar mode of action are being explored in pre-clinical studies.

The availability of a diverse panel of drugs targeting different steps of the viral replication cycle is a prerequisite for long-term successful antiretroviral treatment. It is therefore of interest to consider other aspects of HIV-1 maturation as potential targets for therapeutic intervention. First, the timing of proteolytic maturation with respect to assembly and release is crucial for HIV-1 morphogenesis. Accordingly, not only the inhibition

but also the stimulation of PR activity impairs HIV-1 replication in tissue culture. Premature or enhanced activation of HIV-1 PR, induced, for example, by certain mutations in Gag-Pol, results in intracellular processing of Gag and thus interferes with the assembly and release of immature virions. Interestingly, an increased level of intracellular Gag processing and reduced particle release can be observed in tissue culture experiments upon treatment with some of the therapeutically used non-nucleosidic HIV-1 RT inhibitors. However, drugs that exploit the principle of PR activation for the inhibition of HIV-1 infection have not yet been developed.

Second, a crucial step of virus maturation is the assembly of the conical capsid within the virus after the mature CA protein has been released. On theoretical grounds, this process appears to be an attractive target: interference with a small proportion of the interactions between subunits should disturb the arrangement of the complex higher-order multimer, and the interactions between HIV-1 CA molecules in the lattice are clearly virus specific. The fact that such an inhibitor would have to act within the released virus particle and thus needs to be incorporated during the budding process, while its molecular target, the mature CA protein, is not present at this stage, presents a conceptual difficulty for this strategy, however.

Conclusion

Proteolytic maturation of HIV-1 is essential for virus spread, and the development of effective PR inhibitors blocking maturation in the 1990s strongly contributed to the success of current highly active antiretroviral therapy. Maturation serves as an irreversible switch from the assembly mode to the infection mode and renders the virus particle competent for cell entry and replication. This process has to be tightly regulated in correspondence with virus assembly and release. While results obtained in recent years have provided detailed insights into the structural basis and mechanistic consequences of maturation, the mechanisms for controlling proteolysis are still

not understood. Interfering with the triggering events or disturbing the delicate balance of proteolysis would appear to be one of the most promising remaining targets for antiretroviral therapy.

HIV-1 Mutational Escape from Host Immunity

Anh Q. Le¹, Aniqah Shahid¹ and Zabrina L. Brumme^{1,2}

¹Faculty of Health Sciences, Simon Fraser University, Burnaby, BC, Canada

Definition

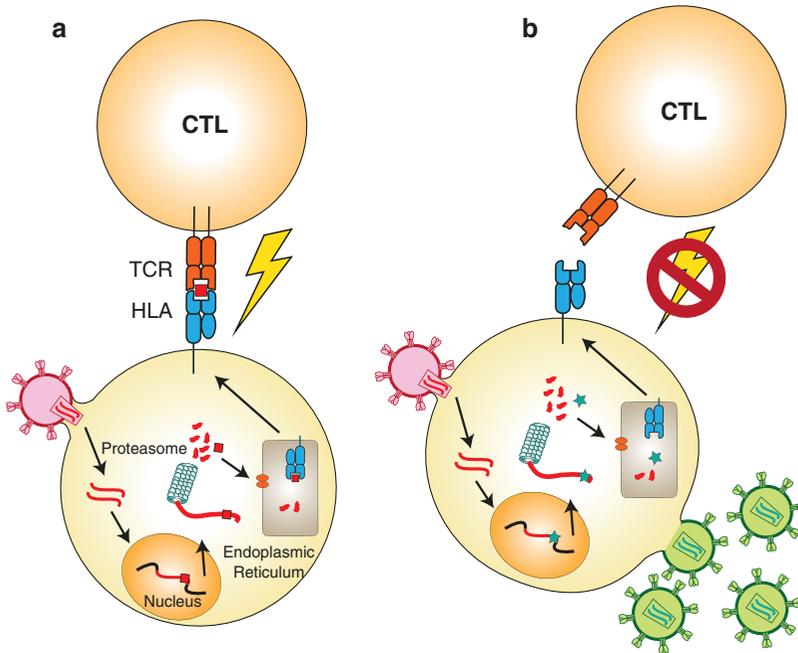

Within an infected individual, HIV-1 develops specific mutations within its genome that allow it to escape detection by host immune responses. As

such, host immunity represents a major selective force driving the evolution and diversification of HIV-1 at the individual and population levels. Here, we highlight HIV-1 mutational escape from adaptive, innate, and vaccine-induced immune responses as highly specific and reproducible processes beginning rapidly following HIV-1 infection. The potential biological implications of immune escape, including viral fitness costs and population-level HIV-1 adaptation to host immunity, are also summarized.

Escape from CD8⁺ Cytotoxic T Lymphocytes

CD8⁺ cytotoxic T lymphocytes (CTL) (► [HIV & SIV, CD8 T Cell Responses](#)) eliminate HIV-infected cells via the recognition of short, virus-derived peptide epitopes that are produced within the infected cell and presented at its surface by the highly polymorphic human leukocyte antigen (HLA) class I molecules (HLA-A, HLA-B, and HLA-C) (► [MHC Locus Variation](#)). HLA-restricted CTL play a major role in HIV-1 immune control. HIV-specific CTL first appear around acute-phase viremia decline and play an active role in its control to set-point levels (Goonetilleke et al. 2009). Experimental depletion of CD8⁺ lymphocytes in rhesus macaques results in their inability to control simian immunodeficiency virus (SIV) infection (Matano et al. 1998). Epidemiological links between host carriage of specific HLA class I alleles and HIV-1 disease progression have been demonstrated in natural history (Carrington and O'Brien 2003) and genome-wide association (Fellay et al. 2007) studies (► [Host Genetics and Genomics](#)). In particular, HLA-B*57 and HLA-B*27 are associated with lower viral loads and slower disease progression (Carrington and O'Brien 2003). Independent effects of HLA-C expression level on HIV-1 control have also been demonstrated (Apps et al. 2013).

That HLA-restricted CTL exert pressure on HIV-1 in vivo is also demonstrated by the virus' ability to escape this pressure via mutation. CTL escape was first described in 1991 when

HIV-1 Mutational Escape from Host Immunity, Fig. 1 CTL escape. (*Panel A*) HIV-1 proteins produced within an infected cell are processed into peptide epitopes by host cellular machinery and loaded onto HLA class I molecules for presentation at the cell surface. CTL eliminate infected cells via recognition of the viral peptide-HLA complex via their T-cell receptor (TCR). (*Panel B*) HIV-1 mutations can arise during the process of reverse

transcription that are then translated into protein. Here, a mutation abrogates the ability of the encoded viral epitope to bind HLA, allowing the infected cell to avoid CTL-mediated killing. Mutant progeny viruses are then released. CTL escape mutations may also hinder CTL-mediated killing of infected cells by interfering with viral antigen processing or by abrogating TCR-mediated recognition of the viral peptide-HLA complex (not shown)

researchers noted temporal shifts (and in some cases permanent loss of recognition) of HLA-B*08-restricted HIV-1 Gag epitopes targeted by patient-derived CTL over time, which coincided with the appearance of viral mutations within them (Phillips et al. 1991). Another key concept revealed by this study is the HLA-restricted nature of CTL escape, due to the requirement that epitopes be bound and presented by a specific HLA molecule for CTL recognition.

CTL escape mutations can be classified into three mechanistic categories. The most intuitive is escape via mutations that reduce or abrogate viral epitope binding to HLA, thereby impairing CTL recognition of infected cells (Fig. 1). Such mutations usually occur at HLA-specific epitope “anchor” residues – typically peptide positions two and/or C-terminus. A well-known example

is the B*27-associated R264K substitution selected at position 2 of the B*27-restricted KK10 epitope in Gag (Kelleher et al. 2001). Escape via abrogation of peptide-HLA binding represents a predominant CTL escape mechanism in vivo, with escape conferring an average (predicted) tenfold reduction in peptide-HLA binding affinity (Carlson et al. 2012a). CTL escape can also act upon processes that occur prior to, or following, peptide-HLA binding. For example, CTL escape mutations can inhibit epitope formation by interfering with their proper intracellular processing. The first such “antigen-processing (▶ [Antigen Processing](#)) escape mutation” to be mechanistically characterized was the B*57:03-restricted Gag-A146P substitution, occurring at the residue immediately upstream of the IW9 epitope, which acts via prevention of N-terminal aminopeptidase-mediated trimming

of this epitope (Draenert et al. 2004). Antigen-processing mutations can also occur within the epitope. For example, a substitution at position 5 of a B*07-restricted epitope in a cryptic Gag reading frame acted via introduction of a proteasomal cleavage site, yielding reduced epitope formation (Cardinaud et al. 2011). The final category of “T-cell receptor (TCR) escape mutations” retains the capability to bind HLA but reduces or abrogates recognition of the peptide-HLA complex by the TCR(s) expressed by the original selecting CTL. TCR escape mutations usually occur at central epitope positions. An example is the B*27-associated L268M substitution (selected at position 6 of the KK10 epitope) (Phillips et al. 1991). L268M-containing KK10 retains the ability to bind HLA-B*27 but abrogates its recognition by key B*27-restricted CTL clonotypes in the repertoire (Iglesias et al. 2011).

Despite substantial HIV-1 and host genetic variation, the mutational pathways of CTL escape are broadly predictable based on the HLA class I alleles expressed by the host. For example, three-quarters of HIV-1 subtype B-infected persons expressing the protective HLA-B*57 allele will select the T242N substitution in Gag (position 3 of the p24^{Gag} TW10 epitope) within weeks or months following infection (Leslie et al. 2004), while 50% will also select G248A at position 9 of this epitope later on (Carlson et al. 2012a). Together, these two mutations confer complete escape from B*57-restricted, TW10-specific CTL (Leslie et al. 2004). In contrast, among HLA-B*27-expressing persons, targeting of the immunodominant B*27-restricted p24^{Gag} KK10 epitope begins in early infection and is often sustained for years thereafter (Gao et al. 2005). KK10 escape begins via selection of the L268M mutation at epitope position 6 that abrogates its recognition by certain autologous B*27-restricted CTL (Iglesias et al. 2011), but complete escape from KK10-expressing CTL, via the R264K anchor residue escape at position 2 of the epitope, does not usually occur until years later (Kelleher et al. 2001). Notably, KK10 escape remains one of the few clear-cut examples where escape directly precedes loss of HIV-1 immune control (Goulder et al. 1997).

The predictable nature of CTL escape has allowed the identification of HLA-associated viral polymorphisms by statistical association. These studies, undertaken in cross-sectional datasets of linked HIV-1 and host HLA genotypes, identify viral polymorphisms significantly over- (or under-) represented among persons expressing a given HLA class I allele, identifying these as likely escape mutations (and their associated immunologically susceptible forms), respectively. The first such study, published in 2002, identified nearly 100 HLA-associated polymorphisms in HIV-1 reverse transcriptase in a cohort of ~400 patients, illustrating the extensive impact of CTL pressures on HIV-1 (Moore et al. 2002). In recognition of the potential confounding effects of viral lineage (or “founder”) effects in such analyses, more recent studies incorporate “phylogenetic corrections” (Bhattacharya et al. 2007), as well as statistical corrections for the confounding effects of linkage disequilibrium between HLA class I alleles and HIV-1 amino acid covariation.

Population-level studies have yielded comprehensive “immune escape maps” of the locations and mutational pathways of HLA-restricted CTL escape in HIV-1. These maps are most detailed for HIV-1 subtypes B (e.g., Carlson et al. 2012a) and C (e.g., Carlson et al. 2008). Population-level studies have also confirmed escape (and reversion, discussed later) as highly reproducible processes in context of host HLA. For example, the strongest HLA association in subtype B is the HLA-A*24:02-restricted Y135F escape mutation in Nef, where 81% of A*24:02-expressing persons harbor this substitution in chronic infection, compared to only 12% of persons who do not express an allele belonging to the A24 supertype (Carlson et al. 2012a). Such a strong statistical association (in this case, an odds ratio of ~30 and a p -value of 8×10^{-118} (Carlson et al. 2012a)) can only be achieved if the mutation is near-universally selected in persons harboring the HLA and reverts consistently in individuals lacking it (Fryer et al. 2012).

Escape is also highly HLA specific. When population-level analyses are undertaken at various HLA resolution levels (e.g., supertype, type, subtype), the majority (>60%) of HLA-

associated polymorphisms are identified as HLA subtype specific, while <10% are identified as shared across HLA supertypes (Carlson et al. 2012a). This high HLA specificity remains true even for closely related HLA alleles that present the same viral epitopes. For example, HLA-B*57:02, HLA-B*57:03, and HLA-B*58:01 all bind Gag-TW10, but they drive significantly different escape pathways within it (Carlson et al. 2012b). Escape pathways can also be complex and varied. Escape at a given viral site may occur along multiple pathways under pressure by a given HLA – for example, B*08-driven escape at Nef codon 94, position 5 of the B*08-restricted FL8 epitope, can occur via K94E, M, N, or Q (Brumme et al. 2007). A given HIV site may be under selection by various HLA alleles that select different, sometimes opposing, substitutions. For example, at Gag codon 147, HLA-A*25:01, HLA-B*13:02, and HLA-B*57:01 escape via selection of “L,” while B*14:02 and B*15:01 escape via selection of “I” (which also happens to be the subtype B consensus at this site) (Carlson et al. 2012a). Identification of HLA-associated polymorphisms has also aided the discovery of novel CTL epitopes, including those in cryptic HIV-1 reading frames (Berger et al. 2010).

HLA Class II-Driven Immune Escape

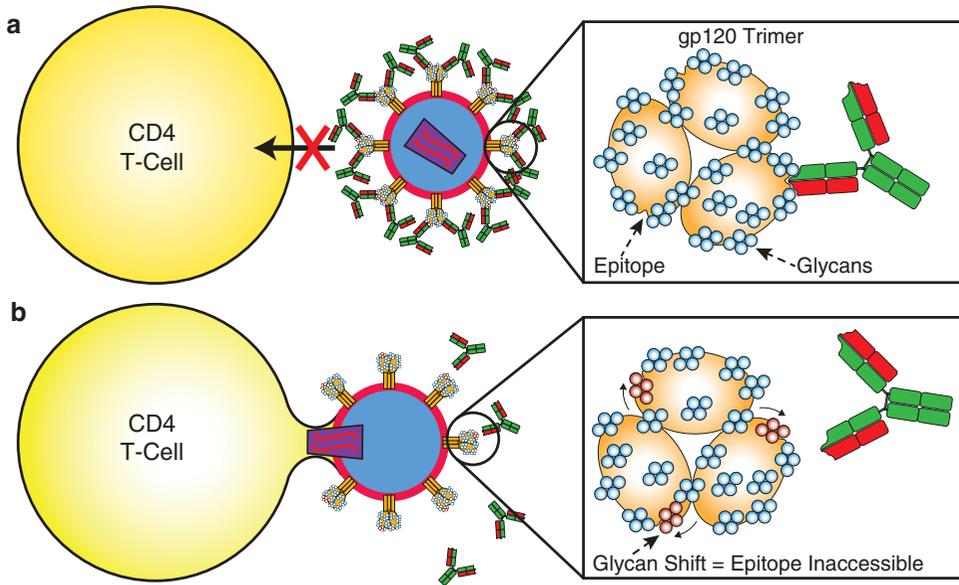

Effective antiviral immunity generally requires CD4⁺ T-lymphocyte help, but CD4⁺ responses rapidly become dysfunctional in HIV-1 infection, in part because of the specific elimination of virus-specific CD4⁺ T cells (► [HIV & SIV, CD4 T cell responses to](#)) (Douek et al. 2002). As such, the contribution of CD4⁺ T cells to HIV-1 control in vivo remains incompletely understood. Though some early studies supported the possibility of in vivo mutational escape from HIV-specific CD4⁺ T-cell responses Harcourt et al. (1998), others did not (Koeppel et al. 2006). Attempts to identify HLA class II-restricted viral polymorphisms by statistical association have yielded no strong evidence of their existence (Wright et al. 2012a).

Escape from Humoral (B-Cell) Immune Responses

HIV-1 envelope evolves rapidly within a host after infection and has diversified to an extraordinary extent at the population level (Gaschen et al. 2002) (► [HIV & SIV, B Cell Responses to](#)). Although CTL escape contributes to this process, the autologous neutralizing antibody (NAb) response is the major driver of envelope evolution. Beginning at approximately 3 months post-infection (Wei et al. 2003), HIV-infected individuals begin to develop antibodies capable of neutralizing their own virus (termed “autologous neutralizing antibodies”; NABs) Richman et al. (2003). However, unlike acute-phase HIV-specific CTL, autologous NABs do not appreciably contribute to virus containment, likely due to the rapid selection and outgrowth of neutralization-resistant escape mutants (Wei et al. 2003). Initial NAb escape exposes novel envelope epitopes against which subsequent waves of autologous NABs arise, driving further envelope evolution.

The fact that antibodies and virus coevolve in cycles of response and escape was first inferred via the ability of autologous sera to neutralize viral variants present in the infected individual 6 (or 12) months prior, but not those present at the time of serum sampling (Frost et al. 2005). Early studies of HIV-1 neutralization escape hinted at a variety of escape pathways including the accumulation of amino acid changes in envelope (Frost et al. 2005) (suggestive of escape through the selection of specific point mutations), changes in N-linked glycosylation patterns (Wei et al. 2003) (Fig. 2), and lengthening of certain hypervariable domains in gp120, notably V1/V2 (Rong et al. 2007). However, the identification of specific genetic events conferring NAb escape began only recently (e.g., the first specific identification of an envelope escape mutation conferring neutralization escape at the single antibody level was not achieved until 2009 (Rong et al. 2009)).

Unlike CTL epitopes whose (linear) sequences can be predicted from HLA-anchor residue motifs in HIV-1 sequences without knowledge of the

HIV-1 Mutational Escape from Host Immunity, Fig. 2 Neutralizing antibody escape. (Panel A) Neutralizing antibodies (NAb) bind to epitopes (shown as an indent) on the viral envelope, blocking their ability to infect target cells. (Panel B) Mutations in HIV envelope – in this case leading to changes in N-linked glycosylation patterns that block NAb access to the

epitope – confer NAb escape. NAb escape may also occur via point mutations, lengthening of certain gp120 hypervariable domains (notably V1/V2), cooperative interactions between different regions on a single or multiple members of the envelope trimer, or other mechanisms (not shown)

T-cell receptor sequence or structure, antibodies directly recognize three-dimensional epitopes whose sequences can span discontinuous sites on one or more members of the envelope trimer, rendering their locations difficult to predict based on viral sequence alone. Recent studies have therefore taken the approach of longitudinally characterizing envelope evolution while simultaneously attempting to isolate individual neutralizing antibodies (and/or the B-cell clonal lineages producing them; e.g., Moore et al. (2012)) in individual patients.

From these studies, a central role of immune-driven envelope evolution in driving autologous neutralization breadth is emerging. In one individual, initial autologous NABs were directed against epitopes in the first and second hypervariable loops of gp120 (V1/V2), and escape was achieved via point mutations in this region including one in V2 that created a putative N-linked glycosylation site conferring escape from two distinct monoclonal antibodies isolated from this patient (Rong

et al. 2009). In the second individual, escape from the initial NAB pool occurred via convergent evolutionary pathways (one involving changes in the V3–V5 gp120 outer domain and the other involving codependent changes in V1/V2 and gp41), whose lineage members subsequently oscillated in frequency (Rong et al. 2009). NAB escape via distinct evolutionary pathways within a single host was confirmed in an individual in whom escape in a V3-proximal epitope occurred along three divergent viral lineages, each featuring a unique amino acid change (Murphy et al. 2013). A study of three acutely infected individuals whose initial response was directed against different conformational epitopes in envelope, where each escaped along distinct pathways (Bar et al. 2012), also supports the strain- and host-specific nature of initial epitope targeting and autologous neutralization escape. That escape occurs via distinct mechanisms (e.g., point mutations, glycan shifts, and cooperative conformational changes between two domains) both within and among

hosts indicates that HIV-1 employs multiple mutational strategies to escape early autologous NAb (Rong et al. 2009). However, the extent to which neutralizing antibody epitopes – and their escape pathways – are shared across patients remains a key question. The observation that, compared to transmitted/founder viruses, chronic subtype C viruses are significantly enriched for a glycan at envelope codon 332 (whose presence can help trigger the evolution of broadly neutralizing antibodies against this key conserved region (Moore et al. 2012)) supports the idea of shared neutralization escape pathways.

In approximately 80% of infected individuals, this process of virus-NAb coevolution results in the continued production of NAb that remain largely specific to the individual's evolving virus. However in approximately 20% of individuals, this process leads to the emergence of antibodies that are capable of neutralizing a broad range of HIV-1 isolates across subtypes. Though individuals producing such “broadly neutralizing antibodies” do not likely derive clinical benefit from them (presumably because their own virus has already escaped) (Euler et al. 2010), the evolutionary mechanisms driving their development are of paramount interest as an effective preventative HIV-1 vaccine will likely require their elicitation (along with effective cellular responses). This discovery has led to the hypothesis that this process could be recapitulated via vaccination with specific transmitted/founder envelopes and their sequential escape variants (Liao et al. 2013), a strategy for which there is preliminary experimental support (Malherbe et al. 2011).

Non-neutralizing HIV-specific antibodies (► [Non-Neutralizing Antibody Responses and Protection Against HIV-1](#)) that mediate antibody-dependent cellular cytotoxicity (ADCC) through activation of effector cells bearing Fc receptors, notably natural killer (NK) cells, may also contribute to natural- and vaccine-induced HIV-1 immune control Wren and Kent (2011). Some evidence also supports ADCC antibodies, including those that do not possess neutralizing activity, as drivers of evolution within HIV-1 envelope and possibly other viral regions (Chung et al. 2011).

Escape from Innate Immune Responses: KIR-Driven HIV-1 Polymorphisms?

Innate immune responses (HIV & SIV, Innate Immune Responses to), in particular natural killer (NK) cells (► [Natural Killer Cells and their Role in Preventing HIV-1 Transmission](#); ► [NK Cells Responses to HIV](#)), may also directly drive immune escape. NK cells express cell-surface receptors belonging to the polymorphic killer cell immunoglobulin-like receptor (KIR) gene family, which comprise a variety of inhibitory and activating receptors that interact with HLA class I ligands on target cells. Engagement of activating KIR delivers a stimulatory signal, while engagement of inhibitory KIR delivers a tolerance signal. When the former overcome the latter, NK effector functions are initiated. Indeed, a major trigger for enhanced NK cell-mediated recognition of HIV-infected cells is the selective downregulation of their HLA-A and HLA-B (though not C) ligands by the viral Nef protein (Cohen et al. 1999), leading to a reduction in signaling through inhibitory KIR. Inhibitory KIRs bind their HLA class I ligands in an allotype-specific manner. For example, KIR3DL1 receptors interact with HLA-B molecules belonging to the Bw4 allotype (determined by amino acids 77–83 of the HLA coding region), notably those harboring isoleucine at position 80 (Bw4-80I), and to a lesser extent those harboring threonine at this position (Bw4-80T) (Cella et al. 1994). Some activating KIRs also recognize HLA class I in an allotype-specific manner, though generally at lower avidity than their inhibitory counterparts (Bashirova et al. 2011).

KIR, alone and in combination with their allotype-specific HLA ligands, may modulate HIV-1 susceptibility and pathogenesis. HIV-infected individuals expressing the activating KIR3DS1 allele in combination with HLA-Bw4-80I exhibit lower viral loads (Qi et al. 2006) and delayed clinical progression (Martin et al. 2002). Higher frequencies of KIR3DS1 homozygosity (Boulet et al. 2008) have been observed in HIV-1 exposed seronegative individuals, suggesting that activating KIR may also confer some level of protection against HIV-1

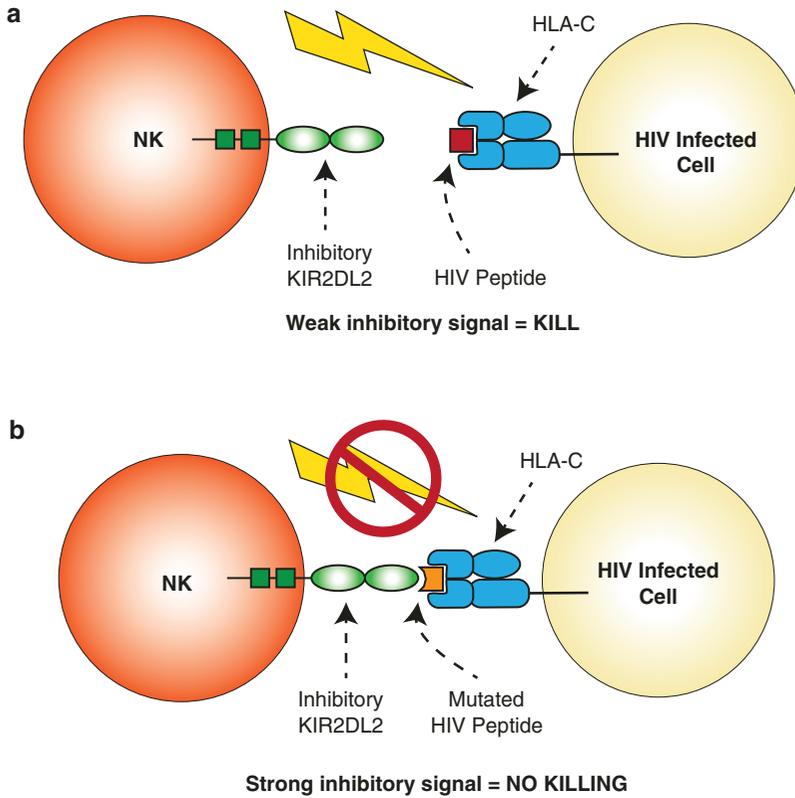

acquisition. Though protection via engagement of an activating KIR seems intuitive, the underlying mechanism remains unknown (KIR3DS1-expressing NK cells can suppress HIV-1 replication in Bw4-80I-expressing cells in vitro (Alter et al. 2007), but direct binding of KIR3DS1 to HLA-Bw4-80I has not been shown). KIR3DL1 alleles possessing a high-expression, high-inhibitory phenotype (termed KIR3DL1*h/*y) may also be protective. When present in combination with HLA-Bw4-80I alleles, notably HLA-B*57, KIR3DL1*h/*y alleles were associated with lower viral loads and conferred protection against HIV-1 disease progression (Martin et al. 2007). KIR3DL1*h/*y-HLA-B*57 co-expression may also protect against HIV-1 acquisition (Boulet et al. 2008). That highly inhibitory KIR receptor-ligand interactions can be protective seems counterintuitive, especially given that the opposing signals of activating KIR may also be protective. Nevertheless, the data support a role, albeit incompletely elucidated, of KIR in HIV-1 control.

KIR-associated immune pressures may also drive the selection of viral polymorphisms that allow infected cells to evade NK-mediated killing. To shed light on how such mutations could arise, we must first briefly revisit KIR-ligand binding. Though not antigen specific in the classical sense, KIR receptor-ligand interactions are nevertheless modulated in part by HLA polymorphism (through their allotype specificity) as well as the sequence of the HLA-bound peptide (Malnati et al. 1995). The idea that naturally arising HIV-1 variants could affect KIR-HLA binding was supported by reduced in vitro binding of KIR3DL1 to its HLA B*57:03 ligand in the presence of the TW10 epitope harboring a G-to-E substitution at position 9 (though this was not claimed to be an in vivo NK-driven escape mutation, as failure to engage KIR3DL1 would render infected cells more, not less, susceptible to NK-mediated killing (Brackenridge et al. 2011)). Rather, NK cell escape could theoretically be achieved via viral polymorphisms that reduce recognition by activating KIR or enhance recognition by inhibitory KIR. Toward the identification of such mutations, statistical association approaches

were applied to $N = 91$ linked KIR/HIV-1 sequences, yielding 22 KIR-associated viral polymorphisms. Two linked polymorphisms in Vpu (71M/71H), located in a region that overlaps the Env reading frame, were overrepresented among KIR2DL2-expressing persons, in particular those KIR2DL2⁺ individuals homozygous for HLA-C group 1 alleles (Alter et al. 2011) (consistent with the greater affinity of KIR2DL2 for HLA-C group 1 ligands (Moesta et al. 2008)). Researchers further showed in vitro that the presence of these polymorphisms enhanced the ability of the inhibitory KIR2DL2 to bind HIV-infected cells, that KIR2DL2⁺ NK cells failed to become activated in the presence of polymorphism-containing HIV-1, and that cells infected with polymorphism-containing HIV-1 were not inhibited by KIR2DL2⁺ NK cells (Alter et al. 2011). These findings suggest that immune pressure by an inhibitory KIR could select in vivo escape mutations conferring enhanced binding of the inhibitory receptor to HIV-infected cells, thereby allowing them to escape NK cell-mediated elimination (Fig. 3). The recent identification of an HLA-C*01:02-restricted p24^{Gag} peptide variant that bound KIR2DL2, that conferred functional inhibition of KIR2DL2-expressing NK cells in vitro (Fadda et al. 2012), provides theoretical support for this model.

Escape from Vaccine-Induced Antiviral Immunity

A challenge in designing vaccines against genetically diverse pathogens such as HIV-1 is the possibility that vaccine-induced immunity (► [Preventing HIV-1 Transmission Through Vaccine-Induced Immune Responses](#)) may protect against infection by strains similar to the vaccine immunogen(s), but not genetically divergent strains. Such “sieve effects” can be identified by retrospectively comparing HIV-1 sequences of vaccine vs. placebo trial participants who subsequently became infected (termed “breakthrough” sequences), to determine genetic differences between them (Gilbert et al. 2001). The idea that vaccine-induced immunity could induce a partial

HIV-1 Mutational Escape from Host Immunity, Fig. 3 KIR escape. Mutations in HIV-1, presumably within viral peptides presented by HLA on the infected cell surface, may impair NK cell-mediated recognition of HIV-infected cells, thereby conferring escape. Based on a putative KIR2DL2 escape mutation described by Alter et al. (2011), this figure illustrates how this process could occur. (Panel A) Weak interactions between the inhibitory KIR2DL2 on the NK cell surface and the viral peptide/HLA-C complex on the HIV-infected cell surface produce

weak inhibitory signals, leading to NK cell-mediated elimination of the infected cell. (Panel B) Viral escape mutations that enhance KIR2DL2-mediated NK cell recognition of the peptide/HLA-C complex on the HIV-infected cell produce strong inhibitory signals that protect the infected cell from NK cell-mediated killing. KIR escape could also theoretically occur via the selection of mutations that abrogate recognition by activating KIR (not shown)

barrier through which antigenically divergent HIV-1 strains could penetrate has been termed the “acquisition sieve effect,” while the related – yet mechanistically distinct – possibility that vaccine-induced immunity would fail to block infection but would instead drive the rapid outgrowth of escape variants has been termed “postinfection sieve effect” (Edlefsen et al. 2013). The latter is particularly relevant to CTL-based vaccines, as these are unlikely to block HIV-1 transmission. Notably, acquisition and postinfection sieve effects can be difficult to distinguish from one another, as both may occur

before HIV-1 RNA can be reliably detected in the blood, and/or may manifest themselves via the presence of identical immune-associated polymorphisms.

Analysis of vaccine trial data support sieve effects in HIV-1. Such effects were first suggested by the presence of atypical V3 amino acid motifs in HIV-1 *env* sequences from individuals vaccinated with recombinant HIV-1_{MN} gp120 (Berman et al. 1997). Recent comparisons of founder HIV-1 strains from vaccine and placebo recipients of the RV144 “Thai” vaccine trial identified differential amino acid frequencies at *env* V2 codons

169 and 181 between the two groups (Rolland et al. 2012), suggesting that the vaccine preferentially blocked viruses harboring specific substitutions at these positions. Rapid selection of CTL escape mutations by vaccine-induced cellular immune responses may also have occurred in the failed STEP vaccine trial (Buchbinder et al. 2008). Inferred T-cell epitope sequences within Gag/Pol/Nef (the regions contained within the vaccine) from infected vaccine recipients exhibited greater genetic distances to the immunogen sequence compared to those of infected placebo recipients, presumably as a result of extensive and rapid immune escape (Rolland et al. 2011). The lack of such differences for epitopes within other HIV-1 proteins also supported this conclusion. HIV-1 sequences from vaccine recipients also exhibited substitutions at Gag codon 84 more frequently than placebo recipients, identifying this as a putative signature site of HIV-1 evolution in response to vaccine-induced CTL responses (Rolland et al. 2011).

The implications of vaccine-induced immune responses on HIV-1 evolution are potentially profound. At the individual level, rapid vaccine-driven escape could accelerate disease progression (Betts et al. 2005), while the use of vaccines capable of blocking infection by only certain HIV-1 strains raises concerns regarding potential shifts in viral polymorphism frequencies and/or HIV-1 lineage distributions (and their clinical and pathogenic consequences) at the population level. That vaccine-induced immune responses (notably CTL) may target slightly different epitopes than those in natural infection Hertz et al. (2013) may further complicate this issue.

A Note on the Role of HIV-1 Accessory Proteins in Immune Evasion

Although beyond the scope of the present entry, certain HIV-1 proteins possess immune evasion functions that deserve brief mention. In particular, downregulation of HLA-A and HLA-B (but not HLA-C) from the cell surface by Nef Cohen et al. (1999) represents a major mechanism of

immune evasion by HLA-restricted CTL, as it reduces their ability to recognize infected cells. HIV-1 Nef, Vpu, and envelope (► [Nef/Env/Vpu/Tetherin](#)) also serve to remove CD4 from the infected cell surface (Chen et al. 1996). The recent observation that interaction of HIV-1 envelope with CD4 on the infected cell surface is required to expose certain ADCC epitopes suggests that cell-surface CD4 downregulation could represent an immune evasion strategy to reduce ADCC-mediated elimination of infected cells (Veillette et al. 2014).

Immune Escape Dynamics in Early Infection

Escape begins rapidly following HIV-1 infection. Recently, detailed studies of intra-host HIV-1 evolution using single-genome amplification (e.g., Salazar-Gonzalez et al. 2009) or next-generation sequencing (e.g., Henn et al. 2012) have advanced our understanding of HIV-1 transmission and escape dynamics. HIV-1 transmission (HIV-1 Transmission Dynamics; HIV-1 Transmission Selection) is characterized by a severe genetic bottleneck. An estimated 80% of heterosexual transmissions are productively initiated by a single transmitted/founder virus (Salazar-Gonzalez et al. 2009), while infection in persons who inject drugs is generally established by more than one closely related founder virus (Bar et al. 2010). In the days following infection, the transmitted/founder virus(es) undergoes rapid population growth and star-like diversification Herbeck et al. (2011), giving rise to a “quasispecies” swarm of related HIV-1 variants. This genetic pool becomes the evolutionary substrate upon which host immune responses exert pressure, driving the selection of escape mutations and the survival of viral lineages harboring them. The first CTL escape mutations appear during acute-phase viremia decline (Goonetilleke et al. 2009); the selection (and in some cases fixation) of CTL escape variants has been observed as early as 21 days postinfection in humans (Herbeck et al. 2011). Selection (and subsequent fixation) of the first NAb escape mutations also occurs

relatively rapidly, though on a slightly longer time course than CTL escape (Bar et al. 2012).

The evolutionary pathways along which these early mutations arise have recently been elucidated in detail. The conceptually straightforward pathway whereby the first selected escape mutation gradually outcompetes the original transmitted form is likely to be true for only a minority of cases (Goonetilleke et al. 2009). More commonly, the first escape variant tends to be followed by the emergence of numerous others, from which the “final” escape form is ultimately selected (Goonetilleke et al. 2009). This is likely because the initially appearing pool of low-frequency mutants often retains some ability to be targeted by existing (or *de novo*) CTL (Brackenridge et al. 2011). This drives the selection of more effective escape variants, often at HLA-anchor residues, that ultimately outcompete both transmitted founder and initial variants. For example, in a B*57:03-expressing individual, initial escape within the p24^{Gag} TW10 epitope occurred approximately 5 months postinfection via a transient, minority G-to-E mutation at position 9 (G248E) that retained the ability to bind B*57:03 and reduced CTL recognition only modestly (Brackenridge et al. 2011). By approximately 1.5 years postinfection, this mutation was outcompeted by variants expressing the canonical B*57-restricted G248A mutation at this position (along with T242N and V247I at epitope positions 3 and 8). Similarly, multiple amino acids often transiently appear in the regions under NAb pressure, from which the final neutralization mutant(s) ultimately emerges (Bar et al. 2012). Escape continues to occur (albeit at a slower rate (Koibuchi et al. 2005)) over the infection course.

Immune Escape as a Major Driver of HIV-1 Diversity

Immune escape is a major driver of HIV-1 diversity within individuals and populations. CTL escape accounts for a major proportion of within-host HIV-1 evolution in the first year of infection. For example, a study of seven newly infected individuals revealed that, 6 months

postinfection, between 9 and 18 positively selected substitutions were observed throughout the HIV-1 proteome (Herbeck et al. 2011). Another population-based study estimated that a minimum of 30% of substitutions in Gag/Pol and 60% in Nef were attributable to HLA pressures (Brumme et al. 2008). Escape is also widespread throughout the HIV-1 proteome. A recent statistical association study identified over 2,100 HLA-associated polymorphisms at ~35% of HIV-1's nonconserved codons (Carlson et al. 2012a), distributed somewhat unequally throughout the proteome. For example, Vpu exhibited evidence for HLA-mediated selection at one-quarter of its nonconserved sites, compared to ~70% of nonconserved sites in Nef (Carlson et al. 2012a). The status of HLA as the most important host genetic factor influencing HIV-1 diversity was recently confirmed via genome-wide association studies (Bartha et al. 2013). Similarly, HIV-1 Gag and Nef sites under HLA selection have diversified to the greatest extent over the past three decades of the North American epidemic, supporting a significant role of HLA in driving global HIV-1 diversification (Cotton et al. 2014).

Fitness Consequences of Escape

Upon transmission, some immune escape mutations selected in the previous host will revert to the original (usually subtype consensus) amino acid (Leslie et al. 2004). While some CTL escape mutations, for example, the B*57-associated Gag T242N, revert consistently and rapidly following transmission (Leslie et al. 2004), most revert more slowly (Crawford et al. 2007) and others rarely or not at all (Leslie et al. 2005). Reversion occurs because these mutations incur a fitness cost (► [Viral Fitness in Hosts](#)). Generally, escape mutations within conserved viral regions tend to be more fitness-costly, while escape in more variable regions tends to be fitness neutral (Troyer et al. 2009). An example of a fitness-costly mutation is the B*27-associated R264K substitution in the p24^{Gag} KK10 epitope, which essentially abolishes *in vitro* viral replication

when engineered alone into HIV-1_{NL4-3} (Schneidewind et al. 2007). Generally though, *in vitro* fitness costs of escape mutations observed *in vivo* tend to be subtler, often requiring multiple substitutions to reduce function. Alone, the B*57-driven Gag-T242N mutation reduces viral replicative capacity only modestly (Brockman et al. 2007), but dose-dependent replicative reductions are observed when it is present alongside other common B*57-driven mutations in p24^{Gag} (Crawford et al. 2009). Other examples of fitness-costly CTL escape mutations include B*13-associated mutations in Gag (Prado et al. 2009), Cw*05-driven mutations in integrase (Brockman et al. 2012), and B*35-associated mutations in Nef (Ueno et al. 2008). Fitness costs ranging from 0% to 24% have been observed for early envelope escape mutants, indicating that NAb escape can also be fitness-costly (Bar et al. 2012). Fitness costs of escape can be offset by the selection of compensatory mutations at secondary sites. Whereas most compensatory mutations occur in relatively close proximity to the primary escape site (e.g., S165N with A163G in B*5703-KF11 in p24^{Gag} (Crawford et al. 2007)), others, such as S173A with R264K in B*27-KK10 (Schneidewind et al. 2007), occur a substantial linear distance away, but may reside nearby in the folded protein structure.

In the case where escape can only occur at a functional and/or replicative cost, the virus' advantage gained via immune escape is offset in part by these costs, thus potentially conferring some residual biological benefit to the host in terms of lower viral loads. For example, the sustained protective effect of HLA-B*81 is believed to be due in part to selection of the fitness-costly Gag T186S escape mutation at position 7 of the immunodominant B*81-restricted TL9 epitope, which is difficult to compensate (Wright et al. 2012b). Relative clinical benefits of fitness-costly escape in HLA-mismatched individuals who have acquired HIV-1 with key Gag escape mutations have also been observed (Chopera et al. 2008). That HIV-1 sequences contain inherent determinants of pathogenesis is supported by the observation that set-point plasma viral load is to a certain extent "heritable" from

one infection to the next (Alizon et al. 2010) and that viral replication capacity correlates positively with viral load (and negatively with CD4⁺ T-cell count) at various infection stages (e.g., Prince et al. 2012). Indeed, acquisition of attenuated HIV-1, followed by further within-host selection of noncanonical fitness-costly escape mutations, is likely to explain a portion of HIV-1 elite control (Lobritz et al. 2011), a rare phenotype where individuals are able to spontaneously suppress plasma HIV-1 RNA to below limits of clinical detection without the need for antiretroviral therapy.

These observations have led to the idea that immune-mediated containment of HIV-1 replication to levels that slow disease progression and possibly reduce transmission might be achievable through the design of vaccines that stimulate CTL responses focused against critically conserved viral regions where escape can only occur at substantial fitness costs (Altfeld and Allen 2006). A related strategy would be to design immunogens featuring both susceptible and common escape variant forms – provided the latter retain the ability to bind the relevant HLA molecules – with the goal of generating broad, potent, variant-reactive CTL responses that, upon infection, will drive HIV-1 evolution down unconventional pathways not unlike those selected in elite controllers (Miura et al. 2009).

Population-Level Adaptation of HIV-1 to Host Immune Pressures

As HIV-1 genomes residing in an individual exhibit adaptations to its host's immunogenetic profile, then HIV-1 sequences circulating in a given host population exhibit adaptations that reflect the distinct immunogenetic profile of that population. This is often referred to as "population-level" adaptation of HIV-1. For example, >50% of HLA-associated polymorphisms identified in HIV-1 subtype B sequences in Mexico (Avila-Rios et al. 2009) and nearly two-thirds of those identified in Japan (Chikata et al. 2014) are distinct from those observed in subtype B-infected cohorts from Canada/USA/

Australia, because the former populations exhibit HLA alleles unique to those populations (e.g., B*39 in Mexico and B*67:01 in Japan). The frequencies of HLA-associated polymorphisms will similarly vary according to the frequencies of their restricting HLA alleles in the population. The B*51-associated I135X mutation in reverse transcriptase (at the C-terminus of the B*51-TI8 epitope, RT codons 128–135) provides an example. In an analysis of nine cohorts spanning five continents, HLA-B*51 and RT-I135X prevalence exhibited a strong positive correlation (Kawashima et al. 2009), indicating that the more frequent an HLA allele is in a population, the more frequent its associated adaptations will be observed in circulating HIV-1 sequences. Other host immune factors (e.g., variability in T-cell receptor genetics) may also play a role in population-specific HIV-1 adaptation. For example, a recent comparative study of HIV-1 subtype B cohorts in Japan versus Canada/USA/Australia identified numerous cases where the same HLA allele selected significantly different escape pathways across cohorts (Chikata et al. 2014), implying factors beyond HLA in driving these differences. HLA-driven escape pathways also differ across HIV-1 subtypes, presumably as a result of genetic differences in the viral backbone. For example, Gag-T242N is commonly selected by B*57 in HIV-1 subtypes B, C, and D, but rarely in subtype A1 (McKinnon et al. 2009).

The persistence of certain immune escape mutations following transmission to a new host has led to a related concern – namely, that escape mutations could gradually spread throughout the population (Goulder et al. 2001). Analogous to the negative impact of transmitted drug resistance mutations on treatment efficacy, acquisition of “escape mutant” HIV-1 by persons expressing the relevant HLA could undermine the ability of their CTL to control infection; as such, escape mutant spread could gradually undermine host antiviral immune potential (and potentially diminish the protective effects of certain HLA alleles as the epidemic progresses). Indeed, the S173A compensatory mutation has been shown to stabilize the B*27-associated R264K mutation in p24^{Gag} upon transmission (Schneidewind

et al. 2009), while the S165N compensatory mutation has been shown to stabilize B*57-associated mutations within the p24^{Gag} KF11 epitope (Crawford et al. 2007), supporting this concern.

The extent to which immune escape mutations are spreading in HIV-infected populations remains incompletely known, in part due to the scarcity of historic data. Nevertheless, it has been suggested that CTL epitopes in European HIV-1 sequences are being “lost” through mutational escape from HLA-B-mediated selective pressures (Schellens et al. 2011); similarly, higher viral polymorphism frequencies have been reported in modern compared to historic HIV-1 subtype B and F sequences in South America (Dilernia et al. 2008). The high frequency of the B*51-associated HIV-1 reverse transcriptase (RT) I135X mutation in Japan, a population where B*51 prevalence approaches 20%, is also suggestive of escape mutation accumulation (Kawashima et al. 2009) (though the possibility that the Japanese epidemic was founded by an HIV-1 sequence containing RT-I135X cannot be ruled out). A comparative study of historic (1979–1989) versus modern (2,000+) HIV-1 subtype B cohorts in North America revealed modest spread of CTL escape mutations over the study period which occurred alongside an approximate twofold increase in HIV-1 diversity during this time (Cotton et al. 2014). Despite limited evidence of escape mutation spread in North America, rates of spread may be higher in populations with high HIV-1 prevalence, older epidemics, differential transmission and dynamics and/or where host HLA diversity is relatively limited, and thus possess more immediate implications.

The gradual accumulation of CTL escape mutations in circulating HIV-1 sequences is paralleled by a similar phenomenon driven by humoral immunity. Two recent studies evaluating antibody neutralization resistance of historic versus modern HIV-1 envelope sequences suggest that HIV-1 is drifting toward a more neutralization-resistant phenotype over time (Bunnik et al. 2010). Furthermore, contemporary sera exhibited lower heterologous neutralizing activity than historic sera, consistent with a gradual undermining of humoral immunity as HIV-1 becomes increasingly

neutralization resistant (Bouvin-Pley et al. 2013). Taken together, evidence suggests that HIV-1 is becoming – albeit gradually – more “preadapted” to host immunity as immune escape mutations spread in circulation. Further studies are therefore warranted to explore the extent of HIV-1 adaptation to cellular and humoral immune pressures in different host populations as their respective epidemics increase in age and diversity, and the potential implications of this adaptation for natural (and vaccine-induced) immunity over time.

Conclusion

In conclusion, mutational escape from host immune responses represents a major selective force driving the evolution and diversification of HIV-1 within infected persons. By extension, immune escape is also responsible for the diversification of HIV-1 globally and for the continued evolution of the virus as the epidemic progresses. Continuing to advance our understanding of the dynamics and pathogenic implications of immune escape within individuals and populations – including how to recapitulate this process by vaccination as in the case of the generation of broadly neutralizing antibodies – will be paramount to achieving our ultimate goal of an effective HIV-1 vaccine.

HIV-1 Pathogenesis in the Gut

Stephanie M. Dillon, Mario L. Santiago and Cara C. Wilson

Department of Medicine, Division of Infectious Diseases, University of Colorado Anschutz Medical Campus, Aurora, CO, USA

Definition

HIV-1 pathogenesis in the gut, considered to be a major driving force behind chronic immune activation and inflammation, is defined by significant immunological and structural abnormalities.

Early in infection, HIV-1 targets gut CD4 T cells resulting in high levels of viral replication and massive depletion of CD4 T cells which are important in maintaining intestinal homeostasis. Furthermore, HIV-1 disrupts innate immunity and is associated with significant gut epithelial barrier damage. The culmination of these dramatic changes in the gut is increased local inflammation, changes in the gut microbiome (dysbiosis) and the translocation of microbes and microbial products from the lumen into the gut tissue and ultimately into systemic circulation. Microbial translocation not only drives further gut mucosal immune activation and inflammation perpetuating the disruption in gut homeostasis, but is considered to be a major contributor to systemic immune activation and inflammation, even in the setting of viral suppression with effective anti-retroviral therapy (ART). Indeed, suppressive ART improves many features associated with gut pathogenesis, but in many instances does not fully reverse the breakdown in intestinal homeostasis. Recent efforts have focused on therapies aimed at restoring gut function by reducing inflammation, blocking microbial translocation or modifying the gut microbiome.

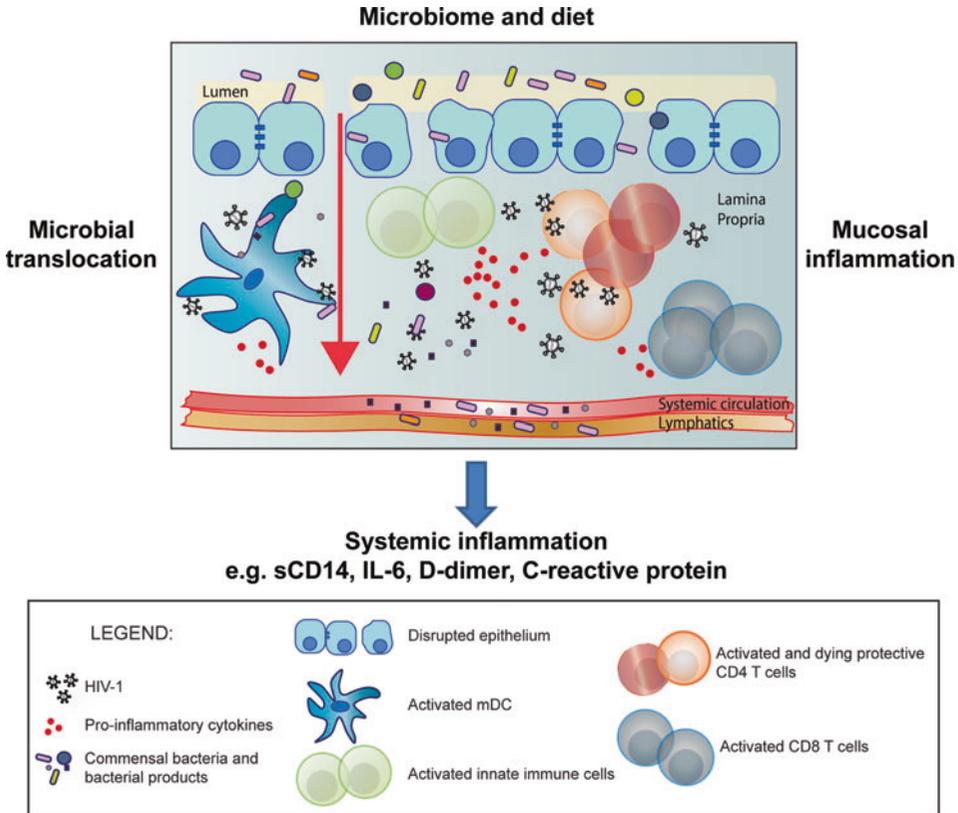

Overview

HIV-1 infection has long been known to induce a state of chronic immune activation, the extent of which predicts disease progression and CD4 T-cell loss in untreated infection and limits immune restoration following initiation of suppressive antiretroviral therapy (ART). Furthermore, chronic immune activation and inflammation during treated infection has been associated with numerous non-AIDS comorbidities and increased mortality, so understanding the mechanisms that drive chronic inflammation is a top priority in AIDS research. This state of chronic immune activation is likely multifactorial, but increasing evidence suggests that damage to the gut epithelial barrier and massive loss of CD4 T cells in the gut-associated lymphoid tissue (GALT) inflicted early in the course of infection may be a major source.

HIV-associated enteropathy accompanied by symptoms of diarrhea, weight loss, malnutrition, and malabsorption was observed in the earliest days of the epidemic. Over the ensuing decades of research in both HIV-infected humans and SIV-infected nonhuman primates, much more has become known about the mechanisms by which HIV-1 targets and destroys the mucosal immune system and thereby disrupts intestinal homeostasis. HIV-associated gastrointestinal (GI) tract pathology is characterized by early and high-level HIV-1 replication in GALT and by immunological and structural abnormalities which include alterations in both adaptive and innate mucosal immunity and substantial epithelial barrier disruption. These changes culminate in increased local inflammation, microbial translocation, and dysbiosis leading to chronic generalized immune activation, inflammation, and associated comorbidities (Fig. 1). Suppressive ART may improve, but in many instances does not fully reverse, this HIV-associated intestinal immune dysfunction.

HIV-1 Replication in GALT

HIV-1 is primarily a mucosally transmitted pathogen, with about 80% of cases linked to sexual transmission. Thus, the nature of HIV-1 strains that initially establish infection is of particular interest in vaccine development. In an infected individual, HIV-1 exists as a “swarm” of evolutionarily related viruses that vary by about 5% from each other. During sexual transmission, about 80% of the viruses that get established in the “recipient” host came from just one HIV-1 strain, suggesting an extreme genetic bottleneck. These “transmitted/founder” or TF virus strains have interesting biological characteristics compared to HIV-1 strains derived from chronic infection. In HIV-1 subtype C strains, which account for about 50% of HIV-1 infections worldwide, TF HIV-1 strains are characterized by more compact envelope glycoproteins that are more competent in fusing to target CD4+ T cells. However, compact envelope proteins were not observed in other HIV-1 strains such as subtype B strains, which are

HIV-1 Pathogenesis in the Gut, Fig. 1 HIV-1 targets and destroys the mucosal immune system and disrupts intestinal homeostasis. HIV-associated gastrointestinal tract pathology is characterized by early and high-level HIV-1 replication in the gut-associated lymphoid tissue and by immunological and structural abnormalities

including alterations in both adaptive and innate mucosal immunity and substantial epithelial barrier disruption. These changes culminate in increased local inflammation, microbial translocation, and dysbiosis leading to chronic generalized immune activation, inflammation, and associated comorbidities

the more prevalent strains circulating in North America and Europe. Nevertheless, HIV-1 subtype B TF strains were more infectious, and this was linked to higher envelope incorporation in virions (Parrish et al. 2013). Replicative fitness would be ideal for the successful initial establishment of HIV-1 infection.

TF HIV-1 strains could have emerged from initial expansion and amplification in the GALT, which harbor large numbers of activated CD4⁺ T cells. However, there is currently a dearth of knowledge on how TF HIV-1 strains replicate in mucosal tissues. To understand better the biology of TF HIV-1 strains, the Lamina Propria Aggregate Culture (LPAC) model has been developed. This model allows for the *in vitro* infection of

primary gut CD4⁺ T cells with various HIV-1 strains in the absence of exogenous mitogens (Dillon et al. 2012; Steele et al. 2014). Using this model, HIV-1 TF viruses were found to replicate to higher levels than counterpart chronic HIV-1 strains derived from the same patient. Of note, a critical property of TF HIV-1 strains is their almost exclusive usage of the CCR5 versus the CXCR4 co-receptor. In sharp contrast to blood and lymph node CD4⁺ T cells, mucosal CD4⁺ T cells express high levels of CCR5. Thus, the preponderance of CCR5-tropic HIV-1 strains in an infected individual may be explained by an initial selection process(es) in the GALT. Of note, it was proposed that HIV-1 may be particularly effective in replicating in the GALT through

the binding of the HIV-1 envelope protein to the integrin $\alpha 4\beta 7$, which facilitates the migration of lymphocytes to the GALT. However, subsequent studies revealed that most HIV-1 strains could not bind $\alpha 4\beta 7$ and blocking these interactions did not inhibit HIV-1 infection.

Intrinsic Immunity Against GALT HIV-1 Infection

The successful establishment of HIV-1 infection would require evasion strategies against host innate immune responses. During acute HIV-1 infection, a cytokine storm in plasma was observed. One of the early cytokines induced was interferon- α (IFN α), which can potently inhibit HIV-1 replication in culture and had modest effects in reducing HIV-1 viral loads when administered in human clinical trials. Of interest, HIV-1 TF strains were more resistant to IFN α compared to chronic counterpart strains, providing indirect evidence for the importance of innate immunity in the initial establishment of HIV-1 infection (Parrish et al. 2013). Type I interferons (a group of antiviral cytokines that include IFN α) regulate hundreds of genes. Among these interferon-stimulated genes (ISGs) are the retrovirus restriction factors, which can directly inhibit HIV-1 replication by interfering with specific steps in the viral life cycle (Malim and Bieniasz 2012). APOBEC3G is a cytidine deaminase that can get incorporated into virions and, in the next target cell, could inhibit reverse transcription and hypermutate reverse transcripts. Tetherin could restrict retrovirus release by “tethering” virion and cellular membranes together. HIV-1 encodes the Vif and Vpu proteins to counteract APOBEC3G and tetherin, respectively. However, these host-pathogen interactions may be subject to (1) the strength of the molecular interactions, as some Vif and Vpu alleles may be weaker, and (2) stoichiometric balance, which could be offset by type I interferon induction of the restriction factors. In fact, about 16% of TF HIV-1 strains harbor extensive hypermutation, indicative of APOBEC3G as a barrier to successful establishment of HIV-1 infection. Additional HIV-1

restriction factors, such as Mx2, IFITM, Schlafen11, and SAMHD1, have also been identified, but their relative contributions in the overall antiviral effect remain an active area of investigation.

Type I interferons consist of several cytokines that include the 12 IFN α subtypes and interferon-beta. These cytokines are released primarily by plasmacytoid dendritic cells (pDCs), which rapidly migrate to mucosal tissues during acute infection based on data in the SIV model. However, type I interferons expressed by pDCs following HIV-1 exposure appear to be dominated by weakly antiviral IFN α subtypes, suggesting a sub-optimal antiviral response (Harper et al. 2015). Another subset of DCs known as myeloid DCs (mDCs) may also play critical roles in early dissemination and spread. mDCs express lectin-type receptors such as DC-SIGN and Siglec-1 that can efficiently bind HIV-1 virions on the cell surface and facilitate *trans*-infection to CD4+ T cells. The formation of a “virological synapse” between DCs, CD4+ T cells, and HIV-1 virions significantly enhances the efficiency of HIV-1 replication compared to having CD4+ T cells alone. The migratory properties of mucosal mDCs could play critical roles in HIV-1 dissemination to various immune compartments. The role of DCs in HIV-1 mucosal immunity will be discussed in additional detail below.

HIV-1-Mediated GALT CD4+ T-Cell Death

A critical outcome of HIV-1 replication in the GALT is the extensive depletion of CD4+ T cells. The underlying mechanism was investigated using the human lymphoid aggregate culture (HLAC) model, which utilizes tonsil CD4 T cells (Doitsh et al. 2014). Infection of HLAC CD4+ T cells with CXCR4-tropic HIV-1 results in the predominant killing of abortively infected cells that have undergone premature reverse transcription. Incomplete HIV-1 reverse transcripts in the cytoplasm were sensed by a single-stranded DNA-binding protein known as IFI16, leading to the activation of caspase-1. This results in a highly

inflammatory form of death known as pyroptosis, characterized by the rapid release of cellular contents. A limitation of these studies with respect to modeling GALT CD4⁺ T-cell depletion was the use of CXCR4-tropic HIV-1 and tonsil CD4⁺ T cells. In the LPAC model, CCR5-tropic HIV-1 killed mucosal CD4⁺ T cells in a caspase-1-dependent manner (Steele et al. 2014). Pyroptosis may be a mechanism driving gut barrier dysfunction that leads to microbial translocation, but the identity of the pyroptosis-induced inflammatory mediators in the GALT remains unknown.

HIV-Associated Immunologic Changes in the GALT

In the GALT, both the innate and adaptive immune systems are important in maintaining immune homeostasis. During HIV-1 infection, most innate and adaptive immune cells are altered in frequency and/or function.

Adaptive Immunity

Progressive HIV-1 disease is characterized by a massive depletion of mucosal effector CD4⁺ T cells that occurs early in disease and includes decreased frequencies of IFN- γ -producing T helper cells (Th1), IL-17-producing cells (Th17), and IL-22-producing cells (Th22). Th17 and Th22 cells, subsets of T cells proposed to play roles in normal mucosal defense and homeostasis, were preferentially infected and killed in some studies, and their depletion is linked to HIV-1 pathogenesis. Mucosal CD4 T cells including Th17 cells are preserved in HIV-infected elite controllers who naturally maintain extremely low viral loads. Increased frequencies of activated and exhausted intestinal CD4 T cells have been observed in untreated acute and chronic HIV-1 infection. In the antiretroviral treatment setting, CD4 T-cell restoration is delayed and typically incomplete in the gut mucosa compared to peripheral blood. Correspondingly, reconstitution of Th17 cell numbers and function is variable and may be limited by defective gut T-cell homing. Long-term ART generally reversed Th22 depletion; however, interindividual heterogeneity was

observed and restoration was not associated with ART duration or blood CD4 T-cell count.

CD8 T-cell frequencies, including frequencies of activated CD8 T cells, are increased in rectal and colonic tissue of HIV-infected subjects and display a polyfunctional HIV-1-specific phenotype that is associated with lower HIV plasma viral load and higher blood CD4 count. However, the persistence of virus in the GI tract during the course of chronic infection suggests that effective CD8 T-cell responses may be delayed, absent, dysfunctional, or varied at different GI tract sites. With ART, frequencies of polyfunctional HIV-specific CD8 T cells diminish.

Regulatory T cells play an important role in modulating inflammation but may also suppress helpful immune responses in some settings. Despite overall decreased frequencies of intestinal CD4 T cells during untreated chronic HIV-1 infection, frequencies of colon and rectal mucosa CD4⁺ regulatory T cells (Tregs), either as a fraction of CD4 T cells or as an absolute number, were preserved in some studies (Angin et al. 2012; Shaw et al. 2011) suggesting these cells were not preferentially depleted. However, increased frequencies of Tregs as a percentage of rectal CD4 T cells and increased frequencies and absolute numbers of duodenal Tregs in untreated HIV-1 infection have also been noted. Duodenal Treg frequencies normalized with ART. These observed differences in Treg frequency may be related to the Treg quantification methods as well as tissue site. Rectal Tregs maintained their suppressive ability *in vitro* indicating that they may potentially contribute to reduced HIV-specific immune response *in vivo*. A decrease in the normal Th17/Treg ratio *in vivo* rectosigmoid biopsies of HIV-infected subjects was associated with markers of pathogenesis, including systemic CD8 T-cell activation and mucosal T-cell activation, and with plasma viral load.

Innate Immunity

Innate immune cells help to contain pathogens early in infection and may also initiate adaptive immunity. Recently identified subsets of innate lymphoid cells (ILCs) are considered to be “first responder” immune cells at mucosal sites and contain groups of cells important in maintaining

intestinal homeostasis. Conventional natural killer (NK) cells belong to group 1 ILCs and are traditionally known for their ability to kill infected cells. During chronic HIV-1 infection, gut NK cell subsets are depleted with some recovery following viral suppression with ART. Studies into group 2 and group 3 gut ILCs during HIV-1 infection remain limited. IL-22-producing ILC3s, cells important in maintaining epithelial barrier integrity, were increased during early (<7 months) HIV-1 infection and were considered to be a compensatory mechanism for the dramatic loss in IL-22-producing T cells (Th22). Preservation of ILC3 frequencies and IL-22-producing ILCs has also been observed in both untreated and in ART-treated subjects with chronic HIV infection.

Antigen-presenting cells (APCs), such as macrophages and DCs, play an important role in the elimination of pathogens and in the induction of adaptive immune responses against them. mDCs are professional APCs found throughout the intestinal tract that serve as a bridge between the innate and adaptive immune responses. In addition to their role in viral transmission (see above), gut mDCs contribute to HIV-associated mucosal pathogenesis. Chronic untreated HIV-1 infection is associated with altered colonic mDC function characterized by an activated, but dysregulated, mDC phenotype (Dillon et al. 2016). Increased mDC activation was associated with both mucosal and peripheral blood T-cell activation, thereby linking gut mDC activation to a marker of HIV-1 disease progression. Levels of indoleamine 2,3-dioxygenase 1 (IDO1), an enzyme important in intestinal homeostasis via its regulation of Th17 and Treg development, were increased in mDCs from rectosigmoid biopsies of chronically infected HIV-1-infected subjects and linked to the inversion of Th17/Treg ratio. The impact of ART on intestinal mDC function is unknown. As detailed above, pDCs are the primary producers of type I interferons and are important in antiviral immunity. Increased numbers of activated colonic pDCs in untreated HIV-1-infected subjects are associated with levels of mDC activation, suggesting that common factors might be driving activation in both DC subsets (Dillon et al. 2016). In another study, high frequencies of ileum pDCs

are associated with plasma levels of IFN α and with mucosal CD8 T-cell activation in untreated HIV-1-infected subjects and did not normalize with ART (Lehmann et al. 2014). Unlike mDCs, pDCs are rarely found in intestinal tissue under steady state conditions; thus accumulation of activated pDCs during chronic HIV-1 infection is likely due to increased migration from the blood to the colon. Frequencies of gut phagocytes including macrophages and neutrophils are also altered during HIV-1 infection. Numbers of macrophages with impaired phagocytic ability increased during chronic HIV-1 infection but normalized after initiation of ART. Neutrophil infiltration was increased during infection and persisted despite effective ART.

Mucosal $\gamma\delta$ T cells play important roles in the earliest stages of immune responses against intestinal microbes. Intraepithelial $\gamma\delta$ T cells were increased in individuals with late-stage HIV-1 infection, and increased frequencies of $\gamma\delta$ T cells were also noted in rectosigmoid biopsies of HIV-infected subjects specifically associated with expansion of V δ 1 in conjunction with the contraction of V δ 2 $\gamma\delta$ T cells. Frequencies remained elevated despite ART. Mucosal-associated invariant T (MAIT) cells are recently identified innate-like mucosal-homing antimicrobial T cells. Reduced numbers of intestinal MAIT cells have been noted in the colon of untreated and treated HIV-infected subjects in one study, while other groups observed no significant loss of MAIT cells as a percentage of total T cells in rectal mucosa of chronically HIV-infected individuals.

HIV-Associated Epithelial Barrier Damage

HIV-1 infection is also characterized by significant intestinal epithelial cell (IEC) damage, including features of apoptosis, impaired regenerative and absorptive capacity, and increased permeability. Expression of various tight junction (TJ) proteins (e.g., claudin 1, claudin 2, ZO-1) is altered in early and chronic HIV infection. Exposure to HIV-1 directly increases epithelial barrier permeability in an epithelial mediated through

HIV-induced inflammatory cytokines (i.e., $\text{TNF}\alpha$) produced by epithelial cells and by disruption of TJ proteins. Extensive collagen deposition leading to fibrosis occurs rapidly in the GALT of HIV-infected persons and limits immune reconstitution during treatment.

Microbial Translocation

HIV-1-associated immunologic and structural changes in the gut mucosa allow for the movement of microbes and microbial products from the lumen into the lamina propria, draining lymph nodes and the systemic circulation. This process, termed microbial translocation (MT), occurs throughout all stages of HIV/SIV infection, starting as early as late acute stages of infection and persisting to AIDS. Levels of bacterial products (lipopolysaccharide (LPS), bacterial DNA) in the blood correlate with levels of T-cell activation, an independent predictor of HIV-1 disease progression. Plasma LPS levels in the first years of chronic HIV-1 infection predict HIV-1 disease progression. MT decreases but does not normalize after plasma viral load suppression during ART, and its persistence has been shown to predict mortality and other comorbidities such as dementia and has been linked to chronic monocyte and T-cell activation and to poor CD4 T-cell recovery. Multiple mechanisms have been postulated to underlie persistent MT after ART, including low-level viremia or persistently infected cells in the gut, failure of gut CD4 reconstitution and resulting epithelial barrier breakdown (especially due to loss of Th17 and Th22 cells), intestinal fibrosis that limits reconstitution, reduced T-cell homing to gut, and alterations or dysbiosis in the intestinal flora.

HIV-Associated Gut Dysbiosis

Intestinal mucosal and fecal microbiomes are altered in both composition and overall diversity during untreated and treated HIV-1 infection, defined as “dysbiosis,” although the nature of these changes vary depending on the patients

studied and type of analysis. HIV-associated dysbiosis has typically been characterized by increased abundances of commensal bacteria with pathogenic potential and decreased abundances of bacteria with known immunoregulatory properties. One study suggested that some of these changes may be due to sexual practices rather than to HIV-1 infection itself (Noguera-Julian et al. 2016). These HIV-altered bacterial communities were associated with increased mucosal mDC and T-cell activation, with mucosal inflammation, with MT, and with systemic T-cell activation demonstrating a link between dysbiosis and HIV-1-associated pathogenesis (Dillon et al. 2014). Higher proportions of *Lactobacillales*, an order of bacteria known to promote a healthy microflora and common in probiotics, were associated with markers predictive of better disease outcome. The normal relationship between diet and gut microbial composition is disrupted during untreated HIV infection. ART did not appear to restore a normal gut microbiome in all cases. Metagenomic and metabolomic studies to address the metabolic activity of these HIV-altered bacterial communities are in their infancy but thus far show an enrichment of genes involved in inflammatory pathways (e.g., LPS biosynthesis, bacterial translocation) in conjunction with a reduction of genes involved in amino acid metabolism and energy processes during HIV infection. Thus, gut dysbiosis may exacerbate chronic immune activation and provide targets for novel therapies.

Gut-Targeted Therapies

Given the major disruption of intestinal mucosal homeostasis associated with untreated as well as treated HIV infection, recent efforts have been focused on therapies aimed to restore mucosal function and limit systemic inflammation by reducing intestinal inflammation, blocking microbial translocation, or modifying the gut microbiome. Unfortunately, gut-targeted therapies in chronically infected individuals have thus far met with limited success. Mesalamine (5-aminosalicylic acid), an anti-inflammatory

agent used to treat ulcerative colitis, when given to HIV-infected individuals with limited CD4 restoration despite ART, had no obvious impact on mucosal or peripheral blood T-cell activation or on systemic markers of inflammation (Somsouk et al. 2014). In a similar patient population, rifaximin, a nonabsorbable antibiotic that decreases LPS in cirrhotics, had only minimal impact on markers of T-cell activation, MT, or systemic inflammation (Tenorio et al. 2015). Sevelamer, another agent meant to block MT by binding chylomicron-LPS complexes, likewise failed to reduce markers of MT, immune activation, or inflammation in a cohort of untreated, HIV-infected individuals (Sandler et al. 2014). Approaches to modify the gut microbiome in HIV-infected individuals on ART, including the use of probiotics, prebiotics, or their combination (“synbiotics”), have had better success, variably resulting in improvements in CD4 counts and decreases in some markers of microbial translocation, immune activation, inflammation, and coagulation. Larger controlled studies of this type are underway. As the underlying mechanisms of persistent gut dysfunction during ART are unraveled, novel therapeutics to target different pathways can be rationally developed.

Conclusion

HIV-1 pathogenesis in the gut, characterized by severe damage to the mucosal immune system and gut epithelial barrier, local inflammation, dysbiosis and microbial translocation, plays a significant role in driving generalized chronic immune activation and HIV-1 disease progression. Novel therapies to restore intestinal homeostasis in HIV-infected individuals are needed in order to reduce chronic inflammation and its adverse clinical consequences.

Definition

► **Preexposure prophylaxis (PrEP)** is any medical or public health procedure used before exposure to the disease-causing agent; its purpose is to prevent rather than treat or cure a disease. The use of ► **antiretroviral** agents as PrEP is an experimental approach to HIV prevention that has recently been shown to successfully prevent the sexual transmission of HIV in several ► **clinical trials**. The challenge now is to determine how to translate these promising findings into a public health impact. Making the leap from clinical trials to real-world implementation of PrEP for HIV prevention presents a particular challenge because it requires multiple biomedical, behavioral, and social interventions in combination to maximize their synergy as appropriate for each unique epidemic setting. In real-world settings, particular effort will be needed to ensure high adherence, which has been shown to be challenging even in controlled clinical trial settings. Despite the numerous challenges in implementing preexposure prophylaxis, it has, in conjunction with antiretroviral treatment for prevention, created newfound optimism in HIV prevention.

Recent Additions to the HIV Prevention Toolkit: Overview of the Evidence for the Effectiveness of Biomedical HIV Prevention Technologies

Since 2010 there have been five randomized trials that have provided compelling evidence that ► **antiretrovirals** (ARVs) can prevent sexual transmission of HIV. The first in a series of trials showing that ARVs can reduce HIV acquisition was the CAPRISA 004 tenofovir gel trial. This trial, conducted among 889 rural and urban South African women, showed that tenofovir gel used before and after sex reduced acquisition of HIV infection in women by 39% (95% confidence interval (CI): 6;60) overall, thereby providing the proof-of-concept that ARVs can prevent sexual transmission of HIV (Abdool Karim et al. 2010). Soon thereafter, the results of the iPREX trial were announced, which showed that the daily oral tenofovir disoproxil fumarate (TDF) and emtricitabine (FTC) combination (Truvada) reduced HIV incidence by 44% (95% CI 15;63) among 2,499 men or transgender women who have sex with men (Grant et al. 2010).

Further evidence for the effectiveness of daily oral preexposure prophylaxis (PrEP) in heterosexual men and women comes from results of the Partners PrEP trial (Baeten et al. 2012) and the Botswana TDF2 trial (Thigpen et al. 2012). The Partners PrEP trial, which included 4,758 HIV-discordant couples from Kenya and Uganda, showed that daily oral TDF and TDF/FTC reduced HIV incidence by 67% (95% CI 44; 81) and 75% (95% CI 55; 87), respectively, while the Botswana TDF2 trial, conducted among 1,200 heterosexual men and women from the general population, found that daily oral TDF-FTC reduced HIV incidence by 62% (95% CI 22;83).

The use of ARVs for treatment of HIV-infected patients (note: this is ARVs as treatment and not as PrEP) has also recently been shown in a randomized clinical trial to prevent onward transmission of HIV to their uninfected partners (Treatment as Prevention – TasP). The HPTN 052 trial, conducted among 1,763 ► **HIV-discordant couples** from nine countries, showed that HIV transmission was reduced by 96% (95% CI, 73;99.5)

when ART was initiated in patients with CD4 counts between 350 and 550 cells/mm³ (Cohen et al. 2011).

This series of scientific breakthroughs in HIV prevention, combined with the recent approval of the first antiretroviral drug (Truvada) as PrEP for reducing the risk of sexually acquired HIV infection by the US Food and Drug Administration (FDA), has made the use of antiretroviral drugs, as part of a comprehensive HIV prevention package, a reality and has created newfound hope that the epidemic can be stopped. This unprecedented opportunity to alter the course of this disease will depend on the extent to which regulators, health service providers, funders, and researchers are able to translate this new evidence into effective large-scale treatment and ARV prophylaxis programs.

Potential Impact of Implementing ARVs as PrEP for HIV Prevention

The provision of PrEP to avert new HIV infections needs to be weighed against the potential costs of providing lifelong antiretrovirals for individuals who may become infected with HIV. Several mathematical models have illustrated the potential impact of ► [oral and topical PrEP](#) on the epidemic trajectory. Up to 3.2 million new HIV infections could be averted in southern sub-Saharan Africa over 10 years by targeting PrEP (having 90% effectiveness) to those at highest behavioral risk (Abbas et al. 2007). Similarly, mathematical modeling has shown that in South Africa alone, over the next two decades, tenofovir gel could avert 1.3 million new HIV infections and over 800,000 deaths (Williams et al. 2011). Mathematical models have also shown that oral and topical PrEP is cost-effective.

Challenges in the Implementation of PrEP

Despite the potential impact of tenofovir or Truvada as PrEP, only the US FDA has officially approved Truvada as an HIV prevention option,

and guidelines for its use in ► [men who have sex with men](#) and in heterosexuals have been developed by the Centers for Disease Control and Prevention. Since Truvada has not been approved by medicine regulators in any other country, country-specific individual patient guidelines and programmatic public health guidelines on implementation of PrEP have not been developed.

Besides the regulatory hurdles and lack of country-specific guidelines, several other challenges could impact on the rapid implementation of PrEP. The concerns about PrEP implementation listed below are not always warranted criticisms but include the following.

The Challenges of Adherence

Adherence is a major challenge for PrEP and long-term, high adherence is essential for its success. Although the CAPRISA 004, Partners PrEP, and TDF2 studies (described in section “[Recent Additions to the HIV Prevention Toolkit](#)” above) have shown that antiretrovirals can be taken with high adherence, two other studies, the FEM-PrEP and the VOICE trials, which were conducted exclusively among women, were not able to demonstrate a protective effect against HIV due to suboptimal adherence. There is a strong correlation between effectiveness and adherence.

Given that adherence can be challenging, even in a clinical trial setting, high levels of adherence may be difficult to achieve in “real-world” settings where PrEP may be implemented in underdeveloped public health-care facilities without adequate attention to adherence support. Not only will poor adherence contribute to suboptimal protection, but it may also impact on drug resistance development.

Therefore, the integration of behavioral interventions into any PrEP implementation program will be essential, and the close links between adherence and effectiveness will need to be emphasized to all potential PrEP users to ensure the highest possible adherence in the real world.

It is worth noting that drug adherence was also one of the key concerns raised when ART first became available as treatment. Concern about poor adherence was actually used as an argument against the implementation of these life-saving

drugs in Africa. Experiences from implementing ► [ART treatment](#) has shown that high levels of adherence are achievable in a real-world setting, even in developing countries. Although high adherence to treatment of HIV-positive people is encouraging, this may not be readily applicable to adherence in healthy asymptomatic people. On the other hand, adherence may not turn out to be an issue as the product's effectiveness may serve as strong motivation for adherence. Regardless, adherence is likely to be a challenge that will require a concerted effort to overcome, and PrEP programs will need to include practical and proven adherence support programs.

PrEP May Undermine Future AIDS Treatment by Causing Drug Resistance

The risk of drug resistance from PrEP is markedly different from that observed when, for example, nevirapine is given to HIV-positive pregnant women, as those taking PrEP generally do not have circulating virus which can become drug resistant. However, the possibility of resistance is present in instances where PrEP is taken for several weeks inadvertently by those with unidentified HIV infection.

A model based on the South African epidemic has shown that after 10 years of ART and PrEP rollout, the number of new infections would have decreased by 38% and the drug resistance prevalence would have increased to 11.4%. This compares with levels of between 10% and 17% observed in high-income countries. Importantly, most of the resistance is predicted to be a consequence of ART rather than from PrEP (Abbas et al. 2011). The main issue regarding resistance, however, is whether the use of PrEP will compromise an individual's future ARV treatment options when they may require ART. At present, there are no data to answer this question.

A separate concern about resistance is the use of the same drugs (e.g., tenofovir) in therapy and prevention. Therapy failure is associated with the development of resistance and thereby the spread of resistant viruses which in turn may compromise the efficacy of the same drugs (or occasionally, the same class of drugs) used for prophylaxis.

Currently there are over 30 licensed drugs to treat HIV, including several cost-effective non-tenofovir containing first-line regimens. Some consideration about setting aside a class (or classes) of ARVs for use in prevention only is warranted.

PrEP Users May Reduce Their Use of Higher-Efficacy HIV Prevention Strategies Like Condoms

The current ► [oral and topical PrEP](#) strategies are only partially effective, ranging from 39% to 73%. Risk compensation (also referred to as behavioral disinhibition) is the selection of lower-efficacy interventions when higher-efficacy interventions are available and is a potential concern when implementing any new suboptimal HIV prevention strategy and is not specific to PrEP. Risk compensation could potentially undermine and even reverse the beneficial effects of PrEP, as shown by mathematical models on HIV epidemics in Botswana, Kenya, and southern India (Vissers et al. 2008). While a low-efficacy intervention may be reversed by risk compensation, current evidence from ► [medical male circumcision](#) implementation has found this concern to be baseless. An assessment of the real-world effect of the rollout of medical male circumcision in a community in South Africa has shown no evidence of risk compensation after 3 years (Auvert et al. 2011). A more important consideration is that some of the PrEP strategies specifically empower women, who have no other alternative HIV protection strategies. Even a low-efficacy product would be critically important to large numbers of young women in South Africa who are unable to ensure their partner's fidelity or condom use. Indeed, PrEP is most appropriate for the target populations where condom use is low or nonexistent.

Antiretrovirals Should Be Prioritized for AIDS Treatment

Some have argued that it would be unethical to divert ARVs that would have been used for treatment for prevention (Macklin et al. 2012), especially since only 54% of those in need of ART

were receiving it in 2011 (World Health Organization 2012). While it is a legitimate concern that eligible HIV-positive patients should be prioritized for ART for their own health and to save their lives, it is spurious to trade off treatment and prevention as if these drugs are being taken away from sick and dying patients to be given to healthy people. Treatment and prevention strategies are a continuum in their use of ARVs – both are needed in conjunction with each other to ensure ART provision is sustainable in the long term and to realize the quest to end the HIV epidemic.

One of the main reasons why so many people who are in need of treatment have not yet accessed is because many do not know their HIV status. Based on ten recent national population-based surveys in sub-Saharan Africa, less than 40% of people living with HIV know their HIV status (WHO et al. 2010). According to the 2008 South African National HIV survey, 74% of those most at risk of acquiring HIV infection were unaware of their HIV status. If self-denial, a common reason for not testing, is not overcome, it will severely limit the potential impact of these new HIV prevention approaches. Initiation of PrEP will require an assessment of HIV status and could therefore be used as an opportunity for not only scaling up PrEP to HIV-uninfected at-risk individuals but also for identifying those who need ART for treatment.

Is It Safe to Give ARV Drugs to Healthy Asymptomatic People?

Tenofovir has an excellent safety profile and low rates of adverse effects. However, tenofovir may reduce bone density and exacerbate existing renal impairment and has been associated with hepatic flares in chronic hepatitis B virus-infected individuals when the treatment is stopped (Nuesch et al. 2008). Emtricitabine has a similar safety profile as tenofovir, and adverse events occurring in clinical trials were generally of mild or moderate severity. While mild side effects are readily tolerated when medication is taken for therapeutic reasons, the same is not necessarily true when medication is taken by healthy asymptomatic individuals where even mild side effects may

compromise adherence. Ongoing drug safety surveillance will need to be a component of plans for large-scale rollout of ARVs for PrEP. Hepatitis B testing and vaccinations for susceptible individuals at high risk may also need to be considered.

Who Would Benefit Most and Criteria for Initiating and Terminating PrEP

When resources are scarce, it is necessary to rationalize and prioritize certain high-risk groups for access to interventions over others. Determining who would benefit most will vary from country to country, and while some groups, like MSMs and injection drug users (IDUs), are easily identifiable, identifying who should be prioritized in generalized epidemics is more complex. Nevertheless, before PrEP can be initiated, it will be important to establish the HIV status of the individuals, and ongoing HIV testing would be an important component of any PrEP rollout program.

The Efficacy: Effectiveness Gap – Implications for Implementation Programs and the Implementation Science Agenda

At present, there are no data available on the extent to which the outcomes achieved in the PrEP trials described earlier (section “[Recent Additions to the HIV Prevention Toolkit](#)”) can be translated into real-world effectiveness. This leap from trials to implementation, generally referred to as the efficacy-effectiveness gap, can be substantial, as seen in implementation of ► [prevention of mother-to-child transmission](#) (PMTCT) programs. For example, a PMTCT program in Cote d’Ivoire showed that 40% of HIV-positive pregnant women did not benefit from zidovudine to reduce mother-to-child transmission as only 60% returned to the clinic for their HIV test results.

Some of the biggest contributors to the efficacy-effectiveness gap anticipated in the PrEP field will be willingness to know and monitor HIV status, suboptimal adherence levels, the extent to which people continue with the other proven prevention interventions (behavior disinhibition), and extent to which the existing public

sector health services can facilitate uptake and maintain clients in long-term follow-up. The extent to which health services in countries most affected are sufficiently well managed to absorb the implementation of antiretrovirals for prevention, in a manner that provides high uptake, adherence, and follow-up, will determine its success or failure. One approach to maximize the chance of success is to integrate PrEP as a component of existing comprehensive HIV prevention programs and services.

The Cost of Implementing PrEP

The implementation of PrEP also faces substantial financial challenges. Besides the drug costs, the programmatic and laboratory monitoring costs, including HIV testing, hepatitis B virus testing, and renal function assessment prior to tenofovir-containing PrEP initiation and then at regular intervals, of yet unknown duration, are likely to be substantial. Unfortunately, HIV prevention programs in regions with the highest HIV burden are already substantially underfunded, and many highly effective prevention options such as condoms are not being used at the scale and intensity needed. A recent analysis shows that the per capita spending on health in high-HIV burden countries like Kenya and Uganda is \$17 and \$16, respectively, with 60.7% and 50.2% of the health expenditure being dedicated toward HIV (Amico et al. 2010). The efficiency of health spending will need to be dramatically improved in these countries if PrEP is to be successfully implemented.

While funds for PrEP may not be readily available at this point, it would be shortsighted to consider this in isolation. For PrEP, the long-term consequences of not implementing PrEP need to be considered, especially in women who may have no other effective options. While the unmet need to provide antiretroviral treatment to all those in need is large, the opportunity to prevent new HIV infections cannot be passed over. Additional funding resources will need to be raised to implement PrEP as part of combination HIV prevention programs to avoid an unsustainable future with ever-increasing numbers of people requiring lifelong antiretroviral therapy.

Consequences of Not Implementing PrEP for HIV Prevention

The challenges of implementing PrEP should not detract from the potential importance of these interventions. The realization of PrEP implementation as part of an overall prevention plan is essential. The emphasis should be both on treating patients who require the ARVs for their own needs and also for those who need it for prevention. As was the case in MTCT, most of the concerns about scale-up can only be addressed in scale-up programs and not in relatively small phase I and II trials.

The regulatory approval of Truvada for PrEP by the FDA provides an opportunity to undertake scale-up programs, but critically, these programs can be used as an opportunity to generate the evidence on how best to address the concerns and shortcomings of PrEP.

Initially, implementation programs could focus on providing PrEP to individuals at highest risk, e.g., MSM and young women in Africa and progressively scale-up PrEP as part of a comprehensive HIV prevention package. To address the issue of the partial efficacy of PrEP, the impact of PrEP implementation should be monitored. Monitoring should include, at minimum, an assessment of HIV incidence rates, PrEP uptake levels, adherence levels, and the impact of PrEP uptake on condom use. Given the importance of adherence, programmatic implementation needs to carefully assess the factors impacting on adherence. In particular, the gender power imbalances and impact on power relations in acquiring HIV need special attention. Resistance will also need to be closely monitored, both from use of Truvada as part of treatment and prevention. Long-term safety will need to be monitored, with special attention to kidney, bone mineral, and hepatitis B-related safety concerns. Implementation of PrEP will address questions about who to prioritize, when to initiate, and when to terminate by monitoring who benefits maximally and the period of highest risk that benefits most from PrEP.

Other ► [clinical trial](#) research should also continue in parallel, with some consideration being given to the assessment of different dosing strategies (daily vs. intermittent) as well as a range of

formulations. Studies on alternative delivery mechanisms for PrEP such as gels and rings should also be pursued simultaneously.

Conclusion

PrEP has created newfound optimism in HIV prevention. ARVs increase options for HIV prevention, especially for specific high-risk populations such as young women in Africa. Despite the inherent challenges that lie ahead, implementation of ARVs for prevention is imperative and will be part of the solution to realizing the goal of finally turning the tide on the HIV epidemic.

Definition

Live, attenuated viral vaccines (LAVs) contain weakened forms of pathogenic microorganisms. Historically, LAVs have been the most effective interventions against viral infections. These vaccines produce a very mild version of natural infection, and they elicit immune responses that are often similar to those found in people recovering from pathogenic viral infections including strong cellular and antibody responses and long-lived immunity. Although safety concerns preclude the use of live-attenuated human immunodeficiency virus (HIV) in humans, LAVs have provided the most reliable protection from virus challenge in preclinical studies of AIDS vaccines. Thus, studying the protective mechanisms of attenuated primate lentiviruses in nonhuman primate (NHP)

Introduction

LAVs represent the first successful method of vaccination. In the eighteenth century, the British doctor Edward Jenner used cowpox virus, which produced mild disease in humans, to vaccinate against smallpox. This vaccination strategy was based on the observation that milkmaids who were occupationally infected with cowpox rarely got smallpox. Later, cowpox-based small pox vaccines were replaced by vaccinia virus-based small pox vaccines. Vaccinia virus causes minimal or mild disease in humans but elicits strong immune responses that cross-protect against smallpox. Using the vaccinia virus-based vaccine, smallpox was successfully eradicated in the late 1970s. The first LAV produced in the laboratory dates from 1880, when Pasteur and colleagues produced an attenuated avian cholera bacillus vaccine. Subsequently, Pasteur employed attenuation of other pathogens such as anthrax and rabies to produce vaccines for animals and humans.

Based on these seminal studies, many successful vaccines have been developed using attenuated bacteria or viruses. LAVs have been administered to millions of people worldwide with minimal adverse effects; LAVs have eliminated smallpox from the world and polio from the Western hemisphere. LAVs are currently used to prevent many human diseases including influenza, measles, mumps, rubella, chickenpox, yellow fever, tuberculosis, and typhoid fever; LAVs have dramatically reduced the incidence of these diseases in geographic regions that achieve high levels of vaccination in their communities.

Despite the advantages of LAVs, there are safety concerns that include reversion of the vaccine strain to wild-type virulence. For example,

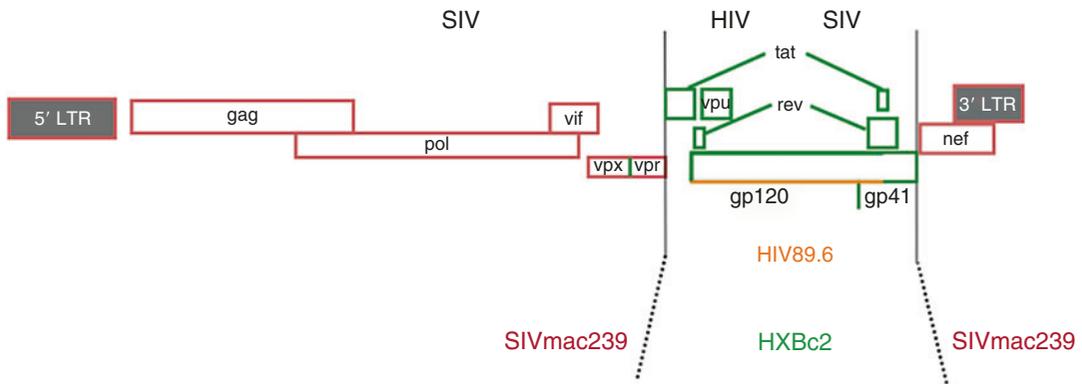

poliovirus revertants in the Sabin polio vaccine have caused local epidemics of polio. For this reason, LAVs are not used for infectious diseases that are uniformly fatal. Attenuated viruses used as vaccines have been derived from naturally arising nonpathogenic viral strains or by serial passage of a pathogenic virus through cells from an aberrant host. Current approaches to the development of attenuated viruses for new vaccines introduce specific mutations into the viral genome, resulting in attenuated viruses with molecular lesions (e.g., gene deletions, mutations in several genes) that will make the next-generation LAVs even safer than those currently in use. Although LAVs are relatively cheap and simple to produce, attenuated vaccines require refrigerated storage, an issue that makes them less useful in developing countries. Finally, individuals with impaired immunity cannot safely receive some LAVs due to the increased pathogenic potential of even attenuated virus strains in these individuals.

Live-Attenuated HIV Vaccines

While most licensed vaccines in use today are LAVs, safety concerns have limited development of live, attenuated HIV vaccines because the vaccine virus could revert to virulence or elicit autoimmune or malignant disease. However, experimentation with the live-attenuated AIDS vaccines has been done using simian immunodeficiency virus (SIV) and chimeric simian-human immunodeficiency virus (SHIV) infections in macaques (► [SIVmac Infection of Macaques, Immunopathogenesis of](#)). A large number of labs using a variety of attenuated SIV and SHIV vaccine strains over the course of more than 20 years have demonstrated that LAVs protect NHP from SIV challenge. Different strategies have been employed to produce attenuated AIDS viruses for immunization. Deletion of the *nef* gene from SIV results in a virus that grows in cell culture and replicates in monkeys but is largely controlled by immune responses and rarely causes AIDS. When animals infected with this attenuated virus were challenged with virulent SIV, they were protected

from the otherwise lethal infection (Daniel et al. 1992). In fact, immunization with SIV239 Δ *nef* or SIV239 Δ 3 has prevented infection in some experiments, while in others, it has led to a substantial reduction in plasma viral load during primary viremia and complete control of viral replication after months to years of infection (Wyand et al. 1996). LAVs are effective against mucosal and systemic routes of challenge, including intravenous, rectal, and vaginal challenge routes. The SIV Δ *nef* vaccine virus establishes a life-long infection with persistent low-level replication. In fact, SIV Δ *nef* can cause AIDS, especially when administered orally to infant monkeys (Baba et al. 1995) because persistent replication of the SIV 239 Δ *nef* vaccine virus generates variants that can replicate more efficiently than the original vaccine strain. Addition of deletions or mutations to the virus results in further attenuation but with a loss of vaccine efficacy (Girard et al. 2006). Indeed, NHP studies have shown that efficacy of AIDS LAVs inversely correlates with the level of attenuation of the virus used as the vaccine (Lohman et al. 1994; Wyand et al. 1996). LAVs that replicate only for a single cycle are not as immunogenic or protective and do not persist as do less attenuated LAVs (Alpert et al. 2010). These results highlight the challenge of making a safe and effective attenuated AIDS vaccine, and they also demonstrate that exposure to persistent antigen that occurs with effective AIDS LAVs is needed to generate reliable protection from challenge.

A human cohort that is infected with a naturally attenuated HIV mutant has provided extremely valuable information regarding the dangers of an LAV approach to AIDS vaccines (Zaunders et al. 2011). The Sydney Blood Bank Cohort (SBBC) is a group of people that were infected with an attenuated, *nef*, and LTR-deleted HIV-1 mutant through blood transfusion. These patients had particularly low levels of HIV-1 RNA and DNA in peripheral blood and survived without symptoms for more than 15 years. However, in three of five patients, there was ongoing low-level replication that allowed viral evolution. Thus, although *nef*-deleted

HIV-1 Prevention Using Live-Attenuated Vaccines, Fig. 1 SHIV 89.6 contains functional HIV-1 *vpv*, *tat*, *rev*, and *env* genes engineered to replace their SIV counterparts within the SIVmac239 proviral DNA. The virus was constructed using the *env* gene from HIV-1 HXBc2

except for the KpnI (nucleotide 5925) to BamHI (nucleotide 8053) fragment, which encodes the ectodomain of the gp120 and gp41 envelope glycoproteins. This *env* fragment in SHIV 89.6 was derived from HIV-1 89.6 (Lu et al. 1996)

HIV-1 had been discussed as a candidate vaccine in humans due to the protective effect observed in the SIV/macaque animal model, the emergence of virulent strains in multiple people infected with a *nef*/LTR-defective HIV-1 strain reemphasizes the point that a live, attenuated HIV vaccine cannot be used safely in humans (Zaunders et al. 2011).

Other LAV approaches tested in NHP include a highly attenuated, antibody neutralization-sensitive mutant of SIV with complete deletion of the V1 and V2 regions of Env from SIVmac239 (SIV239 Δ V1-V2) (Johnson et al. 2002). Infection of NHP with this virus confers potent protection from intravenous challenge by pathogenic full-length SIVmac239 (Mansfield et al. 2008). Insertion of the HIV-1 Env and regulatory genes into an SIVmac239 backbone to produce SHIVs that replicate in NHP can be used to directly test the efficacy of HIV-1 envelope vaccines. Although these chimeric viruses are attenuated for pathogenicity, SHIVs can become pathogenic after serial passage in NHP. Attenuated SHIV viruses have been used as LAVs in NHP that are subsequently challenged with SIVmac239, a model system in which the Env is completely heterologous but the remaining viral proteins are matched (Genesca et al. 2012; Fig. 1). With this LAV vaccine/challenge system, it is possible to determine if non-envelope antigens alone can provide protection from pathogenic SIV challenge.

Mechanisms of Protection

A remarkable feature of SIV LAVs is the efficient control of SIV replication during the first few weeks after challenge in vaccinated animals that become infected. Studies using various LAVs in NHP challenged by mucosal or systemic routes have tested the roles of antiviral T cells or antibodies, innate antiviral immunity, and viral interference in LAV-mediated protection.

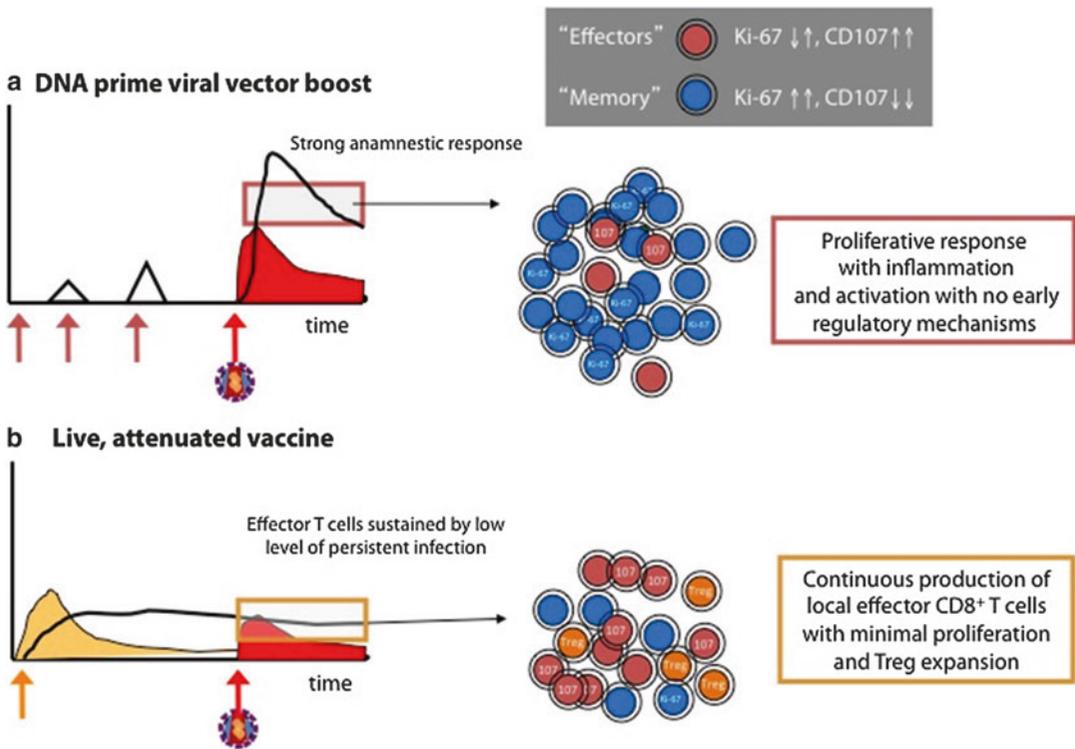

The protection generated in NHP by immunization with SIV/SHIV LAVs seems to be immune mediated, as a period of time must elapse after vaccination before protection develops. It is generally assumed that this interval provides the opportunity for protective immune responses to develop. Virus-specific CD4⁺ and CD8⁺ T cells and neutralizing Abs develop in animals vaccinated with live-attenuated SIV and people infected with attenuated HIV-1 strains (Rollman et al. 2007; ► HIV & SIV, B Cell Responses to; ► HIV & SIV, CD4⁺ T Cell Responses to; ► HIV & SIV, CD8⁺ T Cell Responses to). But the protection afforded by attenuated SIV cannot be transferred with immune plasma (Almond et al. 1997). In addition, nonimmune mechanisms have also been shown to facilitate the effectiveness of retroviral LAV vaccines (Rollman et al. 2007; Genesca et al. 2012; HIV & SIV, Innate Immune Responses to).

While the leading candidate DNA-based and viral vector-based HIV vaccines elicit robust cellular CD8⁺ responses in the peripheral blood (Koff 2006; ► [HIV & SIV, CD8⁺ T Cell Responses to](#)), vaccination with LAV SIV results in rapid development of SIV-specific effector cytotoxic T lymphocytes (CTLs), with robust degranulation and granzyme B release from tetramer-positive CD8⁺ T cells (Rollman et al. 2007). Antiviral CD8⁺ T cell responses have been consistently associated with protection in LAV studies in NHP, and the effector memory CTL elicited by LAV is present in mucosal surfaces of immunized animals (Genesca et al. 2008a). In fact, an attenuated SHIV vaccine that protects NHP from vaginal SIV challenge increases the total number of circulating effector memory CD8⁺ T cells while blunting the number of CD8⁺ T cells that are proliferating, activated, and/or undergoing apoptotic cell death. Simultaneously, terminal effector CD8⁺ T cells with multiple functions including high cytotoxic capacity are present in the vagina of these immunized animals on the day of SIV challenge (► [Mucosal Immunity](#); ► [Vaccine Induced Immune Responses, Preventing HIV-1 Transmission Through](#)). These antiviral effector CD8⁺ T cells elicited by attenuated SHIV protect from vaginal SIVmac239 challenge, as CD8⁺ T cell depletion abrogates protection in the vaccinated NHP (Genesca et al. 2008b).

In preclinical AIDS vaccine studies, many vaccine strategies have decreased challenge virus replication after immunized animals become infected, but few have blocked infection. In fact, LAVs provide superior protection from superinfection compared to all other approaches tested in NHP. This suggests that a persistently replicating vaccine virus that disseminates throughout the body and produces a low level of antigen continuously in the mucosal tissues has the potential to generate protective T cell immunity. A recent study of LAV-mediated protection against highly pathogenic intravenous SIV challenge in a large cohort of LAV-vaccinated rhesus macaques used several versions of attenuated SIV that varied in their level of attenuation, their degree of amino acid sequence homology with the wild-type

SIVmac239 challenge virus, or both (Fukazawa et al. 2012). The magnitude of SIV-specific CD4⁺ and CD8⁺ T cell responses in secondary lymphoid tissues, as well as the SIV suppression capacity of CD8⁺ memory T cells in these tissues were correlated with the degree of attenuation. Further, the degree of LAV-mediated protection against intravenous wild-type SIVmac239 challenge strongly correlated with the magnitude and nature of SIV-specific effector T cells in the lymph node but not with T cell responses in the blood or with other cellular, humoral, and innate immune parameters (Fukazawa et al. 2012).

There are many features of the CD8⁺ T cell response to persistently replicating LAVs that differ from the responses to other vaccine strategies that could explain the effectiveness of CD8⁺ T cell responses in these models. The key feature of LAVs that is responsible for these differences may be the chronic, low level of antigenic stimulation from residual vaccine replication in mucosal tissues. This antigen production generates and maintains a resident effector memory CD8⁺ T cell response at the portal of virus entry (Fig. 2; mucosal immunity; vaccine-induced immune responses, preventing HIV-1 transmission through). Further, after virus challenge, there is little expansion of the mucosal memory CD8⁺ T cells elicited by LAVs (Fig. 2a). The tissue environment after SIV challenge is actively maintained by a T-regulatory cell response (► [Regulatory T Cells](#)) that rapidly expands after SIV challenge to suppress immune activation and prevent T cell proliferation (Genesca et al. 2012; Fig. 2b; ► [Immune Activation and HIV Transmission](#)). After CD8⁺ T cell depletion of LAV-immunized animals, the highest levels of SIV replication are in the genital tract and genital lymph nodes, not in systemic lymph nodes or the GI tract as in control animals (Stone et al. 2009). These very high levels of viral replication in the genital tract suggest that, in the absence of antiviral CD8⁺ T cells, SIV replication in the genital tract is enhanced in LAV-immunized animals compared to unimmunized animals. In fact, SHIV-immunized animals have numerous SIV-specific CD4⁺ T cells in the vaginal mucosa on the day of challenge (Genesca et al. 2012), and they provide cellular

HIV-1 Prevention Using Live-Attenuated Vaccines, Fig. 2 Two patterns of CD8⁺ T cell response to vaccination against SIV. (a) Following a prime/boost vaccine with nonreplicating vectors, a strong anamnestic T cell response is observed post-challenge. (b) Following vaccination with live-attenuated SIV (or SHIV), an anamnestic response is not seen in the blood but it may be present in mucosal

tissue at the site of SIV challenge. In both panels, SIV challenge is indicated by the virion and red arrow and replication of challenge virus is denoted by red-filled curves. In panel (b), replication of attenuated vaccine virus is denoted by the yellow-filled curve (Adapted from (Genesca 2011))

targets that enhance viral replication in mucosal sites of entry in the absence of an effective immune response. Thus, the relative numbers of SIV target cells and vaccine-induced antiviral T cells in the vagina likely determine the outcome of vaginal SIV challenge in LAV-immunized animals (Genesca et al. 2012). The lack of immune activation and T cell division in response to challenge virus exposure coupled with an effector T cell response in the mucosal surface may explain the effectiveness of LAV (Genesca et al. 2012). This interpretation leads to the conclusion that the outcome of challenge results from a dynamic balance between SIV replication in abundant target cells and efficient killing of those infected target cells by antiviral CD8⁺ T cells.

Next-Generation LAVs

Advances in molecular virology and the identification of many viral genes associated with HIV virulence and immunogenicity have driven a new generation of LAVs (► [Overview: Life Cycle](#)), and this information has been used in an attempt to irrevocably attenuate HIV variants. These rationally attenuated viruses include deleterious mutations that alter replication fidelity, codon optimization, and/or susceptibility to control by microRNAs or zinc finger nucleases. While each of these approaches has recently garnered significant attention, further in vitro and animal testing is necessary before progressing to clinical trials (Lauring and Andino 2010). Finally, although in

early stages of development, self-replicating chimeric virus genomes that express lentivirus structural proteins and assemble into infectious particles that present lentivirus immunogens to the immune system in their native and functional conformation may be able to produce immune responses similar to first-generation LAVs, without the inherent safety issues (Jurgens et al. 2012).

Conclusion

The most important feature of LAVs is that they provide a high level of antigen exposure and, to some extent, they also have built-in adjuvanticity. Ideally, LAVs establish a mild infection. They can also be engineered to deliver a sufficiently high antigen load, while avoiding unwanted local inflammatory responses. These attributes are important because prolonged antigen exposure may be required for the maintenance of mucosal immune responses. A major challenge for the development of HIV LAV is the necessary balance between sufficient attenuation and vaccine immunogenicity (Lohman et al. 1994; Wyand et al. 1996). The production of a new generation of LAVs using molecular virology represents a controlled strategy for attenuation, and this approach is highly attractive for developing stable and safe LAVs.

The goal of conventional HIV vaccines is to elicit a strong and broad neutralizing antibody response that can limit infection upon HIV exposure and CD8⁺ T cell responses to clear the infection after transmission. To improve the efficacy of these vaccines against mucosally transmitted HIV infections, new strategies for directing immune responses into mucosal sites are needed. The first evidence that persistent vectors might have a superior ability to control pathogenic lentiviral infection came from analysis of live, attenuated SIV vaccines. Understanding and controlling the relationship between mucosal immune activation and protective adaptive immune responses may be a critical factor in developing an effective mucosal AIDS vaccine.

HIV-1 Rev Expression and Functions

Bastian Grewe and Klaus Überla
 Department of Molecular and Medical Virology,
 Ruhr-University Bochum, Bochum, Germany

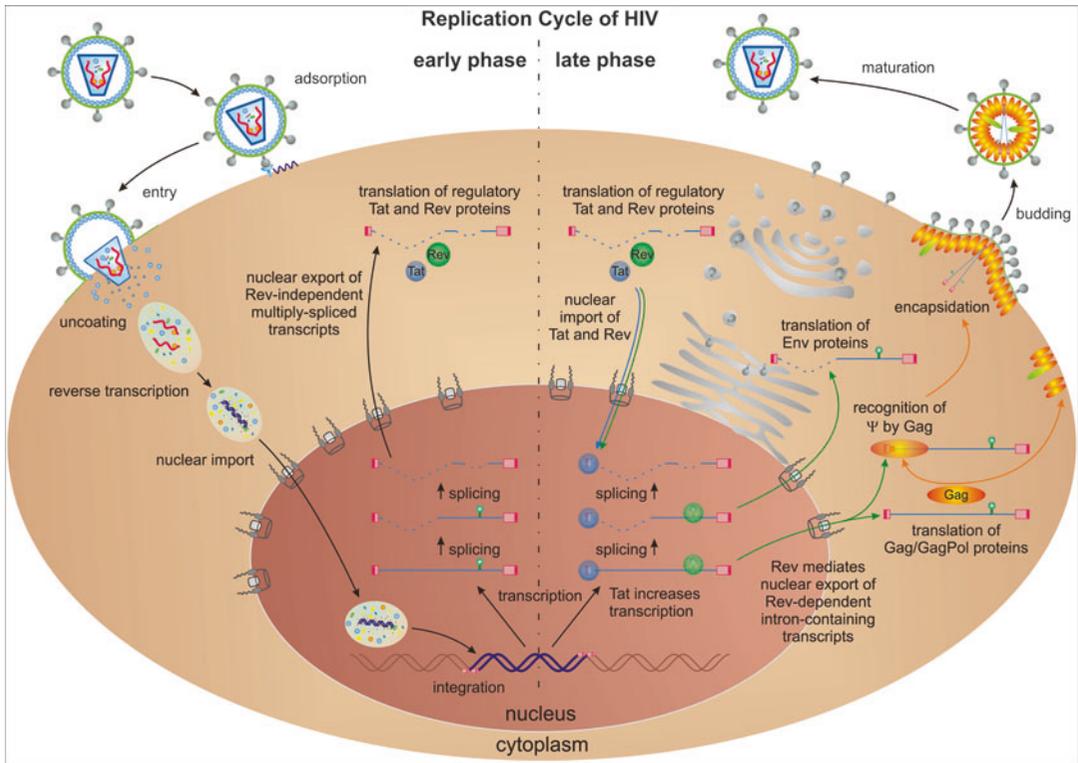

Definition

The viral Rev protein is essential for HIV replication, since it mediates nuclear export of intron-containing viral RNAs. In addition, Rev enhances translation and genomic RNA encapsidation and

prevents superinfection of target cells. The molecular mechanisms underlying these functions of Rev are discussed.

Introduction

Shortly after binding of the human immunodeficiency virus type 1 (HIV-1) to a target cell, the viral interior, containing a complex between (mostly) viral proteins and the genetic construction plan in the form of the viral, genomic RNA, is released from the viral particle into the cytoplasm. In the cytoplasm the genomic RNA is converted (reverse transcribed) to DNA by the viral reverse transcriptase protein (Fig. 1) (► [Reverse Transcriptase - Catalyzed HIV-1 DNA Synthesis](#)). The viral DNA is subsequently transported into the nucleus and integrated as provirus into the cellular DNA with the help of the viral integrase protein (Fig. 1) (► [Integration](#)). In the next step, the cellular transcription machinery generates a full-length RNA copy from the proviral DNA referred to as viral unspliced or genomic RNA/transcript. During and after transcription, some parts of the RNA, the introns, are removed in a process known as splicing (Fig. 1). Splicing of the genomic transcript is very complex and generates more than 40 different RNAs that can be grouped in (1) long (9 kilobases) unspliced, (2) intermediate (4 kilobases) spliced but intron-containing, and (3) short (2 kilobases) multiply spliced intron-less transcripts (Fig. 2). The exact nucleotide sequences of spliced RNAs of the same class, either still containing some introns or being intron-less, slightly differ because different splicing events generate RNAs that are grouped together. Multiply spliced transcripts have lost all their introns and are actively exported from the nucleus to the cytoplasm by cellular proteins. In the cytoplasm these RNAs are used as a construction plan to produce the viral proteins Tat, Nef, and Rev in a process called translation (Figs. 1 and 2) (► [“Nef/Env/Vpu/Tetherin”](#) and ► [“Tat Expression and Function”](#)). This section will focus on the function of the viral Rev (*regulator of expression of virion*) protein during the cellular multiplication of HIV-1 called HIV-1 replication cycle.

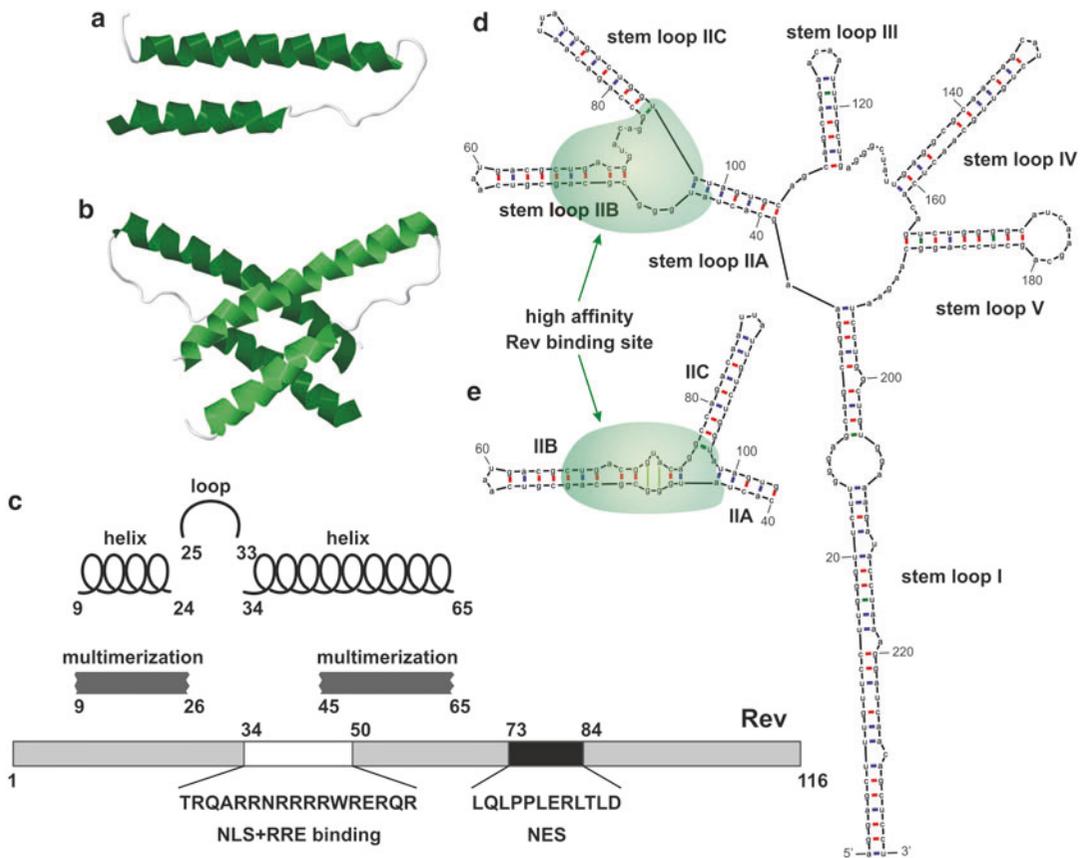

HIV-1 Rev Expression and Functions, Fig. 1 Replication cycle of the human immunodeficiency virus (*HIV*). Binding of the viral envelope protein (*Env*) on the surface of the viral particle to proteins in the plasma membrane surrounding the human cell (cytoplasm in *light brown*, nucleus in *dark brown*) allows fusion of the cellular and the viral membrane and release of viral components into the cytoplasm. After remodeling of the viral RNA-protein complex, the viral genomic RNA is converted into viral DNA in a process known as reverse transcription. The resulting DNA-protein complex is referred to as the pre-integration complex that is imported through the nuclear pores into the nucleus of the cell (*dark brown*). After integration of the viral DNA into the cellular chromosomes, the genomic information of the provirus is transcribed to RNA by the cellular transcription machinery. Complete removal of all RNA fragments called introns in a process known as splicing leads to multiply spliced RNAs that are exported to the cytoplasm where translation takes place. The resulting early proteins Tat and Rev are

imported into the nucleus. (The early protein Nef is not shown here.) In the beginning late phase of the replication cycle Tat interacts with an RNA structure called trans-activation response element (*TAR*) present in all viral transcripts leading to enhanced transcription. Rev interacts with an RNA structure called Rev-response element (*RRE*). This binding allows nuclear export of intron-containing viral RNA. Rev-mediated RNA export allows production of the viral proteins Env and Gag/GagPol. (Accessory proteins Vif, Vpr, and Vpu are also expressed in the late phase but are not shown here.) Gag targets the membrane of the cell and forms new viral particles. Furthermore, Gag binds the viral genomic RNA at an RNA structure called encapsidation signal or Psi (Ψ). This leads to the incorporation of two viral unspliced RNA molecules per viral particle. Maturation of the newly formed viral particle comprises cleavage of viral proteins and rearrangement of the interior of the particle. Mature particles are infectious and can start a new replication cycle (figure modified from Grewe and Überla 2010a)

Molecular Details of Rev and Its RNA Binding Site the Rev-Response Element (RRE)

HIV-1 Rev is a small ~18 kDa protein consisting of 116 amino acids. It can be subdivided in discrete but sometimes overlapping protein domains.

Domains essential for Rev’s activity are the nuclear localization signal (NLS), the RNA-binding domain (RBD), the multimerization domain (MD), and the nuclear export signal (NES) also called activation domain (Pollard and Malim 1998; Felber et al. 2007) (Fig. 3). Rev’s NES is enriched in the amino acid leucine. The sequence

HIV-1 Rev Expression and Functions, Fig. 3 HIV Rev and Rev-response element (*RRE*). (a and b) Structures of the HIV Rev protein monomer (a) and dimer (b) were modeled using the open-source software Jmol (<http://jmol.sourceforge.net>) with the data sets published by Dimattia et al. (a) and Daugherty et al. (b). Please note that very similar structures were obtained by two complementary approaches applied by these two working groups. The structure of amino acids 8/9–64/65 could be resolved and is shown. Remarkably, the NES is located downstream of this ordered sequence at the C-terminus and seems to be a flexible sequence following the second, longer helical structure. (c) A schematic representation of the domain structure of the whole Rev protein is shown. The amino acid sequence of the NES and the overlapping NLS- and RRE-binding domain are depicted in single letter code.

NLS, nuclear localization signal; NES, nuclear export signal; RRE, Rev-response element. (d) The RNA structure of the Rev-response element of HIV was generated using the open-source software mfold (<http://mfold.rna.albany.edu/?q=mfold/RNA-Folding-Form>). The nucleotide sequence 7,124–7,357 of GenBank entry M15654.1 (HIV-1, isolate BH10) (<http://www.ncbi.nlm.nih.gov/nucleotide/M15654.1>) was used with standard settings of mfold. The structure obtained resembles those published earlier (Pollard and Malim 1998). (e) However, the high-affinity Rev binding site (marked in green) shows a distorted structure with two non-Watson-Crick base pairs (G47-A73 and G48-G71, indicated by bright green lines) which are important for Rev binding (Pollard and Malim 1998). The corrected RNA structure is shown in (e)

Rev specifically interacts with incompletely spliced and unspliced RNAs of HIV-1 due to its binding to an elaborated RNA structure referred to as Rev-response element (RRE) containing several discrete stem loop structures (Fig. 3). The RRE is only present in these transcripts, because of its localization in an intron that is lacking in multiply

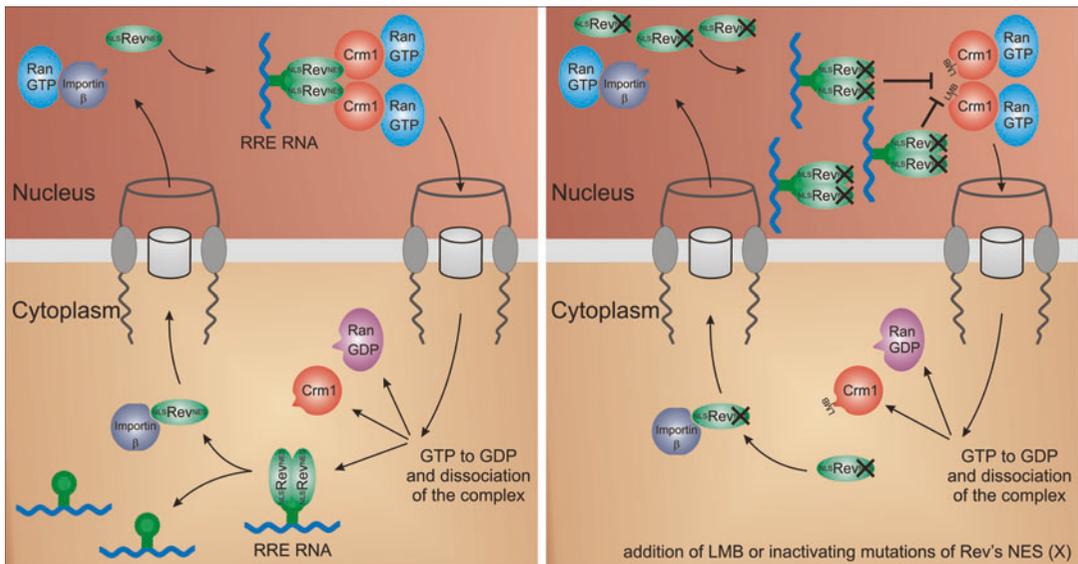

spliced RNAs (Figs. 1 and 2). An RNA stem loop structure is formed by consecutive base pairings of nucleotides on both sides of the stem connected by nucleotides of the same chain forming a loop. Rev especially associates with stem loop IIB of the RRE (Pollard and Malim 1998; Felber et al. 2007; Karn and Stoltzfus 2012) (Fig. 3).

Molecular Mechanism of Rev-Mediated Gene Expression

The nucleus is not freely accessible from the cytoplasm and vice versa, because it is surrounded by the nuclear membrane. Gateways exist in the form of nuclear pores. Regulated nuclear import and export is possible through these huge protein tunnels. However, intron-containing transcripts are not efficiently exported from the nucleus to the cytoplasm in the cell. Therefore, viral transcripts of HIV-1 that contain introns are retained in the nucleus and cannot be translated efficiently in the cytoplasm (for a detailed discussion, see “Additional Functions: Influence of Rev on Translation and Packaging” below) (Fig. 2). This poses a problem for the virus, because translation of these RNAs is

strictly necessary for the virus to complete its replication cycle. This retention mechanism is bypassed by the viral Rev protein. After translation of multiply spliced RNAs in the cytoplasm, Rev binds to the cellular protein importin-beta via its NLS. This leads to the transport of Rev through the nuclear pores into the nucleus (Pollard and Malim 1998; Karn and Stoltzfus 2012) (Fig. 4). Most Rev molecules (one Rev molecule is one Rev protein) are therefore localized in the nucleus and in dense nuclear structures called nucleoli. Recently, it was discovered that besides importin-beta also other nuclear import proteins can transport Rev such as the cellular protein transportin.

In the nucleus, most likely in the nucleoli, Rev associates with the RRE in unspliced and incompletely spliced, viral RNAs via interaction

HIV-1 Rev Expression and Functions, Fig. 4 Rev-mediated nuclear RNA export. *Left:* In the cytoplasm Rev’s NLS interacts with the cellular protein importin-beta leading to directed nuclear import. Association of the cellular protein Ran bound to GTP with importin-beta dissolves the protein complex, and free nuclear Rev is able to interact with the Rev-response element present in intron-containing viral RNAs. After oligomerization of Rev molecules at the RRE, the cellular protein Crm1 interacts with Rev’s NES and mediates nuclear export with the help of Ran-GTP. In the cytoplasm GTP is converted to GDP destroying the RNA-protein complex. Consequently, Rev

and the RRE-containing RNA are exported from the nucleus to the cytoplasm. Rev can reenter this export cycle by binding to importin-beta. *Right:* Mutation of Rev’s NES or inhibition of the association between Crm1 and Rev’s NES by the drug Leptomycin B (*LMB*) prevents Rev-mediated export of RRE-containing RNAs. Rev is imported into the nucleus by importin-beta and associates with the RRE, but a Crm1-mediated export is not possible. Consequently, in this setting Rev and the RRE-containing RNA cannot leave the nucleus. The Rev export cycle is now a nuclear dead-end road

between Rev's RNA-binding domain and the RRE stem loop IIB (Figs. 3 and 4). Subsequently, more Rev proteins assemble onto this complex because of Rev's multimerization domain. The NLS overlaps with the RNA-binding domain and with the multimerization domain (see Fig. 3). After multimerization of approximately 2–8 Rev monomers (one monomer is one single protein) on the RRE, the NLS is therefore believed to be masked by the RRE and by other Rev proteins. In contrast, the NES are accessible and associate with the cellular protein exportin-1 more often called Crm1 (Fig. 4). Analyses of Rev's structure revealed that two monomers interact in a V-shaped dimer (two Rev monomers bound to each other) (Fig. 3). The two disordered NES were proposed to project away from the lower end of this V-dimer enabling association with Crm1 (Daugherty et al. 2010; Dimattia et al. 2010; Hammarskjöld and Rekosh 2011). Since modeling of the RRE together with six single Rev proteins and six disordered NES was reminiscent of a jellyfish equipped with tentacles, this was called to be the jellyfish-like model and Crm1 is believed to bind to these "NES tentacles" (Hammarskjöld and Rekosh 2011; Karn and Stoltzfus 2012). In addition, Crm1 interacts with the cellular protein Ran that binds the small molecule GTP (guanosine triphosphate). Crm1 is the central protein of this protein-RNA complex (RRE-containing viral RNA, Rev, Crm1, and Ran-GTP) allowing the nuclear export through the nuclear pores into the cytoplasm (Fig. 4). In the cytoplasm Ran converts the small molecule GTP to GDP (guanosine diphosphate) thereby destroying the protein-RNA complex (Fig. 4). The components Rev, Crm1, and Ran are reimported into the nucleus. In contrast, the RRE-containing RNA stays in the cytoplasm where translation of unspliced RNA produces the viral proteins Gag and GagPol and translation of the incompletely spliced RNAs produces the viral proteins Env, Vif, Vpr, and Vpu (Pollard and Malim 1998; Felber et al. 2007; Karn and Stoltzfus 2012). The unspliced and spliced but still intron-containing RNAs of HIV-1 are therefore referred to as Rev-dependent transcripts. Gag, GagPol, and Env subsequently form new

viral particles able to infect new target cells (Fig. 1) (► [Virus Assembly](#)). Rev-mediated protein production is furthermore influenced by cellular protein partners interacting directly or indirectly with Rev or the viral RNA (► [“DDX3, Cofactors and RNA Export”](#)). These factors modulate the efficiency of Rev's activities, and their role in HIV-1 RNA transport was recently reviewed in detail (Groom et al. 2009; Williams et al. 2010).

The Rev-mediated nuclear export function is essential to complete the viral replication cycle. Prevention of the association between Rev and RRE (by destroying the *rev* gene and/or the RRE sequence) prevents efficient nuclear RNA export and consequently translation of Rev-dependent transcripts and production of viral proteins needed for the formation of new viral particles. Furthermore, changing the amino acid sequence of important domains like Rev's NLS and NES has the same consequences (Pollard and Malim 1998). For example, inactivating the NES or preventing association between Rev and the cellular nuclear export machinery with the drug Leptomycin B that directly binds to Crm1 sequesters Rev and the RRE-containing, Rev-dependent RNA in the nucleus. Production of Gag, GagPol, and Env, and therefore formation of new viral particles is impaired (Pollard and Malim 1998) (Figs. 2 and 4). Rev and the RRE are therefore essential components of the HIV-1 replication cycle.

Rev's hijacking of the cellular nuclear import and export vehicles in order to export intron-containing, viral RNA to the cytoplasm results in a timely regulated pattern of viral gene expression. The first viral proteins produced in an HIV-1-infected cell are Nef, Tat, and Rev encoded on multiply spliced transcripts. Proteins encoded on incompletely spliced and unspliced Rev-dependent RNAs are translated later in the replication cycle after Rev-mediated nuclear RNA export (see Fig. 2). This chronology is reinforced by the fact that a certain threshold level of the early, regulatory protein Rev is necessary before expression of the late genes from intron-containing RNAs is possible (Pollard and Malim 1998; Karn and Stoltzfus 2012).

Comparison to Other Retroviruses

HIV-1 as a lentivirus belongs to the family of the retroviruses (family of Retroviridae). All other lentiviruses (e.g., HIV-2, SIV, EIAV), some betaretroviruses (e.g., MMTV), and all deltaretroviruses (e.g., HTLV-1, HTLV-2, BLV) encode Rev-like proteins and contain an RRE-like structured RNA element. The overall mechanism of action is conserved between these viruses: Rev-like proteins are imported into the nucleus where they interact with the RRE-like RNA elements followed by a Crm1-dependent nuclear export leading to translation of Gag, (Gag)Pol, and Env. However, the molecular and mechanistic details vary. A prominent difference is the genetic localization of the RRE-like elements. Lentiviruses contain these elements in the *env* gene in the last third of the genome (see Fig. 2). Consequently, the RRE is present in incompletely spliced and unspliced transcripts. Most other retroviruses encode the RRE in the most 3' part of the genome near to or in the so-called 3' long-terminal repeat (LTR) (the "right end" of the genome, see Fig. 2). As a consequence these RRE-like elements are present in all RNA species irrespectively whether they have been spliced or not (Felber et al. 2007).

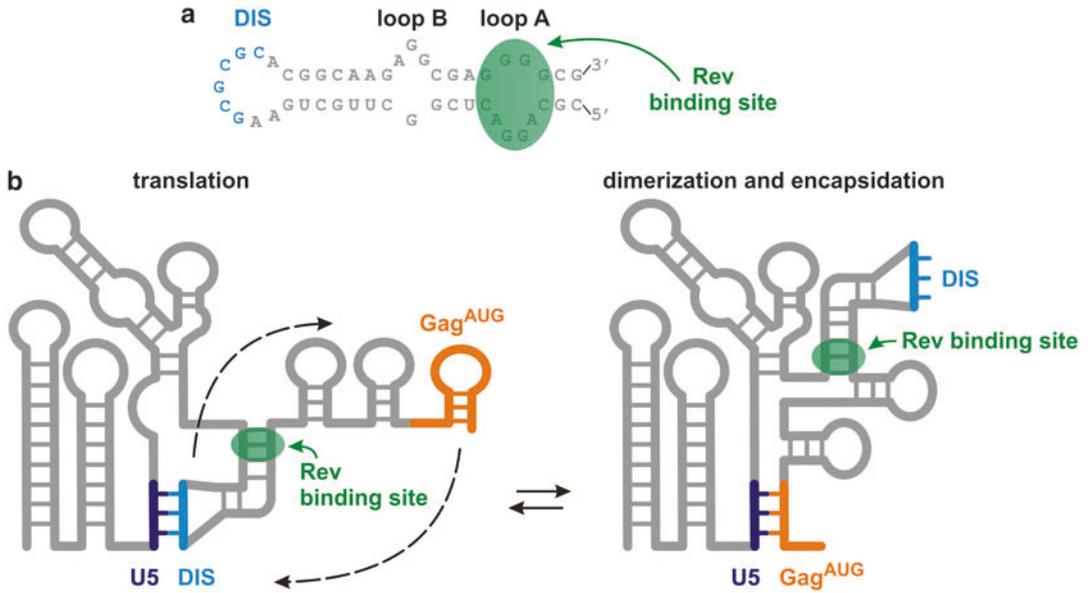

Besides the abovementioned complex retroviruses that encode regulatory (Tat and Rev for HIV) and accessory (Vif, Vpr, Vpu, and Nef for HIV) proteins, simple retroviruses only encode the viral proteins Gag, (Gag)Pol, and Env. Nuclear export of the unspliced RNAs is most often not well understood for these viruses. The best studied examples are those simple retroviruses that contain an RNA element named as constitutive transport element (CTE) like the betaretroviruses MPMV or SRV. The RNA structure of the CTE is directly bound by the cellular protein NXF1 (also called Tap). The heterodimer between the cellular proteins NXF1/NXT (Tap/p15) is known to mediate nuclear export of spliced cellular RNAs. Direct binding of these proteins to the viral unspliced RNA therefore allows export of these transcripts to the cytoplasm and subsequent translation. Similar to complex retroviruses (e.g., HIV-1), these simple retroviruses also hijack a

cellular nuclear export pathway but in this case not Crm1 but NXF1 is used. Interestingly, NXF1 is the main export pathway for cellular RNAs whereas Crm1 is the main export pathway for cellular proteins. Despite this difference the CTE can partially substitute for the Rev/RRE system. Deletion of *rev* and/or RRE can be compensated when a CTE is inserted into the 3'LTR region of the HIV-1 genome. However, these viruses show a reduced replication capacity (Felber et al. 2007).

Additional Functions: Influence of Rev on Translation and Packaging

It is well known that Rev-mediated nuclear export of intron-containing, viral RNAs allows production of the viral proteins Gag/GagPol and Env. When the HIV-1 Gag protein levels are measured, a 100–1,000-fold increased protein amount can be detected in the presence of a functional Rev/RRE nuclear export system. This strong enhancement of protein levels might not only be due to increased nuclear RNA export but could in addition also be based on a direct positive effect of Rev on translation of these RNAs in the cytoplasm. In studies analyzing the second mechanism, a small but significant effect of Rev on translation could be detected. When Rev can bind to the RNA, it increases the efficiency of translation independent of its nuclear export activity by up to 2.5-fold. However, it is not clear whether this effect is mediated by association between Rev and the RRE or between Rev and a second binding site present in the viral 5' untranslated region (5'UTR) (reviewed in Groom et al. 2009; Grewe and Überla 2010a) (see Fig. 5). The 5'UTR is the most "left" or 5' part of the RNA that is not used as template for protein production and is consequently referred to as being "untranslated."

Although a strong enhancement of protein production by Rev can be detected in all experimental settings, a discussion about the amount of intron-containing RNAs present in the cytoplasm in the absence of a functional Rev/RRE system is still ongoing. Whereas in some experiments unspliced and incompletely spliced RNA could not be detected in the cytoplasm at all, other experiments

HIV-1 Rev Expression and Functions, Fig. 5 RNA structure of the HIV genomic RNA 5'UTR. (a) The structure of the dimerization initiation site (DIS) stem loop of the HIV genomic RNA 5' untranslated region (5'UTR) adapted from Groom et al. 2009 (DOI 10.1099/vir.0.007963-0) is shown. The Rev binding site is depicted in green. The structure corresponds to nucleotide sequence 12–58 of GenBank entry M15654.1 (HIV-1, isolate BH10) (<http://www.ncbi.nlm.nih.gov/nuccore/M15654.1>). (b) Schematic representation of the dynamic

structure of the entire 5'UTR adapted from Lu et al. 2011 (DOI: 10.1126/science.1210460). The Rev binding site is depicted in green. It was suggested that depending on the structure of the 5'UTR, either the genomic RNA is translated or it dimerizes and associates with Gag for packaging. U5, nucleotide sequence in the U5 region of the LTR able to pair with the DIS loop; DIS, dimerization initiation site; Gag^{AUG}, stem loop comprising the AUG start codon of the Gag open reading frame

revealed a 3–40-fold reduction of the cytoplasmic RNA levels without Rev/RRE. Data obtained recently in carefully controlled experiments using sensitive detection methods confirmed the latter results. Therefore, Rev has a greater impact on the amount of Gag protein produced (~500-fold enhancement) than on the amount of cytoplasmic RNA (~20-fold enhancement). This discordance demonstrates that Rev's effect on protein amounts cannot solely be explained by its nuclear RNA export activity. Those RNAs that are exported from the nucleus to the cytoplasm by Rev are very efficiently translated resulting in a very strong increase in protein levels. In contrast, those transcripts exported in the absence of Rev are not efficiently translated. Almost no Gag proteins are produced from these Rev-independently exported RNAs (Fig. 2). Since Rev has only a small direct effect on translation in

the cytoplasm (see above), this implies that Rev-mediated nuclear export of Rev-dependent RNAs marks these transcripts for an efficient translation process in the cytoplasm. Correspondingly, it could be shown that Rev-dependent RNAs exported from the nucleus by Rev associate much more efficiently with the cellular translational machinery in the cytoplasm than Rev-dependent RNAs leaving the nucleus in the absence of a functional Rev/RRE system. Therefore, different export routes exist from the nucleus to the cytoplasm with distinct consequences for the exported RNA (Bolinger and Boris-Lawrie 2009; Groom et al. 2009; Grewe and Überla 2010a).

A similar observation was recently made while analyzing the viral encapsidation process in the presence and absence of Rev. Late in the replication cycle, the viral protein Gag forms viral

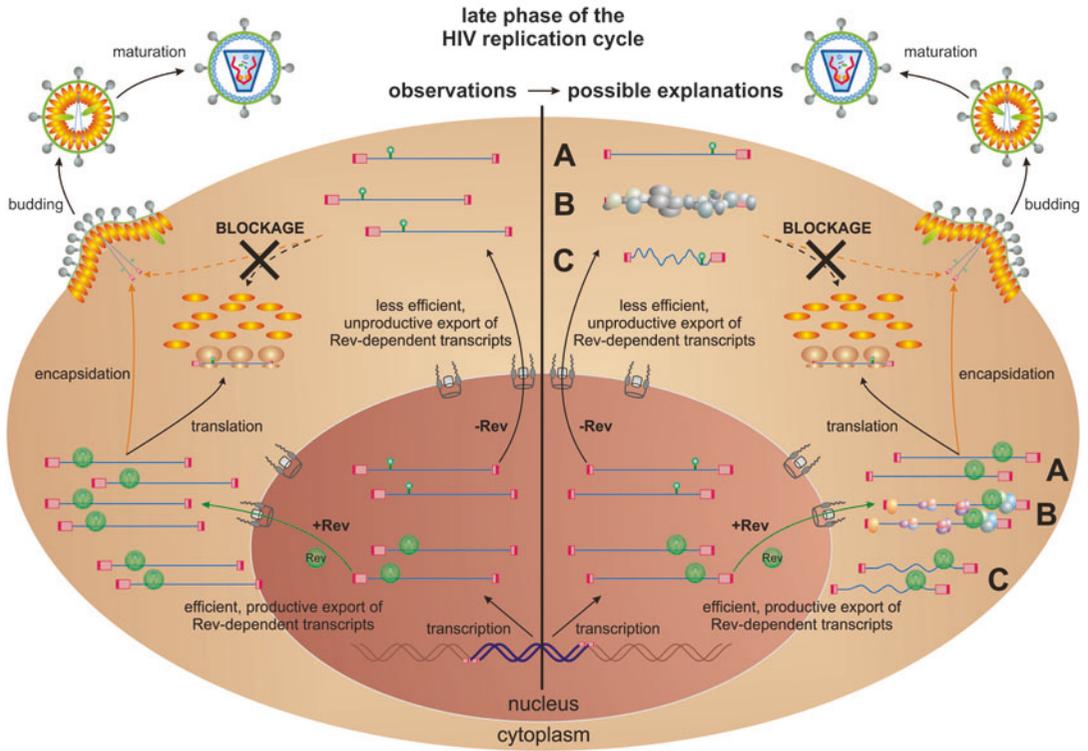

particles at the plasma membrane surrounding the infected target cell (see Fig. 1). Formation of infectious particles requires packaging or encapsidation of the viral construction plan in form of the genomic HIV-1 RNA which must be transferred to newly infected cells to start a new viral replication cycle. Incorporation of the unspliced, genomic RNA is mediated by a cytoplasmic interaction between the viral protein Gag and an RNA structure in the 5'UTR of this RNA referred to as encapsidation signal or Psi (Ψ) (see Figs. 1 and 5). After nuclear export mediated by Rev/RRE, the genomic RNA is very efficiently encapsidated into Gag particles. However, in the absence of Rev, cytoplasmic RNA could still be detected, but albeit high amounts of Gag protein were provided, the packaging efficiency of these RNAs was strongly diminished. Whereas the cytoplasmic amount of unspliced transcript decreased by only sixfold in the absence of Rev, the amount of genomic HIV-1 RNA in viral particles was reduced by more than 1,000-fold. Comparable to the situation observed for the translation efficiency, this shows that intron-containing, HIV RNA exported to the cytoplasm in the absence of Rev is blocked and can neither be utilized efficiently for translation nor encapsidation (Groom et al. 2009; Grewe and Überla 2010a) (Fig. 6).

In the absence of a functional Rev/RRE system, the following three mechanisms could prevent efficient translation and encapsidation of unspliced HIV-1 RNA in the cytoplasm: First, nuclear RNA export could result in an unproductive sub-cytoplasmic localization where translation/encapsidation is not possible (Fig. 6a). The cytoplasm seems to be composed of different sub-cytoplasmic regions comparable to districts in a huge crowded city. It seems possible that in some of these "districts," RNA usage is rather inefficient. Second, an interaction of the RNA with inhibitory cellular proteins (Fig. 6b) and, third, an inhibitory RNA structure (Fig. 6c) might also prevent cytoplasmic usage of the RNA after nuclear export. The RNA structure and inhibitory proteins would impair binding/function of the cellular translation

machinery and would block association of the genomic RNA with the viral protein Gag needed for packaging. A Rev-mediated export would prevent or resolve the negative RNA structure and binding of negative acting proteins. Furthermore, it could direct the exported unspliced RNA to a productive sub-cytoplasmic location where translation and encapsidation is possible (Groom et al. 2009; Grewe and Überla 2010a) (see Fig. 6).

Additional Functions: Nuclear RNA Export Influences the Functions of the Encoded Proteins

Nuclear export of RNA from nucleus to cytoplasm does not only influence the fate of the exported transcripts but can also have far-reaching consequences for the encoded proteins. HIV-1 is unable to replicate in mouse cells. One reason is that in these cells nuclear export of the unspliced HIV-1 RNA mediated by Rev/RRE allows production of high intracellular amounts of Gag protein but these proteins are not able to accumulate at the cellular plasma membrane. The formation of Gag particles is therefore reduced in these cells. Exchanging the Rev/RRE nuclear RNA export system by a CTE (RNA export element of some simple retroviruses – see above) allows production of intracellular Gag and additionally restores formation of Gag particles, because Gag proteins are efficiently targeted to the plasma membrane. Of note, the amino acid sequence of the encoded Gag proteins is identical in both settings. In human cells a similar finding was obtained when nuclear RNA export via Rev/RRE was compared with export mediated by the posttranscriptional regulatory element (PRE). This structured RNA element was discovered in the RNA of hepatitis B virus and promotes RNA stability and nuclear export. The PRE-mediated export allows high intracellular Gag protein levels but decreases the ability of these proteins to oligomerize (bind each other) and bud from the cell (form particles). In this case the Rev/RRE system was superior indicating

H

HIV-1 Rev Expression and Functions, Fig. 6 Nuclear genomic RNA export in the presence and absence of Rev. *Left:* Effects observed in the absence and presence of a functional Rev/RRE system. In the presence of Rev nuclear export of Rev-dependent unspliced RNA is efficient and leads to high amounts of Gag/GagPol proteins. In the absence of Rev discordance between on the one hand cytoplasmic RNA levels and on the other hand translation and encapsidation efficiencies could be observed. Whereas cytoplasmic unspliced RNA levels were reduced approximately 20-fold, translation is reduced by a factor of approximately 500. Very similar, encapsidation efficiency is reduced by a factor of approximately 1,000. The dramatic reduction in translation and encapsidation cannot solely be explained by the reduced nuclear RNA export. Therefore, in the absence of Rev, unspliced RNA is less efficiently exported from the nucleus, and its utilization in translation and encapsidation is furthermore blocked in the

cytoplasm. *Right:* Possible explanations for the prevention of cytoplasmic translation and encapsidation in the absence of a functional Rev/RRE system. Reduced cytoplasmic genomic RNA levels in the absence of Rev are consistent with a pivotal role of Rev in nuclear export of viral intron-containing RNAs. However, the reasons for cytoplasmic blockage of translation and encapsidation of RNAs exported from the nucleus without Rev are undefined. Possible explanations are (A) an unproductive sub-cytoplasmic RNA localization, (B) association with inhibitory cellular factors, and/or (C) inhibitory RNA structures. All of these aspects could prevent cytoplasmic RNA utilization. A Rev-mediated export could lead to (A) a productive sub-cytoplasmic RNA localization, (B) removal of inhibitory factors or prevention of their association with the RNA, and/or (C) RNA structures enabling translation and encapsidation (figure modified from Grewe and Überla 2010a)

that this nuclear export strategy is optimized for HIV-1 replication in human cells. Together these findings clearly show that export from the nucleus to the cytoplasm of RNA can influence characteristics and functions of the proteins produced from these transcripts (Swanson and Malim 2006; Karn and Stoltzfus 2012).

Additional Functions: Prevention of Superinfection

Recently, a new inhibitory function of Rev very early in the replication cycle was discovered. Infection of a target cell with HIV-1 leads to the production of Rev. The presence of Rev in the cell

seems to inhibit infection of the same cell with a second HIV-1 viral particle. This phenomenon called prevention of superinfection is also attributed to the viral proteins Nef and Env. Rev specifically inhibits integration of the second viral DNA into the cellular DNA by inhibiting the nuclear import of the reverse transcribed viral DNA, preventing interaction of the HIV-1 integrase protein with the cellular protein LEDGF/p75 important for integrase's activity, and inactivating the integrase protein. These mechanisms are mediated by direct association of Rev with integrase and LEDGF/p75 (Grewe and Überla 2010b).

Open Questions Regarding Nuclear Events: What Defines an RNA as Rev Dependent? How and Where Does Nuclear Binding Between Rev and RNA Exactly Occur?

In the absence of a functional Rev/RRE system, Rev-dependent HIV-1 RNAs are retained in the nucleus, inefficiently exported to the cytoplasm, and partially degraded in the nucleus and cytoplasm. Furthermore, translation and packaging of cytoplasmic RNA is inefficient in the absence of Rev/RRE. In the presence of Rev, RRE-containing RNAs are efficiently exported from the nucleus to the cytoplasm, stabilized in both compartments, translated, and packaged.

As mentioned above Rev-dependent RNAs have to contain an RRE, because Rev has to bind to the RNA for nuclear export. Furthermore, all Rev-dependent HIV-1 RNAs contain introns. An intron is defined by nucleotide sequences at both ends in combination with intron-internal sequences. Particularly the 5' end ("left" end) is known to be important for Rev dependency, because it stabilizes the RNA. In the absence of an intact 5' splice site (splice donor, SD), the transcripts are quickly degraded and Rev is unable to stimulate the production of Gag/GagPol and Env. Inactivation of the regular 5' splice site can also lead to activation of cryptic splice sites destroying the sophisticated viral splicing pattern and ultimately prevents viral replication. It is

important to note that the stabilizing effect of the 5' splice site is independent of splicing itself. However, the efficiency of the splicing process also influences the degree of Rev responsiveness. Rev-dependent RNAs show an intermediate splicing efficiency. This seems to guarantee that association between Rev and the intron-contained RRE is possible before splicing is completed and all introns (including the RRE) are removed. Too strong splicing signals therefore abolish Rev's ability to promote protein production (Felber et al. 2007; Grewe and Überla 2010a).

Rev-dependent RNAs contain an unusually high amount of the nucleotide adenosine (A) and a surprisingly low amount of the nucleotide cytosine (C) and are therefore A rich and C low. Stretches of these A rich/C low sequences were shown to confer Rev dependency on formerly Rev-independent RNAs. These sequence fragments are called instability sequences (INS) or *cis*-acting repressive sequences (CRS). They act in an orientation-dependent manner. When they are added to Rev-independent RNAs in the normal (sense) orientation, protein production from the resulting RNA becomes dependent on a functional Rev/RRE system. Adding the sequences in the reverse (antisense) orientation only induces slight Rev dependency of protein production. Therefore, it was suggested that cellular proteins associate with these A-rich/C-low stretches and induce Rev dependency. Such a sequence-specific binding event can only take place in the normal (sense) orientation. In the current model, cellular proteins binding to INS/CRS in the nucleus shortly after transcription induce nuclear retention as well as RNA instability in nucleus and cytoplasm. Furthermore, these proteins are believed to transport newly generated transcripts away from splicing hot spots to subnuclear locations where Rev can interact with the RNA allowing nuclear export before the intron-containing RNA is completely spliced. However, up to now not much is known about the INS/CRS binding factors and their mechanisms of action. Those proteins identified to bind to INS/CRS so far are involved in multiple steps of cellular gene expression. It is unclear why such proteins may induce retention and degradation of HIV RNA whereas

other RNAs also bound by these proteins are not influenced in this way. Although the INS/CRS binding proteins should introduce Rev dependency, one study dealing with the cellular proteins p54nrb and PSF demonstrated that increasing the amount of PSF in the cell efficiently degraded intron-containing HIV RNAs. Rev could not induce protein production from Rev-dependent transcripts under these conditions. On the one hand, this supports the notion that CRS/INS binding factors induce RNA instability. On the other hand, it is not easy to combine these results with the model postulating a handover of the intron-containing HIV RNAs by CRS/INS binding factors from splicing sites to Rev for subsequent nuclear export. More detailed studies about the mechanisms of CRS/INS and their sequence-specific binding proteins leading to Rev dependency are therefore needed to verify the current model (Pollard and Malim 1998; Felber et al. 2007; Bolinger and Boris-Lawrie 2009; Grewe and Überla 2010a; Karn and Stoltzfus 2012).

As stated above Rev-dependent RNAs are A rich and C low. Artificial enrichment of the nucleotides guanosine (G) and cytidine (C) in these RNAs without changing the encoded protein sequence (which is possible because of the nature of the translation process and the degenerative genetic code) generates Rev-independent RNAs that allow production of proteins in the absence of a Rev/RRE system. This process is called codon optimization. It changes the RNA sequence but the encoded amino acid sequence remains unchanged. The production of Gag/GagPol that normally relies Rev/RRE is possible without Rev-mediated nuclear RNA export after codon optimization of the RNA. This once more underlines that the sequence composition of the HIV RNA is important for Rev dependency (Felber et al. 2007; Bolinger and Boris-Lawrie 2009; Grewe and Überla 2010a).

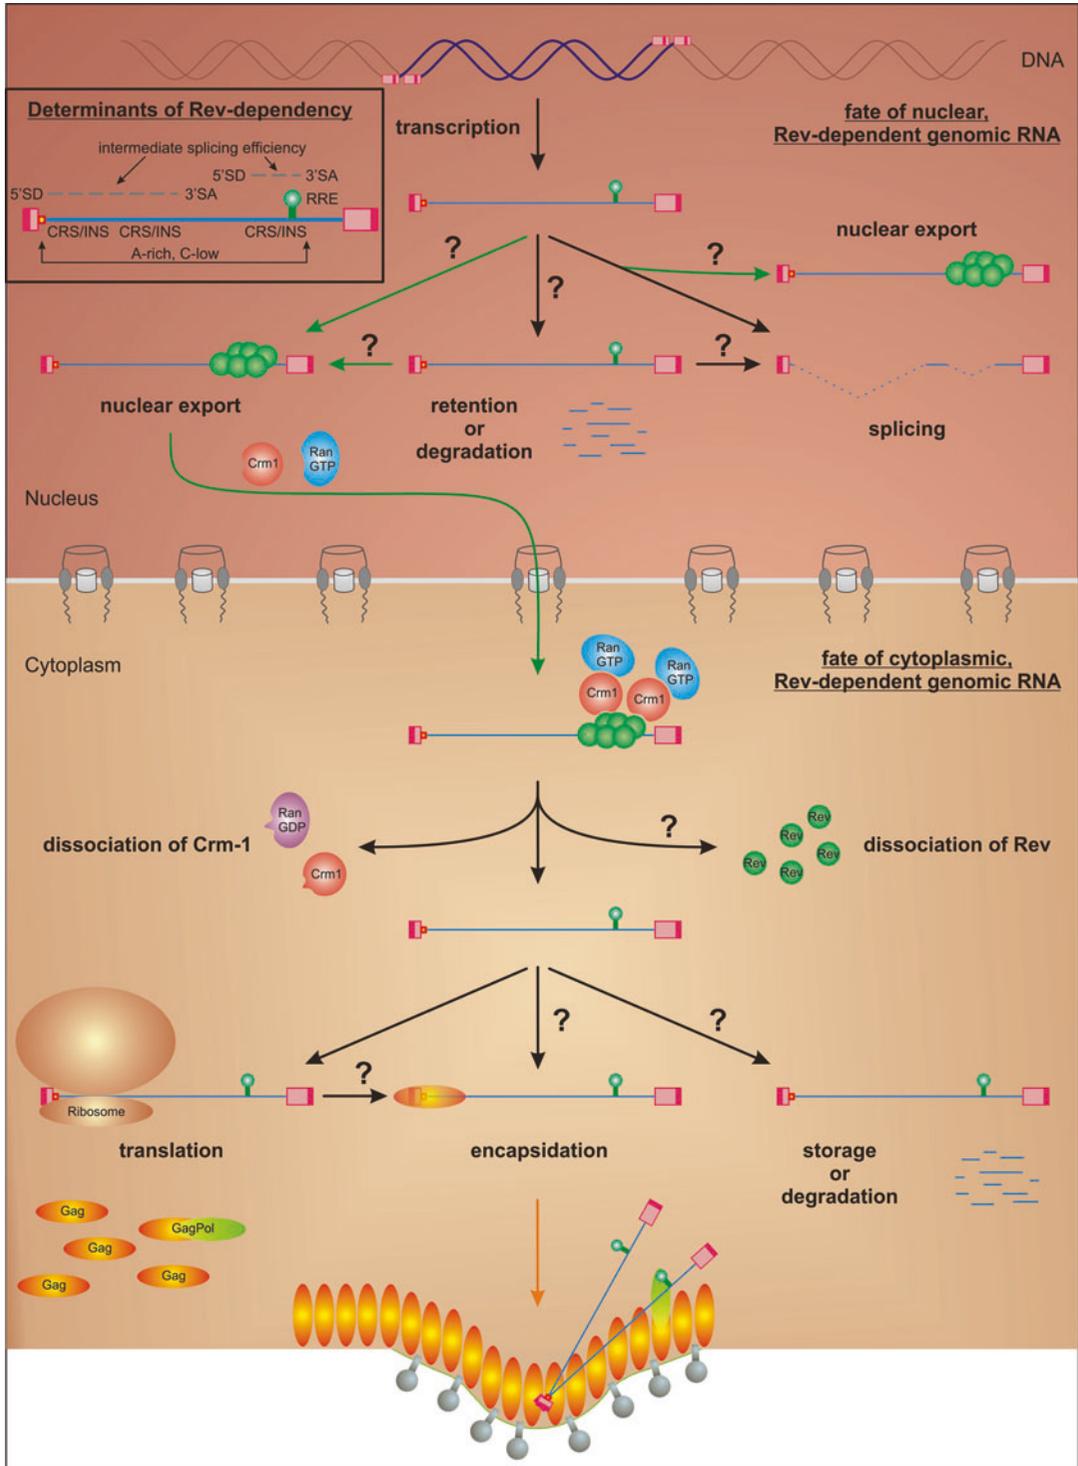

In an attempt to artificially induce Rev dependency, RNA encoding the green fluorescent protein (GFP) was changed from being GC rich to contain a high amount of A. Protein production from the resulting RNA was not possible until a 5' splice site and an RRE were added and the Rev

protein was provided in parallel. This directly proves that induction of Rev dependency is possible by increasing the A-content of an RNA. However, it is unlikely (but not impossible) that artificially increasing the amount of A in an HIV-1 unrelated RNA creates, by chance, a transcript that contains sequence-specific binding sites for cellular proteins comparable to the HIV-1 INS/CRS. These results once more challenge the model of CRS/INS-mediated Rev dependency (Felber et al. 2007; Grewe and Überla 2010a).

Intron-containing RNAs leaving the nucleus in the absence of Rev/RRE cannot be translated and encapsidated. This RNA export pathway is therefore unproductive and prevents further cytoplasmic utilization of the RNA. It was suggested that only nuclear export mediated by Rev and Crm1 is productive but exporting Rev-dependent RNAs via a CTE/Tap export route also allows translation and packaging. Direct association between RNA and Crm1 via Rev or RNA and Tap via CTE could result in a fast and therefore productive nuclear export. The nuclear mark deposited on RNA in the absence of Rev preventing cytoplasmic utilization as well as the detailed nuclear export pathway of these RNAs is not known up to today (Groom et al. 2009; Grewe and Überla 2010a).

Inhibiting the transcription process with the drug actinomycin D stops Rev-mediated nuclear RNA export implying that only freshly transcribed RNA can be exported by Rev. However, recently it was shown that actinomycin D not only stops transcription but also diminishes global Crm1-dependent nuclear protein export and should therefore reduce nucleocytoplasmic shuttling of Rev. Therefore, it is unclear whether newly synthesized or older RNA is a target for Rev-mediated export.

In summary, Rev-dependent protein production requires (1) a functional Rev/RRE system, (2) the presence of a 5' splice site, and (3) a high A-content of the RNA. In the case of an intron-containing RNA, (4) an intermediate splicing efficiency is important, too. However, not all details are known about how and where nuclear binding between Rev and RRE exactly occurs and which cellular factors are involved in this process. The

HIV-1 Rev Expression and Functions, Fig. 7 Multifaceted nuclear and cytoplasmic fate of Rev-dependent genomic HIV RNA. Inset *upper left*: The following

features seem to define RNA as Rev-dependent. Intronic transcripts need at least one splice donor (SD) site to stabilize the RNA. Furthermore, the splicing

reason for nuclear retention and RNA instability in the nucleus and cytoplasm of Rev-dependent RNAs in the absence of a Rev/RRE system is also incompletely understood. Similarly, the inhibitory mechanism preventing translation and packaging after nuclear RNA export in the absence of Rev is undefined. The identification of HIV-1 RNA-binding proteins, dynamic RNA structures, and RNA subcellular localizations is important to clarify these questions in the future (see Fig. 6).

Open Questions Regarding Cytoplasmic Events: What Exactly Happens After Rev-Mediated Export, Translation and/or Packaging?

Subsequent to Rev-mediated nuclear export, the protein-RNA complex composed of RRE-containing RNA/Rev/Crm1/Ran-GTP is dissociated in the cytoplasm. Disruption of the association between Crm1 and Ran is mediated by conversion of GTP to GDP (see Figs. 4 and 7). Dissociation of Rev and the RRE also occurs in the cytoplasm but how this process is regulated is not known. However, the NLS- and the RNA-binding domains in Rev overlap (see Fig. 3). Therefore, it is likely that binding of importin-beta to the NLS in the cytoplasm dissociates Rev from the RRE (see Fig. 4). Rev has a direct, positive but small effect on translation

independent of its nuclear RNA export activity (see above), but details on how Rev increases translational efficiency of RNA are lacking (Groom et al. 2009; Grewe and Überla 2010a).

After nuclear export the genomic, unspliced HIV-1 RNA is either translated or packaged by the Gag protein into viral particles (see Figs. 1 and 7). Translation of the genomic HIV-1 RNA is initiated in a Cap-dependent manner starting at the very 5' ("left") end of the RNA. This should destroy all RNA structures in the 5'UTR that are important for the interaction between Gag and the RNA. Therefore, this mode of translation should prevent subsequent encapsidation. On the other hand, binding of Gag to the 5'UTR of the RNA could prevent binding of the translational machinery and thus targets the RNA for encapsidation. In addition, it has been reported that translation of the genomic RNA is also possible by means of a putative IRES RNA structure in the 5'UTR. IRES-mediated translation might preserve the 5'UTR RNA structures important for packaging. Detailed information about how translation and packaging of the genomic, unspliced RNA of HIV-1 are timely and spatially regulated in the cell is lacking up to now (Fig. 7). Recently, two different, alternative RNA structures of the 5'UTR were proposed either to allow translation or packaging, but how and when these structures are generated is undefined (Fig. 5) (Balvay et al. 2007; Lever

H

←
HIV-1 Rev Expression and Functions, Fig. 7 (continued) efficiency between splice donor and splice acceptor (SA) sites has to be of intermediate strength to allow interaction between Rev and RNA before completion of splicing. Furthermore, the RRE has to be present to allow this interaction. Intron-containing HIV transcripts are A rich/C low and contain CRS/INS. Details about how RNA sequence composition introduces Rev dependency are elusive up to now, but binding of cellular factors is likely to be essential. *Top*: Fate of nuclear genomic HIV RNA. After transcription the unspliced RNA is retained in the nucleus, degraded, exported, or spliced. How retention of intron-containing HIV RNA is mediated is not entirely clear. When after transcription and where exactly in the nucleus/nucleoli Rev interacts with the RRE-containing RNA is not known. Furthermore, it is unclear if Rev binds freshly transcribed RNA or RNA that has been

retained in the nucleus before. In addition, it is not known whether partial assembly of splicing components on the RNA influences Rev-mediated export. *Bottom*: Fate of cytoplasmic genomic HIV RNA. After nuclear export, conversion of GTP to GDP dissociates Crm1 and Ran from the Rev/RNA complex. Since the NLS- and the RNA-binding domains in Rev overlap, binding of importin-beta to Rev's NLS probably leads to dissociation of the Rev oligomers from the RNA. In the cytoplasm the unspliced viral RNA is translated, encapsidated, stored, or degraded. How translation and encapsidation are temporally and spatially regulated is not entirely known. At the end of the replication cycle, new viral particles are formed that contain two viral genomic RNA molecules. The exact details how and where dimerization of two RNAs and binding of Gag occurs have to be defined further

2007; Bolinger and Boris-Lawrie 2009; Lu et al. 2011).

Open Questions Regarding Rev's Action in HIV-Infected Patients: Does Rev/RRE Modulate HIV-1 Replication in Patients?

Substitution of the Rev/RRE system by a CTE in the genome of simian immunodeficiency virus (SIV), a lentivirus closely related to HIV-1, generates a live-attenuated virus in rhesus macaques that cannot efficiently replicate in the infected animals. The virus can be detected in the monkeys but they do not develop the acquired immunodeficiency syndrome AIDS. Although the CTE allows nuclear export of intron-containing SIV RNAs, it does not confer the same replicative capability to the virus as the normal Rev/RRE system. This demonstrates that the exact nature of the nuclear RNA export system can have dramatic effects in an infected animal and perhaps also in HIV-1-infected humans (Felber et al. 2007). HIV-1 sequence changes in infected patients might alter the activity of the Rev/RRE system and might consequently modulate replication capacity, latency, and pathogenesis of the virus.

Conclusions

At the end of the 1980s and the beginning of the 1990s, the key mechanism of Rev-mediated gene expression was discovered. The cellular protein Crm1 was found to export the complex formed between intron-containing HIV-1 RNA and Rev from the nucleus to the cytoplasm allowing HIV-1 late gene expression. This discovery led to the identification of Crm1 as the main nuclear export factor for proteins in human cells. Besides the nuclear export pathway mediated by NXF1/NXT (Tap/p15), it represents one of the two known, regulated routes through the nuclear pores from the nucleus to the cytoplasm. These findings could explain how intron-containing HIV-1 RNAs leave the nucleus for cytoplasmic translation and formation of infectious particles. Rev was therefore

identified as an essential component in the HIV-1 replication cycle. Despite this detailed knowledge about the nuclear export process, a lot of details are not well understood. Most intriguingly is the fact that the exact mechanisms mediating Rev dependency are undefined up to today. The identification of specific protein factors, RNA structures, or subcellular localizations that confer Rev dependency to HIV-1 transcripts will lead to general insights into the regulation of cellular gene expression and will intensify our understanding of HIV-1 replication. Since HIV-1 is the causative agent leading to the acquired immunodeficiency syndrome (AIDS), this detailed knowledge may in future lead to the discovery of new antiviral strategies targeting the essential Rev/RRE axis of HIV-1 gene expression.

Acknowledgments We are grateful to Heiner Schaal for critically reading the manuscript and for helpful suggestions. We would like to thank Bettina Tippler, Klaus Sure, and Annika Mühlenkamp for excellent technical support. Furthermore, we wish to thank Sabine Brandt, Maik Blissenbach, and Bianca Hoffmann for helpful discussions and their experimental contributions. Our work is funded by a grant from the DFG (Ue45/11-1), and Bastian Grewe was supported by a fellowship from the DFG graduate school 1045/2.

HIV-1 Transmission Blocking Microbicides

Carolina Herrera and Robin Shattock
Section of Infectious Diseases, Division of
Medicine, Imperial College, London, UK

Definition

Current available methods to prevent HIV infection, including condoms, male circumcision, and behavioral interventions, appear insufficient to control the epidemic. This may in part reflect the limited number of options for at-risk groups. Microbicides offer an important alternative

strategy for preventing HIV sexual transmission. An effective microbicide should be a safe, acceptable, and affordable product delivered topically as a gel, capsule, tablet, film, or intravaginal ring at the genital (vaginal, penile) and/or gastrointestinal (colorectal) mucosa to prevent, or at least significantly reduce, sexual transmission of HIV and possibly other sexually transmitted infections.

Introduction

Microbicides were originally conceived as affordable, over-the-counter products, not requiring a prescription, that offered protection against a broad spectrum of sexually transmitted diseases. First-generation candidate products included surfactants to disrupt the viral membrane, acid-buffering gels to inactivate HIV by lowering mucosal pH, and long-chain polyanionic compounds to nonspecifically block viral entry into cells. However, these approaches proved disappointing, showing lack of potency (Ramjee et al. 2010) or lack of safety when surfactant-based products were used several times a day (Hillier et al. 2005). These early setbacks drove the field to explore the potential of a new generation of candidate microbicides based on potent HIV-specific antiretroviral (ARV) drugs that inhibit key steps of the viral replication cycle. Viral replication is initiated by binding of the virion to specific receptors on a target cell triggering viral and cellular membrane fusion and then entry of the viral core into the cytoplasm of the cell. The viral RNA genome is then reverse-transcribed to generate a double-stranded DNA copy of its genome (known as the provirus), which then integrates within the host chromosomal DNA in the nucleus. Transcription of the provirus DNA is then triggered by the binding of host transcription factors generating splice and full-length version of its genomic RNA. The former is translated by the cellular machinery of the host cell making de novo viral proteins. These proteins are transported toward the cellular membrane together with full-length viral RNA for assembly of new virions that bud off from the host membrane as immature viral particles.

These immature virions rapidly mature into fully infectious particles following proteolytic cleavage of the Gag-Pol polyprotein by its own protease enzyme. Current ARV-based microbicides have been selected on the basis of their specific inhibitory activity against these different stages of viral replication: specifically viral attachment and entry, reverse transcription, ► [integration](#), and viral maturation. These approaches directly draw on experience acquired through the development of highly active antiretroviral therapy (HAART) and often use the same or very similar drugs.

Inhibition of Viral Attachment, Entry, and Fusion

Infection is initiated by binding of the viral envelope spikes (Envs) that comprise trimers of two glycoproteins (gp), gp120 and gp41, to the primary cellular receptor CD4 and subsequently one of two coreceptors, CCR5 or CXCR4, on susceptible target cells. This in turn triggers a series of conformational changes in Env that allow apposition and fusion of the viral and host cell membranes. The binding of gp120 to CD4 presents an important potential target to block the process of viral binding and/or fusion with target cells (Herrera and Shattock 2013). Binding of gp120 to CD4 can be inhibited by small proteins that mimic CD4, such as M48-U1, by drugs that block the conformational change in gp120 after binding to CD4, such as BMS-378806 and BMS-599793 (also known as DS003); by anionic dendrimers that provide a charge-based inhibition of gp120-CD4 interaction, such as SPL7013 (referred to as VivGel); and by affecting the level of CD4 expression on the cell surface with either down-modulators, such as cyclotriazadisulfonamide (CADA), or with CD4 aptamer-siRNA chimeras that knockdown CD4 gene expression. Alternative approaches include the use of lectins that recognize mannose moieties in *N*-linked glycans on gp120 and prevent Env binding and conformational change required for entry, these include lectins such as cyanovirin-*N* (CV-N) and griffithsin (GRFT) ++. In addition, the recent discovery of an increasing number of highly potent

broadly neutralizing antibodies (bnAbs) that bind to HIV-1 Env has stimulated programs to develop their potential use as microbicides. Nevertheless, large-scale production for many of these molecules needs to be addressed to ensure affordability when formulated as microbicides.

A second point of intervention during viral entry/► [fusion](#) process is the binding of Env to coreceptors, CCR5 or CXCR4. Epidemiological and genetic studies have shown that >90% of sexually transmitted infections worldwide are due to viruses exclusively using the CCR5 coreceptor (known as R5-tropic HIV) and in few instances dual-tropic (R5X4) tropic isolates able to use both CCR5 and CXCR4 (Keele 2010). The predominant role of R5 virus in HIV-1 transmission has driven the development of specific inhibitors of CCR5 binding as potential microbicides. Compounds in this category included derivatives of the chemokine RANTES, PSC-RANTES, and 5P12-RANTES and small molecule CCR5 inhibitors, such as CMP167 and maraviroc (currently used in HAART). A monoclonal antibody against CCR5, PRO140, that inhibits gp120-CCR5 binding also has potential for preventing transmission. In contrast only one small molecule inhibitor of CXCR4 has been explored for potential microbicide use and could be used in combination with a CCR5 inhibitor to prevent transmission of R5X4-viruses and the small proportion of transmitted viruses that exclusively use CXCR4.

The process of viral fusion presents a third point for interrupting the process of viral entry. Binding of gp120 to a coreceptor triggers a conformational reorganization in gp41 inducing the formation of a six-helix hairpin structure, known as six-helix bundle, that brings together viral and cellular membranes into close enough proximity for membrane mixing, fusion, and subsequent pore formation. The six-helix bundle is formed by folding in an antiparallel manner of the C-terminal region (HR2) and the N-terminal domain (HR1) of each gp41 in the Env trimer. Peptide analogs to gp41 HR1 and HR2 inhibit fusion by binding to HR2 or HR1 domains of gp41, respectively, and hence block the formation of the six-helix bundle. Several peptide fusion inhibitors (FIs) that mimic the HR2 sequence

represent potential candidates for use as microbicides, these including T20 (enfuvirtide/Fuzeon), currently used in HAART, C34, C52L, T1249, and L'644. Here issues relating to stability for use in a mucosal environment, where peptides may be rapidly degraded, and their relative cost for manufacture will need to be overcome to ensure their practical use. Here a cholesterol-derivatized version of C34 that shows increased antiviral potency, longer half-life, and persistent activity in the presence of biological fluids thanks to the cholesterol tag that acts as an anchor for L'644 to the cell membrane may prove advantageous. Broadly neutralizing antibodies that target fusion intermediates of gp41, including 2F5, 4E10, and 10E6, may also have potential use as candidate microbicides especially if formulated together with gp120 bnAbs.

Targets for Inhibition During Reverse Transcription

Following release of the viral capsid into the cellular cytoplasm through fusion pores, decapsidation, and uncoating of the viral RNA, the viral reverse transcriptase (RT) enzyme forms the reverse transcription complex by binding to one of the two copies on the viral genomic RNA and drives the synthesis of the proviral double-stranded DNA. Two strategies can be used to block this step, either by substrate competition or by directly targeting the RT enzyme itself (Shattock and Rosenberg 2012). Substrate competition can be mediated by a family of compounds known as nucleoside and nucleotide RT inhibitors (NRTIs) that mimic the natural deoxy-ribonucleotide triphosphates (dNTPs) required for DNA synthesis. These compounds are nucleosides or nucleotide 5'-monophosphates that, unlike natural dNTPs, lack the 3'-hydroxyl group necessary for the formation of a phosphodiester linkage with the next incoming nucleoside in the growing DNA strand, thus acting as premature chain terminators (Mehellou and De Clercq 2010). NRTIs were the first class of drugs developed for HIV therapy. The NRTI tenofovir (9-[(R)-2-(phosphonomethoxy) propyl] adenine

monohydrate /PMPA) is also the first candidate microbicide to have shown efficacy in a clinical trial (CAPRISA 004) when formulated as a microbicide gel (1% tenofovir). This trial indicated that when 1% tenofovir gel was used in a pericoital fashion (applied before and after intercourse), HIV infection was reduced by 39% after 30 months of follow-up (Abdool Karim et al. 2010). Interestingly, after 12 months, the efficiency was higher with a reduction of 50%, and in high adherers (gel used with >80% compliance to the protocol), it was reduced by 54%. However, no protection was observed in an alternative clinical trial performed by the Microbicide Trial Network (MTN, #10) (MTN-003/VOICE), with daily dosing independent of the timing of intercourse (MTN 2011; NIAID 2011), suggesting use close to the act of intercourse may be essential for protection. Currently a second placebo-controlled trial of pericoital use (FACTS 001), due to finish in 2014, has been initiated to confirm and extend the CAPRISA 004 results (CONRAD 2011). Tenofovir gel has also been tested for safety and acceptability as a rectal microbicide (Anton et al. 2012). Additional NRTI are being considered for combination with tenofovir, the most advanced being emtricitabine (FTC), already co-formulated for oral use as Truvada and now in development as a combination gel with tenofovir (Truvada gel) to increase potential efficacy.

Non-nucleoside RT inhibitors (NNRTIs) block reverse transcription by binding directly to the enzyme and inducing conformational changes of the active site of RT. This class of compounds includes structurally diverse inhibitors such as dapivirine (TMC120), UC781, MIV-150, MIV-160, MIV-170, MC1220, and IQP-0528. Dapivirine has shown high activity in preclinical and animal studies and has, therefore, progressed in the microbicide pipeline being formulated as a gel and in an intravaginal ring (IVR). These formulations are currently being tested in clinical trials (Herrera and Shattock 2013). IQP-0528 is one of the newly discovered NNRTIs and in contrast to most NNRTIs is active not only against HIV-1 but also against HIV-2. Importantly, the NNRTIs being developed as candidate microbicides are currently not used in HAART.

Targeting Viral Integration

Once proviral DNA is synthesized in the cytoplasm, the enzyme HIV-1 integrase (IN) catalyzes the processing, transfer, and integration of the proviral DNA into the cellular DNA in the cellular nucleus. Until recently, few IN inhibitors (INIs) have been developed as candidate microbicides; these include raltegravir (MK-0518) and elvitegravir, both of them currently used in HAART; and L-870,812 (Herrera and Shattock 2013). L-870,812 has already been tested in nonhuman primates showing activity in a pilot study.

Inhibition of Viral Maturation

Following integration, viral DNA is transcribed into messenger RNA, which is then translated into HIV proteins. These proteins together with two copies of HIV RNA genome assembled at the cell membrane, and new virions bud out of the infected cell in the form of immature viral particles that require posttranslational processing of precursor viral polyproteins (Pr55^{Gag} and Pr160^{GagPol}) for the budded virions to be infectious. The enzyme responsible for this processing is HIV protease (PR) and this enzyme presents another target for inhibition. Protease inhibitors were originally developed for HIV-1 therapy and remain an important class of drugs for treatment with ten PIs currently approved for clinical oral use. As virion maturation occurs late in the viral life cycle, after viral entry and integration, they would most likely be used in combination with other ARV acting on earlier stages in the viral life cycle. Here PR inhibitors would act as a second line of defense limiting the release of infectious virus not blocked by early acting ARV drugs in any combination. Currently, at least four PR inhibitors are being assessed in preclinical studies as potential candidate microbicides including saquinavir (SQV), darunavir (DRV), lopinavir (LPV), and ritonavir (RTV) (Herrera and Shattock 2012). Proof of concept that PR inhibitors can prevent infection in nonhuman primate models of transmission is likely needed to stimulate

further clinical development as viable microbicide candidates.

Candidate Microbicides with Multiple Mechanisms of Action

Interestingly, some compounds have been shown to inhibit more than one step in the viral replication cycle. These offer potential advantage through increasing the potential breadth and potency. Several NNRTIs such as IQP-0528, while designed to primarily inhibit reverse transcription, also block viral entry. ARV combinations have also been molecularly designed by generation of chimeric molecules containing, for example, an entry and a fusion inhibitor (Zhao et al. 2011). Other candidates with multiple mechanisms include the family of nucleocapsid inhibitors or zinc finger inhibitors (ZFIs) that primarily target the nucleocapsid protein (NCp7). NCp7 is a small protein with essential functions throughout the replication cycle. It is important for reverse transcription and integration and is required for dimerization and packaging of the viral genome late in the viral replication cycle. Its function is critically regulated by the binding of zinc to its two zinc-binding domains. ZFIs block this process and as a consequence block multiple stages in the viral life cycle. This class of compounds includes *S*-acyl-2-mercaptobenzamide thioesters (SAMT), four of which are being considered as candidate microbicides: SAMT-8, SAMT-19, SAMT-89, and SAMT-247 (Herrera and Shattock 2013).

A more conventional approach to targeting multiple stages within the viral replication cycle is the use of different ARV drugs in combination. This builds on the successful use of ARV combinations for HAART. Here combinations are likely to be used to increase the potency of individual compounds showing efficacy in clinical trials. Thus, a number of combination gels based on tenofovir are in early clinical development including the NRTU FTC and the CCR5 inhibitor maraviroc. Alternative combinations based on the vaginal ring platform (described below) have also been designed and at least one tested in a Phase I clinical trial (MTN-013/IPM 026).

Activity and Formulation of Microbicides for Mucosal Environments

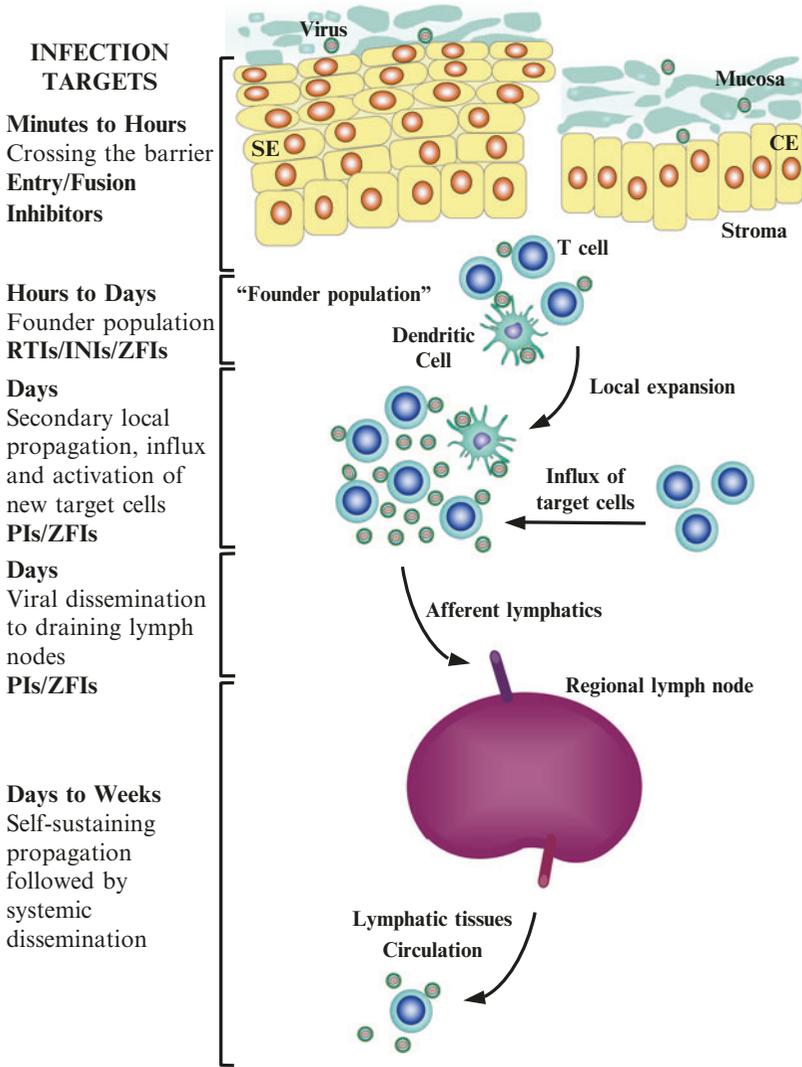

Microbicides are topical agents, and therefore, their mechanism of action inhibiting specific steps of the viral replication cycle needs to be considered within the context of mucosal transmission in the genital and colorectal tracts. Studies in animal models indicate that infection at the mucosal portal of entry is established relatively quickly after exposure to HIV. Indeed, transmission of simian immunodeficiency virus (SIV) in nonhuman primates has been shown to involve the virus crossing the mucosal epithelium in minutes to hours and establishment of an initial focus of infection or “founder population” in the underlying stroma which is originated by a single or a few viruses in the first hours after viral exposure (Li et al. 2009) (Fig. 1). Hence, entry/fusion inhibitors have a time frame of minutes/hours to act before the founder population is established; and this means that a topical inhibitory concentration needs to be present and maintained during this period of time. If production of infectious virus is not inhibited, local expansion will occur in the first few days following exposure (1–3 days), attracting new target cells to expand the initial focus of infection. Dissemination of infection continues with transport of infected cells to secondary lymphoid tissue via draining regional lymph nodes. Infected cells and newly produced virus are then disseminated throughout the systemic circulation (Shattock and Rosenberg 2012) (Fig. 1). Drugs acting post-viral entry will target local amplification and expansion. Specifically, RTIs, ZFIs, and INIs will block viral amplification within the founder population as they act before integration, while PIs and ZFIs, acting post-integration, will inhibit the local expansion phase that is reliant on secondary infection of surrounding CD4 cells and is probably enhanced by interaction with Langerhans cells and dendritic cells (DC) and influx of additional CD4⁺T cells (Shattock and Rosenberg 2012). One potential benefit of compounds acting later in the viral replication cycle, such as INIs and PIs, is that they might allow for postcoital dosing in addition to precoital application and in combination with

pre-integration inhibitors which might provide a much greater window of protection.

Ultimately the efficacy of any microbicide product will depend upon correct product use (adherence) as well as appropriate drug delivery. This is clearly illustrated by the CAPRISA 004 trial of tenofovir gel where volunteers were requested to use the drug in a pericoital fashion, “before and after sex.” Here efficacy of the gel was significantly affected by adherence to the regimen (Abdool Karim et al. 2010). In contrast, daily or coitally dependent dosing with the same gel provided no protection (Herrera and Shattock 2013), suggesting either poor adherence and/or insufficient drug delivery at the time of viral exposure. A range of additional delivery platforms is currently under development to increase choice and improve ease of use including tablets, films, and intravaginal rings (IVRs). The later approach (IVRs) is already used to deliver hormone replacement therapy and hormonal contraception. Microbicide IVRs are based on drug-impregnated rings that release hydrophobic ARVs for prolonged periods (up to 3 months), maintaining concentration sufficient to prevent HIV transmission. The most advanced IVR product contains the NNRTI dapivirine and is currently being assessed in two efficacy trials (MTN-020 Aspire and IMP027). Building on this platform combination, IVRs designed to deliver both hormonal contraception and ARV protection are in early clinical development.

ARV-Based Microbicides and Resistance

Many of the drugs (or drug classes) currently in the microbicide pipeline are already used in HAART regimens. This raises theoretical concerns that widespread use of ARVs as microbicides could induce resistance that would significantly reduced the efficacy of treatment or treatment options for those that became infected. This scenario would involve an individual using ARV-based microbicide even after becoming infected, and therefore, active replication could select for a resistant mutant to the drug contained in the microbicide. However, it is unclear whether

HIV-1 Transmission Blocking Microbicides, Fig. 1 Time line for HIV-1 inhibition of mucosal transmission. Viral infection in the cervicovaginal and colorectal tracts requires the virus present in the lumen to cross the epithelium reaching the stroma where a founder population is established within a few hours post-viral exposure. Entry

and fusion inhibitors prevent formation of initial foci of infection. RTIs, INIs, and ZFIs inhibit viral amplification within the founder population during the first hours/days postexposure, and PIs and ZFIs are candidates to inhibit local expansion and viral dissemination to draining lymph nodes (Adapted from Herrera and Shattock 2013)

topical ARV application, that does not involve high systemic levels of the drug, has the potential to induce resistance. Of importance, no evidence of resistance to tenofovir was seen in participants in CAPRISA 004 that became infected during the trial (Abdool Karim et al. 2010). Nevertheless, more data is needed to fully understand the potential of ARV microbicide use on the circulation of

resistant strains. Thus, for the foreseeable future, ARV-based microbicides will only be made available on prescription to individuals shown to be seronegative and with regular follow-up monitoring. Moving forward, appropriate design of drug combinations is likely to reduce or prevent transmission isolates resistant to any individual ARV class.

Microbicides in Context with Other Prevention Strategies

Microbicides were never intended to replace existing strategies known to impact on transmission rates, behavior change, condom use, and circumcision, but to supplement these approaches with an emphasis on increased availability and choice of prevention options for at-risk populations. Furthermore, microbicides represent one of a number of new biomedical prevention strategies that include oral preexposure prophylaxis (PrEP), treatment for prevention, and vaccines. Effective reduction in HIV incidence will likely depend on effective implementation of this growing number of prevention options, where combined approaches may have the biggest impact (Shattock et al. 2011).

Conclusion

The groundbreaking proof of concept that ARVs can provide safe topical protection against HIV sexual transmission, obtained with the CAPRISA 004 trial testing 1% tenofovir gel, was key for the field of microbicides driving further research to achieve higher levels of protection. The apparently contradictory results of the VOICE trial, testing daily use of tenofovir gel, underlined the clear importance of developing dosing strategies that promote product adherence. This is driving the development of new formulations and delivery strategies designed to increase user acceptability and adherence. In this respect, efficacy studies of the dapivirine intravaginal ring, designed to deliver sustained drug dosing, are likely to be key. Furthermore, better understanding of the mechanism of mucosal viral transmission and the impact of the mucosal environment on transmission will be critical to inform drug prioritization. It is anticipated that the use of ARV with increased potency, the development of ARV combinations that target different stages in the viral life cycle, and their delivery from sustained release platforms will deliver products with increasing efficacy.

HIV-1 Transmission: Influence of Bodily Secretions

Georgios Pollakis and William A. Paxton
Department of Clinical Infection, Microbiology and Immunology, Institute of Infection and Global Health, University of Liverpool, Liverpool, UK

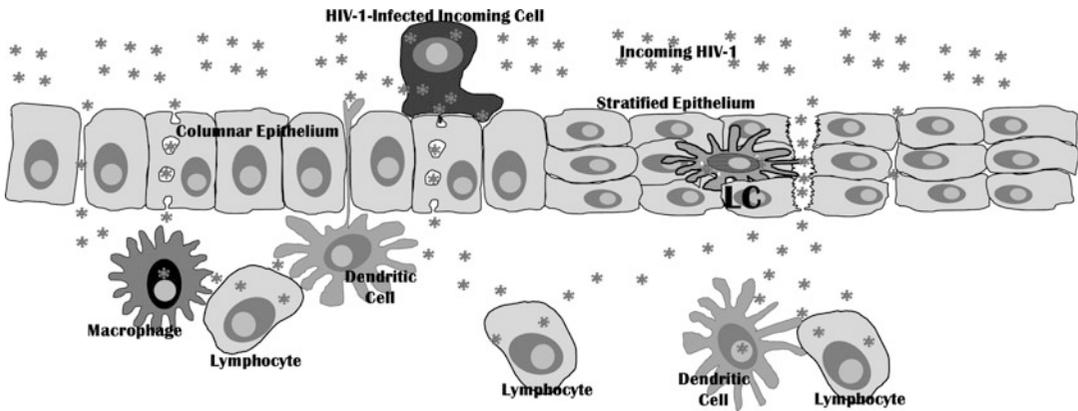

Definition

HIV-1 transmission via sexual intercourse or mother to child transmission (MTCT) requires the passage of virus across a mucosal barrier. The exceptions are exposure via direct injection of virus into the bloodstream through either the administration of contaminated blood or blood products or intravenous drug use (IVDU) with needle sharing. In all transmission cases, a distinctive group of viruses are transmitted and which exclusively utilize, in conjunction with CD4, the CCR5 chemokine receptor for entry (R5 viruses). In some individuals, the virus will evolve to utilize the CXCR4 chemokine receptor (R5/X4 and X4 variants) during disease course and where the switch has been associated with increased viral loads, accelerated CD4 declines, and faster rates of disease progression. Understanding what restricts the preferential transmission of R5 viruses and which host factors contribute to the R5 to X4 switch is poorly understood and remains one of the major questions to be answered concerning HIV-1 pathogenesis. Deciphering such mechanisms will undoubtedly aid in the development of the necessary tools required to prevent viral transmission and/or limit disease progression. The cell types HIV-1 interacts with or infects at mucosal surfaces will contribute to which virus variants establish infection. HIV-1 transmission across the numerous mucosal surfaces will be influenced by the array of host factors to be found within the bodily secretions to be found at these sites of exposure. This entry describes some of the factors to be found within these secretions and which have the potential to modulate HIV-1 infection as well as viral replication.

Cell Types Involved in HIV-1 Mucosal Transmission

HIV-1 transmission will be dependent on the cell types with which the virus interacts at the mucosal surface and will be greatly influenced by factors such as tissue morphology and cellular composition. Concerning sexual transmission, Langerhans cells (LCs) reside in stratified squamous epithelial of the vagina, ectocervix, glans penis, and outer foreskin and will represent the first cells to encounter HIV-1, unless the virus enters via tears in the mucosal wall. Underneath this layer, the dendritic cells (DCs) reside in the lamina propria and compose an additional cell type the virus can interact with. In more sensitive mucosal linings composed of a single columnar epithelium, as found in the rectal, endocervical, and inner foreskin, the LCs are absent but an abundance of DCs are to be found. Tissue macrophages also reside in mucosal tissues and can be one of the first cell types to be infected with HIV-1. There is still much debate as to whether the first cell types of infection are indeed one of these diverse lineages or whether CD4⁺ lymphocytes are the main targets of infection at time of transmission. What is striking is that CD4⁺ lymphocytes at mucosal surfaces can express high levels of the CXCR4 coreceptor, indicating that receptor expression patterns on lymphocytes at sites of infection are not determining selective R5 transmission over the R5/X4 or X4 variants. The complexity of cell types associated with HIV-1 transmission has been highlighted in Fig. 1.

A multitude of receptors expressed on the array of cell types described above can interact with the HIV-1 gp120 envelope molecule, including toll-like receptors (TLRs), C-type lectin receptors (such as DC-SIGN, MMR, BDCA-2, DCIR, DLEC, CLEC-1), as well as the asialoglycoprotein receptor which recognizes the polysaccharide patterns on pathogens and often characterized by their terminal mannose molecules which are uncommon on the surface of mammalian cells (reviewed Pollakis and Paxton 2012). LCs express langerin at the cell surface, a molecule which can interact with gp120; however, it has been shown that once bound, the

HIV-1 Transmission: Influence of Bodily Secretions,

Fig. 1 Depicts two types of mucosal tissue, *left* columnar epithelium as found in the anal mucosa, endocervical region, inner foreskin, and glands corona mucosa and *right* stratified epithelium mucosa as found in the vaginal interstitial region, ectocervical region, glans penis, outer

foreskin, and tonsil. The cell types residing within or below the different layers are shown. On the outer side and where HIV-1 encounters the mucosal barrier an array of bodily secretions can be present, including cervical, vaginal, seminal, and colorectal as well as saliva or breast milk

H

virus is internalized and likely degraded within the Birbeck granules of the cell (de Witte et al. 2007). This can be envisaged as a protection pathway by the host where pathogens crossing the mucosa will be successfully captured by LCs and efficiently eliminated. Similarly other molecules expressed on LCs can capture HIV-1, such as galectin-3 (a β -galactoside-binding lectin) which can modulate HIV-1 capture and transmission. LCs possess a restricted susceptibility to infection due to the lack of CXCR4 expression at the cell surface, one explanation for the preferential transmission of R5 variants. On the other hand, DCs can capture HIV-1 via binding of gp120 to an array of C-type lectins, such as DC-SIGN, and efficiently transfer the virus to CD4⁺ lymphocytes, a mechanism known as *trans*-infection (Geijtenbeek et al. 2000). The model proposed is that HIV-1 can be captured by DCs at mucosal surfaces, either following transcytosis across the mucosal barrier or through tears and breaks in the mucosal lining and subsequently transferred to CD4⁺ lymphocytes residing below the mucosal epithelium or in localized lymph nodes. DC-SIGN can potently bind HIV-1 and cell types expressing this molecule have been shown to heighten HIV-1 infection and replication in other cell types. In addition to *trans*-infection, HIV-1 can infect DCs via the classical infection

pathway through binding CD4 and coreceptor; however, binding of virus to such molecules as DC-SIGN may facilitate enhancement to *cis*-infection. DCs have been shown to successfully capture R5, R5/X4, and X4 viruses and pass virus to CD4⁺ lymphocytes, indicating that this is not the selection pressure favoring preferential R5 virus transmission.

Macrophages are infected with HIV-1 through the classic infection pathway, and such cells derived from the genital mucosa have been shown to support HIV-1 infection and replication. In addition, peripheral monocytes have been shown to be infected with HIV-1 during acute infection (Centlivre et al. 2011). These cells can be infected with HIV-1 at mucosal surfaces and subsequently migrate to adjacent lymph nodes where they can disseminate the virus and establish infection, similar to DCs. In rhesus macaque models of SIV infection, it has been established that foci of infection can be found in plasmacytoid DCs (pDC) within the genital mucosa, indicating this to be a cell type involved early in infection. In addition to being infected, such stimulated cells create an inflammatory response where CD4⁺ lymphocytes are subsequently attracted to the infected site via upregulation of chemoattractants and which will be highly infectious for HIV-1. Various cell types defining the innate immune

system can therefore play a role in influencing HIV-1 transmission as well as subsequent disease progression. These cells cannot only capture HIV-1 and transfer virus to CD4⁺ lymphocytes, they also modulate immune responses at mucosal surfaces and therefore can influence immune mediated clearance of infection or protect against HIV-1 transmission in subsequent exposures.

HIV-1 mother-to-child transmission (MTCT) can occur via a number of routes, either in utero, intrapartum, or during the breastfeeding period and each at approximately equal frequencies. For each route of exposure, the virus has to cross a highly divergent mucosal barrier making each exposure route unique with variant transmission mechanisms at play. When considering in utero transmission, HIV-1 has to cross the placental trophoblast, which is different from the other routes of exposure, where virus will likely be ingested by the child and where HIV-1 has to cross the mucosal barrier of either the oral cavity or the gastrointestinal tract. The differing modes of MTCT transmission are also highly variable when considering the carrier fluids in which the virus will be present and the mucosal environment where transmission will occur, e.g., amniotic fluid, birth canal secretions, or breast milk. When considering transmission via breastfeeding, there are indications that functionally active CD4⁺ lymphocytes are taken up by the infant from the milk during the first days of life which could result in the transfer of HIV-1 infected CD4⁺ lymphocytes. Another possibility is the infection of infant cells at the site of exposure. Oral epithelial cells are susceptible to infection by either cell-free or cell-associated HIV-1 in vitro as well as tonsillar stromal cells and human oral keratinocytes, which have been shown to transfer HIV-1 to lymphocytes in vitro. Since gastric acid production in newborn infants is reduced, intact virus may reach the intestinal epithelial cells which can be infected by HIV-1. Similar to other mucosal transmission barriers, DCs below the epithelia may also have a role to play in viral capture and transfer, especially when coinfections or breaks in the mucosal lining are present. After the application of SIV to the tonsils of macaques, DCs were found to be positive for virus even though the virus was

primarily present in CD4⁺ lymphocytes. Tonsillar DCs have also been found to be positive for HIV-1 after in vitro exposure and have been shown to support infection of T cell lines *in trans*.

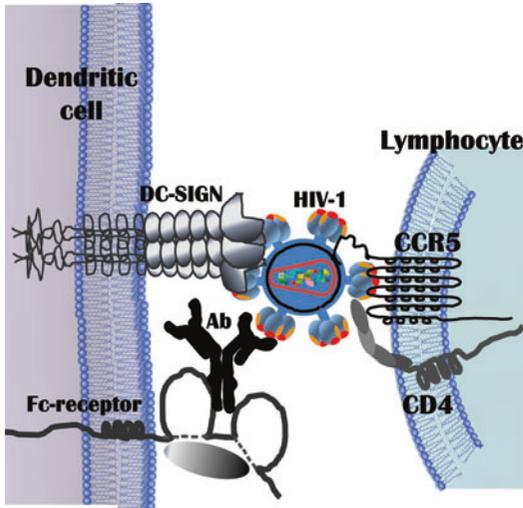

Influence of Antibodies at Mucosal Surfaces on HIV-1 Transmission

The current understanding is that antibodies present at mucosal sites will provide a level of protection against HIV-1 transmission. This has been determined by many monkey studies where animals can be protected by the application of antibodies to the mucosal surfaces or injected into the periphery and then challenging the animals with autologous or heterologous viral stocks at the mucosa. Whether this protection is achieved through virus neutralization or via other mechanism such as antibody-dependent cellular cytotoxicity or complement fixation is still very much in debate. The vaccine field has been spurred by the RV144 Thai vaccine trial where a modest 31% protection was observed in vaccine recipients and where subsequent analysis points to non-neutralizing HIV-1 antibodies responses directed against the V2 region of the gp120 molecule being the protective correlate. Confirmatory vaccine trials testing this hypothesis are currently under development and should indicate indeed whether such responses will be beneficial in curtailing HIV-1 infection. As way of caution, it should be noted that viruses coated with neutralizing antibodies can be more efficiently captured by cells expressing DC-SIGN and that the captured virus can be rendered subsequently infectious for CD4⁺ lymphocytes and as depicted in Fig. 2 (van Montfort et al. 2007). This would indicate that antibodies have the potential to heighten both HIV-1 replication in vivo and HIV-1 transmission. Further evidence for the involvement of DC-SIGN in supporting HIV-1 transmission stems from the findings that genetic polymorphisms within the gene coding for the C-type lectin have been associated with risk of infection, either through sexual intercourse or via MTCT.

A recent study has indicated that autologous neutralizing antibody responses are higher in

mothers and infants where HIV-1 transmission occurred and in comparison to matched non-transmitting controls (Baan et al. 2013). The effect

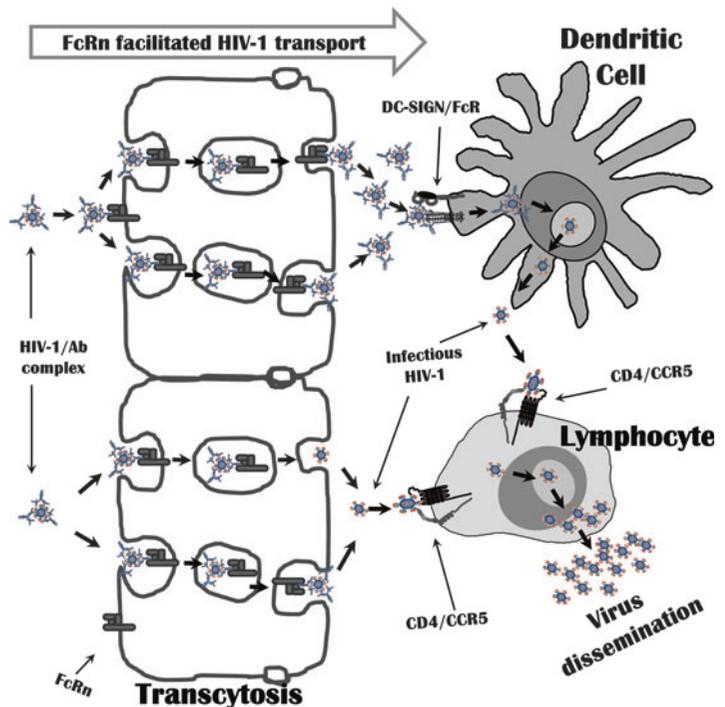

was only and seen for mother-infant pairs where in utero transmission had occurred and was not observed for either intrapartum or breastfeeding transmissions. An additional study has demonstrated that HIV-1 neutralizing antibodies have the capacity to enhance virus transcytosis across an epithelial barrier through interacting with the FcRn receptor, such as would be expected to be present within the trophoblastic layer within the placenta (Gupta et al. 2013). Furthermore, it has been shown that higher antibody levels in monkeys vaccinated against SIV associate with the number of transmitter/founder viruses to be found in the non-protected animals after rectal challenge (Gupta et al. 2014). The authors demonstrate that the sera from such monkeys can enhance viral transcytosis across a rectal model systems and where the FcRn molecule was shown to be expressed in the macaque rectal columnar tissue. These results collectively indicate a novel mechanism whereby immune complexes binding to FcRn may result in antibody-dependent enhancement to HIV-1 transfer across a mucosal barrier and as illustrated in Fig. 3. Vaccine strategies aimed at curtailing HIV-1 transmission may

HIV-1 Transmission: Influence of Bodily Secretions, Fig. 2 Schematic representation of HIV-1 interacting with DC-SIGN and presented to CD4+ lymphocytes. HIV-1 in the presence of gp120 binding antibodies can be captured by Fc receptors on DCs and provide for an enhanced capture and subsequent infection of CD4+ lymphocytes

HIV-1 Transmission: Influence of Bodily Secretions,

therefore have to take into consideration which types of antibody responses are induced and indeed ascertain whether these responses can in fact be detrimental when considering HIV-1 transmission.

Breast Milk and Its Effect on HIV-1 Transmission

Human milk contains a variety of cell types including: CD4⁺ lymphocytes, CD8⁺ lymphocytes, macrophages, monocytes, DC's natural killer cells, as well as mammary epithelial cells, all of which can be either infected with HIV-1 or possess anti-HIV-1 activity and therefore contribute toward viral transmission. Mammary epithelial cells are among one of the most abundant cell types to be found in milk, and these cells are highly susceptible to infection with X4 viruses. The pool of cells therefore contributing to viral transmission is large and with the breastfed infants being exposed to both R5- and X4-using variants. Again the selective transmission of R5 viruses is surprising given the exposure to both variant phenotypes and the preferential expansion of CXCR4 expressing CD4⁺ lymphocytes in newborn infants. A number of molecules, in addition to CC chemokines, can be found in human milk and which possess anti-HIV-1 activity. Lactoferrin is one such molecule and which has been reported to block direct infection of CD4⁺ lymphocytes, but not to a particularly high degree. Furthermore, lactoferrin has been shown to inhibit the attachment of *E. coli* to intestinal cells and also exhibit broader antiviral activity against CMV, HSV-1, as well as fungi such as *C. albicans*. Lysozyme has also been shown to inhibit growth of HIV-1 on CD4⁺ lymphocytes as well as mediate the killing of both Gram-positive and Gram-negative bacteria. An array of cytokines and chemokines are expressed in human milk and all of which have the potential to activate cells at the mucosal surface as well as interfere with viral infectivity. Such cytokines expressed in milk are IL-1 β , IL-6, IL-8, IL-10, TNF- α , TGF- β , as well as the array of CC chemokines with the capacity to bind CCR5 and block R5 virus infectivity.

Aside to blocking CD4⁺ lymphocyte direct infection, human milk has been shown to inhibit DC-SIGN-mediated capture and transfer of HIV-1 to activated CD4⁺ cells (Naarding et al. 2005). In culture experiments, it was demonstrated that both R5 and X4 viruses are inhibited by high dilutions of milk and from binding studies, it was revealed that the factor in human milk interacts with DC-SIGN rather than HIV-1. The blocking effect was also shown to be mediated by immature as well as mature DCs, and the mechanism was at the level of the compound binding to the cells in a DC-SIGN-specific manner. Biochemical analysis revealed the responsible molecule(s) as large with the inhibitory effect being alleviated with antibodies that bound to Le^X sugar moieties, indicating that a glycoprotein was responsible. It was also shown that mothers possessed a large degree of variation through which their milk could block HIV-1 capture and transfer by DC-SIGN. Through protein purification and MALDI-TOF analysis, bile salt-stimulated lipase (BSSL) was identified as a molecule with DC-SIGN binding and HIV-1 inhibitory activity (Naarding et al. 2006). BSSL, otherwise known as carboxyl ester lipase, is a digestive enzyme secreted from exocrine pancreas and has broad substrate specificity. The molecule contributes to the hydrolysis of dietary mono-, di-, and triacylglycerols and is responsible for digestion of fat-soluble vitamin esters and cholesterol esters in the small intestine. In humans, BSSL is also expressed in the lactating mammary gland and is found at high levels in milk.

BSSL is a highly divergent molecule at both the protein and genomic level, with the variation stemming from the number of 11 amino acid repeats coded at the C terminus of the molecule. The number of repeats, each of which carries an O-linked glycosylation signal, varies from 7 to 24 and with 16 being the most frequent. BSSL forms a dimer, and it has been shown that mothers heterozygous for BSSL genes with a low (<16 copies) and high (>16 copies) repeat number provide milk samples with the strongest binding to DC-SIGN (Stax et al. 2011). Interestingly, BSSL forms a functional dimer; hence, structural differences in two variant sized monomers may

provide for the heightened strength to DC-SIGN binding. Whether differences can be identified between mothers who transmit HIV-1 to their infants via breastfeeding versus those who do not remains to be elucidated and is currently being tested. BSSL is also found in plasma but it is not known whether this form binds DC-SIGN. One interesting result has been the association between the different BSSL allele combinations and HIV-1 progression with certain genotypes associated with timing of disease onset. It has been shown that there is a link to the emergence of viruses with the X4 phenotype which is especially interesting in that BSSL has been shown to bind to the CXCR4 receptor (Stax et al. 2012). One other intriguing aspect to this study was the strong trend toward a specific BSSL genotype being overrepresented in an HIV-1 highly exposed but uninfected MSM (men who have sex with men). More and larger cohorts will need to be studied to identify the extent to which such BSSL genotypes can associate with the risk of HIV-1 infection.

Bodily Secretions and Their Effects on HIV-1 Transmission

Over the last years attention has turned to studying the effects that factors within bodily secretions have on influencing HIV-1 transmission. This is in part due to the fact that deciphering which molecules are involved and elucidating their mechanism of action will undoubtedly allow for a better understanding of which cell types and modes of infection support HIV-1 transmission. Any new HIV-1 prevention strategy (such as microbicides and vaccines) will have to prevent the multiple pathways of infection and work within the milieu of host molecules to be found at the different mucosal sites. A large number of extracellular factors are present at mucosal surfaces where HIV-1 transmission occurs, and the virus will be exposed to an array of bodily secretions (including saliva, vaginal secretion, seminal plasma, as well as colorectal mucus). All the described fluids will possess an array of molecules including cytokines, CC and CXC chemokines,

antibodies of variant subclasses (IgA and IgG), as well as an array of (glyco)proteins which have been shown to modulate HIV-1 infectivity and inhibit transmission. The expression of cytokines will have the effects of modulating viral expression within infected cells while CC and CXC chemokines will be able to restrict viral infectivity through the classic HIV-1 infection pathway (CD4 and coreceptor mediated). Numerous genotypes within the genes encoding for such factors are known to restrict HIV-1 transmission, and all contribute toward the overall infectiousness of an individual. Many of the compounds found in bodily secretions are shared or similar and will therefore provide the same function in influencing HIV-1 transmission, including such factors as lysozyme, while other factors will be restricted to the particular secretion in question. There are a large number of small peptides present in secretions which have been shown to possess anti-HIV-1 activity, which include the α - and β -defensin group of peptides which can exert their effects through either disrupting viral particles or altering target cells for infection. The peptide LL-37 cathelicidin is another small molecule which has been shown to possess anti-HIV-1 activity as well as induce expression of α -defensins from neutrophils, and it has been shown that levels of expression of both α -defensin and LL-37 in cervicovaginal lavage, although possessing anti-HIV-1 activity, associate with heightened HIV-1 acquisition within a group of commercial sex workers with bacterial coinfections. Another small molecule inhibitor which has received much attention is the peptide SEVI which has been identified in seminal plasma and which can enhance direct infection of CD4⁺ lymphocytes as well as the transfer of virus by cells expressing DC-SIGN to CD4⁺ lymphocytes (Munch et al. 2007). Small molecule inhibitors have also been identified which have the potential to bind SEVI and neutralize the enhancing effects. It has also been demonstrated that spermatozoa can capture HIV-1 through heparin sulfate expressed on their cell surface and in this way pass the virus to CD4⁺ lymphocytes as well as potentially LCs and DCs found at the mucosal surface.

SLPI is an extracellular innate factor with anti-HIV-1 activity which can be found in a variety of bodily fluids and which was first described in human milk. The molecule prevents HIV-1 from infecting macrophages through binding to the phospholipid-binding protein, annexin II, on the cell surface which is a cofactor required for infection. This would indicate that SLPI expression at mucosal surfaces may protect against HIV-1 infection of macrophages when such cells are exposed, such as within lesions generated from coinfections. A more recent report has indicated that SLPI-treated monocytes have the potential to down-modulate human CD4⁺ lymphocyte proliferation with obvious implications for reducing immune activation and inflammation at sites of exposure. Another group of molecules with the potential to inhibit HIV-1 activity belong to those expressed from the DMBT1 gene and encode for a number of molecules at mucosal surfaces with the capacity to modulate immune responses. One DMBT1 protein fragment has also been shown to bind to gp120 and interfere with viral agglutination.

Mucins, alternatively known as MUC proteins, comprise a large number of molecules to be found in bodily secretions and which have been implicated in interfering with HIV-1 infection and replication. MUC5B and MUC7 from human saliva have been shown to possess anti-HIV-1 activity through blocking direct infection of CD4⁺ lymphocytes via a mechanism whereby the carbohydrates aggregate with virus particles rendering them noninfectious (Habte et al. 2006). It has also been identified that MUC1 in human milk and MUC6 in seminal plasma can interfere with DC-SIGN-mediated viral capture by DCs and the subsequent transfer of virus to CD4⁺ lymphocytes (Reviewed Pollakis et al. 2011). All MUC glycoproteins have one common feature in that they carry fucose sugar containing epitopes which contributes to their receptor-binding characteristics. A large number of posttranslational modifying enzymes are known to play a role in the differential processing of such MUC molecules and which will in all likelihood modulate their receptor-binding properties. The FUT2 and FUT3 genes, encoding fucosyltransferases 2 and 3, are

involved in the synthesis of DC-SIGN-binding Lewis-type sugars, which are known to modify the binding of such glycoproteins to their receptors. Host variations to the posttranslational modification of MUC proteins may influence the HIV-1 inhibitory capacities of such molecules. As with BSSL, the MUC6 gene is highly polymorphic and is composed of a variant number of large repeats in the central region of the glycoprotein, with variation in the number of repeats having been associated with infection with the gut *Helicobacter pylori* bacteria. Clusterin, a molecule found in seminal plasma, has also been shown to bind DC-SIGN and prevent HIV-1 capture and transfer to CD4⁺ lymphocytes. These results point toward an array of molecules to be found in human secretions with the capacity to influence transmission of various pathogens.

MUC proteins also comprise a large part of vaginal secretions and have been shown to vary in composition between the different sites of the female reproductive tract, namely, the cervical mucus (CM) and the cervical vaginal mucus (CVM). Elegant studies have shown that microparticles will diffuse differently within each of these bodily fluids. It would be expected that these differences would have consequences on HIV-1 particle diffusion through the secretory products and thereby influence the likelihood of virus reaching or penetrating the mucosal surface. It has also been postulated that MUC proteins in bodily secretions can likely modulate antibody function. The IgG subclass has been shown to bind both CM and CVM, while the IgA subclass can interact with CM but not CVM (Shukair et al. 2013). Similarly MUC2 in the digestive tract has been shown to bind IgA through the secretory component of the antibody dimer, while an MUC-related protein (FcGBP), which interacts with MUC2, can bind to the IgG Fc region. Collectively, these results indicate that different Ab subclasses can function differently within the diverse array of bodily secretions. The complexities of these interactions need to be understood when considering how effective antibody responses will be when induced at different mucosal sites.

Genetic association is a powerful means to determine which factors are important for influencing HIV-1 transmission as well as disease progression, with the best examples being those identified for the CC chemokine and chemokine receptor axis. Similarly, restrictions within genes of the adaptive arm of the immune response, specifically those within the multi-histocompatibility complex class-I (MHC I) restricted cytotoxic T lymphocyte (CTL) responses (B27 and B57), have been associated with disease progression. The presumed mechanisms linking the MHC haplotypes with disease course can associate with the breadth of CTL epitopes being recognized by the MHC molecule or the strength of binding thereby influencing the capacity through which the induced responses kill HIV-1 infected cells and control infection. CTL responses at mucosal surfaces have been hypothesized to be associated with protection from infection in both commercial sex workers and HIV-1-exposed infants. Many host genetic restrictions have also been described in genes encoding for proteins involved in the innate arm of the immune response, including cytokines, cytokine receptors, TLR receptors, KIR receptors, and C-type lectins (such as DC-SIGN), and all which have been linked with either risk of HIV-1 infection or disease progression. These associations clearly indicate that the network of innate and adaptive immune responses at mucosal sites is paramount in influencing transmission. The findings that many of the molecules to be found at mucosal surfaces can bind these cells and influence HIV-1 capture, and presumably free antigen capture, in a host-restricted manner indicates that induced immune responses will likely vary between individuals and presumably modulate risk of HIV-1 infection.

Conclusions

The vast majority of HIV-1 transmissions require virus to cross a mucosal surface, with each route being composed of a multiple array of cell types and in the presence of a vast array of bodily secretions. These secretions will be composed of

a mixture of cytokines, chemokines, antibodies, antimicrobial compounds, as well as a range of high molecular weight glycoproteins. Many of these factors have been shown to possess an array of HIV-1 modulating activity and will in combination determine the susceptibility of each individual to infection. Vaccines, microbicides, and therapies aimed at preventing HIV-1 transmission will need to function in most of these environments in order to be successful and inhibit the many different routes of infection as well as viral variants present. Understanding the complexities of the host viral interactions occurring at each mucosal surface will need to be deciphered in order to ascertain how successful the different HIV-1 prevention strategies will be. The identification of molecules with HIV-1 inhibitory activity may also allow for the development of new and novel products with the capacity to restrict HIV-1 transmission.

HIV-1 Virion Structure

Owen Pornillos and Barbie K. Ganser-Pornillos
Department of Molecular Physiology and
Biological Physics, University of Virginia,
Charlottesville, VA, USA

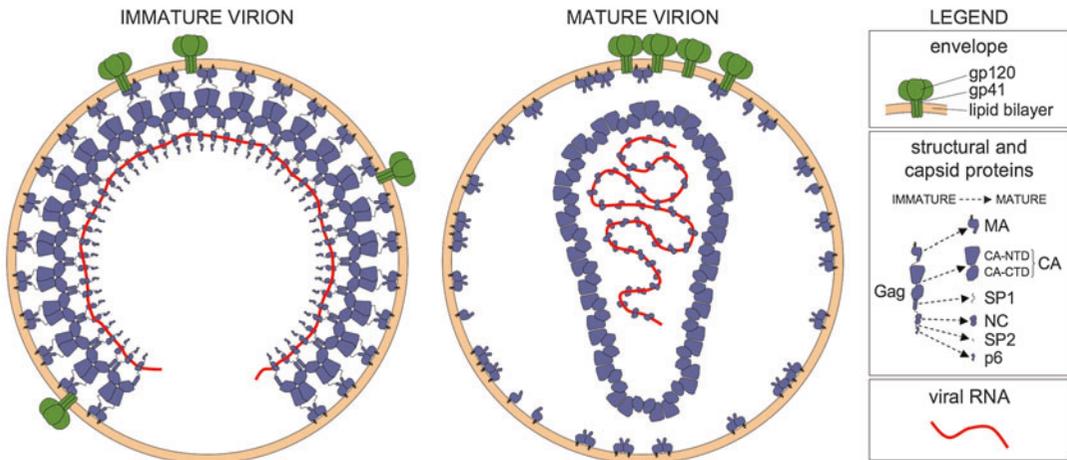

Definition

The HIV-1 particle, or virion, transmits the genetic information of the virus from one host cell to the next. There are two morphologically distinct forms of the virion, called “immature” and “mature.” The immature virion is the form that assembles and initiates budding at the plasma membrane of an infected host cell (► [Budding](#)). This form is not capable of transmitting infection. During or immediately after budding, the virion reorganizes into the mature form. The mature virion is fully infectious.

Overview

The HIV-1 virion is spherical in shape, with a diameter of about 100 nm (1/10,000 of a millimeter). The virion is delimited by an outer coat – the viral envelope – that surrounds and protects the internal components of the virus and contains the proteins that allow the virus to recognize new host cells. Inside the virion are viral structural proteins that assemble into a shell, or capsid, that further surrounds and organizes the viral genome. The HIV-1 genome consists of two strands of single-stranded, positive sense RNA molecules, each of which contains a complete set of viral genes. The function of the virion is to transmit the viral RNA from an infected cell (the “producer cell”) to a new host cell.

HIV-1 virions adopt two distinct morphological states (Ganser-Pornillos et al. 2008; Briggs and Kräusslich 2011; Sundquist and Kräusslich 2012) (see Fig. 1). The virion buds from a producer cell in its immature form, with a spherical capsid composed of the immature or precursor structural protein called Gag (also called p55 or

HIV-1 Virion Structure, Fig. 1 The HIV-1 virion adopts two distinct morphological states. Shown are schematic diagrams of the immature virion (*left*) and mature virion (*right*). The viral envelope comprises a spherical lipid bilayer shell (*orange*) and Env protein spikes (*green*). Inside the virion are the structural and capsid proteins (*charcoal gray*) and the viral RNA (*red*). In the immature virion, the precursor structural protein, Gag, forms a spherical shell that is tethered to both the viral envelope and the viral RNA. During

maturation, Gag is cleaved by the viral protease into three new proteins and several small peptides. The new proteins comprise the mature structural proteins, which reorganize the virion. The mature MA protein is derived from the amino-terminal domain of Gag and remains tethered to the viral envelope. The mature CA protein reassembles into a cone-shaped mature capsid. The mature NC proteins condense with the viral RNA to form a compact ribonucleoprotein complex within the mature capsid

H

Pr55; Gag has a molecular weight of about 55 kDa). To become infectious, the immature virion undergoes a morphological change into the mature form. This process, termed “► [HIV-1 Maturation](#),” is triggered by site-specific proteolytic processing or cleavage of the precursor Gag protein by the viral protease. Gag cleavage by the protease does not lead to protein degradation but instead generates new structural proteins. The mature structural proteins include one called CA (also known as p24), which reassembles into a new, cone-shaped capsid. The mature capsid contains inside it the RNA genome and its associated enzymes. The mature capsid and its contents together constitute the virion “core” – this is the object that is introduced into the cytoplasm of new host cells at the start of a new round of replication (► [Uncoating and Nuclear Entry](#)).

The Viral Envelope

The viral envelope is composed of a lipid bilayer, which is derived from the plasma membrane of

the producer cell when the virion buds from the cell surface. Embedded within the envelope is the viral envelope protein, called Env. Env mediates recognition of and binding to the host receptor protein (CD4) and coreceptors (either CXCR4 or CCR5), which are displayed on the surface of immune cells such as macrophages and T cells. Receptor binding triggers a structural change in Env that facilitates fusion of the viral and cellular membranes and subsequent delivery of the virion core into the cytoplasm of the host cell (► [Fusion](#)). Env proteins are therefore essential for infectivity of the virion.

Env is composed of two proteins: a surface glycoprotein called gp120 (also known as SU) and a transmembrane protein called gp41 (also known as TM). These two proteins together form a single structural unit. Three of these units comprise the Env trimer. Each Env trimer forms a mushroom-shaped “spike,” which protrudes away from the surface of the viral envelope. The gp120 molecules make up the caps, whereas the gp41 molecules form the stem. Each gp41 protein contains a single transmembrane helix, which is

embedded within the membrane and passes through the entire lipid bilayer. The tails of the gp41 transmembrane helices are displayed on the inner surface of the viral envelope and interact with the structural proteins inside the virion.

Modern electron microscopy imaging studies have shown that the HIV-1 virion contains only 7–14 Env spikes (Liu et al. 2008; Zhu et al. 2008) (previous estimates have placed the number at around 70). Superresolution fluorescence microscopy studies have revealed that the spikes are distributed randomly on the surface of the immature virion and then coalesce into a single cluster upon maturation (► [HIV-1 Maturation](#); Chojnacki et al. 2012). Env clustering is important for efficient receptor binding and membrane fusion. The redistribution of Env is suggested to be triggered by a mechanism of “inside-out signaling” that involves interaction of the gp41 tails with the amino-terminal domain of the structural Gag protein. This ensures that only virions that have successfully generated the mature core are competent for membrane fusion.

The Immature Capsid

The immature capsid is a spherical protein shell composed of about 2,500 molecules of the structural Gag protein. The HIV-1 Gag molecule is composed of a series of structural domains and spacer peptides, which are demarcated by flexible linkers. The domains correspond to the mature proteins that are produced when Gag is proteolyzed during maturation and are called MA (matrix), CA (capsid), NC (nucleocapsid), and p6. The amino-terminal end of HIV-1 Gag (which is the MA domain) contains a covalently attached myristyl molecule, which is a saturated 14-carbon fatty acid chain.

The assembled Gag molecules (► [Virus Assembly](#)) are oriented with the MA domains positioned on the outer surface of the protein shell and juxtaposed with the inner surface of the viral envelope. The MA domain interacts with the viral envelope in three specific ways (Saad et al. 2006; Chojnacki et al. 2012): first, the domain binds to the membrane lipid,

phosphatidylinositol-4,5-bisphosphate; second, it inserts the myristyl fatty acid chain into the lipid bilayer; and third, it binds to the gp41 tails of the Env proteins.

The CA domain, together with the spacer peptide SP1, mediates the protein-protein interactions that stabilize the immature shell (Wright et al. 2007; Briggs et al. 2009; Bharat et al. 2012). The CA domain is further divided into two structural domains, called CA-NTD and CA-CTD, which are again connected by a flexible linker or hinge region. These three regions of Gag – CA-NTD, CA-CTD, and SP1 – form a three-layered paracrystalline lattice of hexameric (or sixfold rotationally symmetric) rings. The rings pack against each other side-by-side, like the hexagonal chambers of a beehive. The spacings between the rings have a characteristic value of 8 nm.

The NC domain is oriented toward the center of the virion. This domain contains two zinc knuckles, a small protein structural motif stabilized by a zinc ion, which bind to the viral RNA. Gag molecules within the immature virion are therefore tethered at both ends: the amino-terminal end (the MA domain) is tethered to the viral envelope, whereas the carboxyl-terminal region (the NC domain) is tethered to the viral RNA at the center of the virion.

The p6 domain is the carboxyl-terminal-most domain of HIV-1 Gag. This domain is unstructured and has no known structural roles within the immature virion. However, it is important for forming the virion because it hijacks proteins from the producer cell that are required for virus budding.

Analyses of immature virions by electron microscopy techniques have shown that the Gag shell is incompletely closed, with surprisingly large regions (up to 50% of the available area) devoid of ordered Gag molecules (Wright et al. 2007; Briggs et al. 2009; Keller et al. 2011). One likely explanation for this phenomenon is that Gag assembly (► [Virus Assembly](#)) and virus budding (► [Budding](#)) are in kinetic competition: by this model, incompletely closed shells are a consequence of virions being released from producer cells before complete Gag shells can be assembled (Carlson et al. 2010).

Virion Maturation

The viral protease cleaves HIV-1 Gag at specific sites to produce three new structural proteins: MA (also called p17), CA (p24, containing both the CA-NTD and CA-CTD domains), and NC (p7) (► [HIV-1 Maturation](#)). Proteolysis of Gag disassembles the immature shell, and the new mature proteins rearrange and reorganize the interior of the virion. The mature MA protein remains associated with the viral envelope, forming the “matrix” layer. A subset of the mature CA proteins reassembles into the mature capsid. Inside this new capsid, the mature NC proteins condense with the viral RNA, together with viral enzymatic proteins. As described above, maturation is also coupled to redistribution of the Env proteins. Altogether, the process of maturation reorganizes the entire virion into a particle that is now primed to infect a new host cell.

Proteolytic processing triggers a local refolding event at the amino-terminal end of CA-NTD: the first 13 amino acid residues of this domain change from an extended configuration (immature) into a beta-hairpin fold (mature) (von Schwedler et al. 1998; Tang et al. 2002). Similarly, processing at the CA-CTD/SP1 junction is suggested to induce a structural rearrangement of this segment from a putative alpha-helical bundle into an extended configuration (Wright et al. 2007). These structural changes are thought to comprise molecular switches that control or facilitate the immature-to-mature transition of protein-protein interactions involving the two CA domains. To a large extent, however, the mechanistic details (and in particular, the dynamics) of maturation are not yet well understood.

The Mature Capsid

The mature capsid shell has a similar basic arrangement as the immature shell – it is also composed of an array of hexagonal rings that pack side-by-side. The spacings between the rings are about 9 nm. Unlike the Gag shell, however, the CA shell also contains pentameric (or fivefold rotationally symmetric) rings.

The overall arrangement of the CA hexamers and pentamers that make up the mature capsid is mathematically described as a “fullerene cone” (Ganser et al. 1999). [Fullerene cones are related objects to buckyballs (buckminsterfullerenes) and nanotubes formed by elemental carbon. In fact, elemental carbon can be induced to assemble into fullerene cones (Krishnan et al. 1997).] The body of the HIV-1 capsid cone is composed of about 250 CA hexamers. In order to become a completely closed shell, the lattice incorporates exactly 12 CA pentamers. Unlike a buckyball, however, where the pentamers are distributed symmetrically at the vertices, the pentamers in a fullerene cone are distributed nonsymmetrically: there are seven pentamers at the broad end of the cone and five at the narrow end. As a consequence, the mature HIV-1 capsid is “globally” (taken as a whole) nonsymmetric, even though the CA molecules themselves come together “locally” in symmetric ways to form hexamers and pentamers.

The mature capsid of HIV-1 is not merely asymmetric – it is also pleiomorphic. There is variation in capsid size because each individual capsid can contain a different number of subunits. It is estimated that there are around 1,500 molecules of CA per capsid, which constitute only two-thirds of the available CA protein molecules within the virion. There is also variation in capsid shape, which arises from differences in the relative distribution of the 12 pentamers. It has been suggested that the pleiomorphic architecture of the capsid may reflect evolutionary warfare between the virus and its host (Ganser-Pomillos et al. 2011).

The architecture of the mature HIV-1 capsid is now understood in atomic detail. CA hexamers and pentamers are quasi-equivalent – that is, the two oligomers form by the use of the same sets of protein-protein interactions (Cardone et al. 2009; Pomillos et al. 2011). In both cases, the CA-NTD domains form rings with either sixfold or fivefold rotational symmetry. The CA-CTD domains form a “belt” around the CA-NTD rings and also connect the rings to each other.

An atomic resolution model of the HIV-1 CA fullerene cone, which was created by molecular dynamics and fitting of X-ray crystal structures of the hexameric and pentameric building blocks

into a low-resolution structure solved by electron microscopy, has been proposed (Zhao et al. 2013).

Comparison of the Immature and Mature Capsids

As is evident from the above descriptions, the immature and mature capsid lattices of share some similarities. This is not surprising, because in both lattices, the bulk of the protein-protein interactions are mediated by the two CA domains. However, the details of the interactions are quite different. In particular, the architectural roles of the two domains of CA are reversed: in the immature lattice, the hexameric rings are formed by CA-CTD, whereas in the mature lattice, these are formed by CA-NTD. Side-by-side connections between the hexamers are also different. The immature-to-mature transition of these protein-protein interactions is controlled, in part, by structural switches at either end of the CA polypeptide, which are triggered by the viral protease. Real-time visualization of these transitions is an important frontier in the field of HIV and retroviral structure.

The Viral RNA

The HIV-1 virion contains two molecules of the viral RNA. Each viral RNA molecule is approximately 10 kb (10,000 nucleotides) long. During maturation, the viral RNA condenses with the mature NC proteins into a compact ribonucleoprotein complex within the mature capsid. Early studies have shown that upon maturation, the viral RNA adopts a more stable structure (Fu and Rein 1993). To a large extent, however, the molecular details of how this occurs, the dynamics of viral RNA structure, and the molecular organization of the genome within the HIV-1 virion remain unknown.

Conclusion

The spherical HIV-1 virion consists of (from outside to inside) the viral envelope with embedded

Env proteins, the viral capsid, and the viral RNA with its associated factors. The virion initially assembles in its immature form, with a spherical capsid shell composed of the precursor structural Gag protein. During maturation, the Gag molecules are cleaved by the viral protease, giving rise to new structural proteins, which then reorganize the virion. Inside the virion, the viral RNA is repackaged in the mature capsid, which is a fullerene cone composed of the mature CA proteins. On the viral envelope, the Env protein spikes coalesce into a single cluster. Once maturation is complete, the virion is fully infectious.

HIV-2 Diagnosis and Viral Load Measurements

Neil J. Berry

Division of Virology, National Institute for Biological Standards and Control, South Mimms, Hertfordshire, UK

Definition

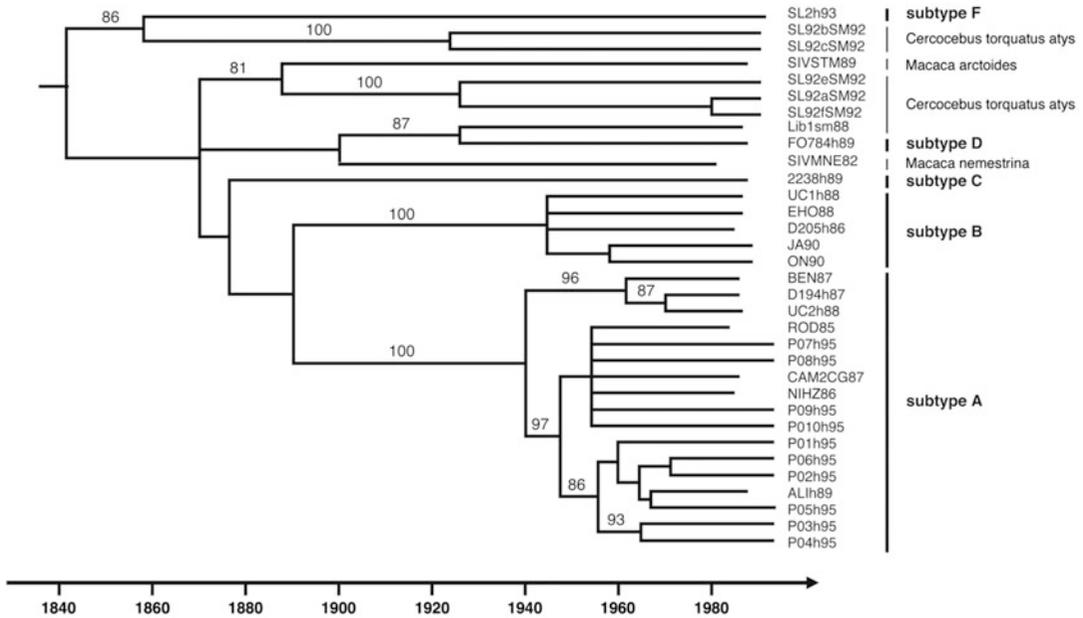

Detection and/or quantification of the presence of HIV-2 in biological materials, distinguishable from related lentiviruses, either directly as virus-

specific nucleic acid or protein or indirectly as immunological responses to infection. Viral load measurements relate specifically to genome quantification and infection dynamics, usually within already diagnosed individuals.

Background

Human immunodeficiency virus type 2 (HIV-2), a member of the Retroviridae, represents a related but distinct group of infections to HIV-1, the global agent of acquired immunodeficiency syndrome (AIDS). While HIV-2 bears similarity to HIV-1, it represents a separate genetic, virologic, and epidemiologic entity of viruses with marked differences in natural history and disease associations (► [HIV Prevention in the Correctional System](#)). Accurate, reliable diagnosis of HIV-2 infections is important not only from an individual perspective but when considering wider epidemiological and clinical consequences of HIV-2. Differences in HIV-2 biology impact on diagnostic approaches to detect HIV-2, either as monotypic infections or simultaneous dual HIV-1 and HIV-2 infections.

From the initial identification of HIV-2 in the mid-1980s, the disease course and relative pathogenicity of HIV-2 have been much debated although a clearer picture has emerged (► [Natural history and clinical features of HIV-2 infection](#)). HIV-2 is recognized as being less pathogenic than HIV-1, the majority of HIV-2 infections presenting as long-term nonprogressors (LTNP), with up to 80% of all HIV-2 infections falling into this category (de Silva et al. 2008). However, HIV-2 clearly can have severe consequences for a significant minority of individuals leading to profound immunological dysfunction, morbidity, and mortality. Hence, accurate diagnosis of HIV-2 infections is important to ensure blood donations remain HIV-2-free. Similar principles to HIV-1 diagnosis apply, including electron microscopy, direct virus isolation, detection of virus antigens, demonstration of virus-specific antibodies, or identification of components of the viral genome. However, only a proportion may be considered appropriate for HIV-2 diagnosis due to the differing

HIV-2 Diagnosis and Viral Load Measurements, Fig. 1 Phylogenetic relationship between members of the HIV-2/SIVsmm lineage of viruses. The timescale and phylogenetic relationship between different members of the HIV-2/SIVsm lineage are shown as depicted by Lemey et al. (2003) in a study of HIV-2 origins from

sooty mangabey-derived viruses. Different HIV-2 subtypes and sooty mangabey/maaque strains are indicated at the tips of the reconstructed phylogeny. The authors represent numbers at the nodes to indicate the percentage of bootstrap samples (of 1,000) in which the right cluster is supported and only values >80% are shown

biology of HIV-2 in vivo compared to HIV-1. In practice, serological detection with sensitive and specific anti-HIV-2 or HIV-2 antigen detection assays provide a frontline laboratory diagnosis, enriched and augmented by the application of molecular techniques for genome detection.

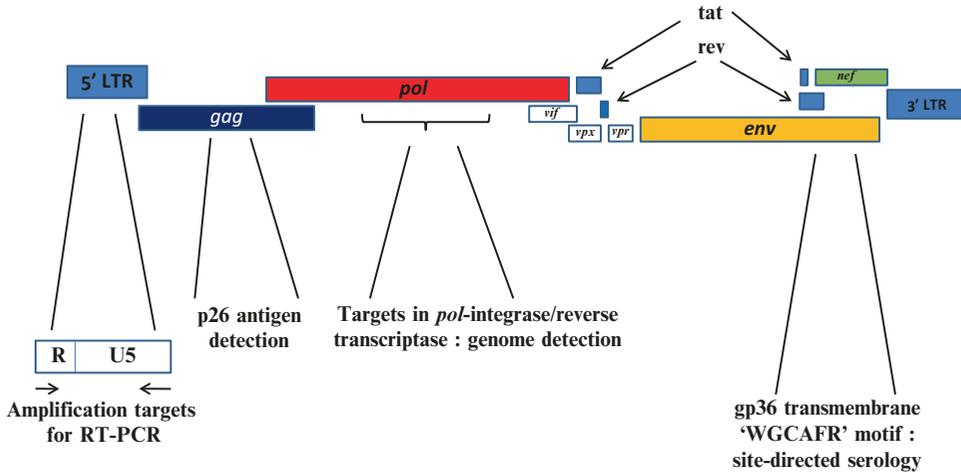

HIV-2 presents a number of particular challenges when effecting a reliable diagnosis, stemming from its evolutionary origins and entry into human populations. One important consideration when identifying diagnostic approaches to virus infection is knowledge of the range and spectrum of the infecting agent; HIV-2 viruses are no exception. Such considerations need to be taken into account when developing diagnostic strategies for HIV-2.

Origins and Diversity of HIV-2

HIV-2 is closely linked to countries of West Africa where it remains endemic, following initial

identification in patients with AIDS-defining symptoms and its recognition as a novel human pathogen (► [Natural history and clinical features of HIV-2 infection](#)). Phylogenetic analyses have confirmed HIV-2 was introduced into humans from Old World primates by multiple cross-species transfers from sooty mangabey monkeys (*Cercocebus torquatus atys*) of SIVsmm viruses (Sharp and Hahn 2011). By comparison, pandemic HIV-1 group M is the result of a single transfer of SIVcpz from the common chimpanzee (*Pan troglodytes troglodytes*). In this key respect, HIV-2 differs markedly from HIV-1 stemming from a different viral lineage which transcends many issues relating to HIV-2 biology, including successful implementation of diagnostic procedures. The phylogenetic relationship between HIV-2 and closely related viruses is depicted in Fig. 1.

Detailed molecular epidemiological and bioinformatics approaches have revealed a broad spectrum of HIV-2/SIVsmm viruses encompassing naturally infected sooty mangabey monkeys in

HIV-2 Diagnosis and Viral Load Measurements, Fig. 2 Genomic structure of the HIV-2 genome highlighting different regions targeted by diagnostic assays. Both coding and noncoding regions provide targets

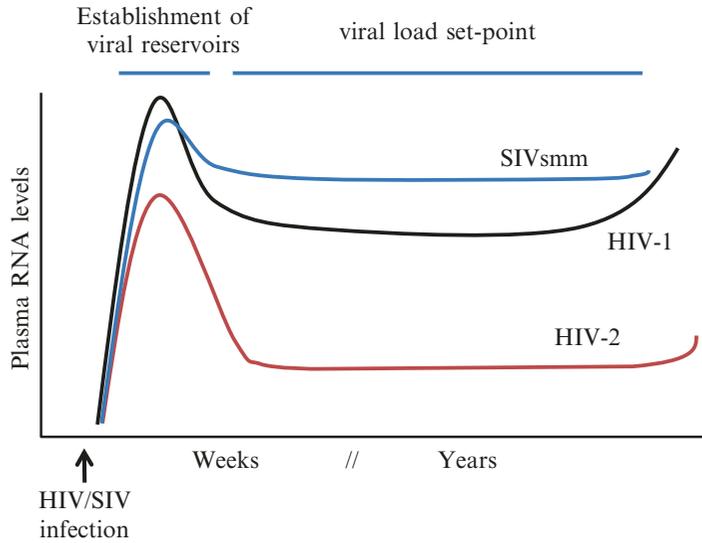

for antibody, antigen, and molecular detection systems where a common feature is the conservation of the genetic sequence or the response to conserved virally encoded epitopes or antigens

equatorial West Africa and at least nine putative HIV-2 subtypes. Each represents an independent transmission event from a reservoir of SIVsmm viruses in the wild, subsequently identified in humans, and highlights the diverse nature of lentivirus infections. However, detection of both clinically important viruses and what might be regarded as obscure, exotic infections is important, to provide a full picture of animal lentiviruses transitioning into human populations and their potential impact on human health.

Genomic Structure of HIV-2

HIV-2 is an exogenous retrovirus represented by two single strands of RNA in a diploid viral genome, encapsulated by retroviral capsid proteins and encompassed by an outer envelope glycoprotein (EGP). Like all retroviruses, HIV-2 undergoes reverse transcription as part of its life cycle. Viral or virion RNA (vRNA) is converted to proviral DNA able to integrate into the host genome. Cell-free vRNA in plasma (or serum) and cell-associated proviral DNA, representing different aspects of the viral life cycle, provide potential for direct viral genome detection in either RNA or DNA form. Virally encoded

proteins which act as targets for host immune responses to infection are also important components of diagnostic algorithms. Figure 2 shows the basic structure of the HIV-2 genome resembling a classical retrovirus *gag-pol-env* structure flanked by two long-terminal repeat (LTR) sequences targeted by antibody, antigen, and genome detection systems. *Gag* encodes group antigens, *pol* viral polymerases (reverse transcriptase, integrase), and *env* the envelope transmembrane (gp36) and external glycoprotein (gp105). Non-coding LTRs, transcriptionally important parts of the viral genome, which do not code for viral proteins, are less susceptible to immunological pressures. Regulatory/accessory genes (*tat*, *rev*, *nef*, *vpx*, *vif*, *vpr*) provide additional targets. Regions within the structural *gag*, *pol*, and/or *env* regions, however, have provided the main focus for serology, although molecular detection systems have employed both coding and noncoding regions to good effect. Highly conserved regions of the 5' R/U5 LTR of genomic RNA, involved in the initiation of reverse transcription in vivo, have provided secure targets for HIV-2/SIVsmm genome detection (Berry et al. 2011). Detailed analysis of HIV-2 molecular structure and properties is covered in the entry ► [Molecular biology of HIV-2](#).

HIV-2 Diagnosis and Viral Load Measurements, Fig. 3 Schematic comparing generalized viral load profiles for HIV-1, HIV-2, and SIVsmm infections during the infection time course. Plasma RNA levels reflecting systemic virus replication characterized by a peak of primary virus replication, as virus is seeded into

multiple lymphoid organs at centralized sites of the body during an exponential growth phase during acute infection. Steady-state plasma RNA levels differ for each virus group with HIV-2 infections having a generally low RNA loads correlating with prolonged survival

Acute Infection

Most HIV-2 infections, like HIV-1, are the result of sexual exposure. Following transmission, most likely at mucosal sites, a burst of virus replication occurs although is less well characterized than for HIV-1. Virus founder populations, limited to a few viral variants established during the first days of infection during an exponential viral growth phase, are preceded by an initial eclipse phase. Increased levels of detectable virus in blood during this acute period may be amenable to diagnosis of recent HIV-2 infection, prior to any form of immunological response. At this time, HIV-2 plasma vRNA is likely to be at its highest during a classical peak viremia although extensive studies of acute HIV-2 infection are lacking. Set-point virus loads, ~ 30 -fold lower than HIV-1, are most likely a direct consequence of a more controlled early viremic phase following primary HIV-2 infection and seroconversion (Andersson et al. 2000).

However, the long-lived nature of HIV-2 infections also stems from early virus dissemination

with establishment of viral reservoirs during this acute period (Fig. 3). HIV-2 infects CD4⁺ T lymphocytes and macrophages eliciting broad immunological responses following initial exposure. Both humoral and cellular responses to major virally encoded gene products occur, although serological responses to viral antigens remaining in the circulation for detection in serum/plasma are critical for viral diagnostic approaches. Hence, although the biology of HIV-2 and HIV-1 infections differs, similarities in general parameters of infection may be applied in a diagnostic setting.

Anti-HIV-2 Detection

Detection of HIV-2 antibody provides a frontline means of initially identifying infection in viral screens. Sensitivity and specificity are central aspects of viral diagnosis, although the nature of cross-reactive epitopes between HIV-1, HIV-2, and SIV makes the choice of viral antigen and assay format critical. Indeed, initial identification of a novel retrovirus in human populations, later

identified as HIV-2, was made with SIVmac viral antigens detecting cross-reactive antibodies to major structural proteins (► [The antibody response to HIV-2](#)), reflecting high levels of antigenic relatedness to HIV-2. It is important to bear this fundamental feature in mind when considering strategies and algorithms for diagnosis and clinical management of HIV-2 infections. Hence, detection of antibodies provides the most robust platform to screen for as many variants as possible within the HIV-2/SIVsmm/SIVmac lineage, irrespective of the originating species. Noninvasive sampling collection techniques may also be applied to identify related retroviruses (Sharp and Hahn 2011).

While the degree of cross-reactivity between HIV-2 and SIVsmm/mac is greater than between HIV-1 and HIV-2, interaction between anti-HIV-2 and anti-HIV-1 is sufficient to obscure accurate serodiagnosis in different circumstances. Responses to virally encoded antigens in *gag* and *pol*, generally more conserved than *env*, which is under greater mutational pressure from the immune system, have frequently resulted in misdiagnoses (Tedder et al. 1988). Specific identification of anti-HIV-2 remains a challenge to many assay systems. One problem of developing diagnostic assays is the need to target conserved epitopes which deliver a consistent antibody response, detectable in all cases. While the HIV-2 EGP (gp105) elicits both binding and neutralizing antibody responses, the transmembrane glycoprotein (gp36) has proved the most reliable platform upon which to base serodiagnoses. Commercially available and “in-house” anti-HIV-2 assays rely principally on the detection of antibody to immunodominant domains within gp36, primarily the WGCAFR motif. This linear epitope universally elicits antibodies of sufficient magnitude and consistency to provide an effective target for site-directed serological assays. Assay specificity has been further improved with synthetic peptides and recombinant antigens, compared to early assays which employed whole viral lysates often in western blot format. However, detecting a monotypic or type-specific response has proved challenging, even when using synthetic peptides to conserved regions. Optimized assays with high

specificity and sensitivity for anti-HIV-2 have often been difficult to achieve; hence, the choice of assay format is important with competition EIAs providing a high level of specificity (Tedder et al. 1988).

Combined HIV-1/HIV-2 assays for antibody and/or antigen are frequently employed in current testing algorithms. However, ability to detect low-level HIV-2 antibody/antigen may cause significant problems in HIV-2 diagnosis, particularly as the HIV-2 limb of any given assay may be suboptimal compared to its HIV-1 counterpart. Hence, ability to specifically diagnose HIV-2 infection may be compromised due to lack of sensitivity. Conversely, some HIV-2 sera remain capable of exhibiting strong cross-reactivity with HIV-1. Where HIV-2 sera are reacted with HIV-1 antigens and vice versa, cross-reactive antibodies to the heterologous virus have frequently been mistaken as evidence of dual HIV-1/HIV-2 infection (► [Dual HIV-1 and HIV-2 infection](#)). Where dual reactivity is present at low levels, distinguishing between the two infections, or identification of a genuine dual infection, may be achieved by serial dilution prior to assay. On the one hand, HIV-2 may be misdiagnosed due to cross-reactive HIV-1 antibodies on HIV-2 antigens. On the other, HIV-2 may be missed since validatory processes for a range of assay methodologies, including combination HIV-1/HIV-2 assays, may be deficient at HIV-2 detection. This raises concern with the introduction of more rapid testing and screening assays without an optimized HIV-2 limb, markedly compromising the ability to diagnose HIV-2 in different settings, either in endemic regions or traditionally low-prevalence countries such as the USA.

A balance also needs to be struck between the speed at which a diagnostic result is obtained with reliability and not poorly diagnose HIV-2 in such situations. Rigorous assay validation with well-characterized panels of reference sera, representative of the target population, is essential to highlight deficiencies in diagnostic tests and detection algorithms. Hence, the application of rapid HIV-2 diagnosis in endemic regions of West Africa raises a significant public health concern particularly where the ability to differentially diagnose HIV

infections in such settings should not be underestimated. As limitations in sensitivity and specificity for HIV-1 are well documented by rapid testing approaches, it raises particular concerns with respect to HIV-2 diagnosis by this approach. Notwithstanding these limitations, application of serological assays as important tools in clinical and epidemiological studies have extended our understanding of the distribution and relationship between primate lentiviruses and their relative impact on human health.

Molecular Diagnosis of HIV-2

While detection of anti-HIV-2 provides the most effective way to screen for HIV-2, detection and/or quantification of HIV-2 genome provides more detailed information to inform clinical decisions and investigate more in-depth epidemiological and virological aspects of HIV-2 infections. HIV-2 molecular diagnosis encompasses direct detection of genome, usually by *in vitro* amplification techniques, as well as investigations into sequence identity and viral phylogeny. HIV-2 exists as a viral quasispecies within infected individuals, where sequence populations of cell-associated provirus DNA or cell-free virion RNA in serum/plasma provide an opportunity to directly identify infection using molecular methods. Application of polymerase-chain reaction (PCR)-based techniques to clinically derived materials has greatly informed our understanding of HIV-2/SIV biology and epidemiology.

Early studies focused on detection and quantification of HIV-2 provirus (Berry et al. 1994; Ariyoshi et al. 1996) by sensitive PCR assays. Selection and application of diagnostically secure oligonucleotide primers is as important for HIV-2 as HIV-1. As full-length sequence became available from eight HIV-2 strains, so a database for prototypic HIV-2 subtype A (e.g., HIV-2_{ROD}, HIV-2_{NIHZ}, HIV-2_{BEN}) and subtype B (HIV-2_{EHO}, HIV-2_{D205}) viruses was established (see <http://www.hiv.lanl.gov>). Sequence comparison with SIVsmm/mac-related viruses enabled design of oligonucleotides to conserved regions, capturing the broad virus variability within the HIV-2/

SIVsm/SIVmac group. Conserved sequences located in *pol* or the LTR frequently provided consistent datasets, although 100% concordance with serological assays has always been difficult to achieve (Berry et al. 1994). This observation provided one of the first clues to the lower abundance of HIV-2 genome within infected individuals since 1–3% individuals confirmed anti-HIV-2 positive remained genome negative.

Amplification of low levels of viral genome, potentially confounded by sequence divergence, is a key consideration when embarking on molecular investigations into HIV-2. Sequence-independent approaches, such as the branched-chain reaction and direct measures of reverse transcriptase activity, may also be applied in such situations, although the ability to reliably detect very low levels of viral genome is a key consideration in HIV-2 genome detection. Sensitive real-time PCR-based assays provide a means of detecting low levels of HIV-2 genome although inherently low viral load is an overriding factor in HIV-2 diagnosis. This also impacts on defining dual infections, since PCR primers designed and optimized for maximal sensitivity to one virus group are likely to be poor at the detection of the other, given the wide genetic diversity of HIV/SIV sequences. The genetic distance between HIV-1 and HIV-2 essentially obfuscates pan HIV-1/HIV-2 detection by molecular assays, given that PCR primers frequently struggle to cope with the genetic variance within the spectrum of HIV-1 group M viruses alone. Hence, specific identification of dual HIV-1 and HIV-2 genomes relies on the ability to detect genomic RNA and/or DNA with assays which focus primarily on one virus family (i.e., HIV-1 or HIV-2) or the other. However, if achieved, molecular detection of monotypic HIV or dual HIV-1/HIV-2 infections provides unambiguous diagnosis, irrespective of serological detection.

Molecular detection of HIV-2 in certain scenarios may be the only means of diagnosing HIV-2, for example, in vertical transmission cases where perinatal or postnatal transmission events may be identified by PCR detection. This circumvents complications of serological diagnosis where passively acquired maternal antibody in

the first 18 months of life may obscure an accurate serodiagnosis. Vertical transmission of HIV-2 is relatively rare, however, frequently characterized by low virus load; hence, even genomic detection may be problematic in such circumstances.

Impact of HIV-2 Subtypes on Diagnostic Assays

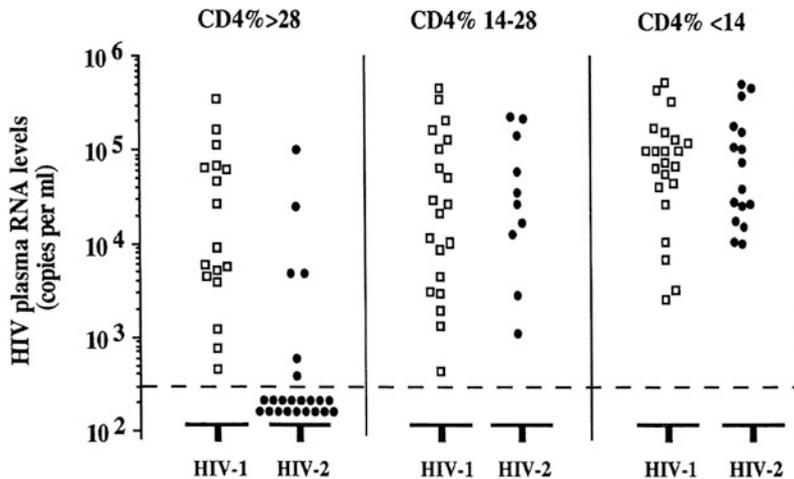

HIV-2 has a more restricted global distribution than HIV-1, both in prevalence and distribution of viral subtypes or genotypes. Only HIV-2 subtypes A and B are epidemically or clinically relevant accounting for the vast majority of HIV-2 cases identified to date. HIV-2 subtype A dominates, thought to have entered human populations in the first part of the twentieth century with estimates of a date for a most recent common ancestor to be 1940 ± 16 years (Lemey et al. 2003). Sequence variance within a single HIV-2 subtype from its estimated time of entry into humans is no greater than the sequence diversity within any single HIV-1 subtype. Hence, the spectrum of genetic variation likely to impact on diagnostic tests for HIV-2 genome is quantifiable and proportionate to the restricted course of the HIV-2 epidemic. As only HIV-2 subtypes A and B have been successful in onward human-human transmission, the focus of diagnostic testing is on these. HIV-2 subtypes A and B both have potential to cause severe lymphopenia and symptomatic disease albeit with differences in localized distribution. HIV-2 subtype B viruses are more closely linked with eastern parts of West Africa, mainly Cote d'Ivoire. The remainder (subtypes C–H) are minimally pathogenic or apathogenic with very low replication potential *in vivo*, considered biological and epidemiological “dead ends,” remaining largely restricted to the specific geographical locales where they were first identified with no onward transmission chain. The phylogeographical impact of HIV-2 has been defined (► [Epidemiology of HIV-2 infection in Europe](#)) relating onward spread to Europe and beyond to be largely attributed to HIV-2 subtype A which predominates in Guinea-Bissau, the country with the highest prevalence of HIV-2

(~8% of the general population). Portugal exhibits the highest prevalence of HIV-2 within Europe.

The development of subtype-specific molecular assays to identify HIV-2 subtypes A and B has delineated the distribution of HIV-2, although the identification of HIV-2 infections *per se* is usually sufficient. Subtype-specific regions in the U3 region of the LTR have been targeted to differentiate HIV-2 subtypes A and B to provide rapid subtyping of the principal HIV-2 subtypes (Berry et al. 2001). While the spectrum of HIV-2 sequence diversity is relatively well characterized, the first HIV-2 CRF (A/B) recombinant form has recently been described. Hence, vigilant monitoring and molecular epidemiological evaluation of circulating HIV-2 viruses will need to be maintained. Novel HIV-2 variants and subtype candidates inevitably impact on HIV-2 diagnosis, given the relatively higher propensity for sooty mangabey viruses to cross into humans leading to a high index of suspicion in regions where SIVsmm is endemic. Hence, the ability for diagnostic assays to detect such variants is always desirable. Ideally, equivalent amplification of all HIV-2 subtypes/clades, including SIVsmm variants, should be sought, achievable by targeting highly conserved regions of the HIV-2/SIVsmm genome (Fig. 2). A lower frequency of recombination events compared to HIV-1, most likely due to the lower replication of HIV-2/related viruses, suggests limited mixing of viral genomes between established viral genotypes. Moreover, rather than sequence diversity *per se*, perhaps the most significant problem facing HIV-2 genome detection is failure to identify low levels of viral genome.

HIV-2 Plasma Viral RNA Load

A major determinant of HIV-1 disease progression which informs clinical management is the level or magnitude of plasma viral load (PVL). With the advent of sensitive molecular assays suitable for measuring genetically diverse HIV, the significance of HIV-2 PVL was investigated in endemic groups in West Africa both in hospital-based studies in urban areas and community-

HIV-2 Diagnosis and Viral Load Measurements, Fig. 4 HIV-1 and HIV-2 RNA levels in a CD4-staged hospital-based cohort. HIV-2 plasma vRNA levels in asymptomatic individuals with a CD4%>28 were below the detection threshold (200 RNA copies/ml) in a high

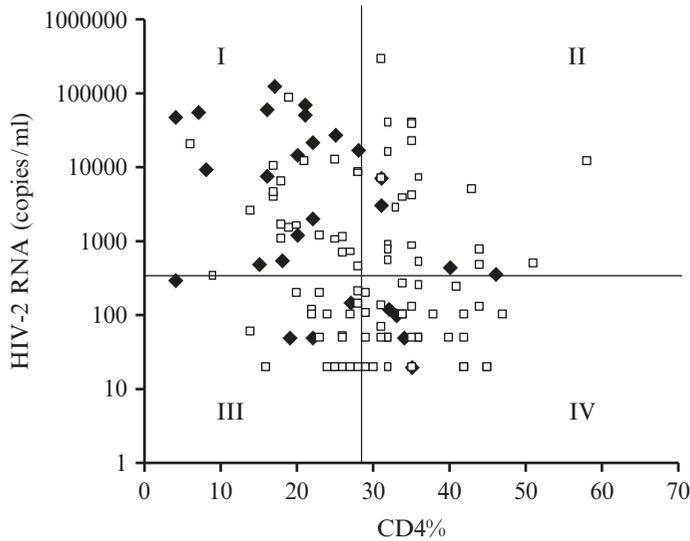

proportion of cases compared to similarly matched HIV-1-infected individuals. In the other CD4 bands, HIV-1 and HIV-2 RNA levels were similar (Reproduced from Berry et al. 1998)

based rural settings. These studies revealed insights into the dynamics of HIV-2 infections on a population basis. Perhaps the single most notable difference between HIV-1 and HIV-2 infections when considering broad distinctions made between the two viruses, their relative pathogenesis, and natural history is the quantity of cell-free virus detectable in the peripheral circulation. Definitively, the level of circulating HIV-2 RNA in peripheral blood during the asymptomatic phase of infection represents one of the largest single factors differentiating HIV-2 from HIV-1 infections in CD4-matched individuals in cross-sectional studies (Berry et al. 1998; Popper et al. 1999). Figure 4 depicts the first report of low HIV-2 RNA levels associated with asymptomatic infection, compared to HIV-1. Low set-point HIV-2 vRNA levels which frequently fall below the detection threshold of sensitive molecular analytical assays represent an underlying feature of HIV-2 infections.

Field-based, community studies of HIV-2 infection have furthered our insight into the long-term effects of HIV-2. A study of HIV-2-infected persons living in Caio, a remote village in northern Guinea-Bissau with an adult prevalence of ~8%, indicated low levels of plasma

viremia and high CD4% to be predictors of normal survival (Berry et al. 2002). Figure 5 compares HIV-2 RNA levels, CD4%, and mortality in this cohort where high levels of HIV-2 RNA broadly correlate with low CD4 and increased mortality. Extended studies of this unique cohort of long-term HIV-2-infection underscore the notion that HIV-2 RNA levels remain stable and largely unchanged over decades of infection (Schim van der Loeff et al. 2010). The net result is a high proportion of HIV-2-infected villagers who survive unaffected by HIV-2, essentially life-long, characterized by 2–3-fold excess mortality in HIV-2-infected subjects compared to age-matched uninfected villagers.

Low HIV-2 RNA load and by corollary high CD4 over many years of infection demonstrate humans can live for prolonged periods with a potentially lethal lentivirus and represent genuine cases of long-term survivors where natural life expectancy will be greater than the time taken to progress to life-threatening illness. Plasma viremia is frequently low, in the 100–1,000 RNA copies/ml range or undetectable (<50 HIV-2 RNA copies/ml). Such low levels of HIV-2 viremia present particular challenges to HIV-2 genome detection systems where <50 HIV-2

HIV-2 Diagnosis and Viral Load Measurements, Fig. 5 Plasma viral load in a community setting. HIV-2 plasma RNA levels and CD4% in 122 HIV-2-infected persons from the Caio village in northern Guinea-Bissau, taken at the 1991 baseline bleed. Stratified

according to median and mean values for HIV-2 RNA and CD4%, a high proportion of deaths (*solid symbols*) are represented in the high RNA, low CD4 grouping. In contrast, deaths were uncommon in the high CD4, low RNA group (Reproduced from Berry et al. 2002)

H

RNA copies/ml or genome equivalents are not uncommon. While below any theoretical threshold required to lead to HIV disease, there would appear to be a balance between low virus replication and a more stable virus-host relationship enabling prolonged periods without extensive or overt pathology. Low vRNA levels and low viral replication represent improved chances of survival with baseline HIV-2 RNA levels providing an independent marker for disease progression during the asymptomatic period (Berry et al. 2002; Schim van der Loeff et al. 2010). However, the predictive power of HIV-2 RNA is reduced during the latter stages of infection when CD4 is the better indicator (Ariyoshi 2000).

In HIV-2 infections, as with HIV-1, the overall inverse correlation between plasma HIV-2 RNA levels and CD4 count indicates increased viral load reflects loss of immunological integrity in the host. In individuals where CD4 counts are low, levels of plasma viral RNA are often similar to HIV-1. Different studies indicate HIV infection levels, reflected in the PVL or vRNA concentration, irrespective of virus type (HIV-1, HIV-2, or dual infection) to be the most important factor

influencing disease progression (Gottlieb et al. 2002). High HIV-2 RNA levels identify those at most risk of disease and poorer outcome. However, the dynamics of HIV-2 infections in vivo remain understudied compared to HIV-1 where high turnover of virus and CD4+ lymphocyte subsets are compatible with an accelerated phenotype in vivo. Comparable studies of HIV-2 turnover are lacking though one preliminary study indicates HIV-2 to have a similar rate of production and clearance to HIV-1, although it is possible that turnover may differ at different disease stages.

The availability of reference materials for HIV-2 RNA testing has also advanced in recent years with collaborative studies improving efforts to accurately measure HIV-2 viral load (Damond et al. 2008), particularly discrepancies in relative detection efficiency of HIV-2 subtype B. Availability of an international standard for HIV-2 RNA to augment standardization and control testing for HIV-2 RNA (Holmes et al. 2011), particularly in light of lack of commercially available assays for HIV-2 RNA detection/quantification, should further improve HIV-2 diagnostic testing. However, it is not mandatory to test for

HIV-2 genome in many countries, including the USA. One additional caveat is the focus to date on HIV-2 subtype A with a need to characterize the range of HIV-2 subtype B sequence diversity and design appropriate assays to maximize detection of both HIV-2 subtypes A and B.

Intracellular Virus Detection and Viral Reservoirs

As HIV-2 plasma viral load is frequently very low, so characterization of cell-associated measures of virus infection assumes greater significance. Similar accumulations of proviral DNA, comparable at matched CDC stages of HIV-1 and HIV-2 infections, have been observed, yet HIV-1 and HIV-2 RNA levels differ during asymptomatic infection (Berry et al. 1998; Popper et al. 1999). The nature of cellular HIV-2 proviral populations and distribution of HIV-2 in different cell subsets *in vivo*, however, remains poorly studied, particularly relative proportions of integrated and unintegrated provirus. Despite a lower viral burst and lower systemic virus levels, HIV-2 seems capable of establishing disseminated virus reservoirs of HIV-2-infected cells, akin to HIV-1. Low transcriptional activity is compatible with low HIV-2 viremia and low burden of HIV-2-infected cells. Studies of quantification of unspliced and multiply spliced mRNA in HIV-2 infection are also scarce, although distinct mRNA species presented as unspliced (full length), partially spliced, or multiply spliced mRNA where unspliced mRNA also serves as genomic viral RNA have been described (MacNeil et al. 2007). The characterization of low-level mRNA transcripts in clinically derived materials suggests this may provide a more direct, sensitive means of detecting HIV-2 genomes in clinical samples. While low virus levels correlate with a low adverse impact on health, long-term effects of continuous, low virus turnover may not be completely benign. HIV-2 infects cells of the monocyte/macrophage lineage, which influence viral tropism for particular reservoirs of the body, including possible neurological complications. The long-term impact of HIV-2 on the brain and neurological

dysfunction is not fully understood, but studies suggest this might be the case (► [HIV-2 Neurological Manifestations](#)).

Moreover, the relatively low impact of HIV-2 infections with controlled viremia reflects lack of high intracellular virus replication in lymphoid organs and tissues. However, in individuals with undetectable plasma viremia and no demonstrable *in vivo* virus production, it is still possible to demonstrate replication-competent virus in peripheral blood using optimized HIV coculture protocols (Blaak et al. 2004). Low HIV-2 genome levels in these individuals may therefore not merely be composed of defective, non-replication-competent virus but cells containing very low levels of replication-competent virus. This low intrinsic replicative capacity of asymptomatic HIV-2 infections, with low peripheral viremia, underlies the distinct pathobiology of HIV-2 infections. This may be important when considering continuous stimulation of immunological responses at subthreshold levels and contribute to the better virus/host balance which seems to prevail in the majority of HIV-2 infections. While HIV-2 activity and the presence of different viral molecular species can be identified, it is the lack of high levels of productive infection which is the hallmark of the vast majority of HIV-2 infections.

Biological Significance of Low Viral Load

Comparative viral fitness studies have shown HIV-2 to be ~100-fold less fit than HIV-1 group M, though exhibit greater relative replicative capacity than HIV-1 group O. This broadly reflects the severity of the distinct human epidemics attributed to each virus group. Marked reductions in replication efficiency and transmission fitness have far reaching effects on the spread of HIV-2. This would seem to be a direct correlate of low viral burden and a key denominator of disease progression and transmission (► [HIV-2 Transmission](#)). HIV-2 is 5–10-fold less transmissible than HIV-1 between males and females and 20–30-fold lower from mother to child, explained by lower maternal HIV-2 PVL. Lower HIV-2

shedding than HIV-1 in female genital secretions and low seminal HIV-2 levels reflect overall low plasma vRNA loads. Taken together, these measures of low viral burden and shedding are a central feature of the reduced transmissibility of HIV-2 infections leading to a contraction in the HIV-2 epidemic.

Linked with prolonged long-term non-progression and survival, epidemiological data also suggest there are subsets of lifelong survivors with HIV-2. Although difficult to address definitively, survivors alive today in the 60–80 years age range may belong to the same birth cohort as those more susceptible to HIV-2 disease who have long since died. In this respect, can those remaining alive be viewed not merely as one part of a virological spectrum but as a unique subset, where measures of viral control is the central tenet of this survival status? Even this scenario would be quite distinct from naturally occurring, apathogenic SIV_{smm} infections in sooty mangabey monkeys, paradoxically typified by high plasma viral load frequently in the 10^6 – 10^8 SIV RNA copies/ml range (Fig. 3). Such levels for HIV-1 or HIV-2 represent uncontrolled virus replication compatible with a disease-progressing phenotype further characterized by systemic immune activation. In this key respect of viral measures, HIV-2 more closely resembles HIV-1, despite being the consequence of a different transmission lineage but presenting with an asymptomatic phenotype of low HIV-2 viral load. This alone marks HIV-2 as being distinct from either asymptomatic HIV-1 or natural SIV_{smm} infections where different scenarios of virus handling exist *in vivo*.

Impact of Virological and Host Factors on Viral Load

The inevitable interplay between virus and host will influence the ultimate outcome of HIV-2 infections where both viral and host genetic factors play a role in determining replication parameters and hence impact on viral load *in vivo*. Virological factors which influence virion output are crucial. HIV-2 LTR structure and differential

mRNA gene expression may be important determinants of cell-type specificity, HIV-2 transcriptional regulation, and viral integration. Differences in packaging and encapsidation of the viral genome are another feature of HIV-2 biology which may impact on viral output. Natural variation in *nef* gene sequence has been linked with low virus load in a cohort of Portuguese subjects (Padua et al. 2003). Minimal PxxP polyproline residues which correlate with low plasma viral load and asymptomatic infection suggest immunological receptor signaling differs according to disease stage. Recent advances in basic cell and molecular virology have identified novel classes of host restriction factors which act as broad inhibitors of retroviral replication, part of the innate response to infection. HIV-2 capsid interactions with TRIM5 α (tripartite motif), which acts as a postentry block to reverse transcription, relate to differences in HIV-2 viral load (► [Interactions between HIV-2 and host restriction factors](#)). Whether these changes represent cause or effect is unclear but highlights potential interactions between virus and host which may influence virus levels. APOBEC3G (A3G), a cytidine deaminase and RNA-editing enzyme which inhibits positive strand synthesis during reverse transcription, antagonized by the viral accessory gene *vif*, may also be active in limiting HIV-2 transmission. Interestingly, the identification of HIV-2_{F0784} in a Liberian rubber plantation worker (see Fig. 1) as the first definitive example of cross-species transmission of sooty mangabey SIV_{smm} to a human was noted for high levels of G>A hypermutation, a hallmark of A3G activity. Aspects of innate immunity which contribute to low set-point virus loads and a better virus/host balance may be key to understanding the prolonged outcome of HIV-2 infections.

Broader differences in host HLA genotypes and non-HLA genetic polymorphisms influencing HIV-2 disease progression and genetic predisposition of an individual to resistance or susceptibility to HIV disease progression represent further factors (► [Immunogenetics of HIV-2](#)). Identifying single measures or multiple factors which contribute to low plasma viral load *in vivo* is an important area which may reveal novel correlates of survival

or disease progression and inform novel areas of treatment or vaccination approaches. It is likely that a complex interplay between innate and adaptive immune responses and host genetics impacts on virus load.

Conclusion

Diagnosis of HIV-2 infections represents an important part of understanding the impact of this potentially AIDS-causing virus on human health, both at an individual level but also in broader comparative pathogenesis studies of human lentivirus infection. HIV-2 may be regarded as part of a spectrum of primate immunodeficiency viruses for which accurate identification of the infecting agent is the cornerstone of subsequent virological, clinical, and epidemiological studies. Sensitive and specific serological, molecular, and virological techniques are essential to properly diagnose HIV-2. The characterization of the differential viral dynamics of HIV-2 compared to HIV-1 and closely related simian viruses has illuminated our understanding of this enigmatic human pathogen.

Definition

The HIV-2 envelope is composed of trimers of gp125 and gp36, two heavily glycosylated proteins that are linked by noncovalent bonds and embedded in a lipid bilayer whose source is the host cell cytoplasmic membrane. The surface gp125 mediates the initial steps in the virus cycle binding to cellular CD4 and/or to chemokine receptors. The transmembrane gp36 mediates virus-to-cell fusion, participates in the assembly of new viruses, and counteracts the activity of

tetherin, enabling the release of new virus particles. HIV-2 Env of R5 isolates are intrinsically more sensitive to neutralizing antibodies than HIV-1. HIV-2 tropism and sensitivity to antibody neutralization are determined by the sequence, size, and conformation of the V3 loop. The evolutionary rate of HIV-2 gp125 (and the V3 region) is significantly higher than that of HIV-1 gp120.

Envelope Biogenesis

HIV-2 (► [HIV-1 Maturation](#); Tetherin Signaling) is a spherical enveloped virus (► [HIV-1 Maturation](#)) with a diameter of approximately 110 nm. The HIV-2 envelope is encoded by the *env* gene and consists of a lipid bilayer containing a transmembrane glycoprotein of 36 KDa (gp36) which anchors an outer surface glycoprotein with 125 KDa (gp125). In the mature HIV-2 virion, these heterodimers associate as trimers (gp125₃/gp36₃). In the infected cell, HIV-2 envelope glycoproteins are produced as a 97 KDa polyprotein by translation of a single-spliced mRNA in ribosomes bound to the endoplasmic reticulum. Glycosylation occurs in the Golgi apparatus on its way to the cell surface and results in a 140 KDa protein (gp140). Gp140 assembles in trimers and is cleaved by furin in the *trans* Golgi into gp125 and gp36 which remain linked by noncovalent bonds. The cleavage positions the fusion peptide at the N-terminus of gp36 and primes the spike for fusion activation. The trimeric envelope complex is transported to the cytoplasmic membrane where the assembly of the viral particles takes place. Release of the new virus particles occurs by budding from the cell membrane. Virus release can be inhibited by tetherin (► [HIV-1 Maturation](#)), a B-cell antigen that is an effector of the interferon-induced antiviral response. Tetherin presumably tethers the nascent virions to the cell surface. In HIV-1 tetherin is antagonized by Vpu. In HIV-2 tetherin is antagonized by the Env gp36. Tetherin binds specifically to the gp36 ectodomain and is subsequently downregulated from the cell surface and sequestered intracellularly in a perinuclear compartment that includes the trans-Golgi network (Hauser et al. 2010).

Envelope Structure and Function

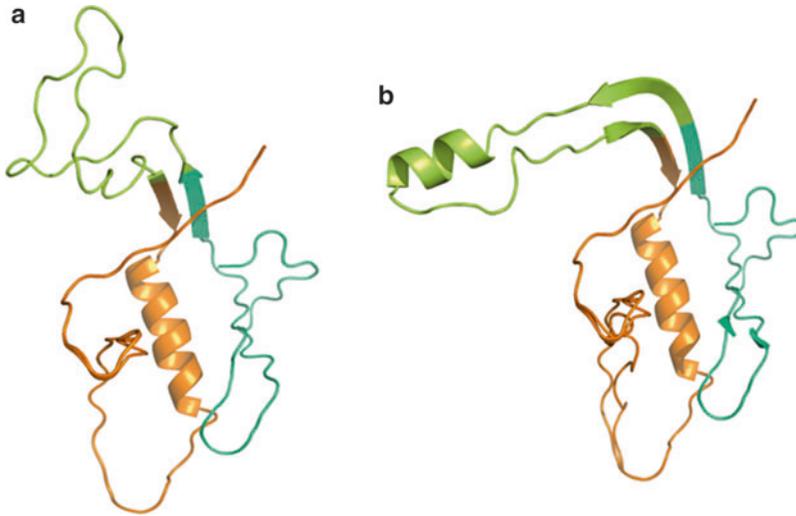

HIV-2 gp125 is a 501–515 amino acid long glycoprotein that is composed of five hypervariable regions named V1 to V5 separated by five more conserved regions named C1 to C5 (NH₂-C1-V1-V2-C2-V3-C3-V4-C4-V5-C5-COOH). In the envelope complex, gp125 binds to the CD4 receptor (► [HIV & SIV, CD8 T Cell Responses](#) to) (HIV main receptor) present in the surface of the host cells (T lymphocytes, monocytes, macrophages, and dendritic cells). The CD4-binding site in gp125 comprises selected amino acids in the relatively conserved C2, C3, and C4 regions as well as in V4. CD4 binding is thought to induce major conformational changes in gp125 and exposure of the coreceptor binding site (mostly comprising the V3 loop). In vivo, the major HIV-2 coreceptors are the chemokine receptors CCR5 and CXCR4 although some HIV-2 isolates from patients in late-stage disease can also use additional chemokine receptors (e.g., CCR1, CCR2b, CCR3, CCR4, Bob, and Bonzo) to enter cells. V3 loop charge and size influence coreceptor interaction such that increasing its size by 1–3 amino acids and charge by the presence of positively charged residues (R, K, or H) at positions 18, 19, and 27 is strongly correlated with CXCR4 usage (Shi et al. 2005; Visseaux et al. 2011). Based on these observations, new computational tools are currently being developed to infer coreceptor use and susceptibility of HIV-2 isolates to CCR5-antagonists such as maraviroc. Increasing the number of HIV-2 env sequences with known coreceptor usage will be crucial to assure that these prediction tools achieve similar performances for HIV-2 as they have achieved for HIV-1.

In primary isolates the size of the transmembrane glycoprotein gp36 varies between 343 and 354 amino acid residues. It has one extracellular domain, one transmembrane region, and one intracytoplasmic domain. The ectodomain starts with the N-terminal fusion peptide, which is highly conserved and hydrophobic in nature. The most conserved region in the fusion peptide is the hydrophobic core Phe₅₁₂-Val₅₁₃-Leu₅₁₄-Gly₅₁₅. Increasing the hydrophilicity of this

region by a single amino acid substitution in the hydrophobic core (Val₅₁₃ for Glu) has been shown to abolish HIV-2 fusion. The fusion peptide is followed by two α -helices containing leucine zipper-like motifs, the heptad repeats 1 (HR1, positions 558–586 in the ROD isolate) and 2 (HR2, positions 755–776). Between these two regions lies the immunodominant region (position 595–603) which contains two cysteine residues involved in a disulfide bond. All HIV-2-infected individuals produce IgG antibodies directed to this highly antigenic region (Marcelino et al. 2008). Within the immunodominant domain is the highly conserved Ala residue at position 598 that has been found to determine tetherin recognition by gp36. Despite the high conservation of the Ala₅₉₈ residue in HIV-2 isolates, not all envelope proteins downregulate tetherin, suggesting that other regions in the gp36 ectodomain might also contribute toward this recognition function.

The transmembrane region (positions 677–700) of gp36 is a highly hydrophobic region with a predominant α -helical content. Its main function is to insert and retain the envelope complex in the cell membrane. The intracytoplasmic domain has an average of 152 amino acids in primary HIV-2 isolates. It mediates the binding of the envelope to the matrix protein during the maturation of new viral particles. A membrane-proximal glycine-tyrosine-X-X-hydrophobic (G₇₀₆Tyr₇₀₇X₇₀₈X₇₀₉ θ ₇₁₀) motif acts to recruit adaptor protein complex 2 (AP-2) which is responsible for the endocytosis and intracellular sequestration of tetherin. In T-cell line-adapted isolates, this region is usually truncated to 138–146 amino acids (MW 32–34 KDa). This truncation has been associated with increased cytopathogenicity in some HIV-2 isolates.

Binding of gp125 to CD4 and coreceptor leads to major conformational changes in the gp36 ectodomain that result in the insertion of the fusion peptide into the host cell membrane. Then, the HR2 trimer folds back on an antiparallel fashion toward the HR1 trimer, forming a six-helix bundle structure stabilized by the hydrophobic interactions between the HR1 domains in the center (central coiled coil) and the HR2

HIV-2 Envelope: Structure, Diversity, and Evolution, Fig. 1 Secondary structures of C2-V3-C3 envelope region from R5 and X4 HIV-2 primary isolates. Secondary structures were determined by homology modeling using the 3-D structure of an unliganded SIV gp120 envelope glycoprotein as template. (a) Representative structure of the C2-V3-C3 envelope region from R5 isolates.

(b) Representative structure of the C2-V3-C3 envelope region from X4 isolates. The V3 loop of R5 isolates is characterized by absence or low amounts of regular secondary structural elements. In contrast, the V3 loop structure of X4 isolates fit into a β - α - β motif characterized by high β -sheet content

H

domains outside. This process brings together the viral envelope and the cell membrane which leads to the formation of a fusion pore through which the viral capsid enters the target cell. Formation of the six-helix bundle structure and subsequent fusion events can be inhibited in HIV-2 by HR2-like peptides that bind to HR1 (e.g., T-1249 and P3) (Borrego et al. 2012).

Binding to CD4 also leads to major conformational changes in gp125 and exposure of the coreceptor binding site (V3 loop). The rate at which the V3 loop becomes exposed after CD4 binding is faster in gp125 than in HIV-1 which promotes a faster Env-mediated fusion in HIV-2 (Gallo et al. 2006). However, it has been shown that, in contrast to HIV-1, CD4 binding may not be a prerequisite for HIV-2 cell entry as several primary isolates have the ability to infect cells via CCR5 and CXCR4 independently of CD4 (Reeves et al. 1999). This suggests that HIV-2 gp125 in its native trimeric state may be more prone to adopt spontaneously a CD4-bound conformation than HIV-1 gp120. As the CD4-bound state of gp125 is a functionally critical state, this

would predict HIV-2 to be highly vulnerable to neutralizing antibodies. In fact, in contrast to HIV-1, most HIV-2 R5 isolates are effectively neutralized by IgG antibodies from HIV-2-infected individuals (plasma or monoclonal antibodies) (de Silva et al. 2012). These antibodies are directed to the CD4 binding site, as well as to V2, V3 (likely to a conformational epitope comprising amino acids Phe-His-Ser-Gln in positions 315–318 and Trp-Cys-Arg in positions 329–331), and V4 (de Silva et al. 2012; Kong et al. 2012). However, X4 isolates such as the reference ROD strain and primary strains that emerge late in infection in some HIV-2 patients with low CD4 counts are highly resistant to antibody neutralization (Marcelino et al. 2012). The V3 loop conformation of X4 and R5 HIV-2 isolates are markedly different, supporting a direct role of this region in the different susceptibility of these viruses to antibody neutralization (Fig. 1). Differences in V3 loop conformation may also explain the higher maraviroc and TAK779 resistance of R5 isolates obtained from late-stage disease HIV-2 patients (Borrego et al. 2012). Interestingly, the fusion inhibitor

T-1249 is more active against X4 isolates than R5 isolates, suggesting that significant conformational changes might also occur in gp36 in advanced HIV-2 infection (Borrego et al. 2012). In summary, in the native envelope complex, the gp125 glycoprotein from R5 isolates seems to be in a CD4-bound conformation more often than HIV-1 gp120, and this may determine a higher susceptibility of HIV-2 to antibody neutralization. However, conformational changes in the V3 loop and gp36 occurring in late-stage disease might reverse this neutralization-sensitive phenotype and change the susceptibility of HIV-2 to entry inhibitors.

Diversity and Evolution

The HIV-2 envelope gene is characterized by high genetic diversity and high rate of molecular evolution. HIV-2 has diversified into 8 phylogenetic groups named A to H and one circulating recombinant form CRF01_AB that results from the recombination of the A and B isolates. Average envelope amino acid diversity between all HIV-2 groups is 23% and between isolates belonging to the most prevalent groups A and B is 14% and 17%, respectively. Diversity is higher in gp125 than in gp36 (20% vs. 14% in group A), which is likely to be related to the greater immunologic pressure that is exerted on gp125. Within gp125, the V3 region has been shown to be highly immunogenic and antigenic, to determine cell tropism, and to have immune modulatory properties (Visseaux et al. 2011; Marcelino et al. 2008, 2010). The multiple functional roles of HIV-2 V3 might explain its relatively low inter-patient amino acid diversity when compared to HIV-1.

The mean within-host *env* nucleotide diversity in patients with chronic infection is 2.1% (SD, 1.1%), increasing along the course of infection in most patients (Borrego et al. 2008). The genetic diversity of the HIV-2 *env* gene may be directly related to the period of infection even in the absence of plasma viremia or disease progression (Borrego et al. 2008; Barroso & Taveira 2005; MacNeil et al. 2007). However, some longitudinal studies have shown that higher variability in the V3 region is generally found in patients with

faster disease progression to AIDS and that in elite controllers (patients infected for ≈ 10 years with normal CD4+ T-cell counts without antiretroviral therapy and with low or undetectable viral load), the rate of *env* gene diversification is positively associated with the rate of CD4+ T-cell number decline (MacNeil et al. 2007).

Remarkably, it has been shown that the within-patient mean evolutionary rate of HIV-2 may be significantly higher than the rate of HIV-1, both in the gp125 (10.15×10^{-3} vs. 6.36×10^{-3} substitutions per site per year) and in the V3 region (29.37×10^{-3} vs. 12.26×10^{-3} substitutions per site per year) (Skar et al. 2010). Nonsynonymous sites evolve at a significantly lower rate than the synonymous sites in gp125, indicating that the higher evolutionary rate in the *env* gene in chronically HIV-2-infected patients is more likely to be related to a shorter generation time or higher mutation rate than to escape from immunological pressure. Indeed, other lines of evidence seem to rule out immunological pressure as the main driver of the high evolutionary rate of the HIV-2 *env* gene at least in chronically infected patients. Firstly, the HIV-2 envelope gene is globally under negative (purifying) selection, and the number and position of the few positively selected sites is usually highly variable. Secondly, the number and position of N-glycosylation sites in the *env* gene is usually highly conserved in HIV-2 patients along the course of infection. In HIV-1, variation in the number and position of N-linked glycosylation sites has been associated with more or less sensitivity to neutralizing antibodies. Thirdly, it has been found that variation of C2-V3-C3-specific IgG response over time in HIV-2-infected patients is inversely associated with the variation in nucleotide and amino acid diversity of the C2-V3-C3 envelope regions (Borrego et al. 2008). However, recent evidence indicates that some R5 isolates and most X4 isolates that emerge in patients with advanced disease and low CD4 counts can escape antibody neutralization. Higher sequence diversity and variation in putative glycosylation sites has been associated with higher resistance of HIV-2 R5 isolates to neutralizing antibodies (de Silva et al. 2012). Resistance to antibody neutralization in X4 isolates has been

associated with longer and higher-charged V3 loops compared to neutralization-sensitive R5 isolates as well as with major V3 loop conformational changes (Marcelino et al. 2012). Hence, neutralizing antibodies may play a central role in HIV-2 *env* evolution in a subset of patients with advanced disease and declining CD4 counts. In contrast to HIV-1, little is known about the neutralizing antibody response and the molecular evolution of the HIV-2 *env* gene in acute and early infection because the vast majority of HIV-2 patients are diagnosed many years after the original infection when the chronic phase is already established.

Conclusion

Biochemical, virological, and computer modeling data suggest that the HIV-2 envelope gp125 is in a CD4-bound conformation (open conformation) more often than HIV-1 and that the conformation of the V3 region differs significantly in R5 and X4 isolates. This is likely to explain the opposing susceptibilities of R5 and X4 HIV-2 isolates to neutralizing antibodies. Atomic or near-atomic-level structural models of the HIV-2 Env bound and unbound to CD4 and to neutralizing antibodies are urgently required to fully understand how gp125 interacts with these molecules and how this interaction affects the structure of the HIV-2 Env. This will be vital for the identification of neutralizing epitopes and subsequent development of an effective HIV-2 vaccine.

The determinants of the rapid evolutionary rate of HIV-2 gp125 are currently unknown. Escape from neutralizing antibodies plays a central role in the molecular and phenotypic evolution of the HIV-2 *env* in a subset of patients in late-stage disease, but it does not explain the rapid Env evolution in most chronic HIV-2 patients. Further research is needed on the molecular, structural, and functional evolution of the HIV-2 *env* gene in chronic as well as in acutely infected adult patients and/or children infected via vertical transmission as this will contribute crucially to a better understanding of the interplay between the virus, the host cell, and the immune response.

HIV-2 Infection in Europe, Epidemiology of

Ana Cláudia Miranda and Kamal Mansinho
Serviço de Infeciologia e Medicina Tropical,
Hospital de Egas Moniz, Centro Hospitalar de
Lisboa Ocidental, E.P.E., Lisbon, Portugal

Definition

The incidence of HIV-2 infection shows signs of decline in the endemic regions of West Central Africa, while HIV-1 infection continues its pandemic global spread (Silva et al. 2008).

The HIV-2 epidemic remains largely confined to West Africa, where it peaked in prevalence in the 1970s and 1980s, with an epicenter in and around Guinea Bissau (Fig. 1).

The processes of globalization and migrant population mobility have contributed to and will continue to facilitate the spread of HIV-2 into European nations and other parts of the world.

In Europe, the countries with highest recorded prevalence of HIV-2 infection are those that share

historical, cultural, and economic relationships with the endemic West African countries, mainly represented by Portugal, France, and Spain.

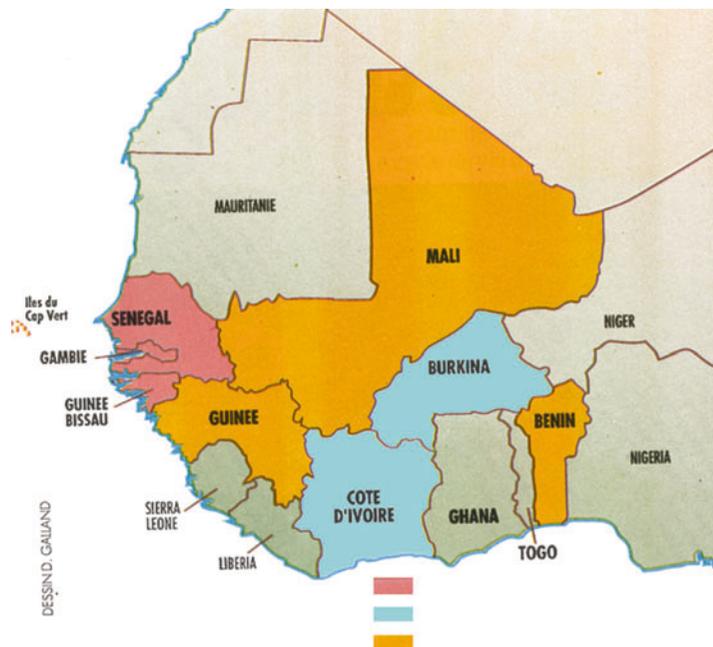

Previous estimates suggested that an estimated 1–2 million people were infected with HIV-2, but there are no data for the past two decades. Accurate data on HIV-2 prevalence would be very valuable in estimating the current burden of infection and identifying potential areas of increased transmission.

HIV Agents: Differences and Similarities

Acquired human deficiency syndrome (AIDS) results from the infection by two closely related viruses, members of the *Retroviridae* family and Lentivirus genus, HIV type 1 (HIV-1) responsible for the pandemic spread and HIV type 2 (HIV-2) mostly confined to some West African countries.

Both viruses share about 40% nucleotide sequence homology, the same life cycle, cellular targets, transmission routes (sexual, vertical, and blood-borne exposure), and pathogenic behavior that lead to chronic debilitating disease (Bock and Markovitz 2001).

HIV-2 Infection in Europe, Epidemiology of, Fig. 1 HIV-2 infection prevalence in West Africa: *Pink* areas: HIV-2 predominant; *Blue* areas: HIV-2 and HIV-1 in the same proportion; *Yellow* areas: HIV-2 less frequent (Caroline D et al. Science et vie 1992;179:38–41)

HIV infection is responsible for chronic inflammation and persistent immune activation which promotes progressive immunological dysfunction and exhaustion.

Natural History of Infection

The natural history of HIV infection is characterized by three stages: primary or acute infection, the asymptomatic stage, and AIDS, when opportunistic infections and tumors develop, reflecting a severely compromised immune system.

HIV-2 infection shows markedly lower transmission rates, slower immunologic depletion, and disease progression, with a prolonged asymptomatic stage and reduced mortality rates, compared with HIV-1 infection.

While the majority of untreated HIV-1 infected individuals progress to AIDS, only 20–30% of HIV-2 infected persons develop symptomatic disease in the same way as HIV-1 (Esbjornsson et al. 2012). An unusually high proportion of HIV-2 infected patients present as long-term non-progressors (LTNP), exhibiting a slower CD4⁺ T-lymphocyte decline and lower or undetectable plasma viral load and survival rates similar to the general noninfected population.

Since HIV-2 plasma RNA is frequently undetectable, disease monitoring is essentially based on clinical and immunological parameters, such as CD4⁺ and CD8⁺ T-cell counts, and levels of inflammatory markers, such as β_2 microglobulin.

Treatment options and the choice of antiretroviral regimens are limited by the fact that HIV-2 strains are intrinsically resistant to nonnucleoside reverse transcriptase inhibitors (NNRTIs) and to first generation fusion inhibitors (enfuvirtide) and are less susceptible in vitro to some protease inhibitors (atazanavir, amprenavir) (see chapter “► Antiretroviral Therapy and Drug Resistance in HIV-2 Infection”).

HIV Origin, Human Adaptation, and Dissemination

Phylogenetic studies have shown that both HIV-1 and HIV-2 evolved after multiple cross-species

transmissions of Simian Immunodeficiency Virus (SIV) that naturally infected African primates and which, subsequently, spread to humans (Hahn et al. 2000).

The two different types of HIV derive from distinct simian species: HIV-1 from SIV_{cpz} (chimpanzee) and HIV-2 from SIV_{sm} (sooty mangabey – *Cercocebus torquatus atys*) (Sharp and Hahn 2011). HIV-2 presents a high genetic sequence homology (~75%) with SIV_{sm} and only about 40% with HIV-1 (Bock and Markovitz 2001; Markovitz 1993).

SIV_{sm} was found to be highly prevalent in rural areas of West Africa, affecting sooty mangabeys both in captivity and the wild, but infection is not usually associated with the development of disease in its natural host.

The way humans became infected with these simian viral precursors of HIV is not known, but it is thought that transmission must have occurred after cutaneous or mucous membrane exposure during hunting practices, preparing bushmeat, or by maintaining wild animals in captivity as domestic pets. Nevertheless, the genetic similarities, phylogenetic evolution, geographic coincidence, prevalence of infection in natural hosts, and plausible routes of transmission together strongly support the evidence for zoonotic transmission of SIV into humans.

Extended viral replication and accumulation of mutations presumably permitted viral adaptation to the human host, and social circumstances such as the expansion of urban centers, population migration, increases in the prevalence of sexually transmitted infections, and large scale vaccination campaigns, all present in West Africa during the twentieth century, probably contributed to HIV-1 and HIV-2 adaptation and dissemination.

HIV-2 was first described in 1986 in isolates from West African patients, where it is currently endemic and seems to have been present before the 1960s (Clavel et al. 1987; Markovitz 1993; Peeters et al. 2013).

Since its first description, eight different lineages of HIV-2 have been identified and termed as group A to H, although only groups A and B are considered epidemic subtypes and have spread between humans to a significant degree (Lemey

et al. 2003). Group A is found mainly in West Africa and group B predominates in Ivory Coast and Mali (Sharp and Hahn 2011). The remaining six nonepidemic groups (C-H) were anecdotally found in single patients, assuming incidental infection with very limited or no secondary transmission.

HIV-2 Epidemiological Distribution

The African endemic areas of HIV-2 infection are Guinea Bissau, the country that recorded the highest HIV-2 prevalence in the 1980s, Senegal, Cape Verde, Ivory Coast, Gambia, Mali, Sierra Leone, Nigeria, Benin, Burkina Faso, Ghana, Liberia, Angola, Mozambique, and Sao Tome (Bock and Markovitz 2001).

In the late 1980s, some of these countries reported a prevalence above 1% of the national population, leading to the estimate of 1–2 million HIV-2 infected people living in West Africa.

In recent years, HIV-2 prevalence is reported to be declining in several African countries, especially among younger individuals. For instance, in a rural area of Guinea Bissau, the prevalence declined from 8.3% in 1990 to 4.7% in 2000; however, HIV-1 prevalence increased in the same population from 0.5% to 3.6% over the same period (Campbell-Yesufu and Gandhi 2011).

Additionally, in endemic West African regions 0.3–1% of patients with HIV infection are considered to be concomitantly infected (dual infection) with both HIV-1 and HIV-2 (Barin et al. 2007; Esbjornsson et al. 2012).

It is very difficult to estimate the exact prevalence of HIV-2 infection in Africa because of the high rates of population mobility, difficulties in diagnostic techniques, and deficient tracing and case notification.

While the overall prevalence of HIV-2 infection appears to be declining, even in endemic regions, there is a parallel increase in the spread of HIV-1, which may be explained by a lower efficiency in vertical and sexual transmission of HIV-2. Compared to HIV-1, HIV-2 vertical transmission by breast-feeding, in the absence of anti-retroviral therapy, is less than 4% (~25% in

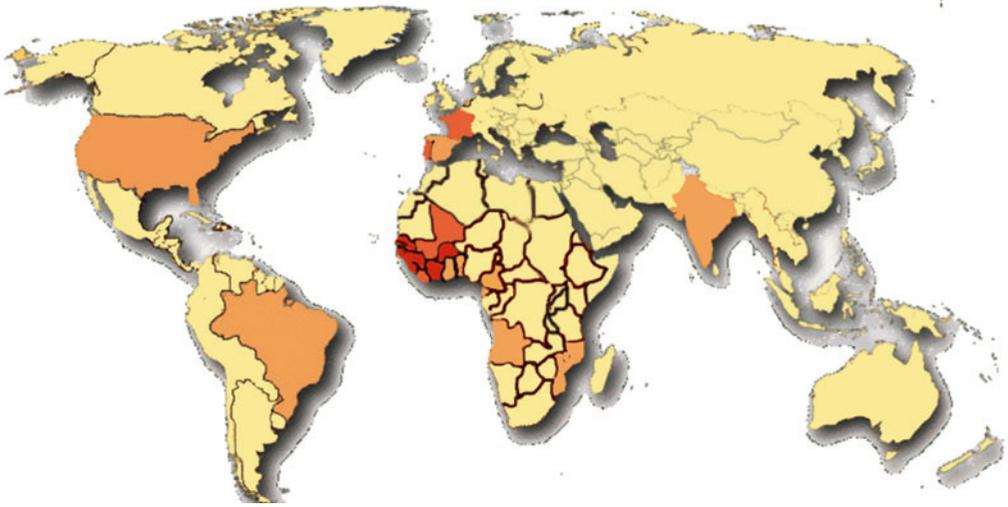

HIV-1). Similarly, shedding of HIV-2 in genital secretions is much lower and the virus levels in semen strongly correlate with plasma viral load levels (Sharp and Hahn 2011). The rates of sexual and vertical transmission of HIV-2 infection are around 5–9 times and 10–20 times lower, respectively, than for HIV-1 (Carvalho et al. 2011).

HIV-2 Infection: The European Scenario

In recent decades, HIV-2 infection has also expanded to some European countries, mainly Portugal and France, because of the historical and persistent social, cultural, and economic ties between these nations and countries in West Africa that promote a strong migrant population flow. Infection with HIV-2 has also been identified in North America, South America (Brazil), and in India (Fig. 2). The most frequent transmission route is usually heterosexual contact with individuals from endemic areas or who have traveled in those regions.

In Europe and other Western nations it is also difficult to assess the exact prevalence of HIV-2 infection, since asymptomatic patients do not usually seek medical attention: moreover barriers to accessing health services such as cultural beliefs and language constraints are likely to delay the diagnosis in immigrant populations. Furthermore, few clinicians outside West Africa are likely to consider HIV-2 infection in their differential diagnosis, further reducing the likelihood of diagnosing the infection.

In Europe, Portugal is the country with the highest reported prevalence of HIV-2 infection, estimated as being the cause of 4.5% of all AIDS reported cases at the end of twentieth century (Soriano et al. 2000). HIV-2 infection has been present in Portugal since the early 1980s. HIV-2 infection in Portugal is probably related to population flows, such as the mobilization of soldiers in the 1960s and 1970s to former Portuguese colonies that took place during the independence wars, and later repatriation and migration of people from African endemic territories. Nowadays, strong cultural and economical relations still remain and perpetuate the close relationships

HIV-2 Infection in Europe, Epidemiology of, Fig. 2 Global HIV-2 infection prevalence: ~1,000,000 people infected in West Africa. Highest prevalence: Guinea-Bissau (8–10% general population: >20% in

55–80 age group). Highest prevalence in Europe: Portugal, followed by France (Adapted: Rowland-Jones S, CROI 2007)

H

between Portuguese and African nations, particularly, Angola, Cape Verde, Mozambique, and Guinea Bissau.

HIV-2 infection in Portugal is almost entirely due to subtype A, with a cumulative number of cases of 1813 notified by the end of the year 2008 (Sharp and Hahn 2011). In the beginning of 1990s, HIV-2 infection accounted for about 10% of the annually notified AIDS cases, but a significant drop was reported in the following decade, showing a decrease to 2.3% in 2008. Dual infections (HIV-1 and HIV-2) accounted for a minority of reported cases (3.6%) (Carvalho et al. 2011).

A recent published study characterized a sample of 442 patients living in Portugal, representing a wide geographic distribution and 37% of all HIV-2 infection cases notified in this country by the end of 2007 (Carvalho et al. 2011). Cases were analyzed over a period of almost 20 years (1985–2007), revealing the presence of distinct characteristics according to the date of diagnosis. Until 2000, the majority of HIV-2 infected patients were of Portuguese origin and were mainly men living in the north of the country. However, from 2000 until 2007, patients diagnosed with HIV-2 infection were predominantly West African immigrant females, residing in the capital Lisbon, located in

the central region of Portugal. The most frequent transmission route identified was heterosexual contact (58.8%); blood transfusion was referred to in 15.4% of cases; injection drug use in 2.3%; and 1.1% of patients were men that have sex with men. Vertical transmission was a rare event (0.9%). As expected, the majority of patients were asymptomatic at diagnosis (64%) and 45% remained treatment naïve.

In France, of 10,184 new HIV diagnoses between 2003 and 2006, 1.8% were infected with HIV-2 (1.6% with HIV-2 monoinfection and 0.2% with HIV-1 and HIV-2 dual infection) (Barin et al. 2007). In this study, most patients infected with HIV-2 were citizens of a West African country (65%), mainly Ivory Coast, Mali, and Senegal, but 12% were European (20 from France and 2 from Portugal). Female gender accounted for more than half the cohort (63%) and 72% of patients acquired the infection by heterosexual transmission.

Data collected from the French National Agency for AIDS Research, published in 2001, characterized a cohort of 124 HIV-2 infected patients (Damond et al. 2001). Sequencing and phylogenetic analysis revealed significant diversity among HIV-2 strains isolated in France, to the

extent that one third of patients were infected with subtype B. There were no differences between the epidemiological or clinical aspects between patients infected with HIV-2 subtype A or with HIV-2 subtype B, suggesting that both subtypes show similar pathogenic behavior. However, as HIV-2 subtype B shows significant viral diversity with substantial differences from subtype A, this could have public health implications for HIV-2 screening, diagnosis, and appropriate treatment.

There is a lack of systematic and updated prevalence data or estimates for HIV-2 infection in other European countries.

A recent epidemiological study published in 2007 performed in a Northern Italian Center screened 2941 HIV-infected patients and reported a prevalence of 10.6% of HIV-2 infection (Costarelli et al. 2007). In that same evaluation, most HIV-2 patients had a West African origin, predominantly from Ghana, Senegal, Nigeria, and Guinea. No differences were noted in the patient gender distribution and, once again, the predominant transmission route was unprotected heterosexual intercourse.

Between 1985 and 2003, 1324 individuals were diagnosed with HIV infection in the United Kingdom and Northern Ireland who had probably acquired the disease in West Africa (Dougan et al. 2005). Of those, 69% were infected by HIV-1 and 6% by HIV-2 – the HIV type was not reported for the remainder. As expected, 96% reported heterosexual contact as the likely risk factor: of note, women with HIV-2 were older at diagnosis (median age 35 years) than those with HIV-1 (median 30 years).

In Spain, from 1988 to 2006, 146 new HIV-2 infections were identified. The Belgium-Luxembourg database included 65 patients with HIV-2 in data collected up to 2007 (Carvalho et al. 2011).

While the number of HIV-2 infection diagnoses remains relatively low and stable over time in European countries, clinicians should be aware that the HIV-2 prevalence can be high in particular African settings. The growing migrant African population should be considered as an important target to screen for infection with both HIV-1 and HIV-2, in order to identify and treat infected individuals promptly, thereby reducing both the risk

of onward transmission and the development of HIV disease.

The scarcity of available HIV-2 infection data emphasizes the need for a systematic data collection system in order to characterize the prevalence of HIV-2 infection in each community, trying to address the specific needs for diagnosis, clinical monitoring, and treatment management of this infection.

Monitoring the progression of HIV-2 infection is, essentially, based on the evolution of clinical and immunological markers. Plasma HIV-2 viral replication is usually lower compared to HIV-1 replication rates, and validated assays for clinical quantification are not yet available. Several laboratories provide different “in-house” real-time PCR assays with primers and probes located in various regions of the HIV-2 genome. A collaborative effort to generate an accurate and standardized plasma HIV-2 RNA assay has been made in recent years (ACHIEV₂E), which has significantly improved the determination of viral load for HIV-2 group A. Unfortunately, a similar improvement was not achieved for group B HIV-2 RNA quantification, probably a consequence of the high genetic diversity found in HIV-2 group B isolates (Damond et al. 2011).

Conclusion

Although less prevalent than HIV-1, HIV-2 infection remains an important public health issue in West Central Africa, as well as in some European countries.

Both viruses share several genetic, pathogenic, and epidemiological characteristics but, at the same time, they have distinct biological features regarding transmission efficiency, time of clinical latency, cellular receptor usage, viral replication level, immune activation response, and susceptibility to current antiretroviral drugs.

Understanding those differences may prove vital to the development of more efficient treatment and prevention strategies for HIV-1 and HIV-2 infections.

Currently, there are several questions that remain unanswered that illustrate the difficulties

in achieving optimal management of HIV-2 infection, such as identifying the optimal time to start antiretroviral therapy, the ideal sequence of antiretroviral regimens, the validation of a gold standard RNA quantification assay, and an algorithm to analyze the impact of ART resistance mutations interpretation. The design of randomized controlled clinical trials would constitute a fundamental step in response to some of these persistent concerns in HIV-2 management.

HIV-2 Infection: The Role of Immune Activation in Pathogenesis

Salma Nowroozalizadeh¹ and Marianne Jansson^{1,2}

¹Department of Laboratory Medicine, Division of Medical Microbiology, Lund University, Lund, Sweden

²Department of Microbiology, Tumor and Cell Biology (MTC), Karolinska Institute, Stockholm, Sweden

Definition

Human immunodeficiency virus type 2 (HIV-2) is a retrovirus of the *Lentivirus* genus that may cause AIDS. However, the pace of disease development during an HIV-2 infection is much slower as compared with the course of an HIV-1 infection. In fact, many HIV-2-infected individuals may never develop AIDS. Several parameters influence the rate of HIV disease progression, and heightened level of chronic immune activation is one such factor. Chronic immune activation can be depicted by a wide range of dysregulated immunological responses, including increased frequencies of activated, but virus-unspecific, immune cells. Elevated levels of circulating cytokines, inflammation markers, and microbial products are also traits of chronic immune activation during an HIV infection.

HIV-2 Infection, a Long-Term Nonprogressive Lentiviral Disease

The human immunodeficiency virus type 2 (HIV-2) is a *Lentivirus* with distinct pathogenesis, despite its close relationship to HIV-1 (Table 1) (de Silva et al. 2008). HIV-2, which was introduced to humans by the zoonotic spread of simian immunodeficiency virus (SIV) from sooty mangabeys, is in contrast to the globally spread HIV-1

HIV-2 Infection: The Role of Immune Activation in Pathogenesis, Table 1 Comparison of HIV-1 and HIV-2 in relation to pathogenesis

	HIV-1	HIV-2
Distribution	Pandemic	Endemic in West Africa
Clinical outcome	Majority develop AIDS, LTNP only ca 2%	Majority LTNP
CD4+ T-cell decline	Steady Decline	Normal in LTNP, but declining in progressors
Plasma viral load	Set point 10 ⁴ –10 ⁵ RNA copies/ml	At least 1 log lower, and many times undetectable
Immune activation	Elevated	Less pronounced, but increasing in progressors

mainly confined to West Africa (► [The Epidemiology of HIV-2 Infection in West Africa](#) and ► [Phylogeographic Insights into the Origins and Epidemic History of HIV-2](#). Furthermore, the rates of transmission (► [HIV-2 Transmission](#) and ► [Transmission HIV-2: Origin, Epidemiology, and Phenotype](#)) and progression (► [Natural History and Clinical Features of HIV-2 Infection](#)) towards AIDS are slower in HIV-2 infection as compared to HIV-1 infection. In fact, the common clinical course of HIV-2 infection is in several aspects similar to that of the small group of HIV-1 long-term nonprogressors (LTNP) (► [Long Term Non-progressors & Elite Controllers](#)). Moreover, many HIV-2-infected individuals also display features of HIV-1 elite controllers (► [Long Term Non-progressors & Elite Controllers](#)), since plasma viral load is commonly not detected. This means that most HIV-2-infected individuals remain asymptomatic and display viral load control for an extended period of time. However, a subset of HIV-2-infected individuals still progresses at a rate similar to most HIV-1-infected individuals.

Chronic Immune Activation in Progressive HIV Infection

In HIV-1 infection it is well established that chronic and progressive disease is characterized

by heightened level of systemic immune activation (Douek et al. 2009). This condition, which is known as ► [chronic immune activation](#), can be depicted by a wide range of dysregulated immunological responses. This includes increased T-cell turnover higher frequencies of T cells expressing activation markers (► [Lymphocyte Activation Markers](#)), such as CD38 and HLA-DR; as well as polyclonal B-cell activation translating into hypergammaglobulinemia. In addition, elevated levels of proinflammatory cytokines (► [Inflammatory Cytokines](#)) and a broad range of soluble immune activation markers (► [Soluble Markers of Immune Activation](#)), including beta-2 microglobulin (β 2m), can be detected in peripheral blood of chronically infected HIV-1 individuals. Indeed, level of chronic immune activation has been shown to be a marker that independently predicts HIV-1 disease progression, even better so than plasma viral load. Multiple instigating factors behind chronic immune activation have been proposed, including excessive innate immune activation (► [Chronic Immune Activation](#) and ► [Immune Activation and HIV Transmission](#)) elevated T-cell turnover. Additionally, microbial translocation (► [Microbial Translocation](#)) from the gut, as the result of preferential replication of the virus in the gut-associated lymphoid tissue (GALT), has been implicated in immune activation. However, the relative contributions of the different factors to chronic immune activation in HIV-1 infection are not well established. Furthermore, the underlying mechanisms behind the long-term nonprogressive disease course of most HIV-2-infected individuals and the influence of chronic immune activation on this outcome are not fully understood. Yet, accumulating findings point to a complex interplay between the virus and the host that influences level of chronic immune activation also in HIV-2 infection.

HIV-2 Clinical Progression, Viral Load, and Immune Activation

It is well acknowledged that the clinical progression rate and decline in CD4+ T cells (► [Natural](#)

[History and Clinical Features of HIV-2 Infection](#)) in the common HIV-2 infection are significantly slower than that generally observed in HIV-1 infection (Table 1) (de Silva et al. 2008). One explanation for this can be attributed to the fact that the plasma viral load set point (► [TRIM5 Alpha and HIV-2 Infection](#)) is low or undetectable in HIV-2 infection. Still, elevated plasma viral load in HIV-2 infection can be linked to shorter survival. However, it is clear that plasma viral load is not the sole determinant of HIV-2 disease progression. Level of immune activation, for example, assessed by the analysis of the concentration of β 2m in plasma, has been shown to be independently predictive of survival also in HIV-2 infection (Jaffar et al. 2005). Elevated β 2m plasma levels have also been documented with decreasing CD4+ T-cell count and disease severity (Whittle et al. 1993). Furthermore, HIV-2-infected individuals display, in a manner similar to HIV-1 long-term nonprogressors and elite controllers, heightened level of immune activation markers as compared with HIV-seronegative subjects. Both increased concentrations of soluble immune activation markers and higher frequencies of activated T cells can be observed, also in HIV-2 infections where plasma viral load cannot be detected. Still, in line with the milder disease course, the common feature of HIV-2 infection is less apparent immune activation as compared to the general pattern of HIV-1 infection. The causal relationships between CD4+ T-cell depletion, plasma viral load, and immune activation in HIV-2 infection are nonetheless a matter of discussion. One report showed that numbers of activated T cells were elevated with lowered CD4+ T-cell count, despite the fact that a majority of the study subjects had undetectable viral loads, suggesting that immune activation is directly associated with the CD4+ T-cell count and only secondary to viral load (Sousa et al. 2002). Another study conducted on a different cohort observed no relationship between CD4+ T-cell count and markers of immune activation in HIV-2-infected individuals with undetectable viral load (Leligdowicz 2010a). The latter study, which also included viremic HIV-2-infected subjects, instead found a direct relationship between

levels of immune activation and plasma viral load (Leligdowicz 2010). The explanation for the divergent findings may be several, including more viremic subjects in one group, indicating individuals experiencing longer duration of infection. As of today, no study has yet addressed the impact of HIV-2 duration on immune activation. This is mainly because information on HIV-2 seroconversion dates is rare or nonexistent. Another explanation for the different observations could be the fact that the two study cohorts resided in two distinct locations, which may translate into divergent genetic background (► [Immunogenetics of HIV-2 Infection](#)) and also altered exposure to various copathogens (► [Immunopathogenesis of HIV Co-infections](#)). Thus, higher microbial burden, including parasites, helminths, and other pathogens, may elevate immune activation independent on HIV infection disease stage. Studies addressing the impact of duration of HIV-2 infection and copathogens on immune activation in HIV-2 infection may further clarify the causative relationships.

Innate Immune Activation During HIV-2 Infection

The detailed mechanisms that trigger chronic immune activation in pathogenic lentiviral infections are to be revealed; however, several lines of evidence suggest multiple causes. From studies of SIV infections in the sooty mangabey (► [Non-Pathogenic SIV Infection of Sooty Mangabeys](#)) and African green monkeys (► [SIV Infection of African Green Monkeys](#)), it is clear that in these natural SIV hosts, viremia may exist without causing chronic immune activation and pathogenesis (Bosinger et al. 2011). These studies indicate that the downregulation of the strong innate immune response, triggered during the acute infection (► [Immune Activation and HIV Transmission](#)) of both HIV-1 and SIV, is associated with non-pathogenic lentiviral infections. Instead, in HIV-1 infection the hyperactivation of innate responses (► [Chronic Immune Activation](#) and ► [Immune Activation and HIV Transmission](#)), including type 1 interferon signaling, appears to be

maintained and linked to the establishment of chronic immune activation. Suggested mechanisms behind the benign outcome in the natural SIV hosts include weaker signaling via the toll-like receptors (TLRs) expressed by plasmacytoid dendritic cells (pDCs). Since acute phase HIV-2 infections have not been described, studies on innate immune responses and the establishment of chronic immune activation during the transition from the acute to the chronic phase of the infection are not available. However, it has been reported that frequencies of circulating pDCs (► [Natural Killer Cells and Innate Immunity in HIV-2 Infection](#) and ► [Role of Dendritic Cells in HIV-2 Pathogenesis](#)) in chronically infected HIV-2 individuals, both viremic and aviremic, are reduced as compared to HIV-seronegative individuals, in a manner similar to observations reported for HIV-1-infected subjects (Cavaleiro et al. 2009). Moreover, the degree of pDC depletion in HIV-2-infected subjects appears to be negatively correlated with the expression of activation markers on both CD4+ and CD8+ T cells. In addition, mRNA expression levels of *MxA*, a gene mainly induced by interferon-alpha (IFN- α), were found to be increased in parallel with elevated immune activation, higher viral load, and decreasing frequency of pDC. Reduced in vitro responsiveness of pDC, assessed by IFN- α expression after TLR9 stimulation, also seems to correlate with elevated expression of immune activation markers, as well as declining CD4+ T-cell count and higher viral load (Cavaleiro et al. 2009; Nowroozalazadeh et al. 2009). Thus, these studies suggest that pDCs are hyperactivated and depleted/anergized in vivo and less responsive to in vitro restimulation during progressive HIV-2 infection. These observations have been made despite the fact that in vitro experiments indicate that pDCs, as well as myeloid DC (mDC), are less susceptible to HIV-2 infection as compared to HIV-1 infection (Duvall et al. 2007). Hence, mechanisms, independent of productive infection, may influence the frequency and function of these cells in vivo. On the other hand, studies have revealed that HIV-1 and HIV-2 are differently sensitive to an intracellular restriction factor (► [Interactions](#)

Between HIV-2 and Host Restriction Factors) present within myeloid cells, sterile alpha motif and HD domain 1 (SAMHD1) (Laguette and Benkirane 2012). The Vpx (► [Molecular Biology of HIV-2](#)) protein, which is produced by HIV-2 and related SIV strains but is lacking in HIV-1, counteracts SAMHD1. Accordingly, replication of HIV-1 is restricted by SAMHD1 in myeloid cells, whereas HIV-2 is not. These results may seem paradox, but it has been suggested that HIV-2 antigen presentation by myeloid cells favors a more efficient antiviral immune response. However, the impact that the SAMHD1-Vpx interaction has on chronic immune activation and disease progression in HIV-2 infected is to be revealed. Similarly, the frequency and function of myeloid cell, monocytes, and mDC, in HIV-2-infected subjects at different disease stages, are also to be disclosed. Nevertheless, it appears that the production of mDC-secreted cytokines after in vitro TLR7/8 stimulation of the whole blood from HIV-2-infected subjects is comparable to that of HIV-negative individuals, whereas corresponding in vitro responsiveness appears defective in HIV-1 infection (Nowroozalizadeh et al. 2009). Still, studies on the kinetics of innate immune activation during the transition phase, from acute to chronic disease, in HIV-2 infections may reveal regulatory properties that control systemic immune activation.

Regulation of T-Cell Activation in HIV-2 Infection

Another factor that has been proposed to influence chronic immune activation is the interaction between the negative regulatory factor (Nef) (► [Molecular Biology of HIV-2](#)) protein and the T-cell receptor (TCR)-CD3 complex. The interaction between Nef of HIV-2 mediates downregulation of the TCR-CD3 complex and inhibition of cell death, whereas Nef of HIV-1 does not (Table 1) (Schindler et al. 2006). In HIV-2-infected individuals with low viral load, being either nonprogressor or progressors, the ability of Nef to downregulate TCR on CD4+ T cells has been found to correlate with the level

of T-cell immune activation (Feldmann et al. 2009). However, the TCR down-modulating effect of Nef did not appear to protect against disease progression in these HIV-2-infected subjects. Instead, in viremic HIV-2 infections, it has been shown that increased potency of *nef* alleles to mediate down-modulation of TCR-CD3 and CD28 correlates with higher CD4+ T-cell counts (Khalid et al. 2012). It was also shown that down-modulation of TCR-CD3 and CD28 suppresses the expression of markers linked to T-cell exhaustion (► [HIV Associated Immune Exhaustion](#)) and death, such as Fas, Fas ligand, programmed death-1 (PD-1), and cytotoxic T-lymphocyte antigen 4 (CTLA-4). Thus, these findings suggest that the ability of HIV-2 Nef to act on T-cell activation may translate into better prognosis for the viremic individuals by suppressing T-cell exhaustion and death. In line with these observations, it has been reported that elevated expression levels of PD-1 and its main ligand, PD-L1, on CD4+ and CD8+ T cells of HIV-2-infected individuals, correlate with increased immune activation and CD4+ T-cell depletion (Tendeiro et al. 2012). Thus, similar to the immunopathogenic events in HIV-1 infection, it appears that immune activation in progressive HIV-2 infection triggers the upregulation of inhibitory receptors, such as PD-1, which in turn may downregulate virus-controlling immune responses. Indeed, strong Gag-specific T-cell responses (► [The Cellular Immune Response to HIV-2 Infection](#)) are elicited in long-term nonprogressive HIV-2 infections, and frequency of highly avid and early differentiated HIV-2 Gag-specific CD8+ T cells appears to be inversely correlated with the level of immune activation (Leligdowicz 2010b). Furthermore, in vitro findings suggest that the HIV-2 surface envelope glycoprotein (► [HIV-2 Envelope: Structure, Diversity and Evolution](#)), gp105, may suppress T-cell activation in a monocyte-dependent but T regulatory cell-independent manner (Cavaleiro et al. 2007). In contrast, gp120 envelope glycoprotein of HIV-1 did not suppress T-cell activation. Thus, the interaction between virally encoded proteins and host defense structures may regulate the level of T-cell immune activation in HIV-2 infection. Moreover, this regulation may

take place within infected target cells or on a bystander cell level.

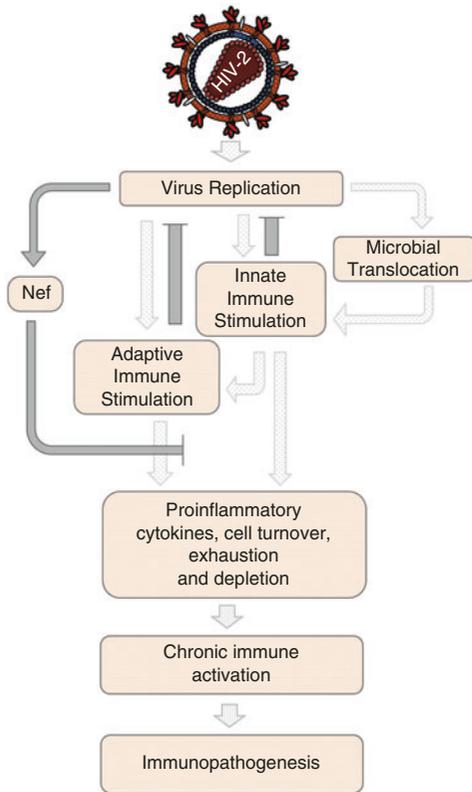

Microbial Translocation and HIV-2 Infection

With the identification of massive depletion of CD4⁺ T cells in the GALT (► [Microbial Translocation](#)) during the acute phase of HIV-1 infection in humans and SIV infection in nonhuman primates, the focus on pathogenic effects mediated by these viruses has been shifted to events taking place in the gastrointestinal tract. Therefore, in line with damage to the gut mucosa, the level of microbial translocation (► [Microbial Translocation](#)) has been studied in different pathogenic and nonpathogenic lentiviral infections. Microbial translocation, being translocation of microbes and/or microbial products from the gut to the peripheral blood without the cause of overt bacteremia, is usually analyzed by quantification of lipopolysaccharide (LPS), and LPS triggered host-related factors in plasma. In these studies it has been shown that elevated microbial translocation can be detected in chronically HIV-1-infected humans and SIV-infected rhesus macaques (Douek et al. 2009). Furthermore, it has been proposed that microbial translocation contributes to chronic immune activation in HIV-1 infection since degree of microbial translocation correlates with plasma concentrations of IFN- α and frequency of activated CD8⁺ T cells. In addition, HIV-1-infected elite controllers display lower levels of microbial translocation, in parallel with reduced immune activation, than detected in viremic individuals. Similarly, microbial translocation in HIV-2-infected subjects with undetectable plasma viral load has been found to be significantly lower than in those with viremic infections (Nowroozalizadeh et al. 2010). In addition, it has been noted that microbial translocation correlates with severity of disease independently of type of HIV infection, as studied in a cohort of HIV-1- or HIV-2-infected individuals residing within the same West African location. However, care has to be taken when drawing causal relationships between microbial translocation, chronic immune

activation, and disease progression in HIV infections. This since HIV-mediated microbial translocation can be masked in cohorts residing in locations where infections with other gastrointestinal pathogens are abundant (Redd et al. 2009). Thus, for the clarification of causal relationships between microbial translocation, chronic immune activation, and viremia in HIV-2 infections, longitudinal studies also taking into account copathogens would be helpful. Furthermore, studies on the distribution and degree of CD4⁺ T-cell depletion in GALT of HIV-2-infected subjects, which are lacking, could also shed light on the relationship between pathogenic events localized to the gut.

Conclusions

Findings from accumulating studies suggest that chronic immune activation is not only a contributing factor to HIV-1 disease progression but also part of the pathogenesis of HIV-2 infection. However, along with the long-term nonprogressive disease, chronic immune activation is less pronounced in HIV-2-infected individuals, as compared to that detected during the common course of HIV-1-infected subjects. The reason for this is likely multifactorial, including low or undetectable viremia in HIV-2 infection, which can be the consequence of viral replication features, as well as the efficacy of virus-controlling immune responses (Fig. 1). Still, immune activation elevated above the level found in HIV-seronegative individuals is detected in aviremic HIV-2-infected subjects, similar to HIV-1 elite controllers, during chronic asymptomatic infections, suggesting that early events in the infection may play an important role in the trigger of chronic immune activation. The knowledge on immunological and virological events taking place in acute HIV-2 infections is, however, lacking and if available could shed light on the causal relationships between immune activation, viremia, and disease progression. Additional mechanisms that influence level of immune activation and disease progression in HIV-2 infections have been shown to be related to the

HIV-2 Infection: The Role of Immune Activation in Pathogenesis, Fig. 1 Schematic view on factors that may contribute to (light grey arrows) or restrict (dark grey arrows) HIV-2 chronic immune activation

interactions between virally encoded proteins, such as Nef, and target cell structures linked to the regulation of immune activation. Thus, comparative longitudinal studies on the different HIV-2 progressor groups, meaning HIV-2-infected subjects which disease progression rate is similar to HIV-1-infected subjects and the long-term nonprogressive HIV-2-infected individuals, would be helpful in delineating full understanding of factors that drives disease progression in HIV-2 infection. The relative impact of chronic immune activation to disease progression in different HIV-2-infected progressor groups would optimally also be conducted in cohorts longitudinally followed from the time point of infection and resident within the same geographical area, with similar genetic background and comparable environmental exposure to other pathogens. However,

with the declining HIV-2 incidence, the window of opportunity to study the long-term non-progressive lentiviral disease caused by this virus is becoming smaller.

HIV-2 Neurological Manifestations

Youngjee Choi¹ and David B. Clifford²

¹Department of Medicine, Washington University in St. Louis, St Louis, MO, USA

²Departments of Medicine and Neurology, Washington University in St. Louis, St Louis, MO, USA

Definition

Neurological manifestations of HIV-2 include neurocognitive dysfunction and peripheral neuropathy. They may include primary complications caused by the HIV-2 virus or secondary complications due to opportunistic illnesses or toxicity of therapy that develops during chronic HIV-2 infection.

Neurological Disease from Human Immunodeficiency Virus (HIV) Infection

One of the most underappreciated aspects of retroviral infection has been the serious neurological complications that commonly occur. In the case of HIV-1, it is known that shortly after infection, the virus enters the nervous system and can be recovered from it at almost any time during the ongoing years of infection. As immune dysfunction develops, there is increasing prevalence of both neurocognitive decline and peripheral neuropathy. Furthermore, opportunistic neurological conditions such as cryptococcal meningitis, toxoplasmic encephalitis, cytomegalovirus encephalitis, progressive multifocal leukoencephalopathy, and primary CNS lymphoma develop as immunodeficiency emerges. The neurological complications, both central cognitive and peripheral nerve system related, are believed to be driven by the HIV virus itself but mediated through inflammatory responses and viral protein toxicities. While the severity of these problems has been attenuated by the development of effective antiretroviral therapy, the problems persist even in optimally treated patients. Thus, current HIV-1 patients are known to have ongoing neurocognitive impairment and peripheral neuropathy, which become clinically significant and especially concerning as patients age. Much less is known about the parallel situation with HIV-2 which is endemic in West Africa and seen in populations emerging from West Africa.

HIV-2 Virus Epidemiology and Biology

HIV-2 is a retrovirus relatively confined to West Africa, with the highest prevalence (8%) reported in Guinea-Bissau (Poulsen et al. 1993). Emigrants from West Africa with HIV-2 may also be seen in developed countries, most commonly in Portugal, France, and Spain, but are rare enough that coordinated studies have never been attempted outside of West Africa. The importance of HIV-2 as a model for evaluation of mechanisms of key biological properties of HIV-1 has been underutilized, including in reference to

neurological disease. Like HIV-1, HIV-2 uses co-receptors CCR5 and CXCR4 to infect CD4 cells and demonstrates similar proviral loads; the two viruses share 60% homology of key genes *gag* and *pol* (Leligdowicz and Rowland-Jones 2008). Despite the genetic similarity between HIV-1 and HIV-2, most individuals infected with HIV-2 are long-term nonprogressors (LTNPs) with a normal life span, undetectable viral loads, and normal CD4 counts (Leligdowicz and Rowland-Jones 2008). Often treatment is used late in HIV-2, in part because of the more indolent characteristics of the disease, in part because of the limitation of resources in endemic areas, and in part because of the more limited armamentarium of antivirals active against HIV-2. With the current HIV research goals including ways to cure those infected or at least achieve preservation of health without pharmacologic interventions, HIV-2 provides hope as a potential model. HIV-2 patients can progress to AIDS, but they die at a higher CD4 count compared to their HIV-1 counterparts (Martinez-Steele et al. 2007). Less immune activation, neutralizing antibodies, and broad cytokine production by CD4 and CD8 cells are among the proposed factors of disease attenuation in HIV-2 (Leligdowicz and Rowland-Jones 2008). Because more than 80% of individuals with HIV-2 are LTNPs (compared to less than 2% of individuals with HIV-1), HIV-2 has been studied in the hopes of discovering the immune responses responsible for better viral control and ultimately the increased survival seen in the majority of HIV-2-infected individuals (Leligdowicz and Rowland-Jones 2008).

HIV-2 and Neurological Disease

Since HIV-2 is largely found in West Africa where formal neurological evaluations are rarely performed, there is a paucity of observations relevant to neurological manifestations of HIV-2. However, limited observations are consistent with neurological disease being part of the pathophysiology of chronic HIV-2 infection. The characterization of HIV-2 neurological disease has mostly been limited to case reports and rather

simple studies with imprecisely defined criteria for neurologic diagnosis. Studies in the early 1990s from West Africa noted myelopathy, neuropathy, meningoencephalitis, and pathologically diagnosed HIV-encephalitis among HIV-2 individuals (Ramiandrisoa et al. 1991; Lucas et al. 1993). Coinfection with HTLV-1 and HIV-1 is common in West Africa, and careful exclusion of these coinfections is not always perfectly documented. However, the evidence published is consistent with HIV-2 sharing neuropathologic stigmata also described with HIV-1. More recently, Martinez-Steele et al. (2007) noted “neurological impairment sufficient to prevent independent daily activities” (taken as a presumptive diagnosis) in 10.3% of its HIV-2 cohort. Other case reports and studies have reported demyelinating encephalomyelitis, toxoplasmosis, cryptococcal meningitis, and spastic paraplegia (Klemm et al. 1988; Mabey et al. 1988; Moulignier et al. 2006; Martinez-Steele et al. 2007), all neurological complications seen in HIV-1.

Biological markers of neurological involvement are even less commonly reported. The evidence of HIV-2 CSF infiltration and CNS histopathology indistinguishable from HIV-1 indicates a basis for neurological disease in HIV-2 individuals; multinucleated giant cells in brain specimens and HIV-2 RNA in CSF have been demonstrated in small numbers of HIV-2 individuals (Lucas et al. 1993; Arvidson et al. 2004). However, CSF and neuropathological studies remain rare in areas where HIV-2 is endemic, and the benign clinical course seen in the majority of HIV-2 individuals has discouraged invasive evaluations of those living with this disease. Thus, the details of the neurobiology of HIV-2 chronic infection are poorly described currently.

Because HIV-2 has been limited predominantly to West Africa, neurologic studies on HIV-2 have encountered the challenges of conducting research in the developing world. In developed countries, cognitive involvement has been recognized by quantitative neuropsychological testing, with significant normative data collected in the same countries. In the developing

world, neither the norms nor many of the tests are considered reliable. Much groundwork is required for neuropsychological testing to be validated and local matched control participants to be evaluated for normal values. An alternative approach to gain reliable insights has been to make blinded comparisons of community matched volunteers with and without the retroviral infection. Recently, a blinded, randomized controlled study was undertaken in Guinea-Bissau that systematically evaluated HIV-2 individuals and community controls by clinical, neurological, and neuropsychological examination (Choi et al. 2011). This study included patients with advanced HIV-2 (CD4 < 200) and patients with HIV-2 for over 20 years as well as comparative participants in the same community.

HIV-2 and Cognitive Impairment

One area of interest in HIV-1 has been the prevalence of HIV-associated neurocognitive disorders (HAND), which varies from severe (HIV-associated dementia or HAD), to mild functional impairment (minor neurocognitive disorder or MND), to subtle disease associated with sub-optimal testing performance but without clinical impairment (ANI or asymptomatic neurocognitive impairment). One of the special tools that has been used to tackle the challenge of assessing cognitive performance in the developing world is the International HIV Dementia Scale (IHDS) (Sacktor et al. 2005). This test includes immediate and delayed recall of four common words in the local language, a motor learning task with alternating hand movements, and timed, rapid, alternating hand movement task. This task is probably most appropriate for detecting HIV-associated dementia. HAD, is seen primarily in advanced or untreated patients (McArthur et al. 2005). Based on the rate of >80% LTNP with HIV-2, a relatively low prevalence of dementia has been assumed in HIV-2 individuals. In Guinea-Bissau, there was no evidence of a difference in dementia rates among HIV-2 and seronegative controls, as assessed by the IHDS. However, both HIV-1 and

HIV-2 studies have suggested that lower education attainment may have a greater negative effect on this measure than the effect of HIV serostatus itself (Waldrop-Valverde et al. 2010; Choi et al. 2011), making the IHDS a less sensitive measure in populations without formal education. The relatively simple IHDS tasks are not well designed for the detection of more subtle neurocognitive impairment.

Exclusion of the milder forms of HAND has been very difficult even under optimal research conditions in developed countries, and the task is substantially more difficult across cultural and language barriers. Thus, it is unclear how prevalent MND or ANI are in the developing world. It is possible that similar to other clinical manifestations being milder compared to HIV-1, HIV-2 yields a smaller effect size for the measures of cognitive impairment. In HIV-1 studies, several investigations in geographically diverse areas of the world have demonstrated HAND in the developing world in a pattern similar to what has been seen in developed countries. It remains to be determined whether milder forms of neurocognitive disease are prevalent in HIV-2. There is a suggestion that those with more severe HIV-2 by CD4 count have more subjective complaints of concentration and more difficulty in verbal fluency, as assessed by an animal naming task (Choi et al. 2011). These findings may reflect early HAND that testing is unable to confidently measure. However, with the limited observations to date, this remains unconfirmed.

HIV-2 and Peripheral Neuropathy

Peripheral neuropathy is the most common neurologic disorder in HIV-1 (Pardo et al. 2001), and it appears that HIV-2 may demonstrate a similar pattern of peripheral neuropathy as HIV-1. Retroviral disease severity is a risk factor for peripheral neuropathy in HIV-2, with neuropathy more likely in those HIV-2 individuals with lower CD4 counts, as has been widely demonstrated in HIV-1 (Lichtenstein et al. 2005). However, the rate of peripheral neuropathy and neurological exam findings has been shown to be no different

from the general population. To investigate this area more reliably in HIV-2-infected individuals, there is a need for studies controlling for meaningful comorbidities such as alcohol intake, undiagnosed diabetes, and other nutritional deficiencies that are likely to contribute to peripheral nerve disease.

HIV-2 and Myelopathy

Myelopathy, presenting with increasing spastic paraparesis and often loss of bladder function, as well as a variety of sensory deficits, is well recognized as a complication of HIV-1. In HIV-1, vacuolar myelopathy (VM) is the most common neuropathological manifestation of myelopathy, but it is usually found alongside those with AIDS (McArthur et al. 2005). While myelopathy has been documented in HIV-2 patients (Ramiandrisoa et al. 1991), given that most individuals have higher CD4 counts in HIV-2, myelopathy has rarely been described in HIV-2 patients (zero cases in the recent study by Choi et al. (2011) where coinfection with HTLV-1 was also carefully excluded).

Conclusions

There is yet to be a study with a large battery of neuropsychological tests evaluating all the major domains of function in HIV-2-infected patients. Performing such testing has serious limitations in the populations mostly infected by HIV-2. In particular, low formal education level in some countries limits the type and complexity of testing traditionally performed. For example, the Color Trails has been used as a substitute for the widely used Trail Making Test, but this test requires knowledge of Western numerical conventions. It is thus impossible to use in the nonreading populations in rural African countries such as Guinea-Bissau where HIV-2 is most prevalent. Furthermore, norms from developing world populations (Sacktor et al. 2005) may be higher than the participants' in West Africa and limit some of the neurologic tools available at this

time. Attention to robust collection of norms is only now underway to better allow neurocognitive characterization in the developing world populations.

There is much room for further characterization of HIV-2 neurological complications. Given the frequency of neuropathy, quantitative measures of peripheral nerve integrity, such as nerve conduction studies and skin-punch biopsies, could be performed to better characterize peripheral neuropathy. Better metabolic and nutritional testing would help characterize comorbid factors as well as the type of peripheral nerve pathology seen in HIV-2. It appears that specific studies of the cognitive impact of HIV-2 will be difficult to conduct with the challenges of neurocognitive assessments across cultures, but increasing attention to norms and appropriate testing modalities should allow for more nuanced description of cognitive performance in the future. Biomarkers for neurocognitive dysfunction are being evaluated, and when they become available, HIV-2 may yet be finely characterized and become a fruitful neurological model of long-standing HIV-1.

HIV-2 Transmission

Geoffrey S. Gottlieb
 Division of Allergy and Infectious Diseases,
 Department of Medicine and Department of
 Global Health, University of Washington School
 of Medicine, Seattle, WA, USA

Definition

HIV-2 transmission encompasses the spread of the virus from one person to another. Human-to-human HIV-2 transmission can occur through

multiple routes including sexual, mother to child, and blood-borne.

Introduction

Not long after the discovery of HIV-1 in 1983 (Barre-Sinoussi et al. 1983) and HIV-2 in 1986 (Clavel et al. 1986) as the etiologic agents of AIDS, it became clear that the global HIV/AIDS pandemic was caused primarily by HIV-1 (De Cock et al. 1993). Of the ~34 million people living with HIV/AIDS and the >30 million AIDS-related deaths since the beginning of the epidemic, only ~1–2 million infections have been due to HIV-2 (although accurate global HIV-2 disease burden data is not available) (Gottlieb et al. 2008a). HIV-2 is endemic in West Africa but has had limited spread to other locales worldwide (see HIV Database: <http://www.hiv.lanl.gov>). Ultimately, the reason why there is no HIV-2 pandemic is due to different transmission dynamics between HIV-1 and HIV-2.

Genetic and epidemiologic evidence suggests that HIV-2 started as a zoonosis, originally transmitted from West African *sooty mangabeys* to humans, and that this probably occurred at least 8 times, represented by the HIV-2 groups A through H (see HIV Database: <http://www.hiv.lanl.gov>). Examination of stored sera suggests that HIV-2 has been circulating in humans in West Africa since at least 1966 (Kawamura et al. 1989), and phylogenetic data suggests it may have been present since the early 1900s (Lemey et al. 2003). HIV-2 appears to have reached a peak prevalence in West Africa in the 1980–1990s, with Guinea-Bissau having >10% adult prevalence (Poulsen et al. 1993). More recent data suggest that HIV-2 prevalence may be slowly declining in West Africa, although the reasons for such a decline remain unclear (Eholie and Anglaret 2006).

Routes of HIV-2 Transmission

Similar to HIV-1, routes of HIV-2 transmission have been reported to include heterosexual

(De Cock et al. 1993; Poulsen et al. 1993), men who have sex with men (MSM) (Brucker et al. 1987), mother to child (MTCT) (Matheron et al. 1990), and blood-borne (e.g., injection drug use (IDU) (Ferroni et al. 1987), blood transfusions (Dufort et al. 1988) and blood-derived products, and unsafe medical and traditional practices (Pepin 2011). The epidemiology of routes of transmission appears to have changed over the course of the epidemic, with unsafe medical practices possibly playing an important role in the 1960–1970s during the multiple wars of independence in West Africa during that time period (Lemey et al. 2003; Pepin 2011). The current predominant mode of HIV-2 transmission is thought to be heterosexual.

Risks of HIV-2 Transmission

Heterosexual Transmission of HIV-2

In West Africa, where the majority of HIV-2 transmission occurs, heterosexual contact has been the dominant mode of transmission (De Cock et al. 1993; Poulsen et al. 1993). Several studies suggest that HIV-2 is significantly less transmissible via heterosexual routes than HIV-1 (De Cock et al. 1993; Donnelly et al. 1993). A study by Gilbert and colleagues in Senegal suggests that HIV-2 infectivity is ~3.5 times less than that of HIV-1 (Gilbert et al. 2003). The most important correlate of HIV-1 sexual transmission is plasma viral load (Quinn et al. 2000), and while this is likely to be the case for HIV-2, it has yet to be demonstrated. The significantly lower viral loads in HIV-2 infection, compared HIV-1, are thought to be the reason for the substantially reduced transmission of HIV-2 (Simon et al. 1993; Gottlieb et al. 2002). Other HIV-1 transmission correlates include low CD4⁺ T-cell count, advanced clinical stage infection, and concurrent sexually transmitted infections (STIs); all of which are also likely to be important for HIV-2 sexual transmission.

HIV-2 MTCT

Similar to sexual transmission, mother-to-child transmission of HIV-2 infection has been shown

to be significantly less efficient than HIV-1, with several studies showing rates <5% without ART (Adjorlolo-Johnson et al. 1994).

Other Modes of HIV-2 Transmission

Although case reports of HIV-2 transmission in MSM and in IDU have been reported, the absolute and relative risks compared to HIV-1 are undefined; however, like heterosexual and mother-to-child transmission, the relative risk compared to HIV-1 is likely low. Given the high prevalence of HIV-2 in some regions of West Africa and its apparent inefficient transmission, some have suggested that unsafe medical and traditional practices may have amplified the epidemic early on (Pepin 2011).

Transmitted HIV-2 Drug Resistance

Assessing the extent and prevalence of HIV-2 transmitted drug resistance (TDR) has been hampered by the lack of validated and clinically available HIV-2 resistance genotyping assays. In addition, because of the relatively recent availability of ART for HIV-2 in West Africa and the small numbers of HIV-2 cases in developed countries, reports of transmitted drug resistance are rare. Transmitted drug resistance must also be differentiated from *de novo* mutations and surreptitious ARV use which may be difficult.

Jallow and colleagues reported the occurrence of the multi-nucleoside resistance mutation, Q151M, in a 66-year-old, ARV-naïve, HIV-2-infected female from rural Caio, Guinea-Bissau, from multiple samples dating back to 1997 suggesting transmitted drug resistance (Jallow et al. 2009). Ruelle and colleagues reported the occurrence of possible TDR in 2 of 21 samples ARV-naïve HIV-2 patients from Burkina Faso: one with the M184V NRTI mutation and Q151M + M184V in the other (Ruelle et al. 2007). In Senegal, one ARV-naïve female subject had the HIV-2 reverse transcriptase M184I mutation detected in genital tract secretions (but not PBMCs) that is known to confer 3TC/FTC resistance in HIV-2 (Gottlieb et al. 2008b). In a study in Belgium and Luxembourg, Q151M or

M184I was found in 2 ARV-naïve HIV-2 patients suggesting transmitted drug resistance (Ruelle et al. 2008). The Q151M mutation was from a recently diagnosed ARV-naïve MSM patient originating from Belgium, and phylogenetic analysis showed that this virus was linked to a 2nd HIV-2 strain from another MSM which also had the Q151M mutation suggesting a TDR of HIV-2 between MSM (Ruelle et al. 2008). There have also been reports of HIV-2 protease polymorphisms/mutations in ARV-naïve individuals in West Africa and Europe, but the role in resistance has not been established (Gottlieb et al. 2008b; Ruelle et al. 2008). To date there have not been any reports of TDR of HIV-2 integrase inhibitors (INIs), which is likely due to lack of availability of INIs in West Africa, and only limited and recent use of raltegravir in HIV-2 in developed countries (Gottlieb et al. 2011).

HIV-2 Genital Track Shedding

Similar to other sexually transmitted infectious agents, risk of HIV transmission is associated with the presence and quantity of HIV in genital tract secretions (Quinn et al. 2000). Factors previously shown to be associated with cervicovaginal HIV-1 RNA or DNA detection include systemic factors such as high HIV RNA plasma load and low CD4⁺ T-cell count and local (genital) factors such as elevated vaginal pH, bacterial vaginosis, genital ulceration, and infection with *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, herpes simplex (HSV), *Candida albicans*, or human papillomavirus.

Thus, understanding the patterns of and risk factors for genital HIV-2 shedding is important for developing strategies to control its transmission. Unfortunately, to date, there are only three published studies of HIV-2 female genital shedding (Ghys et al. 1997; Seck et al. 2001; Hawes et al. 2008). Two of these studies were cross-sectional in design and compared detection of HIV RNA or DNA in the genital secretions of African women with HIV-1 and HIV-2 and found genital HIV RNA or DNA among 25–50% of HIV-1- and 5–15% HIV-2-infected

women (Ghys et al. 1997; Seck et al. 2001). The largest study to date by Hawes (Hawes et al. 2008) and colleagues in Senegal, West Africa, evaluated HIV DNA and RNA detection in cervicovaginal specimens among 168 HIV-1- and 50 HIV-2-infected women, and in a subset of 31 women (20 with HIV-1, 11 with HIV-2), they conducted a prospective study in which cervicovaginal specimens were taken at 3-day intervals over a 6-week period. They found significantly lower rates and levels of HIV-2 RNA (58% shedding; 13% with >1000 copies/ml) in the female genital tract than HIV-1 RNA (78% shedding; 40% with >1,000 copies/ml) and shedding correlated with plasma viral load irrespective of virus type (odds ratio = 1.9, 95% confidence Interval = 1.3–2.8 for each log₁₀ increase in HIV viral RNA). Plasma viral load, not HIV type, was the strongest predictor of genital viral load. Over 80% of closely monitored women, regardless of HIV type, had at least intermittent HIV RNA detection during every 3-day sampling over a 6-week time period. Concurrent STIs were infrequent in this population.

Correlates of HIV-1 shedding in semen have been less well studied, but plasma viral load appears to be a strong correlate as do concurrent STIs. To date, the sole study examining male genital tract shedding of HIV-2 which found a significantly lower level of semen HIV-2 RNA than that of HIV-1 (Gottlieb et al. 2006). In this small cross-sectional study, HIV RNA was detected in semen in 21 of 22 (95%) of HIV-1- and 7 of 10 (70%) of HIV-2-infected subjects ($P = 0.07$). However, the levels of HIV RNA present in semen were markedly different between those with HIV-1 and HIV-2, with a mean of 4.4 log₁₀ copies/ml among those with HIV-1 and a mean of 2.6 log₁₀ copies/ml among those with HIV-2 ($P < 0.001$). In multivariate analysis, plasma viral load and HIV type, but not CD4 cell count, were independently predictive of semen viral load ($P = 0.03, 0.05, 0.48$, respectively) (Gottlieb et al. 2006).

Although the four, small, published studies on HIV-2 genital shedding suggest lower transmission rates of HIV-2 are likely due to lower genital tract viral loads, further natural history data would be of interest given HIV-2's slower disease

progression, slower decline in CD4⁺ T-cell count, lower plasma viral loads, and lower rates of mother-to-child and sexual transmission. In addition, determining whether ART reduces HIV-2 genital tract shedding, comparable to HIV-1, is important for assessing treatment as prevention strategies where HIV-2 is endemic.

Prevention of HIV-2 Transmission

There have been no clinical trials specific to HIV-2 that have assessed potential interventions that might reduce the risk or prevent HIV-2 transmission. Whether any of the global interventions that have been implemented to reduce HIV transmission in general are at least partially responsible for the apparent declining HIV-2 prevalence in West Africa is unclear (Eholie and Anglaret 2006). Interventions such as the use of condoms, sterile injection equipment in IDUs, implementing safe medical practices, and screening the blood supply for HIV have likely contributed to reduce transmission on HIV-2, in addition to that documented for HIV-1.

Regarding the prevention of MTCT (pMTCT) in HIV-2, randomized trial data is lacking; however, data from an observational HIV-2 cohort of pregnant women (including 223 HIV-2-infected women and 367 births) in France from 1986 to 2007 suggest that reductions, in the already low level of transmission, may be improved with effective maternal ART (Burgard et al. 2010). In over 20 years in the French Cohort, there were only two cases of HIV-2 MTCT: one case in 1993 occurred following maternal primary HIV-2 infection, and the other case occurred postnatally in 2002 and involved a mother with severe immune deficiency. The overall mother-to-child transmission rate for HIV-2 was 0.6% (95% confidence interval, 0.07–2.2%) (Burgard et al. 2010).

Recent data from a randomized controlled trial of antiretroviral treatment as prevention as well as previous cohort studies have demonstrated a significant reduction in the risk of sexual transmission of HIV-1; these results are likely applicable to antiretroviral treatment as prevention for HIV-2, although no such data yet exists. Similarly, other

interventions that have been studied for HIV-1 transmission prevention such as sexual, IDU, and occupational postexposure prophylaxis (PEP), preexposure prophylaxis (PREP), and topical microbicides will likely have potential efficacy in HIV-2 transmission prevention.

Conclusion

Overall, HIV-2 is significantly less transmissible than HIV-1, and this is reflected in the relative prevalence of HIV types in the global HIV/AIDS epidemic. The likely proximal cause for the different epidemiology between HIV-1 and HIV-2 is the significantly lower viral load burden in HIV-2. The mechanisms for this difference remain to be elucidated but will hopefully eventually provide insight into strategies to end the HIV/AIDS pandemic.

Acknowledgements I would like to thank Robert Smith and Papa Salif Sow for helpful discussions.

Definition

Multiple cross-species transmissions of SIV from sooty mangabeys gave rise to various HIV-2 groups in West Africa, but only HIV-2 groups A and B established an appreciable human transmission history since the 1940s. Phylogeographic analyses reveal considerable migration of HIV-2 group A in West Africa, with a relatively rapid growth in the number of infections in countries like Guinea-Bissau in specific past time periods, and dispersal patterns out of Africa that are in line with colonial history.

Viral Phylogeography

Phylogeography is a discipline that aims to explain the spatial processes that gave rise to the contemporary distribution of genetic lineages. Whereas historical biogeography has focused on macroevolutionary processes, phylogeography has traditionally dealt with microevolutionary patterns in populations of a single species or among closely related species. In viral epidemiology, phylogenetic inference has also been extensively used to examine the relatedness of viral lineages sampled at different geographic locations. Although this may represent timescales that are several orders of magnitude smaller than classical species-oriented phylogeography, many RNA viruses accumulate extensive genetic diversity during epidemic spread. As a consequence, processes such as viral population growth and ancestral migration can leave a measurable signature in RNA virus genomes (Holmes 2009). HIV is a primary example of this, and the changing epidemiology of the virus has frequently been scrutinized at the molecular level due to the availability of large amount of sequence data. In fact, many of the state-of-the-art developments in evolutionary and population genetic models and computational inference have been motivated by the desire to shed light on the epidemic history of HIV and other viruses (Holmes 2009).

Uncovering the genetic imprint of spatial processes in viral genomes is now considered to be only one aspect of the broader field of phylodynamics (Pybus and Rambaut 2009), which in general terms aims to explain infectious disease behavior that arises from a combination of evolutionary and ecological processes. Such studies can complement seroprevalence data from surveillance studies and may offer complementary detail to traditional epidemiology, which is limited in its ability to provide historical insights. This entry discusses the fundamental starting point offered by classical HIV-2 epidemiology (► [The Epidemiology of HIV-2 Infection in West Africa](#)) and molecular virology, the important insights gained from molecular epidemiology, and specifically how phylogeographic and phylodynamic

analyses can further contribute to our understanding of the epidemic history of HIV-2.

Discovery of the Zoonotic Origin of Human Immunodeficiency Virus Type 2 (HIV-2)

HIV-2 was identified in 1985 (► [The Epidemiology of HIV-2 Infection in West Africa](#)) in healthy Senegalese sex workers on the basis of different preferential serological cross-reactivity to SIV antigens compared to HIV-1. In 1986, the virus was isolated (► [The Epidemiology of HIV-2 Infection in West Africa](#)) from two immunodeficient heterosexual men who did belong to any particular risk group for HIV infection, one from Guinea-Bissau and one from Cape Verde (Clavel et al. 1986). Three years later, the primate species *Cercocebus atys*, which is indigenous in West Africa and is commonly named sooty mangabeys, was proposed as the reservoir species of simian immunodeficiency virus (SIV). The ability of SIVs to jump between nonhuman primate species has been established as an ancient feature intrinsic to SIV evolution (Sharp and Hahn 2011). Within a few years, several lines of evidence for a natural transfer of HIV-2 from sooty mangabeys into humans were presented: SIVsmm (► [SIV Infection of Sooty Mangabeys](#)) and HIV-2 show high similarity in genomic organization (► [HIV-2: Viral Structure, Sequence Variation and Pathogenesis](#)) and close phylogenetic relatedness; the prevalence of SIVsmm was relatively high in its natural host; there was a geographical range overlap for sooty mangabeys; and HIV-2 infection and plausible routes of transmission have been identified (Reeves and Doms 2002). Currently, HIV-2 accounts for around 1–2 million infections alone in West Africa (► [The Epidemiology of HIV-2 Infection in West Africa](#)).

Geographic Distribution of HIV-2 and its Donor Species

Several studies have suggested that HIV-2 infection is characterized both by an enhanced immune

response (► [The Antibody Response to HIV-2](#)) and lower viral replication (► [HIV-2 Envelope: Structure, Diversity and Evolution](#)) as compared to infection with its human counterpart HIV-1 (de Silva et al. 2008). As a consequence, HIV-2 infection results in a relatively low degree of viremia (► [HIV-2 Diagnosis and Viral Load Measurements](#)) and lesser genital shedding (► [HIV-2 Transmission](#)) that help explaining why the HIV-2 epidemic in and outside West Africa is of limited proportions compared to HIV-1. In fact, there is still a large overlap in the spatial distribution of HIV-2 infection and that of its primate donor.

The historical geographic range of sooty mangabey extends the coastal forest areas from the Casamance River in Senegal to the Nzo/Sassandra River systems in western Côte d'Ivoire (Fig. 1). However, due to habitat destruction and commercial hunting in the last decades, sooty mangabeys are now likely to be extinct in Senegal and Guinea-Bissau (Santiago et al. 2005). Epidemiological studies conducted in Liberia, Sierra Leone, and Côte d'Ivoire have shown that the prevalence of SIVsmm in sooty mangabeys can be as high as 60% in wild-ranging communities (Santiago et al. 2005). This primate has been frequently hunted for its meat, and high prevalence of SIVsmm has been found in bush-meat markets in Sierra Leone. In addition, sooty mangabeys are often kept as household pets, providing ample opportunity to cross-species transmission (Pepin 2011).

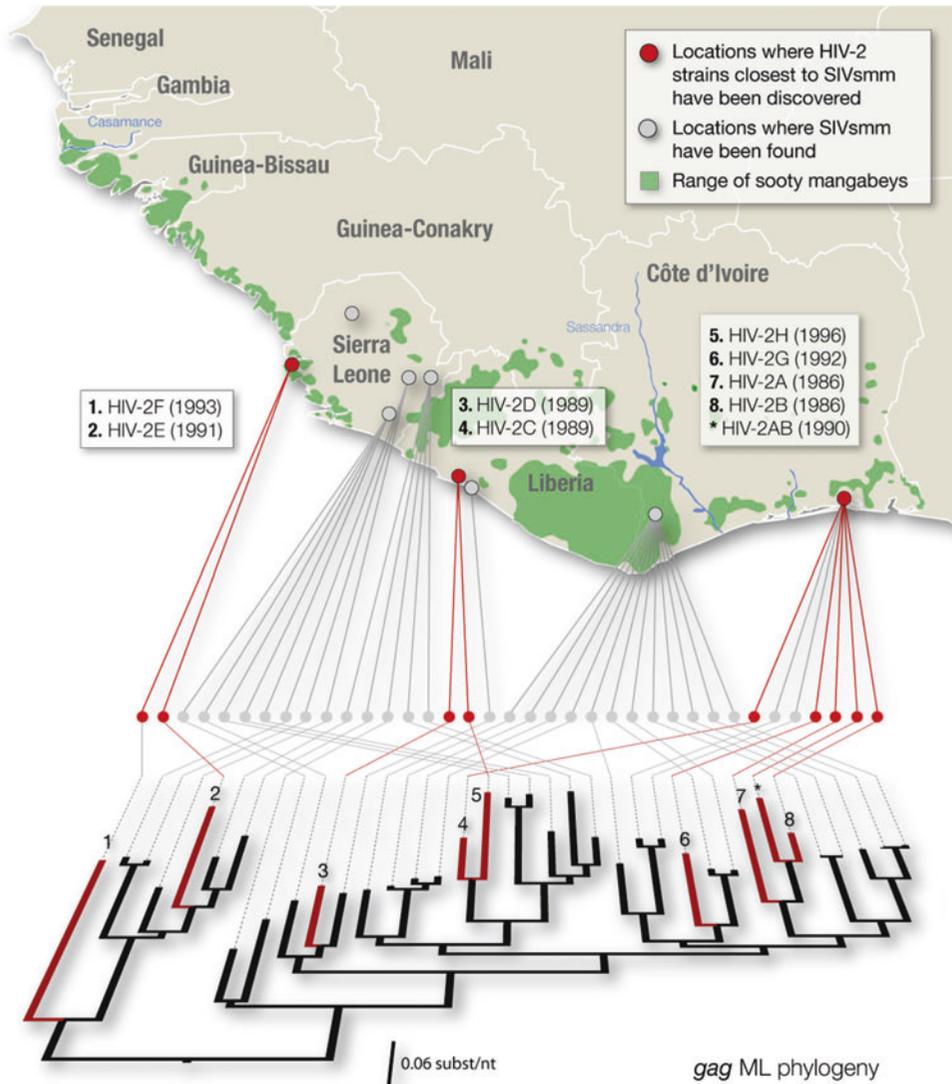

To date, eight different cross-species jumps of SIVsmm to humans have been identified in West Africa. While groups A and B represent virus lineages that evolved to establish sustainable epidemics within humans, groups C to H seem to represent dead-end infections since they were almost exclusively detected in one individual. Specifically, groups C and D have been identified in Liberia, while groups E and F in Sierra Leone. For these, only partial nucleotide sequences are available. Conversely, full-length genomic sequences from groups G and H strains have been collected in Côte d'Ivoire. Exceptionally, a second individual infected with a group F strain was recently identified in the United States. The immunodeficient patient originated from Freetown, Sierra Leone, and potentially acquired the

virus through human-to-human transmission in the patient's country of origin (Sharp and Hahn 2011). In addition, one circulating recombinant form of HIV-2 (HIV-2 CRF01_AB) (► [Recombinant Forms of HIV-2](#)) has been identified in 1990 in Côte d'Ivoire. This recombinant form was recently isolated from one Japanese and two Nigerian individuals living in Japan. Figure 1 illustrates the locations in Liberia, Sierra Leone, and Côte d'Ivoire where SIVsmm's have been identified to date and indicates where the phylogenetically closest HIV-2 groups (as well as the first isolate of CRF01_AB) (► [Recombinant Forms of HIV-2](#)) have been sampled. Traditionally, phylogeographic insights in viral epidemiology have been limited to interpreting the location distribution at the tips of phylogenetic trees as exemplified in this figure. Recent advances in the field, however, aim to uncover the process that gives rise to this distribution and attempt to estimate where virus resided at ancestral nodes in the tree. Below, the application of such techniques to HIV-2 group A is illustrated in more detail.

Epidemiological and Phylogenetic Origins of HIV-2 Groups

The great majority of SIVsmm strains (82%) have been identified in Sierra Leone (Santiago et al. 2005). Notably, this country has a large HIV-2 diversity (groups A, B, E, and F) but a very low overall prevalence of HIV-2 (0.02%). While the presence of groups E and F can be explained by local zoonoses from SIVsmm-infected sooty mangabeys that resulted in transmission dead ends (Pepin 2011), groups A and B in Sierra Leone have probably been imported from elsewhere. Moreover, epidemiological surveys of HIV-2 in West Africa (► [The Epidemiology of HIV-2 Infection in West Africa](#)) indicate a strikingly low prevalence in Liberia and Conakry, Guinea (De Cock and Brun-Vezinet 1989).

New insights into the geographic origins of the more prevalent groups A and B arose from a noninvasive molecular survey in 2002 of SIVsmm in a well-studied community of 120 wild-ranging sooty mangabeys in the Tai forest in southwestern

H

HIV-2, Phylogeographic Insights into the Origins and Epidemic History, Fig. 1 Geographical distribution of SIVsmm and the historical range of *Cercocebus atys atys* (sooty mangabeys). A maximum likelihood (ML) phylogenetic tree (genome numbering according to HIV-2 BEN: 1214–1993) including all available overlapping gag SIVsmm strains (black branches) and one

strain per HIV-2 group (red branches) was projected in geographical coordinates. The gray and red lines connect the terminal branches in the phylogeny representing SIVsmm strains and HIV-2 groups, respectively, to the locations in West Africa where these have been discovered. The dates represent the sampling year of the first available strains for each HIV-2 group

Côte d’Ivoire (Santiago et al. 2005). Phylogenetic analyses based on gp41 env fragments recovered from two SIVsmm strains isolated from sooty mangabeys clustered closely to HIV-2 group A with strong statistical support, providing the strongest evidence for a simian origin of this group in Côte d’Ivoire. Taken together, this

study supported an origin for groups A, B, C, G, and H in the southwestern region of Côte d’Ivoire. Accordingly, epidemiological data has shown that the geographic distribution of HIV-2 group B (► [The Epidemiology of HIV-2 Infection in West Africa](#)) seems to be mostly restricted to Côte d’Ivoire and the neighboring countries of

Ghana and Mali (de Silva et al. 2008; Reeves and Doms 2002), which lie outside the spatial range of sooty mangabeys.

Epidemiological and phylogenetic evidence seemingly disagree about the geographic origin of the predominant HIV-2 group A. The identification of regions with high seroprevalence in Guinea-Bissau (► [The Epidemiology of HIV-2 Infection in West Africa](#)) has led to the suggestion that this may represent the origin of HIV-2 group A, which is difficult to reconcile with the geographical origins of the closest SIVsmm strains found nearly 1,400 km southwards in the Tai forest in western Côte d'Ivoire (Pepin 2011; Santiago et al. 2005). While the closest SIVsmm from groups A and B have been identified in Côte d'Ivoire (Santiago et al. 2005), the prevalence of HIV-2 in Guinea-Bissau has been highest in West Africa, more than the double of the prevalence found in Côte d'Ivoire. However, high prevalences in particular areas may result from processes that do not necessarily require the virus to be originally introduced in these areas.

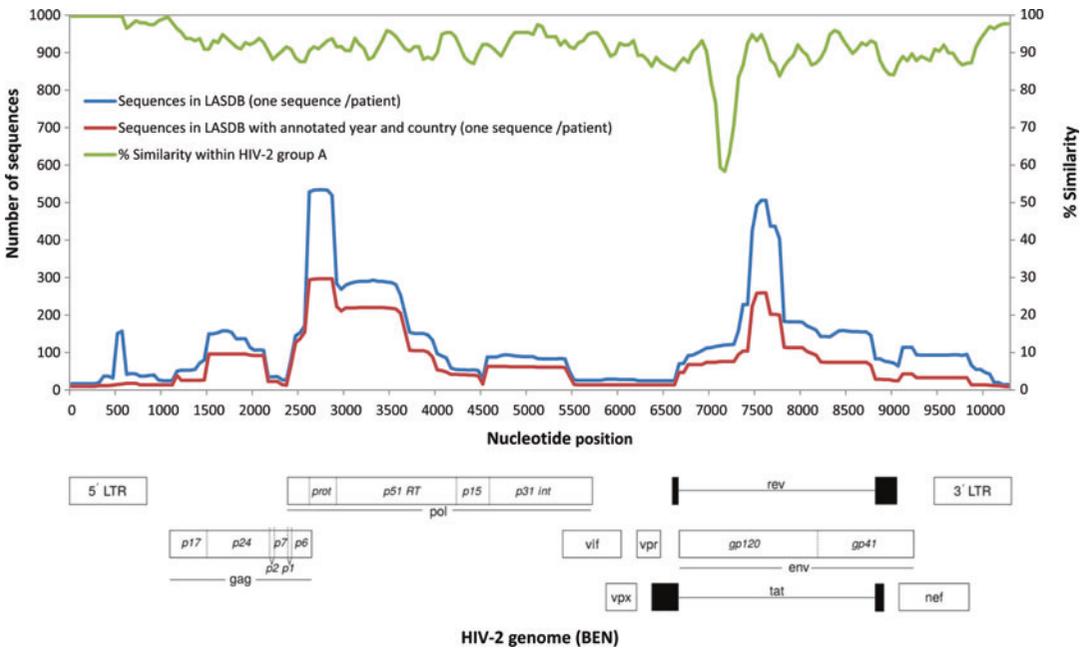

To shed light on the origins and dispersal patterns of group A, a comprehensive collection of 248 partial *env* and 320 partial *pol* nucleotide sequences sampled in 19 worldwide countries was recently investigated. Phylogeographic analyses geared toward time-calibrated genealogies that take into account uncertainty at the phylogenetic and dispersal level, placing Guinea-Bissau at the ancestral root location of group A (Faria et al. 2012). Moreover, molecular epidemiology insight revealed significant support for gene flow between localities within Guinea-Bissau, as well as from there to Senegal and between Gambia and Senegal. Interestingly, an epidemiological link between Côte d'Ivoire and Gambia was also recovered from the viral genetic data (Faria et al. 2012).

At face value, a spatial origin in Guinea-Bissau seems in line with the epidemiological evidence showing the HIV-2 prevalence among West African countries (► [The Epidemiology of HIV-2 Infection in West Africa](#)). However, accurate phylogeographic estimation of the ancestral root location of viruses is critically dependent on

dense, representative sampling, both in terms of year and location. In addition, genetic regions of sufficient length and variability are required to adequately inform such reconstructions. To illustrate the available sequence data for HIV-2, a search of the Los Alamos sequence database (in March 2012 <http://www.hiv.lanl.gov/>) was able to retrieve 761 geo-referenced sequences with known sampling date. The available sequences were distributed over the entire HIV-2 genome (► [Molecular Biology of HIV-2](#)) in a nonrandom fashion (Fig. 2), but even for the most covered regions in *pol* and *env*, the collective number of sequences available for analysis remained restricted. Particularly, the number of gene sequences available from Côte d'Ivoire appears to be insufficient compared to those available from Guinea-Bissau to build datasets robust to the effect of sampling bias. Taking this is in mind, the phylogeographic evidence for an origin in Guinea-Bissau can be considered as circumstantial, and it remains possible that the virus emerged in Côte d'Ivoire and was transported to Guinea-Bissau or surrounding countries early after entering the human population. Arguably, archival samples of group A from Côte d'Ivoire and Guinea-Bissau could provide the most compelling evidence for a geographic origin of group A.

The Chronological Origins of HIV-2 Endemic Groups

There are several indications that HIV-2 was present in West Africa during the 1960s and 1970s, and retrospective cases were confirmed mostly in Portuguese individuals who had lived in Guinea-Bissau during this period. In addition, retrospective testing of more than 3,000 stored sera suggested two positive samples from 1966 sampled in Côte d'Ivoire (Pepin 2011). These observations suggest that the predominant groups A and B emerged in the human population decades before its widespread molecular isolation. But when did these HIV-2 endemic lineages originate? Molecular clock analyses have often been used to offer insight in the age of the most

HIV-2, Phylogeographic Insights into the Origins and Epidemic History, Fig. 2 Number of available HIV-2 sequences (one per patient) across the genome (blue line) and the subset that is annotated with year and country (red line, potentially useful in phylogeographic analyses) in Los Alamos sequence database (LASDB;

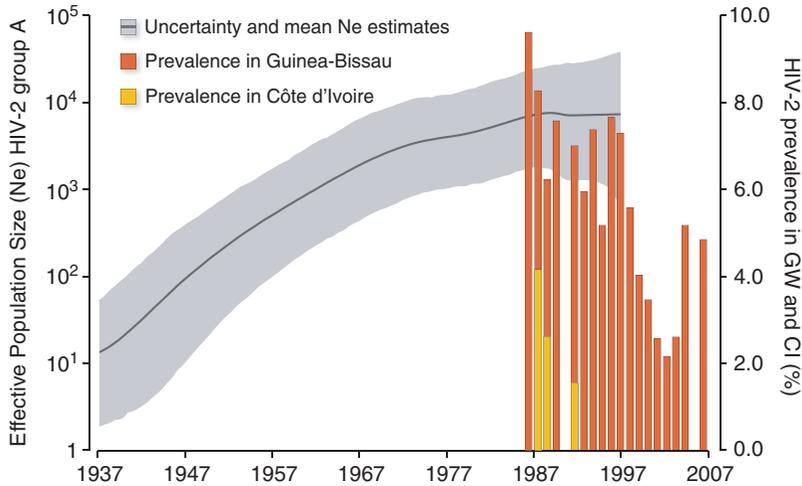

<http://www.hiv.lanl.gov/>). The green line displays the diversity over the genome within HIV-2 group A, as indicated by a similarity percentage. Data was produced using a stepwise sliding window approach. Bottom: map of the HIV-2 genome in relation to nucleotide positions of the top diagram

recent common ancestor of a viral lineage based on how fast they accumulate mutations in their genomes over an observable timescale. Molecular clocks, both strict and several relaxed versions, have recently been integrated with phylogenetic and phylogeographic inference models. Phylogenetic analyses aimed at investigating the time of origin of HIV-2 have found that group A arose during the 1930s (between 1906 and 1956) (Faria et al. 2012; Lemey et al. 2003; Wertheim and Worobey 2009). More recent estimates that included globally sampled data further suggested an introduction of this group in India in or around 1964 (between 1951 and 1974). Group B most likely arose within the same period of time (between 1907 and 1961). Finally, CRF01_AB (► **Recombinant Forms of HIV-2**) emergence has been dated between 1964 and 1973, although the small number of sequences available for this lineage resulted in estimates that are bounded by wide uncertainty intervals (1933–1986).

The Epidemic History of HIV-2 Group A

In addition to molecular clock and phylogeographic models, coalescent analyses have proven very useful in molecular epidemiology. These models are able to explain the phylogenetic tree shape as function of population size changes through time, which in turn may reflect important changes in epidemic patterns. After cross-species transmission from sooty mangabeys, a coalescent analysis of nucleotide sequences sampled in Caió, Guinea-Bissau (Lemey et al. 2003), suggested an initial period of stasis of group A, followed by an exponential increase in the number of infections between 1955 and 1970 (Fig. 3). By extending the sampling interval of the molecular epidemiological analysis, a more recent molecular epidemiological study corroborates a leveling off on the estimated number of HIV-2 infections since the early 1990s (Faria et al. 2012). Such decline in the number of

HIV-2, Phylogeographic Insights into the Origins and Epidemic History, Fig. 3 Demographic history of HIV-2 in Guinea-Bissau inferred using a molecular epidemiology approach. Bars indicate prevalence of HIV-2 in Guinea-Bissau and Côte d'Ivoire. Demographic history

was estimated using 80 partial *pol* HIV-2 group A strains sampled in Guinea-Bissau from 1986 to 1997 (location from start of HIV-2 BEN: 7553–7851) under a Bayesian skyride demographic model

new HIV-2 infections is in line with several epidemiological reports in West Africa (► [The Epidemiology of HIV-2 Infection in West Africa](#)) (Pepin 2011). Interestingly, in Guinea-Bissau, the highest prevalence of HIV-2 has been found in older groups and has been declining since the late 1980s (Pepin 2011). For example, a large study on 20,422 women in a maternity clinic in the capital of Guinea-Bissau showed a decline of HIV-2 prevalence from 8.3% in 1987 to 2.5% in 1999 (Mansson et al. 2009). Several explanations have been put forward to explain the exceptional rise of HIV-2 prevalence in Guinea-Bissau during this period and its subsequent decline.

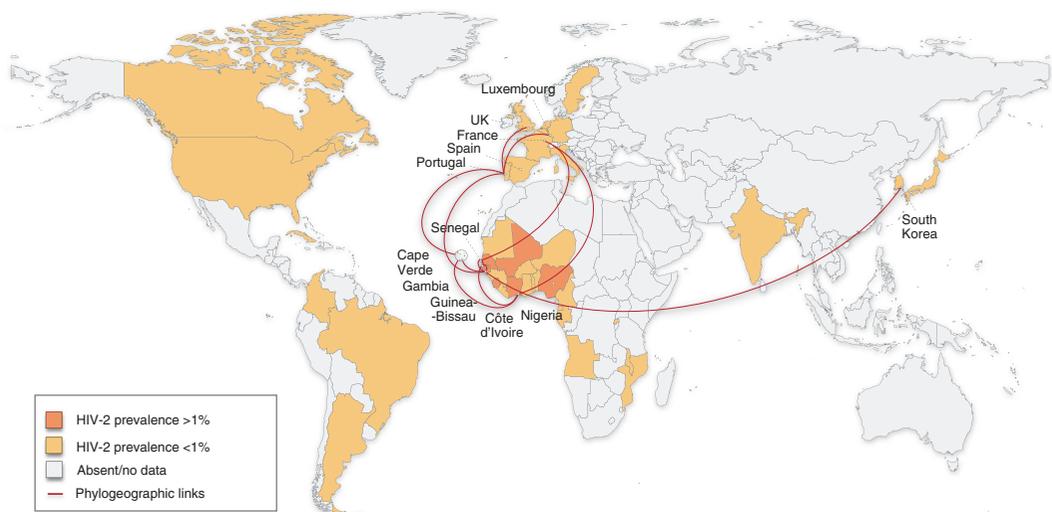

In Guinea-Bissau, the war against the Portuguese colonial power (1963–1974) has been suggested as a period offering increased opportunities for HIV-2 transmission. Prior and during this time, blood-borne transmission may have been facilitated by vaccination campaigns as well as other healthcare-related actions, such as blood transfusion and treatment of nosocomial infection. However, also increased commercial sex worker activity and higher migration of soldiers may have contributed to increased transmission. Pépin and colleagues inquired 1,608 individuals aged over

50 years and found significant associations between HIV-2 infection and treatment for sleeping sickness and tuberculosis (Pepin 2011). Outside West Africa, HIV-2 has also declined in the last decades. In Portugal, HIV-2 infections accounted for 10–12% of AIDS cases in the early 1990s but dropped to 3–8% around 2003 (Gomes et al. 2003). An investigation of the date of birth of HIV-2 infected patients attending the Egas Moniz Hospital in Lisbon between 1997 and 2002 (most with Guinea-Bissau origin) indicated that the majority of patients were born between 1940 and 1970, with median at 1957 (Gomes et al. 2003). This suggested that these patients were not sexually active during the period of colonial war, thus further arguing for a role of parenteral exposure as a key route for the spread of this virus during this period. In addition, a recent study suggests that the high incidence of genital ulcer diseases around the estimated ancestor of HIV-2 predominant groups might have created a unique opportunity for the initial spread of HIV in general (Sousa et al. 2010). Most likely, the explanation for the successful establishment of HIV-2 in West Africa stands on a combination of the above mentioned factors.

HIV-2 Out of Africa

In 1991, a pioneering study conducted on a geo-referenced database of the global incidence of HIV-2 infection has suggested a primary role of human migratory fluxes in the dispersal of this virus beyond West Africa (Smallman-Raynor and Cliff 1991). Since then, several countries have reported cases of HIV-2 infections. More recently, the study of the main corridors of viral diffusion out of West Africa was confirmed and further extended using molecular data (Faria et al. 2012). The map in Fig. 4 depicts the countries where HIV-2 has been detected and the dispersal links inferred through a phylogeographic analysis based on a comprehensive dataset of globally sampled nucleotide data. Interestingly, some of the strongest supported links were identified between West African countries and their former colonial powers, such as between Guinea-Bissau and Portugal, Cape Verde and Portugal, Côte d'Ivoire and France, and Senegal and France, demonstrating that molecular sequences contain information about viral spatiotemporal spread and phylogeographic analyses have the potential to uncover these.

Portugal has had the highest number of HIV-2 infections outside West Africa. Also, in France the virus accounted for 1.8% of 10,184 new HIV diagnoses between 2003 and 2006, with 3 HIV-2 cases among non-African men who have sex with men (Campbell-Yesufu and Gandhi 2011). Most of HIV-2 infections in Europe (► [Epidemiology of HIV-2 Infection in Europe](#)) can be traced to people from West Africa, or people who traveled there or had sexual contact with the West Africans. However, there have been reports of cases of HIV-2 transmission within Europe, particularly in Portugal and France. Moreover, phylogeographic analyses were able to uncover epidemiological links between Portugal and the United Kingdom and Luxembourg (Fig. 4). In the Americas, HIV-2 infection is rare, although present in the United States, Canada, Brazil, and Colombia (Campbell-Yesufu and Gandhi 2011; De Cock and Brun-Vezinet 1989). In Asia, HIV-2 infection is also uncommon and has only been reported in India, South Korea, and Japan. While in India the virus seems to be spreading, albeit at a limited pace, only few cases have been detected in South Korea and Japan, mostly linked to heterosexual contacts with people from West Africa.

HIV-2, Phylogeographic Insights into the Origins and Epidemic History, Fig. 4 Global map of HIV-2 epidemiology and phylogeographic links. Countries having a reported prevalence exceeding 1% in the national

population in the late 1980s are highlighted (Campbell-Yesufu and Gandhi 2011). Links represent statistically significant phylogeographic links of viral dispersal between countries (Adapted from (Faria et al. 2012))

Conclusion

Molecular analyses complement traditional epidemiology by providing a historical perspective on the contemporary distribution of viral pathogens. Such analyses have evolved from reconstructing evolutionary relatedness among strains to the application of probabilistic models that integrate sequence evolution, molecular clocks, processes of population size change through time, and spatial spread. Studies on HIV-2 evolution and molecular epidemiology have benefitted from these developments, but the lack of systematic and widespread sampling of HIV-2 sequence data represents a considerable limitation to the insights that can be obtained. This is the case for reconstructions of the origin of HIV-2 A in West Africa, which is sensitive to sampling heterogeneity in time and space. Nevertheless, recent phylogeographic estimates are in agreement with epidemiological links established by colonial history, providing evidence that such analysis captures important details of historical spread.

Definitions

Acquired immunodeficiency syndrome (AIDS): a clinical syndrome caused by the human immunodeficiency virus (HIV). Its

pathogenesis is related to a qualitative and quantitative impairment of the immune system, particularly a reduction of the CD4⁺ helper T lymphocyte cell count (surrogate marker of the disease). After an average of 10 years if untreated, HIV⁺ individuals can develop opportunistic diseases (i.e., infections and cancers rarely detected in people with normal immune systems). The natural history of the disease can be dramatically modified with administration of combination therapy composed of antiretroviral (ARV) drugs. This is seen in both HIV-1 and HIV-2 diseases.

Beta chemokines: a family of proteins produced in response to acute or chronic inflammation to attract a variety of white blood cells. They are characterized by a double cysteine (C–C) in their primary sequence. They bind to cellular targets by specific beta-chemokine receptors that are one of the members of the 7 transmembrane chemokine receptors. They include: CCR5, MIP1 α , and MIP 1 β .

CCR5: is a cell membrane protein expressed on several cell types including peripheral blood-derived dendritic cells, CD34⁺ hematopoietic progenitor cells, and certain activated/memory Th1 lymphocytes. This receptor is well defined as a major coreceptor in conjunction with CD4⁺, implicated in susceptibility to HIV-1 and HIV-2 infection.

CD4⁺: is a large glycoprotein that is found on the surface of helper T lymphocyte cells, regulatory T cells, monocytes, and dendritic cells. Its natural function is as a coreceptor that assists the T cell receptor (TCR) to activate its T cell following an interaction with an antigen-presenting cell. CD4⁺ is a primary receptor used by HIV-1 and HIV-2 to gain entry into host T cells.

CD4⁺ T cell: an immune cell, lymphocyte (white blood cell) characterized by the CD4⁺ antigen (protein) on its surface. This is a T lymphocyte considered to have a “helper” function to enhance the cellular immune response. The CD4⁺ is the primary receptor for the HIV-1 and HIV-2 virus, and upon infection the virus can destroy the CD4⁺ cell. In HIV-infected people, the drop in CD4⁺ T lymphocyte cells is a major determinant of the progression of HIV infection to AIDS.

Coreceptor (CCR5 or CXCR4): protein molecules on the surface of lymphocytes or monocytes that bind to the gp120 protein of HIV and facilitate, with CD4, binding, fusion, and entry of the virus into the susceptible cell.

CXCR4: is an alpha-chemokine receptor specific for stromal-derived factor-1 (SDF-1, also called CXCL12), a molecule endowed with potent chemotactic activity for lymphocytes. This coreceptor is one of the several chemokine receptors that HIV isolates can use to specifically infect CD4⁺ T cells.

DNA (deoxyribonucleic acid): is a nucleic acid that contains the molecular basis of heredity for all known living organisms and some viruses and is found in the nuclei and mitochondria of eukaryotes. Chemically DNA consists of two polymer strands of units called nucleotides made up of one of four possible bases plus sugar and phosphate groups. The polymers are joined at the bases by hydrogen bonds to form a double helix structure.

Human immunodeficiency virus type 1 (HIV-1): the virus that causes acquired immunodeficiency syndrome (AIDS). It is a lentivirus belonging to *Retroviridae* family and was discovered in 1983 by Robert Gallo and Luc Montagnier. HIV infects and destroys helper T cells of the immune system causing a marked reduction in their numbers. Loss of CD4 cells leads to generalized failure of the immune system and susceptibility to life-threatening opportunistic infections. It is transmitted mainly through sexual intercourse, exchange of contaminated syringes among intravenous drug users, and contaminated blood transfusion. HIV-1 is the HIV type most frequently detected worldwide and responsible for the global pandemic.

HIV-1 subtypes or clades: genetically related HIV strains that are essentially phylogenetically equidistant, generating a star-like phylogeny. Subtypes A, B, C, D, F, G, H, J, and K are currently known; subtypes A, B, C, and D are highly prevalent; others have low prevalence and limited geographic distributions.

HIV-2: the second HIV virus discovered in registered sex workers in Dakar, Senegal in 1984, the virus is more closely related to the

simian immunodeficiency virus of primates. Although HIV-2 can cause AIDS, it has a distinct epidemiology, lower rates of transmission, and slower progression to disease.

Immunoblot: also termed “Western blot” is a technique to detect antibodies to proteins. The proteins of interest are typically electrophoresed and then transferred to nitrocellulose paper. Serum or plasma is incubated with the viral protein-impregnated paper, and using an antihuman Ig coupled with suitable colorimetric, the presence of the bound antibody can be detected by color.

Incidence: rate describing the number of new cases of disease occurring within a given time period, expressed as new cases per person-time.

Integrase: an enzyme found in retroviruses including HIV that permits the reverse transcribed viral DNA to be integrated into the infected cell’s DNA. Integrase is an enzyme encoded by the polymerase gene of HIV.

Prevalence: number of cases of disease in a defined population at a specific point in time; it is often expressed as a percentage.

Radioimmunoprecipitation: a technique where virus-infected cells were grown in media containing a radioactive-labeled amino acid, which results in radiolabeling of viral proteins which can be detected by antibodies directed to those viral proteins. The technique with SDS-polyacrylamide gel electrophoresis (PAGE) indicates that radiolabeled proteins are then lysed in SDS detergent and subsequently subjected to electrophoresis through a polyacrylamide gel.

RNA (ribonucleic acid): this a universal form of genetic material typically transcribed from DNA; it differs from DNA in that it contains ribose and uracil as structural components. In retroviruses like HIV, RNA is their primary genetic material and is found in a mature virus particle.

Human immunodeficiency: virus types 1 and 2 (HIV-1 and HIV-2) are members of the *Lentivirus* genus of the *Retroviridae* family of RNA viruses and are ~50% related at the genetic level. HIV-2, although more closely related to the simian immunodeficiency virus (SIV), is the second human immunodeficiency virus and

constitutes the closest known human virus related to the prototype AIDS virus, HIV-1. HIV-2 shares many virologic and biologic features with HIV-1. Although HIV-1 and HIV-2 are highly related lentiviruses, they maintain some distinctly different epidemiologic and biologic characteristics (Kanki and Meloni 2009; Barin et al. 1985). HIV-2 is largely confined to West Africa, while HIV-1 infection is prevalent worldwide and accounts for over 98% of all HIV infections globally. Importantly, disease progression to AIDS occurs much more slowly in HIV-2. In comparison to HIV-1, these biologically relevant characteristics of HIV-2 infection in vivo appear to model those of an attenuated HIV infection. To date, the precise mechanisms responsible for this attenuated phenotype of HIV-2 remain unclear. However, HIV-2, like HIV-1, causes AIDS, although more slowly, and it was based on these initial similarities that some believed that HIV-2 might cause a second worldwide AIDS epidemic. Now, 29 years after the discovery of HIV-2, no such epidemic has occurred. Rather, research studies conducted both in the laboratory and in HIV-2-infected people in West Africa have highlighted distinct biological differences between these related viruses (Kanki and Meloni 2009). The initial discovery of HIV-2 in registered sex workers in Dakar, Senegal, was conducted through a unique collaboration between Souleymane Mboup and his team, Cheikh Anta Diop University, Francis Barin, University of Tours (France), Francois Denis, University of Limoges, and the Harvard School of Public Health, USA (Barin et al. 1985). This interuniversity convention worked together for more than two decades to continue its studies on the biological and clinical significance of HIV-2. Much of the research was based on studies conducted on a cohort of registered female sex workers in Dakar, Senegal. A brief summary of the history and key studies are provided in this entry.

History of HIV-2’s Discovery in Sex Workers in Dakar, Senegal

In 1970, the Ministry of Health in Senegal established a public health program whereby

self-identified commercial sex workers were registered to attend a clinic, which provided regular evaluation and free sexually transmitted infection (STI) treatment. For many decades, the Institut d'Hygiene Sociale (IHS) clinic in Dakar, Senegal, has been the outpatient clinic administered by the Senegalese Ministry of Health responsible for overseeing all self-identified female commercial sex workers in the capital city, Dakar, as well as other urban centers throughout the country. Women attended the clinic where regular clinical and STI examinations were performed and free STI treatment was offered. The Laboratoire de Virologie at CHU Le Dantec hospital nearby provided the laboratory services for IHS and has been led by Professor Souleymane Mboup since the early 1980s.

In 1985, when 289 sera from registered female sex workers in Dakar, Senegal, were screened for antibodies to HIV-1 antigens by immunoblot, 20 (6.9%) of them showed extensive cross-reactivity for the virus gag antigens but minimal antibody binding reactivity for the HIV-1 envelope proteins (Barin et al. 1985). Yet, when the same sera were assayed on the then recently described simian immunodeficiency virus (SIV) antigens, they reacted strongly with the envelope proteins as well as the gag antigens, suggesting infection with a virus that was more closely related to SIV than to HIV-1. This serologic relationship was also demonstrated using S³⁵ cysteine-labeled SIV and HIV-1 antigens in a radioimmunoprecipitation and SDS-PAGE (RIP-SDS-PAGE) analysis (Kanki et al. 1985). It is now recognized that HIV and closely related viruses in primates, termed SIVs, exist. The close antigenic relatedness of both SIV and HIV-2 to the prototype HIV-1 virus prompted both the discovery and further classification of these related viruses.

In 1985, the number of AIDS cases reported in Senegal and most of West Africa was quite low. The original Senegalese sex workers from IHS that had evidence of HIV-2 were healthy, and testing of hospitalized patients in Dakar that might have AIDS or an AIDS-like disease revealed HIV-1 infection and often a connection to Central Africa. The isolation of LAV-2 from an

AIDS patient originating from Cape Verde (Clavel et al. 1987) and subsequent AIDS case reports prompted the AIDS research community to fear for a second global AIDS epidemic. It therefore became critical to assess the immunopathogenic potential of this newly described virus. With the recognition that progression to disease in HIV-1 infection might take years, it was reasoned that further serologic surveys of control, risk, and disease populations throughout West Africa might be informative. Serum samples from 4,248 individuals from Senegal, Guinea, Guinea-Bissau, Mauritania, Burkina Faso, and Ivory Coast were tested on HIV-2 and HIV-1 antigens using both immunoblot and RIP-SDS-PAGE analysis (Kanki et al. 1987a). HIV-2 prevalence varied by country with Guinea-Bissau showing the highest rates and Mauritania without positives in the 184 samples evaluated. Healthy sexually active individuals in the "risk" category had the highest prevalence compared with the hospitalized disease category of individuals. Reactive positive samples were tested on variously named HIV-2 isolates including: LAV-2, HTLV-IV (MS), SBL-6669, and even SIV with identical results.

With evidence that a virus more closely related to SIV than to HIV-1 was present in Senegalese sex workers, more extensive studies were undertaken to determine if the SIV-related virus was more widely distributed in Africa. AIDS cases were targeted to determine if HIV-2 could be associated with what was already recognized as a significant AIDS epidemic in Central Africa. The screening of 1,508 high-risk individuals from Zaire (DRC), Burundi, Tanzania, Kenya, Zambia, and Cameroon, including many individuals with AIDS and other STDs, revealed no evidence that HIV-2 was present in the same regions in which HIV-1 was so common (Kanki et al. 1987b). However, pockets of infection with HIV-2 were detected in Mozambique and Angola, which, though distant from West Africa, were often on the same Portuguese trade routes as Guinea-Bissau and Cape Verde, both West African countries with some of the highest rates of infection. Even within Senegal, prevalence rates for HIV-2 were substantially higher in the

southern region of Casamance, which borders Guinea-Bissau, compared to other regions of Senegal (Kanki et al. 1987a).

The close relatedness of HIV-2 to HIV-1 also meant that methods to diagnose the virus, through antibody, antigen, and even genetic material, required specific assays. Early on it was recognized that HIV-2 was less prevalent globally and therefore commercial companies failed to develop HIV-2 specific diagnostics. This became even more pertinent, when the description of HIV-2 and HIV-1 dually infected individuals was first noted, relying heavily on unequivocal type-specific diagnosis of both viruses. The World Health Organization assisted with the formation of the HIV-2 working group to develop recommendations for HIV-2 diagnosis, which served as the basis for research and public health surveillance on the virus.

Studies conducted in the late 1980s and 1990s with type-specific serologic methods documented the prevalence of HIV-2 in most West African countries, surprisingly a distinctly different worldwide distribution compared to that of HIV-1 (Kanki and Meloni 2009). In most other countries of West Africa, such as Burkina Faso, Ghana, Ivory Coast, Nigeria, and Mali, infection with HIV-1 was more prevalent than infection with HIV-2, ranging from a 3- to 24-fold rate ratio (HIV-1 versus HIV-2). In recent times, most national serologic surveys have not distinguished these virus types; however, it is widely considered that HIV-2 prevalence rates are diminishing. This supports the hypotheses raised by Anderson and May, who analyzed the available biological and epidemiological data on HIV-1 and HIV-2 and used simple mathematical models to study the competition between the two viral types and predict the eventual outcome at a population level (Anderson and May 1996).

Epidemiology of HIV-2

Risk Determinants for HIV-2 and HIV-1 in Dakar Sex Workers

The prospective study of all registered sex workers in Dakar began in 1985 and in 1987 expanded to two other smaller clinic facilities in

the urban areas of Kaolack in western Senegal and Ziguinchor in the South, near the Guinea-Bissau border (Kanki et al. 1992). All women were asked to participate and informed consent was obtained and annual testing for HIV-1 and HIV-2 serology was performed along with a questionnaire to assess risk. The clinic's dynamic nature resulted in an open cohort design in which sequentially followed women were included irrespective of their date of entry. All women visiting the clinic were counseled on HIV/STI prevention, provided with free condoms at each visit, and offered free medical care as needed. These self-identified sex workers ranged in age from 18 to 70 years old, and over 90% of the approximately 2000 HIV-infected and uninfected women regularly attended the clinic. In studying the risk determinants of HIV-2 versus HIV-1 infection between 1985 and 1990, the variable prevalence of HIV-2 by sex worker cohort was confirmed, with Dakar being the lowest at 10.0% (128/1275), Ziguinchor 38.1% (106 /278), and Kaolack 27.4% (43/157) (Kanki et al. 1992). Step-up logistic regression analysis revealed that increased years of sexual activity (OR = 1.64; 95% CI = 1.06–2.57) and history of traditional scarification (OR = 1.65; 95% CI = 1.25–2.14) were positively associated with HIV-2 infection. The approximate log-linear relation of HIV-2 infection with increasing years of sexual activity was consistent with the hypothesis that the virus had been in the population for at least several decades. This differed from risk determinants for HIV-1 where history of hospitalization (adjusted OR = 2.12, 95% CI = 1.11–4.03) and a shorter period of registered sex work (adjusted OR = 0.23; 95% CI = 0.09–0.59) were associated with infection. In the Dakar and Ziguinchor clinics, Ghanian and Guinea-Bissau nationalities were significantly associated with higher HIV-2 prevalence.

Incidence of HIV-2 and HIV-1 in Dakar Sex Workers

The most common modes of HIV transmission in HIV-2 endemic areas is perinatal and heterosexual transmission; since Senegal like most West African countries had evidence of both HIV-1 and HIV-2 infections, measurement and comparison of incidence rates for both viruses was possible.

The incidence of HIV-1 and HIV-2 in the Dakar sex worker cohort ($n = 1,452$) was studied between 1985 and 1993 (Kanki et al. 1994). The overall incidence of HIV-2 was 1.11 per 100 person-years of observation (pyo) and was 1.11 per 100 pyo for HIV-1. Over the 8-year period, the annual incidence of HIV-1 dramatically increased, with a 1.4-fold increased risk per year and thus a 12-fold increase in risk over the entire study period. The incidence of HIV-2 remained stable, despite a higher HIV-2 prevalence of 11.3% compared to 6.2% for HIV-1. In this high-risk group, the heterosexual transmission of HIV-2 was significantly slower than that of HIV-1, which strongly suggested differences in the heterosexual transmission potential of these two related immunodeficiency viruses.

In modeling studies by Donnelly et al. the male-to-female transmission rates of HIV-2 and HIV-1 were estimated using maximum likelihood estimation theory and goodness-of-fit methods. Data from 780 sex workers followed from 1985 to 1990 revealed a 5.8–8.9-fold increased transmission probability of HIV-1 compared to HIV-2 (Donnelly et al 1993). Using a larger set of data from the Dakar sex worker cohort ($n = 1,948$) between 1985 and 1999, Gilbert et al. performed a modeling study of HIV-2 and HIV-1 to compare transmission potentials, where new nonparametric competing-risks failure-time methods were used, which minimized modeling assumptions and controlled for risk factors for HIV infection (Gilbert et al. 2003). The HIV-1 versus HIV-2 infectivity ratio over time was estimated by nonparametric kernel smoothing of the HIV-1/HIV-2 infection hazard ratio adjusted by an estimate of the relative HIV-1 versus HIV-2 prevalence in the partner population. HIV-1 was found to be significantly more infectious than HIV-2 throughout the follow-up period ($P < .0001$). The HIV-1/HIV-2 infectivity ratio was inferred to be approximately constant over time, with an estimated ratio of 3.55. The mathematical model of the concomitant transmission of the two viruses within the same sexually active population suggested a positive association between pathogenicity and reproductive success, indicating that HIV-1 would competitively displace HIV-2 in the long term. In the

HIV-2: Lessons from the Dakar Cohort, Table 1 Key differences between HIV-1 and HIV-2

	HIV-1	HIV-2
Geographic distribution	Worldwide	West Africa
Heterosexual transmission		Three to sixfold lower
Perinatal transmission	15–45%	0–5%
Plasma viral load		30-fold lower
Time to AIDS	7–10 years	10–25 years
Treatment		NNRTIs ^a ineffective

^aNon-nucleoside reverse transcriptase inhibitors

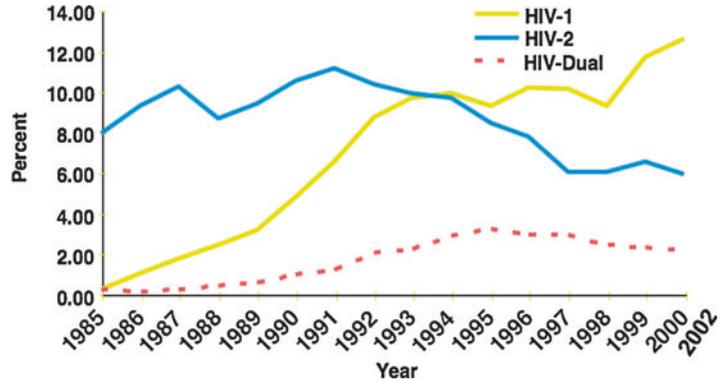

study of both viruses in Dakar, Senegal, over more than 25 years, the decrease of HIV-2 prevalence accompanied by the increase in HIV-1 prevalence was indeed observed (Hamel et al. 2007).

Maternal or perinatal transmission of HIV-2 also appears to be less efficient than for HIV-1. Perinatal transmission of HIV-2 and HIV-1 has been studied in Guinea-Bissau, Ivory Coast, France, and Senegal, with all demonstrating extremely low rates of HIV-2 perinatal transmission (0–3.7% transmission) in contrast to that of HIV-1 (15–45% transmission) (Kanki and Meloni 2009). In studies that measured perinatal transmission of both viruses, the rate of HIV-1 transmission was 10- to 20-fold higher than that of HIV-2 (Table 1).

A 20-year study of the prevalence and incidence of HIV-2 and HIV-1 subtypes in the Dakar sex worker cohort described the dynamic nature of these two related viruses (Hamel et al. 2007). Among the 3,910 women enrolled between 1985 and 2004, HIV-2 prevalence decreased from a range of 8–11% between 1985 and 1995 to 5.5% in 2003. HIV-1 prevalence has climbed steadily since its introduction in 1985 to just below 10% in 1993 stabilizing from 1993 to 1998, and then continuing to rise again to 13.8% in 2003 (Fig. 1). The annual incidence rate for HIV-1 increased from 0 in 1986 to 2.5/100 person-years of observation (PYO) in 1992, while HIV-2 and HIV-D have decreased to less than 0.3/100 PYO each, since 1999. In comparison to the previous assessment, this represented a fourfold decrease in HIV-2 incidence.

Clinical Significance of HIV-2

HIV-2-Related Disease and Differences in Disease Progression

Early case reports described HIV-2-infected people with disease consistent with an AIDS diagnosis (Romieu et al. 1990). The disease characteristics, including tuberculosis, chronic diarrhea, and *Candida* infections, were similar to diseases seen in HIV-1-associated AIDS in the same settings. Central nervous system involvement has also occasionally been described in HIV-2 AIDS cases. However, classical African AIDS comorbidities, such as tuberculosis, often have had only a weak epidemiological association with HIV-2, even in HIV-2 endemic areas.

In 1988, a cross-sectional clinical study of compared 18 HIV-2-infected Dakar sex workers with 14 HIV-negative sex workers as well as HIV-negative surgery patients (Marlink et al. 1988). Significant elevations of T8 lymphocytes ($p = .03$), IgG ($p = .0001$), and beta₂-microglobulin ($p = .03$) were described. The mean T4 lymphocyte count in seropositive was not depressed and not different from seronegative sex workers (757 vs 1179, $p = .15$). There were no differences in lymphocyte stimulation studies. Skin-test energy to various antigens was also less pronounced in HIV-2 infection. Therefore, the clinical picture from this small study failed to demonstrate immunosuppression similar to HIV-1 but rather the immunologic alterations of a persistent viral infection. Similar cross-sectional studies of HIV-2 infection were conducted in the late 1980s; they were intrinsically limited in their

ability to describe the natural history of HIV-2 infection, which required a prospective study design (Romieu et al. 1990).

The prospective cohort study of Dakar sex workers initiated in 1985 provided the unique opportunity of measuring the infection and progression rates of both HIV-1 and HIV-2 infections (Marlink et al. 1994). Importantly, the study compared disease progression in women with known time of infection, with follow-up exceeding 22 years, representing one of the longest HIV natural-history studies in the literature to date. The Kaplan–Meier analysis of HIV-2-infected individuals indicates that 85% (95% CI, 50–96%) remain AIDS-free after 8 years of HIV-2 infection. These differences in survival probabilities between HIV-2 and HIV-1 were also seen for CDC stage IV disease and CD4 lymphocyte counts below 400 cells/mm³ and below 200 cells/mm³, as outcomes (Fig. 2).

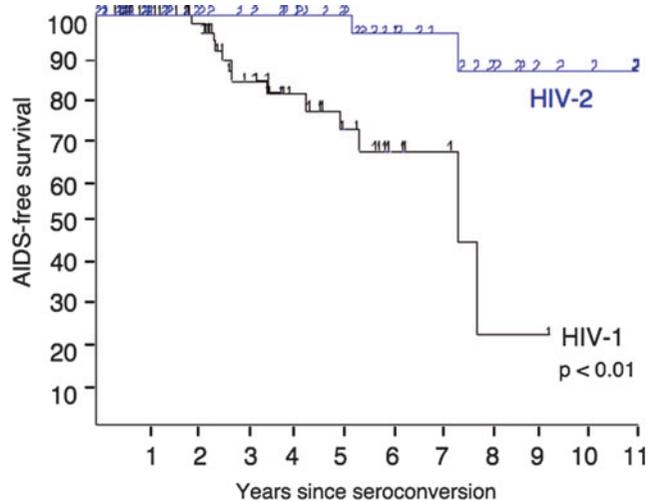

In the prospective study of HIV-2-infected individuals, individuals who fit a definition of long-term nonprogression were identified and further characterized (Kanki and Meloni 2009). Using a definition of long-term nonprogression of greater than or equal to 8 years of infection in the absence of AIDS or related symptoms and stable CD4 lymphocyte counts greater than 500 cells/mm³, 39 of 41 women (95%) could be classified as long-term nonprogressors.

Viral Characteristics of HIV-2

As studies continued to document HIV-2's distinct differences in epidemiology, transmission, and pathogenicity, other pertinent research

H

questions emerged to identify and characterize the responsible viral and host immune mechanisms. Evidence for a lower viral burden in HIV-2-infected individuals was first reported from the decreased ability to isolate virus and later on quantitative PCR-based DNA and RNA studies. HIV-2 proviral DNA was measured with a quantitative competitive DNA PCR assay using nested gag primers and an internal competitor in the first round target sequence (Dieng-Sarr et al. 1998, 1999). DNA samples from 35 HIV-2 and 33 dually seroreactive Dakar sex workers were evaluated for levels of HIV-2 and HIV-1 proviral DNA, with assays demonstrating the same level of sensitivity. Despite similar CD4 levels, the median proviral loads differed significantly, with the HIV-2 group ranging from 63.2 to 669.8 copies/ 10^5 CD4+ cells and demonstrating an inverse correlation with CD4+ lymphocyte count. The HIV duals showed less variation in HIV-2 provirus levels, ranging from 9.9 to 43.3 copies/ 10^5 CD4+ cells; and in dually infected individuals low HIV-2 proviral load was correlated with low CD4+ lymphocyte counts. The HIV-2 proviral loads in HIV dually infected persons were significantly lower than those in HIV-2 monotypically infected individuals, despite comparable CD4+ lymphocyte counts. Immune-competent dually infected individuals regularly demonstrated both HIV proviruses, whereas those with low CD4

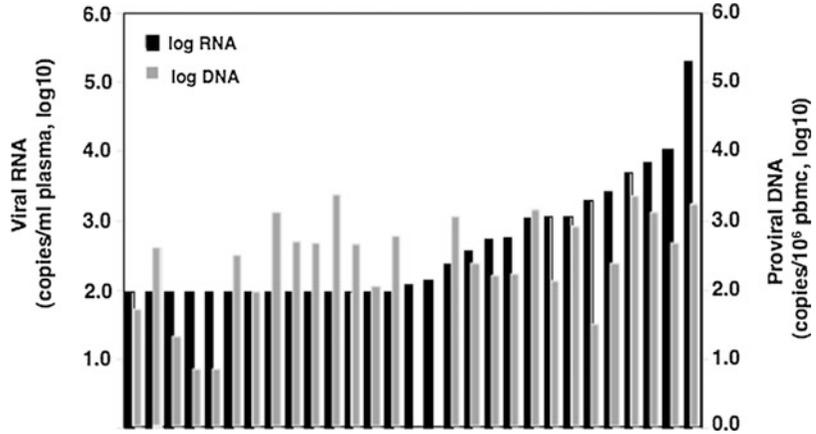

count were more likely to only have evidence of HIV-1 provirus (Dieng-Sarr et al. 1998). This suggests that during progression to disease, HIV-1 has a replicative advantage and outcompetes HIV-2 for available target cells, a phenomenon also observed in vitro.

The level of HIV virus in the plasma was also studied in the Dakar sex worker cohort with an internally controlled quantitative reverse transcriptase–polymerase chain reaction assay (Popper et al. 1999). HIV-2 viral RNA was detectable in 56% of all samples tested; the median plasma viral load was 141 copies/mL and inversely correlated to CD4 cell counts. HIV-2 and HIV-1 viral loads were compared among newly infected women in the cohort; the median viral load was 30-fold lower in the HIV-2-infected women ($p < .001$), irrespective of the length of time infected. This reinforced the concept that HIV plasma viremia was linked to the differences in the pathogenicity of the two viruses.

To further identify the source of this difference, viral RNA and proviral DNA were quantitated in matched samples from 34 HIV-2-infected individuals (Popper et al. 2000). Levels of HIV-2 proviral DNA were similar to those of HIV-1 but failed to correlate with levels of viral RNA. Thus, it appears that significant differences occur upon expression, release, and/or maintenance of HIV-2 virions in the bloodstream (Fig. 3).

HIV-2 Integration and Replication

Based on an HIV-1 integration mapping study that demonstrated a major effect on viral transcription, 202 HIV-2 integration sites were mapped during *in vitro* infection of peripheral blood mononuclear cells with a primary HIV-2 isolate (p1629) (MacNeil et al. 2006). In addition, the *in vivo* proviral integration within heterochromatin in 21 HIV-1-infected and 23 HIV-2-infected PBMCs from the Dakar sex worker cohort was determined, using an alphoid repeat PCR assay. During *in vitro* infection, HIV-2 displayed integration site preferences similar to those previously reported for HIV-1. Notably, 82% of HIV-2 integrations mapped to RefSeq genes, and integration strongly favored regions of the genome with high gene density and high GC content. Though rare, the proportion of HIV-2 samples (5/23) with evidence of proviral integration within heterochromatin *in vivo* was significantly higher (p value = .05) than that of HIV-1-infected samples (0/21). Thus differences in integration sites did not appear to play a major role in differences between HIV-2 and HIV-1.

Subsequent studies demonstrated that HIV-2 is able to establish a stable, integrated proviral infection *in vivo*, but that accumulation of viral mRNA is attenuated in HIV-2 infection, relative to HIV-1 (MacNeil et al. 2007a). The differences in viral mRNA were consistent with the differences in plasma viral loads between HIV-1 and HIV-2 and suggested that lower plasma viral loads, and possibly the attenuated pathogenesis of HIV-2,

could be explained by lower rates of viral replication *in vivo*.

HIV-2 Viral Diversity

HIV diversity is considered a major determinant in the virus' pathobiology. In evaluation of the C2–C3 envelope sequences of blood and cervical samples from HIV-1- and HIV-2-infected Dakar sex workers, only rare tissue-specific subclustering was noted where most of the majority viral sequences from the two tissue compartments were intermingled (Sankalé et al. 1998).

The viral sequence evolution in the C2V3C3 region of the viral *env* gene was demonstrated in 8 HIV-2 infected individuals from Dakar, Senegal, over the course of approximately 10 years (MacNeil et al. 2007b). To compare results to HIV-1 infection, data was reanalyzed from a previous study that prospectively examined inpatient viral evolution in HIV-1-infected individuals from the same population. HIV-2 sequences from early and late time points were phylogenetically intermixed for all subjects, and no distinct trends were observed in terms of increases or decreases in fragment size or number of N-linked glycosylation sites. In overlapping *env* C2V3 sequence, rates of viral divergence and diversification were slower in individuals infected with HIV-2 compared to individuals with HIV-1. Viral evolution occurs slowly in HIV-2 infection, which is consistent with the slow disease progression observed in HIV-2 infection, and supports the notion that viral evolution

may be a relevant correlate for disease progression.
